There is now broad recognition that the distinction between so-called ecological time scales (i.e., days to years) and evolutionary time scales (i.e., thousands of years) is a false one – microevolutionary changes can occur rapidly, within human lifespans. Thus, effective conservation must consider both the evolutionary and ecological consequences of any management action or inaction (Ashley *et al.*, 2003; Stockwell *et al.*, 2003). Latta (2008) points out two ironies that challenge our ability to control our evolutionary impact on nature: first, humans select against the very traits that we most value in the wild species that we harvest. For example, fisheries typically select against the largest and fastest-growing individuals, removing those genotypes from the gene pool (Biro and Post, 2008), just as trophy hunting selects against the traits that hunters most prize (Coltman *et al.*, 2003). The second irony is that the species and populations we often wish would remain static (such as insect pests, weedy plants, and pathogens) usually have the greatest potential to evolve resistance to our actions, while the species we hope would adapt to environmental change (i.e., rare, endangered taxa) are least likely to be able to do so. Thus the challenge facing conservation biology is to find ways to proactively manipulate evolutionary processes to achieve conservation goals. To thwart unintended anthropogenic selection, this might mean establishing reserves to act as reservoirs of particular genotypes (e.g., Baskett *et al.*, 2005); to promote adaptation to climate change, this could mean translocating more drought- or heat-tolerant genotypes from a lower latitude to a higher one (Aitken and Whitlock, 2013). Applied evolution has been successfully used in agriculture and medicine; although there are inherent risks associated with attempting to harness and shape evolutionary processes, the need for applied or prescriptive evolution in conservation and resource management has never been greater (see reviews by Hendry *et al.*, 2011; Lankau *et al.*, 2011; Smith *et al.*, 2014).

Conservation Biology, Quantitative Genetics in

A Caballero, Universidad de Vigo, Vigo, Spain

Glossary

Effective population size (N_e) The number of individuals required to account for the actual rate of increase in inbreeding or genetic drift in a real population. Real populations violate the assumptions of the models used to predict the rate of increase in inbreeding or genetic drift, and therefore N_e will differ from the actual population size (N).

Inbreeding depression Change in the mean of a quantitative trait because of inbreeding. It implies a deterioration of fitness traits.

Mutational meltdown Accelerated decay in population size driven by fixation of deleterious mutations occurring in small populations, where genetic drift overcomes the purifying effect of natural selection. The decrease in population size exacerbates the power of genetic drift over that of selection, further increasing the fixation of deleterious alleles in a recurrent cycle leading the population toward extinction.

Nondirectional dominance Situation where the alleles with decreasing (or increasing) effect on the trait have not a tendency to be either recessive or dominant. Fitness traits usually show directional dominance in the sense that alleles decreasing fitness tend to be recessive.

Outbreeding depression Decline in mean population fitness due to crossing of individuals from populations adapted to different local conditions.

Purging Reduction in frequency of deleterious mutations due to selection against recessive effects that are expressed because of inbreeding.

Q_{ST} Index of quantitative genetic differentiation between populations, analogous to Wright´s fixation index, F_{ST}.

Recessive lethal equivalent A group of deleterious mutations that, combined additively, account for the same inbreeding depression as a single recessive lethal. Its average number is typically estimated from the regression slope of fitness measures on the inbreeding coefficient.

Synergistic (reinforcing) epistasis Type of gene interaction in which the joint effect on a quantitative trait of the alleles of two (or more) loci is higher than the sum of the individual effects of the corresponding alleles. The contrasting type, or antagonistic epistasis, results when the joint effect of the alleles is lower than the sum of their individual allelic effects.

Introduction

The maintenance of biodiversity is one of the main worries of our societies, as the extinction of species continues at a dramatic rate and the number of those requiring human intervention to secure their viability is becoming increasingly large (Frankham *et al.*, 2010; Allendorf *et al.*, 2013). Conservation biology is not only focused on wild animal and plant species, but also on rare animal breeds associated with local production systems of cultural interest or supplying quality products of economic demand (Oldenbroek, 2007). Environmental deterioration and pollution, human structural developments, commercial overexploitation, and introduction of exotic species are some of the main factors responsible for the increasing rates of biodiversity loss.

The vast majority of traits related to the survival and adaptation of species, as well as those pertaining to production systems of economic value, are quantitative traits. Thus, most of the main concerns associated with endangered species and conservation programs are related to quantitative trait issues (Frankham, 1999). Unfortunately, estimation of genetic components of variation for quantitative traits is usually difficult, except in controlled situations where genealogical information or genotypic data from molecular markers is available, such as in the main commercial animal breeds and plant strains, some wild species where genetic monitoring is undertaken, or some plant species where common garden experiments can be carried out with relative ease.

Species or breeds at the brink of extinction, or those which are threatened or require human intervention, are almost invariably characterized by permanent or temporal low census sizes, geographical fragmentation, and high levels of isolation. The main genetic consequences of these factors are (Allendorf *et al.*, 2013): (1) The loss of genetic variation through the loss of alleles by genetic drift. For quantitative traits, this implies a reduced potential of populations for adaptation to new environmental threats, such as climate change or competition with introduced foreign species. (2) The increase in inbreeding rates, leading to inbreeding depression, the deterioration of fitness traits because of inbreeding. (3) Finally, for *ex-situ* conservation programs focused on the maintenance of genetic variation under captive conditions, the adverse collateral effects on future survival, due to adaptation to captivity and relaxation of natural selection, with possible consequences on the genetic architecture of quantitative traits. These aspects are explained more deeply in what follows.

Fitness Decline in Small Populations

One of the most important consequences of the small population sizes of endangered species is the decline in the mean of quantitative traits associated with fitness (such as viability, fecundity, or mating success). This decline occurs through two highly related processes. First, inbreeding depression, which is mostly due to the expression of recessive deleterious

 doi:10.1016/B978-0-12-800049-6.00056-1

mutations in homozygosis as a consequence of the unavoidable mating of relatives (Charlesworth and Willis, 2009). Second, the eventual random fixation of deleterious mutations, because of the prevalence of random genetic drift over natural selection. This latter process, called mutational meltdown (Lynch *et al.*, 1995), implies an increasing accumulation of fitness-reducing mutations which further lowers the population size in a recurrent cycle leading the population toward extinction. Note that although the two above processes are a consequence of inbred mating and low population sizes, they can be considered separately. Inbreeding depression regards to the concealed deleterious genetic load (that due to recessive deleterious mutations segregating in heterozygous condition), whereas mutation meltdown refers to the eventual fixation of deleterious mutations and these, once fixed, do not contribute to inbreeding depression. In addition, additive deleterious mutations contribute to mutation meltdown but not to inbreeding depression. The magnitude of these processes depend on the rate, mean effect, dominance, and distribution of effects of deleterious mutations, becoming generally enhanced in stressful environments (Reed *et al.*, 2012).

The estimations of the deleterious mutation rate and mutational effects arise from mutation-accumulation experiments or molecular-based inferences. Mutation-accumulation experiments have been carried out in a number of species using populations of small census size, initially devoid of genetic variation, where natural selection is minimized to allow random fixation of deleterious mutations (Mukai, 1964). Estimates of the genomic haploid mutation rate from these experiments vary largely between species but the mean across 31 estimates reviewed by Halligan and Keightley (2009) in higher eukaryotic species is 0.08 (median of 0.04), with a mean deleterious homozygous effect on fitness traits of 0.22 (median of 0.16). This suggests that mutations detected in mutation-accumulation experiments are relatively rare and have very substantial effects on fitness. Different lines of evidence indicate that the majority of these mutations show partial recessivity, with an average heterozygous effect of about 20% of the homozygous effect (García-Dorado and Caballero, 2000).

The necessarily short temporal scale of mutation-accumulation experiments, the lack of power associated with phenotypic measures of fitness components and the problems of finding appropriate non-mutated control lines imply that these experiments are only able to detect mutations of relatively large effect. Analyses of sequence data making assumptions about the fraction of the genome constrained by selection yield much higher estimates of the genomic mutation rate. For example, the estimated haploid genome-wide deleterious mutation rate using this approach is as large as 0.6 in *Drosophila* and 1.1 in humans, with a distribution of effects dominated by large-effect mutations (Halligan and Keightley, 2009; Keightley, 2012). The discrepancy between both kinds of estimates is likely to be that most deleterious mutations accounted by molecular-based approaches have tiny effects which are relevant in evolutionary timescales but cannot be detected in mutation-accumulation experiments (García-Dorado *et al.*, 2004).

From a conservation point of view, where the timescale of the pertinent programs is usually short (dozens or hundreds of generations), the relevant deleterious mutations would be those with mild to severe effects and substantial recessivity, i.e., those typically detected in mutation-accumulation experiments. These mutations will rarely cause mutational meltdown but, in large populations, can account for substantial genetic load due to recessive effects concealed in heterozygotes. Therefore, they are responsible for inbreeding depression after a reduction in population size. This is one of the main issues in conservation biology, as inbreeding depression is virtually ubiquitous in endangered and captive species. In fact, in a survey of 119 zoo populations, Boakes *et al.* (2007) found that inbreeding depression for neonatal survival was significant across all populations, although its extent varied widely among taxa.

On the other hand, inbreeding depression can be opposed by purging, as inbreeding produces homozygous individuals in which recessive deleterious effects are exposed to natural selection (see review by Leberg and Firmin, 2008). It has been theoretically shown that purging can restrain to a large extent the decline in fitness in moderate size populations (García-Dorado, 2012). For example, simulations assuming a model with 0.05 partially recessive deleterious mutations per haploid genome per generation, with average effect 0.2 in homozygosis (mean effect of 0.04 in heterozygotes), show a decline in fitness of only about 10% in a 100 generation period for populations of size $N=10$, instead of the 40% decline expected in the absence of purging (**Figure 1**; Pérez-Figueroa *et al.*, 2009). Purging, however, is not too evident in captive populations, and in the survey of Boakes *et al.* (2007) it was significant in some of the populations studied but produced an average increase in fitness lower than 1%. However, it must be kept in mind that zoo populations may have been subjected to previous substantial purging, whose consequences pass undetected in this type of studies. Deliberate inbreeding has been proposed as a way to eliminate deleterious recessive mutations, but the results from Boakes *et al.* (2007) suggest

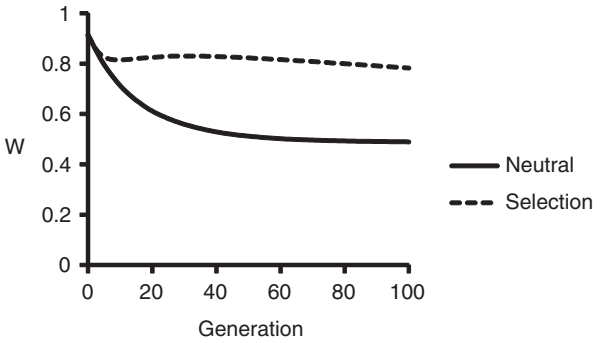

Figure 1 Simulated mean change in fitness (W) in a population of census size $N=10$, assuming deleterious mutations appearing at a rate of 0.05 mutations per haploid genome and generation with effects obtained from an exponential distribution with homozygous mean effect 0.2 and heterozygous effects, negatively correlated with homozygous effects, and mean 0.04. The continuous line assumes a model without selection, whereas the broken line assumes purging selection. Data from Pérez-Figueroa, A., Caballero, A., García-Dorado, A., López-Fanjul, C., 2009. The action of purifying selection, mutation and drift on fitness epistatic systems. Genetics 183, 299–313.

that the efficiency of this procedure is very questionable (see also de Cara *et al.*, 2013).

Consequences of Bottlenecking and Fragmentation on the Genetic Variance for Quantitative Traits

Endangered populations are characterized by permanent low census sizes or frequent populations shrinks (bottlenecks) and population fragmentation. Immediate consequences are the loss of genetic variation and the increase in between-population differentiation. Under neutrality, the contribution of additive loci to the additive variance of a quantitative trait after bottlenecks is expected to decline linearly with the inbreeding coefficient (F) (Wright, 1951), but that of dominant or epistatic loci may initially increase until a critical F value is reached, followed by a final decline (Robertson, 1952; López-Fanjul *et al.*, 2002). Thus, it has been suggested that an excess of additive variance after some inbreeding may enhance the adaptive potential of populations through an assumed conversion of nonadditive into additive variance (Wade and Goodnight, 1998). Laboratory experiments indicate that an increase in additive variance after bottlenecks was small or absent for morphological traits but large for life-history traits (Van Buskirk and Willi, 2006; Taft and Roff, 2012). Both results are compatible with the general assumption of morphological traits being controlled by genes with little or nondirectional dominance (i.e., where the alleles with decreasing, or increasing, effect on the trait do not show a tendency either to be recessive or to be dominant) and showing no inbreeding depression, and fitness component traits with an additive variance determined by deleterious recessive alleles segregating at low frequencies and strongly depressed by inbreeding.

Neutral theoretical models predict that the contribution of epistasis to the increase in genetic variance after bottlenecks can be substantial (Wade and Goodnight, 1998). However, simulations accounting for purifying natural selection strongly constrain the boost in additive variance for fitness, mainly through purging of deleterious recessive alleles, rendering small increases in variance after bottlenecks with or without epistasis (Pérez-Figueroa *et al.*, 2009). Thus, whereas synergistic (reinforcing) epistasis for fitness implies an excess of increase in variance with bottlenecks over that expected without epistasis (due just to dominance; Robertson, 1952; black lines in **Figure 2**), purging selection reduces considerably the magnitude of the increase in additive variance and almost completely removes the excess due to epistasis (red lines). On the other hand, for metric traits subject to stabilizing selection, an excess in additive variance following bottlenecks could not be attributed to simple dominance and was only observed when synergistic epistasis was present, although its magnitude was again considerably constrained by selection (Ávila *et al.*, 2014). Thus, for both selection regimes, a drift-induced excess in additive variance is unlikely to produce a net increase in the adaptive potential of populations. In addition, observed increases in additive variance could not be attributed to a depletion of nonadditive variance through a conversion process.

Fragmentation of populations and further isolation is usually an undesirable phenomenon from the conservation point of view. However, between-group differentiation for quantitative traits can also be considered a desirable property in some circumstances. For example, it has been reckoned that about half of the total genetic variation of importance in animal breeds is between-breed variation (Oldenbroek, 2007). This variation could become useful if livestock production needs to be quickly adapted to new challenges, and conserving breeds with particular characteristics is a rational and important strategic objective. In the wild species context, the possibility of a given subpopulation to adapt to a given environmental change may largely depend on the possibility of receiving rare advantageous alleles by migration from other subpopulations (Blanquart and Gandon, 2011). In fact, quantitative genetics theory predicts that, at low levels of inbreeding, the total amount of genetic variance in a subdivided population is $(1 + F_{ST})$ times larger than that of an undivided population (Wright, 1969), where F_{ST}, essentially a scaled measure of the variance in allele frequency differences among subpopulations, is a measure of the level of differentiation among them. Thus, a certain differentiation among subpopulations might be considered as a way of keeping reservoirs of variation.

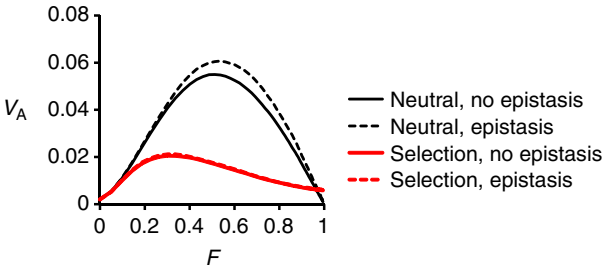

Figure 2 Simulated change in additive genetic variance (V_A) after consecutive bottlenecks of size $N = 10$ during 100 generations, plotted against the inbreeding coefficient. The initial bottlenecked population is taken from a large base population at mutation-selection-drift equilibrium where deleterious mutations appear at a rate of 0.05 mutations per haploid genome and generation with homozygous effects obtained from an exponential distribution with mean 0.2. Heterozygous effects have mean 0.04 and are negatively correlated with homozygous effects. The continuous lines assume non-epistatic gene action and the broken lines assume strong synergistic epistasis between pairs of loci. Black lines assume a model without selection, whereas red lines assume purging selection. Data from Pérez-Figueroa, A., Caballero, A., García-Dorado, A., López-Fanjul, C., 2009. The action of purifying selection, mutation and drift on fitness epistatic systems. Genetics 183, 299–313.

Minimum Viable Population Size

A question of utmost interest in conservation biology is the minimum effective size enabling a population to persist over a certain time under the threats of inbreeding depression and loss of variation by genetic drift. There are several arguments to answer this question based on quantitative genetic reasoning (reviewed by Frankham *et al.*, 2014). A first issue is the minimum viable population size needed for persistence in the short term. Because typical animal breeding programs aim to a

maximum rate of increase in inbreeding ($\Delta F = 1/2N_e$, where N_e is the effective population size; Wright, 1931) about 1% per generation, a minimum value of $N_e = 50$ is deduced (Soulé, 1980; Franklin, 1980). Frankham *et al.* (2014) suggest a more specific proposal. Considering a maximum decline in fitness of 10% over a short-term period of five generations, and assuming a total genetic load for vertebrates of about six recessive lethal equivalents, the necessary N_e would be 142. Following this argument, Frankham *et al.* (2014) suggest a minimum viable population size of at least $N_e = 100$ for minimizing inbreeding depression in the short term.

The second issue is to determine the minimum viable effective population size sufficient to retain evolutionary potential in the long term. Assuming a mutation-drift model of variation, the equilibrium additive genetic variance (V_A) for a quantitative trait is about $V_A = 2N_eV_M$ (Lynch and Hill, 1986), where V_M is the mutational variance, i.e., the input of per-generation additive variance due to neutral mutation. Because the mutational variance takes values around $10^{-3}\ V_E$, where V_E is the environmental variance, this means that for a typical quantitative trait of heritability $h^2 = 0.5$ (so that $V_A = V_E$), the critical effective size must be around 500 individuals (Franklin, 1980; Lynch and Lande, 1998). The incorporation of selection to the model indicates that it should be at least doubled (Frankham *et al.*, 2014), although it also shows that, at some point, selection becomes the factor limiting genetic variance, so that no further increase in V_A is expected by further increases in N_e (Amador *et al.* 2010). Simulations considering other factors such as the mutational meltdown process explained above have also concluded that populations of N_e at least 1000 individuals are necessary to guarantee population survival for periods of about 100 years (Lynch *et al.*, 1995; Lynch and Lande, 1998).

For captive breeding programs, it has been proposed that the minimum long-term viable population size should be that required to maintain at least 90% of the genetic diversity during a period of 100 years (Frankham *et al.*, 2010). A review of 188 published studies of *ex-situ* conservation programs where different estimates of variation are available (most from neutral markers but also from studbook data) concludes that to accomplish this criterion a minimum number of 15 founders and a minimum size of the captive population of 100 individuals are sufficient (Witzenberger and Hochkirch, 2011).

The above theoretical arguments suggest that minimum viable effective population sizes should be of the order of 100 to avoid a substantial impact of inbreeding depression in the short term and of 1000 to avoid a substantial loss of variation and fitness in the long run. Because the ratio between the effective size, estimated with demographic or molecular marker data, and the census size has been found to be about 10–20% (Frankham, 1995; Palstra and Fraser, 2012), this would imply that viable populations should include a number of breeding individuals, an order of magnitude higher than their N_e estimates. However, the considerable variation across populations and species for the ratio between effective size and census size questions the applicability of this relationship in a general way (Jamieson and Allendorf, 2012). The above arguments are also constrained by the limitations of the model assumed and ignore many other factors such as demographic stochasticity and the structure of the populations. Population viability analyses (see meta-analysis by Traill *et al.*, 2007) may consider these and other factors to provide more specific recommendations for a given probability of persistence over a specified period of time. Frankham *et al.* (2014) propose to standardize a 99% probability of persistence for 40 generations for a typical outbreeding species. Nevertheless, the recommended minimum viable population sizes should be taken only as rough indications, as extinction risks may arise from a complex interaction of factors and the uncertainty and contingency of the data may impede proposing any universally applied figure (Flather *et al.*, 2011). Furthermore, since purging operates on the basis of previously accumulated inbreeding, it should be taken into account to predict the expected declines in the medium-long term, when it may restrain fitness losses to a large extent (Pérez-Figueroa *et al.*, 2009; García-Dorado, 2012; see **Figure 1**).

Neutral Molecular Variation as a Surrogate or Complementation to Quantitative Genetic Variation

Theoretical studies show that estimates of quantitative genetic variation can be more informative than molecular markers to detect human-induced impacts on genetic diversity, particularly when these involve changes in environmental variance, shifts in local optimal conditions due to environmental contaminants, or fluctuations in the migration rate between populations adapted to different optima (Carvajal-Rodríguez *et al.*, 2005). However, because estimating genetic components of variation for quantitative traits is generally difficult or even unfeasible, estimates from neutral molecular markers of gene diversity (expected heterozygosity, H; Nei, 1987) and allelic richness (El Mousadik and Petit, 1996) are used as surrogates of heritability and additive genetic variance. Likewise, gene frequency differentiation (F_{ST}; Wright, 1951) and its derivatives such as G_{ST} (Nei, 1987) or allelic type differentiation statistics (El Mousadik and Petit, 1996; Jost, 2008; Caballero and Rodríguez-Ramilo, 2010) are used as proxies for quantitative trait genetic differentiation, usually quantified by the statistic Q_{ST} (Spitze, 1993). This is defined as $Q_{ST} = V_B/(V_B + 2V_W)$, where V_W and V_B are the additive within- and between-population components of the genetic variance for the quantitative trait. As in many situations, such as those for most endangered species, genetic components of variance cannot be obtained and a proxy of Q_{ST} (called P_{ST}) has been proposed, based on using phenotypic rather than genetic variance components and making assumptions about the proportion of the total phenotypic variance due to additive genetic effects. This method is obviously not recommended, because phenotypic plasticity is very common (Pujol *et al.*, 2008), but should not be completely dismissed as a first approximation in some instances (Brommer, 2011).

The comparison between statistics of gene frequency differentiation and quantitative genetic differentiation has useful applications in conservation biology. For example, because F_{ST} for neutral markers should be approximately equal to Q_{ST} for neutral additive traits, the comparison between both statistics gives information on the presence of divergent selection for the pertinent quantitative trait among populations, implying

$Q_{ST} > F_{ST}$ (see e.g., Kremer and Le Corre, 2012). Uniform selection across populations ($Q_{ST} < F_{ST}$) is more difficult to prove, as both dominance and epistatic gene action usually imply $Q_{ST} < F_{ST}$ even in the absence of selection (López-Fanjul *et al.*, 2003). The empirical evidence indicates that Q_{ST} is generally larger than F_{ST} (Leinonen *et al.*, 2013), which suggests that a considerable part of the observed population divergence for quantitative traits should be attributed to differential selection pressures imposed by local environmental conditions. This has important implications in conservation management as hybridization of different populations may cause outbreeding depression (Edmands, 2007), i.e., the decline in fitness when highly different populations are mixed, arguing against forced migration policies.

The empirical relationship between molecular variability and morphological, behavioral, or life-history variability seems to be generally low to moderate. The mean correlation between molecular heterozygosities and estimates of genetic variation for a range of quantitative traits across 71 studies was about 0.22 (Reed and Frankham, 2001), whereas the correlation between variation at neutral markers and fitness traits was 0.43 in another meta-analysis of 34 studies (Reed and Frankham, 2003). Moreover, the relationship between individual genetic diversity and fitness-related traits (heterozygosity-fitness correlation) is generally low (Chapman *et al.*, 2009), although can be relevant in small populations or those recently affected by bottlenecks (Szulkin *et al.*, 2010). However, direct associations between neutral marker variation and adaptive changes for quantitative traits have been found experimentally. For example, Santos *et al.* (2012) found significant associations between variation for nine microsatellite markers and changes in life-history traits as a result of adaptation to laboratory conditions for 21 generations of six populations sampled from two natural locations. In addition, simulation studies have shown that neutral molecular markers are reasonable predictors of the global genetic potential for adaptation of subdivided populations. In particular, gene frequency measures of molecular variability are good predictors of short-term response to selection for quantitative traits, whereas allelic number measures are better predictors of long-term and total response (Caballero and García-Dorado, 2013). This is in concordant with theoretical arguments which suggest that short-term response to selection mostly depends on heterozygosity, whereas long-term selection is highly dependent on the number of alleles (Allendorf 1986; Allendorf *et al.*, 2013), as deduced from the fact that population bottlenecking, which has a large impact on allelic diversity, constrains the response to selection (James, 1970). Simulation and empirical data with *Drosophila melanogaster* confirms that total selection response for quantitative traits is higher for populations where the number of alleles for molecular markers have been maximized than for analogous populations where the marker heterozygosity has been maximized (**Figure 3**; Vilas *et al.*, unpublished).

The possibility of applying next-generation sequencing techniques to an increasing number of non-model species is enabling a huge improvement in the precision of genetic estimates, the assessment of the levels of introgression and differentiation among populations, the identification of regions that have been subject to selection, and the mapping of genetic variants for important traits through Genome Wide Association Studies (Steiner *et al.*, 2013). Thus, fine scale analyses from conservation genomics are opening a large number of possibilities for improvement of conservation programs.

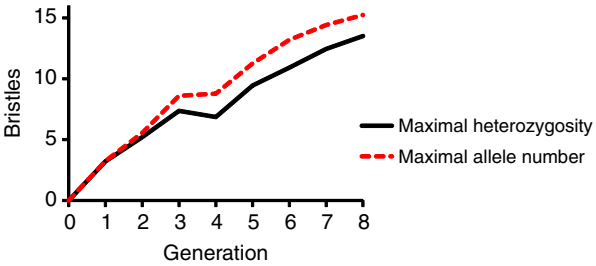

Figure 3 Divergence between the means of lines selected for increased and decreased sternopleural bristle number during eight generations. The two scenarios differ in that the starting population was obtained maximizing the expected heterozygosity for nine microsatellite markers (continuous black line), or maximizing the number of alleles for the same markers (broken red line). In each generation truncation selection was performed in which 50 individuals of each sex were scored and the 10 individuals of each sex with the highest or the lowest bristle number were used as breeding individuals. Data from Vilas *et al.*, unpublished.

Implications of Conservation Management on Quantitative Trait Variation

From a genetic perspective, the objective of any conservation program is to maintain the largest possible levels of genetic variation in the populations so as to keep their evolutionary potential, to avoid inbreeding depression and to restrict adaptation to captivity to a minimum (Frankham *et al.*, 2010; Allendorf *et al.*, 2013). For some captive species or plant reservoirs in *ex-situ* conservation programs, manipulation of breeding schemes can be at least partially undertaken and simple strategies followed to maintain genetic diversity. These strategies, based on maintaining the largest possible N_e, are basic procedures to avoid changes in population size over generations, keeping a balance sex ratio and avoiding inbred matings. In addition, equalizing contributions from parents to progeny, i.e., each pair or individual contributes the same number of progeny to the next generation, is a well-known method to double N_e, thus reducing to one-half the rate of increase in inbreeding and genetic drift (Gowe *et al.*, 1959; Wang, 1997). This method can be generalized using genealogical or molecular marker information to find the contributions from parents such that the average coancestry (kinship) of the progeny is minimized. This method is expected to maximize gene diversity and N_e (Caballero and Toro, 2000, 2002). When individuals are unrelated or uniformly related, the method simply reduces to the equalization of contributions.

Equalization or minimum coancestry contributions maintain the maximum possible gene diversity, but has also a number of collateral consequences on adaptive variation. If individuals or pairs are forced to contribute the same number of progeny, natural selection on fecundity is avoided, except

for complete mating failures, and selection for viability occurs only within families. This implies an overall relaxation of natural selection with both positive and negative consequences. On the positive side, selection for adaptation to captivity is reduced, a desirable aspect if reintroduction of the species in the wild is an intended objective (Frankham, 2008; Williams and Hoffman, 2009). On the negative, relaxation of selection may enhance the fixation of fecundity deleterious mutations over generations, implying a reduction in fitness over time. Despite this disadvantage, analytical and simulation studies indicate that equalization of contributions is expected to produce higher fitness than random contributions for small populations (below about 50 individuals) in the short term (up to 10–20 generations) (Schoen *et al.*, 1998; Fernández and Caballero, 2001; Theodorou and Couvet, 2003; García-Dorado, 2012). The available experimental data confirm these theoretical expectations. Empirical comparisons involving a range of population sizes (from 8 to 100) and generation periods (from 4 to 38 generations) either did not find evidence to suggest that equalization of contributions entailed an important disadvantage in the fitness of the population or even produced evidence for some fitness advantage (Loebel *et al.*, 1992; Borlase *et al.*, 1993; Montgomery *et al.*, 1997; Rodríguez-Ramilo *et al.*, 2006; Sánchez-Molano and García-Dorado, 2011; Ávila *et al.*, 2013).

Most endangered species, both in natural settings and captive conditions, are characterized by being structured in different breeding groups showing some degree of isolation. Thus, management methods have to consider this structuring of the populations. Isolation between subpopulations implies an excessive increase in local inbreeding and, therefore, some degree of migration among subpopulations is advised in conservation programs. A classical rule, based on the island model derived by Wright (1951), is to allow for one migrant per generation and subpopulation (Mills and Allendorf, 1996). More sophisticated methods, making use of demographic (Wang, 2004) or genealogical or molecular marker information (Fernández *et al.*, 2008; Ávila *et al.*, 2011), can provide a more effective control of the relative levels of diversity between and within subpopulations. Migration, however, has to be kept to a minimum when different subpopulations may be adapted to different local optima for one or more quantitative traits subject to selection (Storfer, 1999; Hereford, 2009; Sánchez-Molano *et al.*, 2013), since hybridization of different populations may cause outbreeding depression (Edmands, 2007).

One of the main consequences of *ex-situ* conservation programs is the genetic adaptation to captive conditions caused by both natural and artificial selection (Frankham, 2008; Williams and Hoffman, 2009). Because of its benign characteristics, captivity implies selection for variants possibly deleterious in wild conditions. Quantitative trait analysis can be particularly useful in the study of adaptation to captivity through the use of the animal model for zoological records (Pelletier *et al.*, 2009). Regarding management methods, both empirical (Frankham *et al.*, 2000) and simulation studies (Fernández and Caballero, 2001; Saura *et al.*, 2008) have shown that minimum coancestry or equalization of contributions procedures are effective in reducing adaptation to captivity. However, there is little direct evidence to support an increase in fitness after reintroduction by implementing some of these conservation methods (Frankham, 2008; Williams and Hoffman, 2009). Other recommendations have been made with this purpose, such as reducing the number of generations in captivity and fragmenting the populations, if possible, allowing for some migration between them as a way to control local inbreeding (Frankham, 2008; Williams and Hoffman, 2009).

Convergent Evolution, Adaptive Radiation, and Species Diversification in Plants

TJ Givnish, University of Wisconsin-Madison, WI, USA

Glossary

Adaptive radiation It is the rise of a diversity of ecological roles and associated adaptations within a lineage. Component species of an adaptive radiation often show convergence with ecologically similar members of other lineages.

C_4 photosynthesis C_4 photosynthesis is one of three biochemical pathways that plants use to fix CO_2 as reduced carbon (sugar) as food. It has evolved dozens of times from the more common pattern of C_3 carbon fixation, especially in plants of hot, sunny, seasonally dry habitats. C_4 photosynthesis uses PEP carboxylase to capture (carboxylate) CO_2 initially as an organic acid throughout the leaf mesophyll, then ships the acid to cells around each vein bundle, where the CO_2 is released and fixed via light capture and ordinary C_3 photosynthesis in those cells. This spatial separation of CO_2 capture and light capture reduces the inefficiency of photosynthesis caused by the C_3 carboxylating enzyme RUBISCO running photosynthesis in reverse when CO_2 is at low levels inside the leaf. C_3 photosynthesis is often more productive in moist or shady habitats.

CAM (crassulacean acid metabolism) photosynthesis It is an unusual photosynthetic variant seen in succulent plants of deserts, as well as in some epiphytes or plants of salt marshes, in which the stomata open only at night, and CO_2 is initially captured as an organic acid; CO_2 is then released from the acid by day and fixed using ordinary C_3 photosynthesis. It greatly reduces water loss but also reduces the total potential amount of carbon fixation.

Convergent evolution (evolutionary convergence) It is the rise of similarities in form, physiology, and behavior among distantly related organisms that inhabit similar ecological conditions, despite phenotypic differences among their ancestors.

Cordilleras Cordilleras are extensive chain of mountains, such as the Andes or the New Guinea Highlands.

Epiphytes Plants that grow on the branches or trunks of woody plants are called epiphytes; the main groups of vascular epiphytes are orchids, bromeliads, ferns, and members of the philodendron family.

Giant rosette shrubs They are unbranched or sparsely branched woody plants with large leaves ($>$ 20 cm long) clustered around the single terminal bud of each stem; often a dominant growth above treeline in equatorial regions.

Marcescence It is the retention of dead organs (e.g., leaves) that would otherwise be shed from stems.

Mycorrhizae Mycorrhizae are mutualistic associations between plant roots and fungi; the mycorrhizal fungi aid in obtaining water and mineral nutrients, especially phosphorus, from the soil, based the very small diameters and great surface-to-volume ratio of the fungal threads.

Krummholz Krummholz (crooked or twisted wood in German) is a short, mat-like growth form assumed by some tree species above treeline. These mats can be one to a few tens of centimeters in depth, shelter in the ground boundary layer, and have aerodynamically smooth canopies. In essence, they are gigantic cushion plants. Often they are sheltered under snow during the winter.

Paramo It is a distinctive vegetation-type found in the equatorial alpine zone of the Andes in South America, marked by dominance of giant rosette shrubs of *Espeletia* of the daisy family (Asteraceae) and occasionally *Puya* of the bromeliad family (Bromeliaceae). Evergreen, small-leaved shrubs and grasses and sedges are usually also present. A convergent vegetation-type occurs above treeline on the high volcanoes of equatorial East Africa, in the so-called Afro-alpine zone.

Phreatophyte It is a plant in a dry region that taps a more or less permanent source of moisture in the underlying water table. Such water tables can be shallow in desert washes, where water carried by floods associated with rainstorms infiltrates the ground, or in low areas in a semi-arid landscape where groundwater can accumulate after flowing from other areas nearby.

Pith It is soft, spongy tissue inside plant stems that can act as a storehouse for moisture and nutrients.

Pollinia (singular, pollinium) They are discrete packets of hundreds to tens of thousands of pollen grains that are transferred between plants as intact units, attached to pollinators by sticky points of attachment or mechanical yokes. Pollinia have evolved in some orchids and in milkweeds.

Sheet flow It is a surface movement of water across nearly flat, relatively smooth soil or rock surfaces in the form of a thin, continuous film or deeper layer or sheet.

Species sorting It is the emergence of different distributions of species along an ecological gradient that results from their context-specific advantages in competition, avoiding predation, and/or interacting with mutualists under particular conditions, based on differences in their biological equipment.

Stomatal conductance It is a measure of the permeability of the stomata of a leaf to the diffusive movement of water vapor and, thus, of carbon dioxide as well. At a given difference between the humidity (or CO_2 concentration) inside and just outside a leaf, the rate of water loss (or CO_2 uptake) will increase proportionally with stomatal conductance. The latter reflects the density, size, and degree of opening of stomata in a complex fashion.

Vascular plants They are plants with specialized cells (xylem) that die when mature and act as pipes to conduct water efficiently along the length of a plant, a stem, or a leaf. Vascular plants include the angiosperms (flowering plants), gymnosperms (conifers, cycads, *Gingko*, and their allies), and ferns.

Evolutionary convergence is the rise of phenotypic similarities among distantly related organisms that inhabit similar ecological conditions. Similar habitats, microsites, or ways of making a living should generate similar selective pressures that, in turn, favor morphological and physiological traits that maximize fitness and competitive ability under those conditions, and lead to convergence among species despite differences among their ancestors. Presumably, this is why alpine plants in so many lineages have a cushion growth form and small, thick leaves; why annuals and succulents with small, silvery, or spiny photosynthetic surfaces dominate so many deserts; and why plants pollinated by hummingbirds tend to have reddish tubular flowers that secrete large amounts of dilute, hexose-rich nectars (Figure 1).

Fitness and competitive ability are context-dependent (Givnish, 1986). The growth forms and traits that maximize success in certain environments (e.g., cushion shrubs with small, thick leaves in alpine and arctic tundra) will almost inevitably be disadvantageous under other conditions (e.g., tropical rain forests). Differential adaptation of plant species to one or another set of conditions – and convergent evolution in traits that determine that adaptation – are thus important drivers of plant diversification at large spatial scales. Where physical conditions are key prime determinants of survival and reproduction – as might be expected in extreme environments, in which one or a few conditions are severe or highly unusual and limit the growth and survival of most species – then convergence over evolutionary timescales should be marked. Over shorter periods, local conditions can also allow species to sort themselves along ecological gradients based on their differential ability to survive and compete successfully under different conditions, reflecting differences in their biological equipment. As a result, species sorting – a process operating over relatively short, ecological timescales – can also generate convergence among species at specific points along ecological gradients (Weiher and Keddy, 1995).

Convergence in a particular kind of environment suggests that the trait in question is adaptive there, but functional

studies are required to understand why that trait enhances fitness under those conditions (Givnish, 1997). Concerted convergence – involving two or more genetically, developmentally, and functionally independent traits – can arise through selection pressures imposed by different, correlated features of a given environment. For example, selection for thin broad leaves in forest understories favors net-like venation for biomechanical reasons, while selection for effective seed dispersal in windless understories favors the rise of fleshy fruits. Both traits have arisen, almost always together and associated with the invasion of forest understories, more than 20 times in monocots (Givnish *et al.*, 2005).

Similarities in form and physiology can often lead plants to compete intensely with each other. Consequently, selection and competitive sorting may also favor divergence among locally coexisting species (Stubbs and Wilson, 2004), creating a tension between the amounts of convergence versus divergence expected within a habitat or species assemblage. Divergence may be especially favored under less extreme conditions in which interactions with other plants, rather than the external environment, play a more important role in determining plant survival and reproduction.

Close relatives can often be each other's most potent competitors, based on their phenotypic similarity with each other (e.g., see Burns and Strauss, 2011). Divergent selection among such relatives can lead to adaptive radiation, the rise of a diversity of ecological roles, and attendant adaptations within a lineage (Givnish, 1995; Schluter, 2000). Adaptive radiation is more likely where alternative resources are underutilized by members of other lineages, perhaps as a result of mass extinction, the colonization of isolated islands, mountains, or lakes by few other groups, or the evolution of a 'key innovation' (e.g., the epiphytic habit) that allows a lineage to invade and ecologically partition a new range of habitats or resources (Givnish, 2015). Adaptive radiation and evolutionary convergence are often two sides of the same evolutionary coin, with species within a radiation adapted to a particular habitat or pollinator class exhibiting convergence with members of other lineages adapted to the same conditions.

Adaptive radiation is often conspicuous in plants on oceanic islands and archipelagoes, with the extent of variation in habitat, growth form, leaf shape, and pollinators being extraordinary in such groups as the Hawaiian lobeliads (**Figure 2**), mints, silverswords, and *Schiedea* (pink family); *Sonchus* (daisy family), *Echium* (viper bugloss family) and other groups on the Azores, Canary Islands, Madeira, and Cape Verde Islands; and *Scalesia* (daisy family) and *Opuntia* (cactus family) on the Galápagos (Carlquist, 1965; Givnish, 1998; Lindqvist and Albert, 2002; Carlquist *et al.*, 2003; Sakai *et al.*, 2006; Kim *et al.*, 2008; Givnish *et al.*, 2009; Stocklin, 2009). But adaptive radiation can also arise on continents, as exemplified by such groups as mariposa lilies (*Calochortus*, lily family), beardtongues (*Penstemon*, plantain family), and rein-orchids (*Platanthera*, orchid family) in North America (Hapeman and Inouye, 1997; Patterson and Givnish, 2004; Wilson *et al.*, 2007), *Brocchinia* (bromeliad family) in the Guayana Shield (Givnish *et al.*, 1995), lupines (*Lupinus*, legume family) in the Andes, the Brazilian Highlands, and western North America (Drummond *et al.*, 2012), and *Eucalyptus* (myrtle family) and *Banksia* (protea family) in Australia (Williams and Woinarski, 1997; Mast and Givnish,

Figure 2 Adaptive radiation in growth form and habitat in the Hawaiian lobeliads: (a) Giant rosette shrubs in alpine bogs in *Lobelia* sect. *Galeatella*; (b) treelets of wet subalpine openings in *Trematolobelia*; (c) sea cliff succulents in *Brighamia*; (d) canopy trees, exemplified by *Cyanea hamatiflora* (long leaves) in cloud forests on Maui; (e) understory treelets under intact canopies, exemplified by *Cyanea floribunda* on Hawaii; (f) multi-stemmed shrubs of rain- and cloud-forest edges, canopies, and canopies in *Clermontia*; and (g) treelets of mesic scrub in *Delissea* (Givnish *et al.*, 2009).

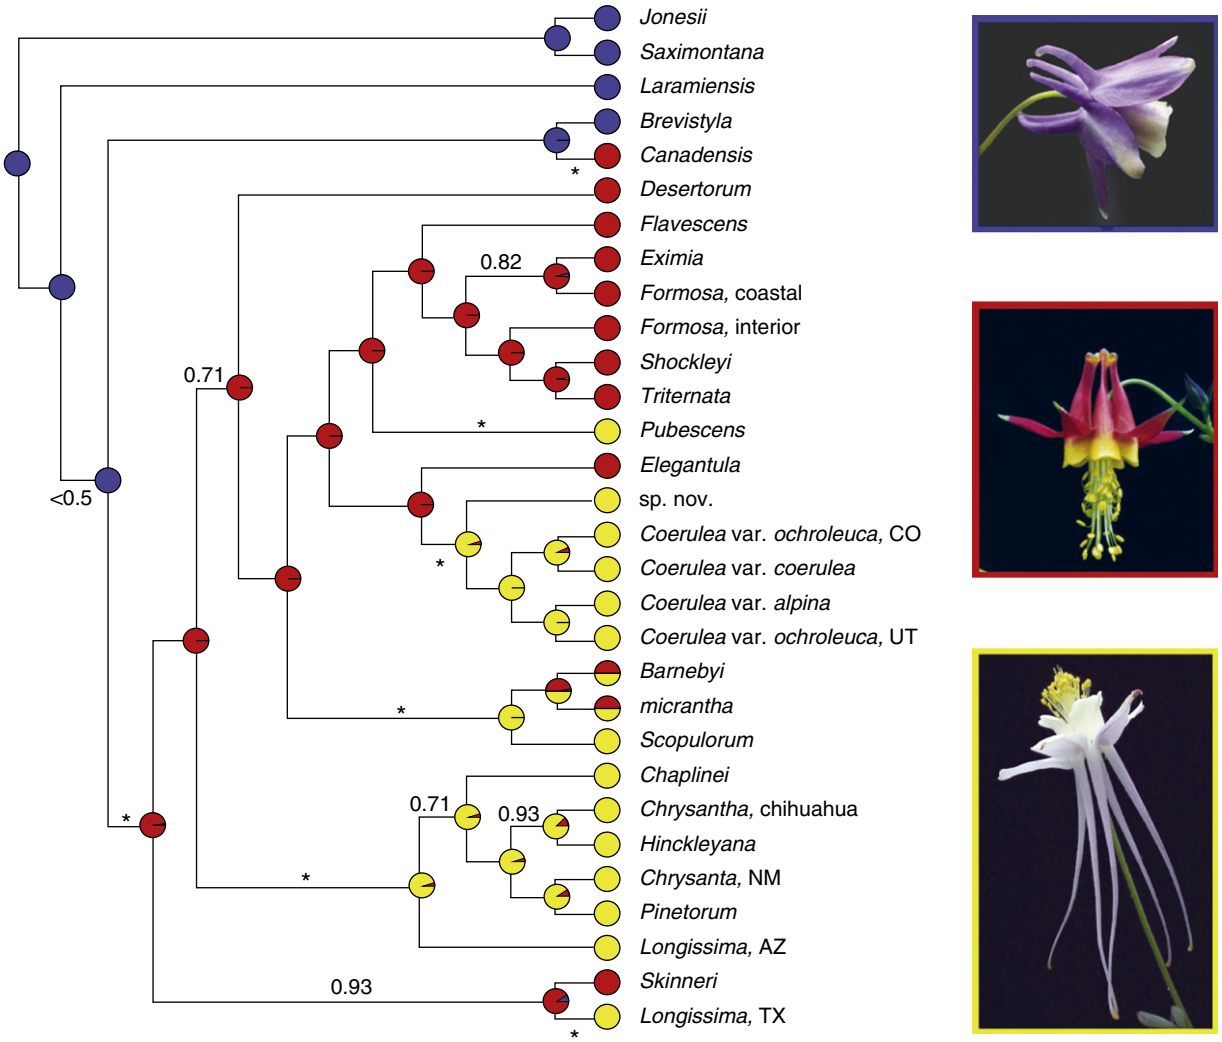

Figure 3 Adaptive radiation involving the sequential evolution of floral adaptations to bumblebees (blue), hummingbirds (red), and hawkmoths (yellow) in North American *Aquilegia*. The probability of each syndrome at each ancestral node is shown by the width of slices in the pie charts. Asterisks indicate inferred shifts in pollinators, including two from bumblebees to hummingbirds, and five from hummingbirds to hawkmoths. All inferred shifts involved an increase in the lengths of floral spurs (containing the nectar) and pollinator mouthparts. Figure from Givnish (2010a), redrawn from Whittall and Hodges (2007).

2002). Given the much wider range of parent materials present on continents versus volcanic or uplifted limestone islands, it is not surprising that adaptive radiation by soil type or bedrock is essentially a continental phenomenon (e.g., invasion of serpentine, gypsum, alkali, clay, loamy, and sandy soils by *Calochortus*, and invasion of serpentine and vernal pools by the pincushion plants (*Navarretia*, phlox family) (Givnish, 2010a)). In the California Floristic Province, over 200 species have become specialized entirely on serpentine soils with aberrant Mg:Ca ratios and high levels of heavy metals (Brady *et al.*, 2005).

Adaptive radiation can lead to increased rates of species diversification within a lineage. Whittall and Hodges (2007) inferred that adaptive radiation in floral form and associated pollinators was a central force driving diversification in columbines (*Aquilegia*) of the Ranunculaceae (buttercup family) (**Figure 3**). Carlquist (1970) argued that adaptive radiation in habitat, growth form, and pollinators was a key driver of plant speciation on islands, and Stebbins (1974) made a similar argument for adaptive radiation helping drive the global diversification of angiosperms at the level of families and genera. Set against these ideas, however, is the fact that many lineages exhibit phylogenetic niche conservatism, in which close relatives remain ecologically quite similar and do not appear to undergo adaptive radiation. Crisp *et al.* (2009), for example, showed that stasis within biomes in plants of the Southern Hemisphere appeared to outweigh biome shifts by more than 25:1 – although this does not exclude the possibility that lineages that remained within a biome have instead radiated with respect to finer-scale variation in habitat, pollinators, seed dispersers, or mycorrhizal fungi. More importantly, there are striking cases of adaptive radiation – for example, Darwin's finches with their great diversity in beak form and diet, and bromeliads in the genus *Brocchinia*, with

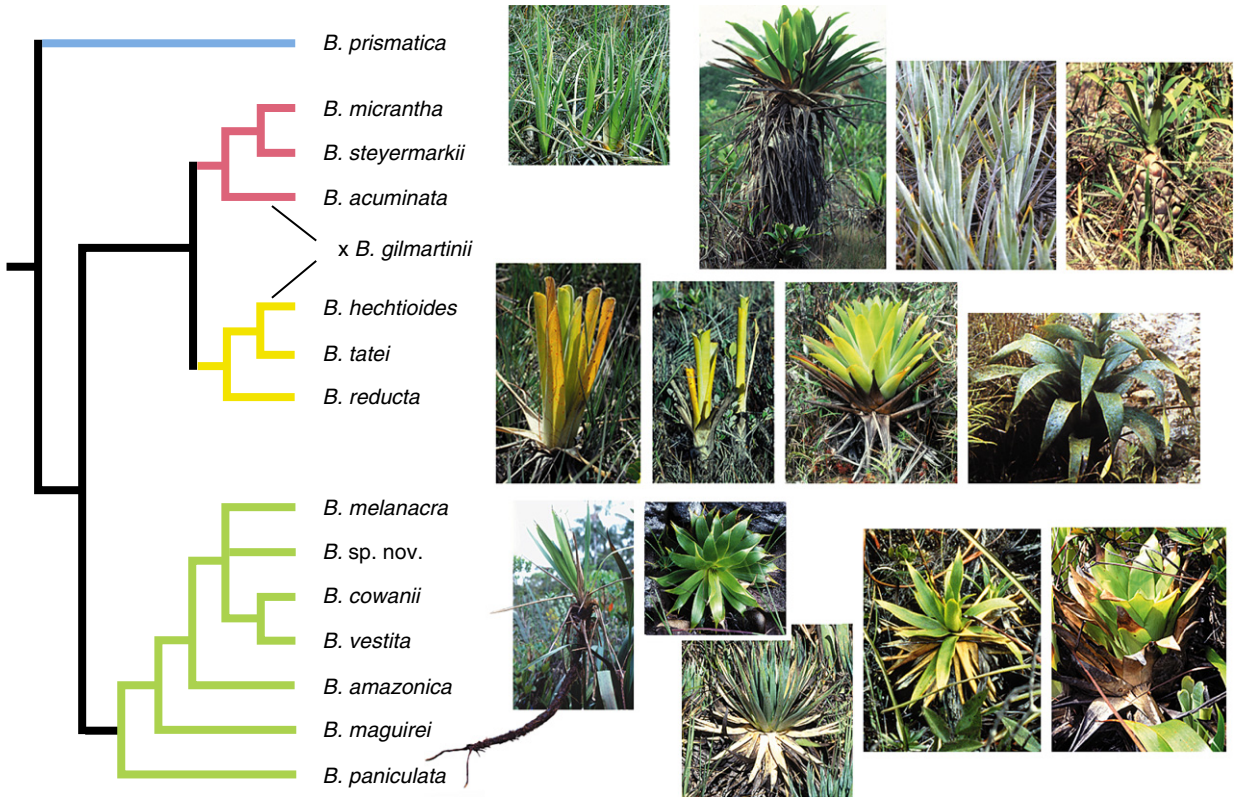

Figure 4 Adaptive radiation in growth form and nutrient capture strategy in *Brocchinia* of the bromeliad family (Bromeliaceae). *B. prismatica* (blue) and all members of the Melanacra Clade (green) except for *B. paniculata* have loosely overlapping leaves, impound no rainwater, have small and sparse leaf hairs (trichomes), and apparently obtain all of their nutrients from bog peats and damp sands and sandstone surfaces. *B. paniculata*, *B. micrantha*, and *B. acuminata* of the Acuminata Clade (red), and all members of the Reducta clade (yellow) have tightly overlapping leaves that form tanks in which rainwater accumulates, and have larger or denser arrays of leaf trichomes. In the Acuminata clade, *B. acuminata* (first image, second row) is a gigantic, unbranched tree-like plant that impounds several liters of water among its leaf bases, in which frogs often live; *B. acuminata* (third image) is an ant-fed plant, with ants living among the swollen, tough, chlorophyll-lacking leaf bases; and *B. steyermarkii* (second image) has lost the tank habit and apparently relies on nutrient absorption via roots from the soil. In the Reducta clade, *B. hechtioides* and *B. reducta* (first and second images, third row) are carnivorous plants, specialized on bees and wasps vs. ants, respectively. *B. tatei* can grow on the ground (as shown in the third image) or as an epiphyte, and catches falling plant debris; terrestrial populations have been seen with N-fixing cyanobacteria growing in their tanks. *B. gilmartinii* (last image, third row) apparently is a hybrid between *B. acuminata* and *B. hechtioides*; its ecology remains uninvestigated. *B. paniculata* (last image, last row)has a growth form similar to that of *B. micrantha*; the remaining species obtain mineral nutrients from the soil. The tough leaf tips of *B. melanacra* (first image, last row), a bog species, are non-functional in fully expanded leaves but protect the terminal bud from fire when young. Phylogeny and images from Givnish *et al.* (1997).

their greater range of strategies for nutrient capture than any other plant genus (**Figure 4**) – that show either the same rate of species diversification as close relatives, or a much lower rate (Givnish, 2015). Other factors – notably short generation times, and limited seed dispersal leading to genetic differentiation within species at small spatial scales and, ultimately, speciation – can have a profound effect on species diversification independent of ecological divergence among relatives.

Based on the phylogenies (family trees) of various plant lineages derived from DNA sequences and calibrated against time using fossils, comparisons show that the rates of net species diversification tend to be higher in herbs (especially annuals) than in woody plants, in animal- versus wind-pollinated species, in families with a greater diversity of growth forms, pollination mechanisms, and species distributions, in families at lower latitudes, in clades with hermaphroditic versus unisexual flowers, in plants with bilateral versus radial symmetry of flowers, in plants with hummingbird pollination or with spurred or tubular flowers, in epiphytic lineages, and in young lineages (see review by Givnish, 2010a, as well as Ricklefs and Renner, 1994, 2000; Whittall and Hodges, 2007; Magallón and Castillo, 2009; Smith and Beaulieu, 2009; Givnish *et al.*, 2014). High rates of species diversification in the grass family (Poaceae) are correlated with the evolution of C_4 photosynthesis and climatic aridification in the Miocene (Spriggs *et al.*, 2014). High rates of diversification in orchids, the largest angiosperm family, are correlated with the evolution of pollinia, epiphytism, CAM photosynthesis, pollination by butterflies, moths, and euglossine bees, and (especially) life in extensive tropical cordilleras (Givnish *et al.*, 2015). As predicted long ago by Ehrlich and Raven (1964), speciation in mustards (order Brassicales) appears to have increased as a result of a coevolutionary arms race involving their chemical defenses and the detoxification abilities of the cabbage butterflies (family Pieridae) whose larvae feed on them. Edger *et al.* (2015) showed that species diversification in the

mustards accelerated with their evolution in sequence of indolic glucosinolates (mustard oils), then methionine-derived glucosinolates, then novel glucosinolate variants. Species diversification in pierids similarly accelerated with evolution of abilities to detoxify indolic, then methionine-derived, then structurally novel glucosinolates. Gene and genomic duplication events appear to have been involved on both sides of this arms race each time it escalated.

Evolutionary Convergence, Divergence, and Diversification within Plant Communities

Arid environments – Deserts are extreme environments, with very low mean rainfall ($< 25\,\mathrm{cm\,y^{-1}}$), high to very high temperatures and low humidity in summer, cool to cold temperatures at night and during winter, and often thin, sandy or rocky soils. The great deserts of the world are mostly centered at 30° N and 30° S latitude, where large masses of hot, dry air descend to the surface after having ascended and lost their moisture via convective thunderstorms near the equator (Allaby, 2006). Dry conditions are exacerbated by the rain shadows created by mountains upwind, and by cold water offshore the western edge of continents. Rainfall is infrequent and highly variable from year to year, especially in deserts receiving the lowest mean rainfall. Where cold water is offshore and upwind (e.g., in the Coloradan Desert of California), almost no rainfall falls in winter; when warmer water is offshore (e.g., in the Sonoran Desert of Mexico and Arizona), monsoons can also bring heavier rainfall during the summer months.

Convergence and divergence are both hallmarks of desert floras (Orians and Solbrig, 1977a). Desert plants include *drought avoiders*, *drought evaders*, and *drought tolerators*. *Drought avoiders* include desert annual herbs that germinate after rains, and grow, flower, and set seed while the soil is relatively moist. In most deserts, these annuals are active almost exclusively after winter rainfall. In deserts with summer and winter rains, there are different groups of species that are summer and winter annuals. Annuals are short in stature, and allocate heavily to flowering and seed production. Species vary substantially in leaf thickness, reflectance, stomatal conductance, and photosynthetic capacity, from thick, hairy, silvery leaves with low rates of photosynthesis and transpiration, to thin, dark green leaves with high rates of photosynthesis and transpiration. *Drought evaders* include deciduous shrubs and herbs in the open desert, which shed their leaves when faced with drought, as well as phreatophytic trees, shrubs, and perennial herbs that live along washes and can tap a constant source of water. Washes serve as watercourses after rains, and substantial amounts of water brought by surface flow infiltrate their soils. Phreatophytes can tap a relatively permanent water table that is often several meters below the surface. *Drought tolerators* include evergreen shrubs like creosote bush (*Larrea*) with small, thick, tough leaves, and leaf or stem succulents like *Agave* and *Opuntia* that have CAM photosynthesis; these groups can also tolerate prolonged and intense droughts while retaining live leaves (**Figure 5**).

Among these growth forms, there is an inverse relationship between maximum photosynthetic rate per unit leaf mass and ability to maintain high photosynthetic rates as soil water content and water potential drop (Orians and Solbrig, 1977a,b). Desert annuals have the highest maximum rates of photosynthesis, but those rates are achieved with high stomatal conductance and rates of transpirational water loss, and so their photosynthetic rates drop rapidly as soils dry. Evergreen shrubs and especially succulents have much lower maximum rates of photosynthesis, but can remain active with

Figure 5 Examples of plant growth forms characteristic of the Sonoran desert of North America: (a) Stem succulent (saguaro, organ pipe, and cholla cacti (*Carnegiea, Stenocereus, Opuntia*) are visible) and drought-deciduous shrub (brittlebush (*Encelia farinosa* of the daisy family, with conspicuous yellow flowers and silvery leaves); (b) evergreen shrub (creosote bush (*Larrea divaricata*, family Zygophyllaceae) with narrow, tough leaves); (c) stem succulent with photosynthetic bark and drought-deciduous leaves (ocotillo (*Fouquieria splendens*), family Fouquieriaceae); (d) leaf succulent (*Agave palmeri*); (e) winter annual (*Phacelia calthifolia*, phlox family); and (f) summer annual (*Pectis papposa*, daisy family). All succulents shown have CAM photosynthesis except ocotillo, which is C_3.

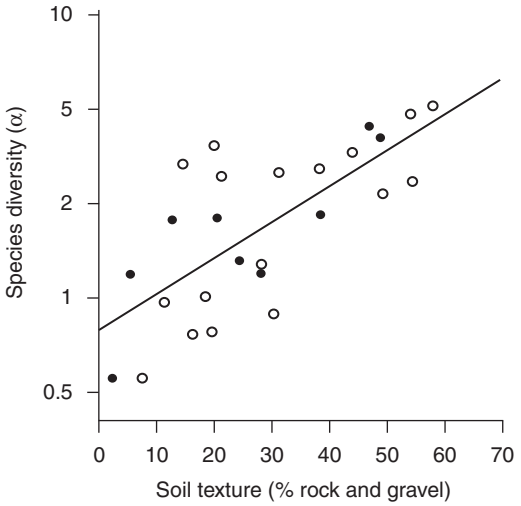

Figure 6 In the caption, use hollow and solid circles to refer to the North and South American deserts. Species diversity (Fisher's α index) vs. soil texture in North American (○) and South American (•) deserts (redrawn from Orians and Solbrig, 1977a,b). Note the convergence in the relationship of diversity to soil texture; more species are found per unit area on coarser soils with more rock and gravel.

relatively little fall-off in carbon capture even when soils are very dry (predawn water potential approximately -6 MPa). As a result of the inverse relationship between photosynthesis and its sensitivity to water potential, as soils dry after the winter (or summer) rains cease, there will be periods when each growth form – annuals, then deciduous herbs and shrubs, then evergreen shrubs, then succulents – has a photosynthetic advantage. The greater the range of moisture conditions present during a year, the greater the diversity of growth forms should thus be able to coexist, via a seasonal partitioning of photosynthetic advantage (Orians and Solbrig, 1977b). In deserts with sparse rainfall, coarse sandy or gravelly soils store the most moisture because they have high infiltration rates and little water is lost through evaporation at the surface after a storm; finer-grained soils have low infiltration rates and wind up storing less moisture. Consequently, we would expect the diversity of growth forms – and of plant species – to be higher on coarser soils. Indeed, Orians and Solbrig (1977b) found remarkably tight and similar relationships between species diversity and percentage of sand and gravel in deserts in Arizona and Argentina (**Figure 6**). Based on the alluvial sorting of soil texture, sites high on bajadas (desert slopes) have coarse soils and high diversities of both life forms and plant species, while those low on bajadas and alluvial flats have finer soils and lower diversities of life forms and species. In addition, in areas with lower rainfall – and thus, greater proportional variation in rainfall from year to year – deserts become increasingly dominated by annuals (Schaffer and Gadgil, 1975).

High rates of diversification are expected in desert annuals, based on their short life cycles (Lewis, 1966), tendency toward inbreeding (Raven and Axelrod, 1978), and dearth of effective means of long-distance seed dispersal (Givnish, 2010a). Little is known quantitatively on the actual rates of diversification, however. Over 2000 species of desert and vernal-pool annuals comprise 26% of the vascular flora in the California Floristic Province, and most of these most likely arose in the last 15 million years following the uplift of the Sierra Nevada and the origin of winter rainfall (Raven and Axelrod, 1978). Evans *et al.* (2009) showed that a clade of *Oenothera* (Onagraceae, evening primrose family) composed almost exclusively of desert winter annuals spawned at least 11 species in 250 000 years, which would correspond to a net rate of species diversification D ($= \ln(S)\, T^{-1}$, where S is the number of species in a clade, and T is the stem age of that clade) of 9.6 sp sp^{-1} My^{-1} – an extraordinarily high rate that exceeds that of all plant groups studied to date (e.g., $D < 7.6$ My^{-1} for European *Dianthus* in the pink family (Valente *et al.*, 2010); $D < 5.2$ My^{-1} for Andean *Lupinus* (lupine; Drummond *et al.*, 2012)). Succulents in the Aizoaceae (ice plant family) of the South African Karoo also have a high rate of species diversification ($D < 1.75$ My^{-1}), but this appears related to their exceptionally poor powers of long-distance seed dispersal (splashed from capsules by raindrops) rather than their growth form (Klak *et al.*, 2004; Ellis *et al.*, 2006).

Another mechanism that might promote high rates of diversification in desert winter annuals, and maintain high levels of species richness, involves competition across years based on their differential responses of germination, survival, growth, and seed production in response to variation in rainfall within a growing season (Angert *et al.*, 2009). Annuals vary greatly in leaf thickness, reflectance, stomatal conductance, and photosynthetic capacity. Those with thin, green leaves have high photosynthetic rates and can produce large numbers of seeds in a rainy year, but are sensitive to drought; those with thicker, more silvery leaves have lower rates of photosynthesis and seed production but can survive in years with less rainfall. Angert *et al.* (2009) demonstrate that this tradeoff, combined with the high incidence of multi-year dormancy in winter annuals and their persistence in the seed bank, can permit a large diversity of annuals to coexist locally over long periods of time.

Across life forms, thicker, more reflective, and more steeply inclined leaves and lower stomatal conductance reduce water loss per unit leaf mass while reducing photosynthesis to a lesser extent. The high cost of water loss in dry environments, in terms of roots required to replace transpirational water losses, thus favors the evolution of thick, reflective leaves with low stomatal conductance. Narrow leaves reduce water loss per unit leaf area and increase convective cooling, and thus should also be favored in deserts (Givnish, 1986). Seasonal water shortage prevents perennial herbs or shrubs from covering the entire ground surface, allowing annuals – which perforce are short over much of their life cycle – to compete successfully with such taller plants. Low coverage, even after rains, favors short stature throughout the life cycle in desert annuals, and limited stature in perennial dominants (Givnish, 1982; Tilman, 1988).

C_4 photosynthesis – while much less common that the C_3 photosynthetic pathway worldwide – often results in higher photosynthetic rates at low rates of transpirational water loss under warm, dry, sunny conditions. In deserts, C_4 photosynthesis is seen in many summer-active annuals and perennials, especially in grasses, sedges, amaranths, chenopods, and knotweeds, and is especially common in salt flats, where

reductions in water lost result in less energy being expended to excrete salt from the leaves, or to exclude it from being absorbed in the first place.

CAM photosynthesis reduces water loss even more than C_4 photosynthesis, although at the cost of greatly reduced carbon uptake. Not surprisingly, succulent plants with CAM photosynthesis are common in many deserts and semi-arid areas, including cacti and *Agave* species in New World deserts, and morphologically convergent *Aloe* and *Euphorbia* species in the Old World. Both C_4 and CAM involve CO_2 concentrating mechanisms that yield an advantage when atmospheric CO_2 levels are low. Cacti and Agave in the New World, and Aizoaceae in the Old World, underwent rapid species diversification starting 15 million years ago, suggesting that aridity and a drop in atmospheric CO_2 levels may have been drivers of a global diversification of succulent CAM plants (Arakaki *et al.*, 2011). A more detailed study, however, also suggests that the invasion of Central and North America as well as the rise of pollination by birds, bats, and hawkmoths may also have driven diversification in the cactus family (Hernández-Hernández *et al.*, 2014).

Among succulents generally, stature increases with the density of competing vegetation in which they occur: stone plants (*Lithops*, ice plant family) occur on nearly bare ground and are just a centimeter tall, while saguaro cacti – the tallest members of the cactus family – often grow in fairly dense desert woodlands on sites receiving abundant sheet flow, and can grow up to 12 m in height. Even so, desert succulents on different continents and in different families often show striking convergence, involving stem succulents in the cactus and spurge families (Cactaceae and Euphorbiaceae) in the New versus Old World, leaf succulents in the agave and aloe families (Agavaceae and Aloeaceae) in the New World versus Africa, and bark succulents in the ocotillo and Madagascar succulent families (Fouquieriaceae and Didieraceae). Slow-growing but water-rich succulents defend themselves from herbivores with spines, stinging hairs, and caustic sap, and in some cases (e.g., the famous stone plants) may have avoided being eaten by ostriches through visual mimicry of the stony soil on which they grow. Some cacti (e.g., *Pediocactus* and *Sclerocactus*) have flattened, brown spines that appear to mimic the dried leaves of grasses among which they grow.

Alpine tundra – Alpine habitats above treeline on mountains are another kind of extreme environment, with low temperatures ($< 10\ ^\circ C$ mean during summer), short growing seasons, frequent freeze–thaw cycles, cold winters, heavy UV irradiation, and in many localities, high winds, heavy snows, and thin soils (Körner, 2003). Treeline elevation varies from sea level at the continental limits to tree growth in the Arctic (ca. 60° N) and Antarctic (ca. 70° S) to 3800–4500 m in the tropics and subtropics. In areas with adequate moisture and soil, areas of continuous tree cover correspond roughly to areas with at least 100 days with mean temperatures $\geq 6.5\ ^\circ C$ (Körner, 2003). The mean ground temperature at 46 treeline sites between 68° N and 42° S is $6.7^\circ \pm 0.8\ ^\circ C$ (Körner and Paulsen, 2004). The strong correlation of treelines with thermal conditions strongly suggests that temperature is a key determinant of their position.

Although the limits of tree growth along moisture and light gradients has long been viewed to result from limited carbon capture (Boysen-Jensen, 1949), some authors have stated that carbon limitation does not set the position of alpine treelines, despite the negative effects of lower temperatures and shorter growing seasons on carbon capture. Körner (1998, 2003) argued that the position of alpine treelines is set not by carbon limitation but by limitations of cell growth – especially of the roots – by cold temperatures. Trees roots should be especially vulnerable to this limitation because even short saplings would create cold soil conditions by shading the ground and insulating it with a thick layer of air; sunlit compact herbs and cushion shrubs should, on the other hand, warm the soil immediately below them well above air temperature. But the hypothetical limitation of root growth under tall plants would still leave carbon balance as a prime determinant of treeline position: taller plants would simply be unable to continue aboveground growth without matching root growth to enable absorption of water and nutrients, with negative effects on photosynthesis likely. In fact, tree height decreases smoothly and linearly with elevation in the European Alps, far below the range at which the hypothesized limitation of trees by cold soil would operate, with tree height at treeline of 5 m in Norway spruce (*Picea abies*) and 8 m in Swiss stone pine (*Pinus cembra*) (Paulsen *et al.*, 2000).

So an abrupt decline in maximum height by a few meters near treeline may, as argued by Körner, be driven by cold soils under taller trees and by an elevation of leaf temperature and hence photosynthesis by assuming a krummholz cushion form (**Figure 7**) within the ground boundary layer, but carbon limitation is important in setting treeline position. Recent CO_2-addition experiments have confirmed an increase in growth by European larch (*Larix decidua*) but not Swiss mountain pine (*Pinus uncinata*) near treeline – clearly implicating carbon limitation – although the strength of this effect weakened after 6 years (Dawes *et al.*, 2015). Experimental warming of soils in the same experiment elevated growth by pine (but not larch), with the expected increase in root allocation.

In non-equatorial alpine environments, the dominant growth forms are krummholz, cushion shrubs, and compact to tall herbs (Körner, 2003). The aerodynamically smooth canopies of krummholz and cushion shrubs allow air to move past them without much mixing, permitting their leaves to warm 5–15 °C above the air only a meter or two above the ground boundary layer. Elevated leaf temperatures in a thermally limited environment can clearly be advantageous; such a benefit, as well as increased root temperatures, should also accrue to short herbs. In addition, smooth canopies of krummholz and cushion shrubs should divert winds around rather than through canopies, greatly reducing transpirational water loss under windy conditions, and decreasing sand- and ice-blasting of exposed plant parts. Desiccation or mechanical abrasion may indeed help shape the canopies of krummholz and cushion plants by eliminating projecting parts. Plants in many different families (e.g., Apiaceae, Asteraceae, Caryophyllaceae, Diapensiaceae, Ericaceae, Rubiaceae, Saxifragaceae, Stylidiaceae – the carrot, daisy, pink, diapensia, heath, coffee, saxifrage, and triggerplant families) have evolved this habit in alpine and arctic tundra communities across the Northern and Southern hemisphere. The warmth and sheltering influence of cushion plants, together with the moist

Figure 7 Krummholz of balsam fir (*Abies balsamea*) on Mt. Washington in northern New Hampshire.

soil they shelter, can permit them to have a beneficial effect on nearby plants in harsh alpine habitats (Badano and Lohengrin, 2006).

Narrow, thick leaves reduce water loss per unit leaf mass with small decreases to photosynthetic rate (see above), and so should be advantageous in alpine habitats with cold soils that restrict water uptake. Short-statured plants with streamlined canopies have advantages in elevating leaf temperature and reducing transpiration and mechanical damage in cold, windy alpine environments, but should be at a disadvantage in competing for light against taller competitors. Therefore, we expect taller competitors with looser canopies to replace short, cushion-form plants at lower elevations and in less exposed microsites, as can be frequently observed in many areas (e.g., see Billings and Mooney, 1968; Slack and Bell, 2014). Small changes in microtopographic position – involving shift of only a few centimeters – can have dramatic effects on wind exposure and snow accumulation, and on the plants inhabiting a microsite; such variation may partly account for the large numbers of species that co-occur in many alpine habitats. The short growing season in such habitats is, no doubt, responsible for their brief but spectacular period of flowering.

Frosts occur often throughout the growing season in many alpine environments, and increasingly so at higher elevations and more northerly exposures (Körner, 2003). Many species – including several cushion plants – have evolved the ability to supercool (that, chill below freezing without ice nucleation) or have internal ice barriers to prevent crystals from growing and damaging other parts of a plant once nucleation has begun (Kuprian *et al.*, 2014). Thermal gradients resulting from heating of the underlying soil by day can also prevent freezing damage to vegetative parts in cushion plants (Hacker *et al.*, 2011). The inflorescences of some plants project above the vegetative body and are therefore more exposed to both radiative and convective cooling, and somewhat decoupled from thermal inputs from the underlying soil. Reproductive shoots are often less frost resistant than vegetative shoots (which frequently can tolerate ice formation), but some species can supercool to at least $-22\ ^{\circ}C$ without damage (Kuprian *et al.*, 2014).

Frequent freeze–thaw cycles during the growing season can heave seedlings and small plants from the soil. This should strongly favor plants which spread vegetatively and that do not depend as strongly on seedling establishment. Not surprisingly, 87% of vascular plant species in the Swiss alpine zone exhibit vegetative spread (Hartmann, 1957). Freeze–thaw cycles should hit seedlings of trees especially hard, given that they are non-clonal and have no vegetative connection to deep-rooted individuals.

Above treeline on equatorial mountains, there is essentially no thermal seasonality, but summer every day and winter every night (Hedberg, 1964; Smith and Young, 1987). Such communities are dominated by unbranched, giant rosette shrubs with marcescent leaves (i.e., those that persist on the stem after they die) (**Figure 8**). This highly unusual growth form has evolved convergently in *Espeletia* (daisy family) and *Puya* (bromeliad family) in Andean paramo and puna; in *Dendrosenecio* (daisy family) and *Lobelia* (lobelia family) in the Afro-alpine zone; and in *Agyroxiphium* (daisy family) and *Lobelia* in Hawaii. Different lineages evolved the giant rosette habit on different continents within the daisy and lobelia families (Knox, 2014; Givnish, 2010b).

The unbranched habit in equatorial alpine rosette shrubs permits concentration of foliage around a single terminal bud; in many species of *Espeletia* and *Dendrosenecio*, the heavily pubescent leaves wrap around the bud at night and prevent it from freezing and dying (Meinzer and Goldstein, 1986). In *Lobelia keniensis* of the wet Rwenzori Mountains in equatorial East Africa, rainwater collects among the tightly packed terminal leaf rosettes; its terminal buds apparently survive nightly frosts by sitting at the bottom of a small pool formed by the plant itself (Hedberg, 1964). The unbranched habit should also increase the rate of height growth, taking plants from the thermal extremes (frost by night, warm conditions by day) near the ground surface to more buffered conditions a meter or two above the ground (Smith and Young, 1987). The massive stems of the rosette shrubs enclose a large volume of pith; plants withdraw water from the pith early in the morning, when photosynthesis becomes possible after the sun rises but the plants are unable to withdraw water from the still-frozen ground (Meinzer and Goldstein, 1986). Species of *Espeletia* at higher elevations have a higher ratio of pith volume to leaf area, based either on a reversed elevational cline in plant height, or an increase in pith diameter. Leaf marcescence

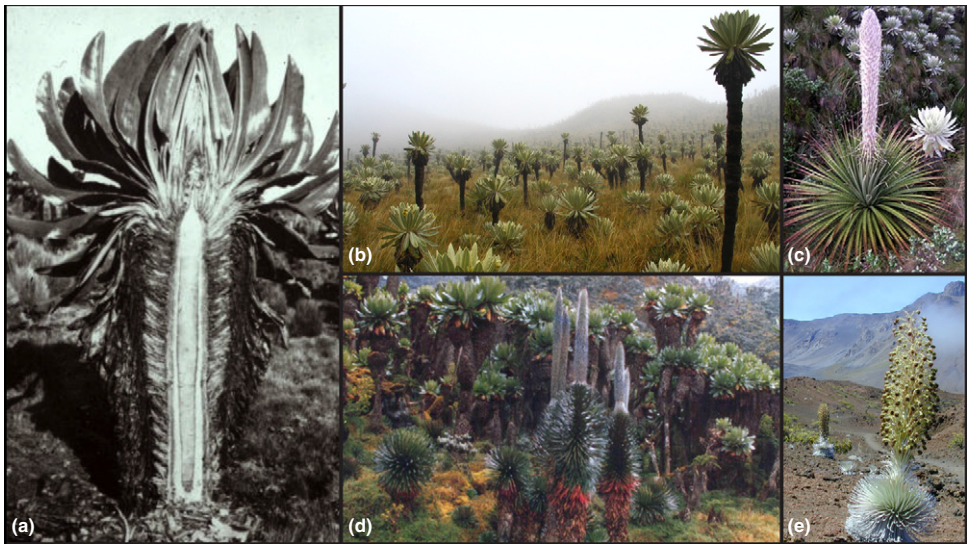

Figure 8 Giant rosette shrubs of the equatorial alpine zone. (a) Section through a *Dendrosenecio* (Asteraceae (daisy family) from the equatorial alpine zone in East Africa; (b) stand of *Espeletia pycnophylla* in an Ecuadorean paramo; (c) *Puya clava-herculis* in an Ecuadorean paramo; (d) *Lobelia wollastonii* (with elongate, silvery inflorescences) and *Dendrosenecio adnivalis* growing in the Afro-alpine; and (e) Haleakela silversword (*Agryoxiphium sandwichense*, daisy family) growing near 3000 m elevation on east Maui.

produces an insulating blanket around the stem that prevents the pith from freezing and dying, and facilitates morning photosynthesis (Meinzer and Goldstein, 1986).

Alpine plants have undergone high rates of diversification around the globe, with rates D from 0.37 to 0.81 My^{-1} in Himalayan larkspurs (*Delphinium* subg. *Delphiniastrum*), 0.35 to 2.19 My^{-1} in New Zealand rock-cresses (*Pachycladon*), and 0.60 to 1.60 My^{-1} in Andean groundsels (Espelitiinae), 1.48 to 3.21 My^{-1} in Andean gentians (*Gentianella*), and 1.56 to 5.21 My^{-1} in Andean lupines (*Lupinus*) (Hughes and Atchison, 2015). Doubtless these high rates reflect the recent formation of many alpine regions through glacial retreat and orogeny, the archipelago-like nature of many mountain ranges, and the short life cycles of some of the plants involved.

Summary

Alpine habitats and deserts exemplify extreme environments, where plant growth and survival are strongly limited by one or a few factors, and where strong similarities in plant form or physiology often arise through convergent evolution and through species sorting along environmental gradients based on the traits with which different plants are endowed. Phenotypic divergence among species – reflecting divergent evolution, or species sorting based on dissimilarities among species – arises via competition. Closely related species are often very similar phenotypically and thus are each other's most intense competitors. Selection for divergence among species in habitat, form, physiology, or mutualists within a lineage leads to adaptive radiation; species sorting can lead to community assembly based partly on advantages accruing to species with similar traits adapted to environmental conditions, and based partly on advantages accruing to species with divergent traits that reduce competition among them. Under certain circumstances, adaptive radiation can lead to accelerated rates of speciation and net species diversification. But limited dispersal, and differences among lineages in growth form, generation length, and extrinsic barriers to dispersal and gene flow within the habitats they occupy, may be as or more important in driving different rates of net species diversification.

Cooperation and Public Goods, Bacterial

CJ Rose, New Zealand Institute for Advanced Study, Massey University, Auckland, New Zealand
PB Rainey, New Zealand Institute for Advanced Study, Massey University, Auckland, New Zealand; and Max Planck Institute for Evolutionary Biology, Plön, Germany

Social behaviors are those that have fitness consequences for both actor (the individual performing the behavior) and recipient (West *et al.*, 2007). Hamilton (1964a) first classified social interactions according to whether the fitness consequences for the actor and recipient are beneficial or costly (**Table 1**). If a behavior increases the fitness of the recipient, it is deemed either 'mutually beneficial' (when the actor also gains a fitness advantage), or 'altruistic' if the behavior is costly to the actor. Alternatively, 'selfish' behavior increases the fitness of the actor at a cost to the recipient, while 'spiteful' behavior is costly to both.

Definition of Cooperation

A cooperative behavior is generally described as an investment in resources that benefits an individual (the recipient) other than the actor (Chase, 1980). Two important features of cooperation are:

1. that the behavior exhibited by the actor is costly relative to a nonactor, and
2. that the behavior increases the fitness of other individuals, regardless of whether or not they adopt the same behavioral strategy.

Under this definition, both mutualism and altruism (**Table 1**) are considered to be cooperative interactions because they both increase the fitness of the recipient. Velicer (2003) emphasizes that altruism is a subset of cooperation in which there is no direct benefit to the actor, cautioning that semantic confusion arises when the use of the terms 'cooperation' and 'altruism' are used interchangeably.

There are two categories of explanation for the evolution of cooperation (Calcott, 2011). First, there is a need to explain how cooperation generates a benefit, and secondly, there is a need to explain how individually costly behaviors can continue to exist.

Benefits of Bacterial Cooperation

Cooperative groups in many lineages may have obtained advantage from colonization of new niches, or from the advantage of increased size afforded by the ever-present open niche at the top of the size scale (Bonner, 1988, 2000). One proposed advantage of increased size is that larger assemblages of cells avoid predation by filter feeders (Bell, 1985; Boraas *et al.*, 1998). The argument may be reversed such that increased size enhances feeding efficiency. For example, a low sucrose environment selects for multicellular clumps in experimental populations of the yeast *Saccharomyces cerevisiae* because this nutrient is digested extracellularly by a secreted enzyme (invertase), preventing solitary cells from growing at low cell and sucrose concentrations (Koschwanez *et al.*, 2013). Primitive flagellated or ciliated cells may be able to swim faster as part of a group, enabling the group to catch prey (Bonner, 1998). Both the eukaryotic myxomycetes (true slime molds) and the prokaryotic myxobacteria can feed more effectively by increasing the size of the feeding mass (Bonner, 1998). These species produce extracellular enzymes to digest large food, which they subsequently absorb directly. This form of feeding was originally termed 'pack' feeding in the case of myxobacteria (Dworkin, 1972) and is now more commonly referred to as 'wolf-pack' feeding. Cooperative feeding may have arisen in heterotrophs because the formation of multicellular groups allowed cells to benefit from the efficiency of aerobic respiration (Pfeiffer *et al.*, 2001). The higher yield of ATP (chemical energy) resulting from cooperative resource consumption during respiration is produced at a lower rate than from fermentation and therefore may be advantageous in the presence of a slowly diffusing food source.

Other advantages of cellular cooperation include benefits associated with both fixed surface attachment and enhanced dispersal. Single cells located in an ideal position for growth may be swept away by currents or wind, whereas an increased ability to adhere to surfaces by cell clusters might be selectively advantageous (Bonner, 1998). Conversely, primitive clustering aggregates may enhance dispersal of spores (Gross, 1994).

Table 1 Classification of social interactions

		Effect on recipient	
		+	−

Explanations for Cooperation

Cooperation exists in all kingdoms of life, and yet the phenomenon has sparked debate in the field of evolutionary biology for the greater part of the last century (Wright, 1945; Wynne-Edwards, 1962; Hamilton, 1963; Maynard Smith, 1964; Williams, 1966; Trivers, 1971; Wilson, 1975; Dawkins, 1976; Frank, 1998). The challenge is to explain how individually costly behaviors can continue to exist. Natural selection favors types that are relatively more fit than others, and therefore the evolution of cooperative behaviors seems paradoxical because such behaviors are, by definition, costly to actors relative to recipients.

Various methods have been proposed that can, in principle, explain how cooperative behaviors can exist in an evolutionary

context. These explanations can be viewed as mechanisms by which the cost of a cooperative behavior can be offset by benefits gained at different levels of the biological hierarchy. Individually costly behaviors have been explained at the level of selection below the individual (e.g., genes), at the level of the individual (e.g., reciprocal interactions between individuals), and at levels above the individual (e.g., interactions between groups). These three categories of explanation for the evolution of cooperation are discussed in the following subsections.

Shared Genes

Inclusive fitness theory (Hamilton, 1964a,b), kin selection (Maynard Smith, 1964), and selfish gene theory (Dawkins, 1976) are all variations of explanations for cooperation involving shared genes. According to these theories, cooperation can be maintained in a population when one individual benefits another individual with whom it shares genetic material through descent from a common ancestor. By definition, this mechanism can only explain cases of cooperation between members of the same species (Sachs *et al.*, 2004). Inclusive fitness theory posits that if cooperative behaviors are directed toward relatives, the 'inclusive fitness' (a measure of an individual's fitness that includes the reproductive success of its kin) of the actor can increase because other copies of its genes receive the benefit of the cooperative action. In other words, cooperation increases the reproductive success of the actor's genetic material (which encodes the cooperative trait), regardless of the reproductive fate of the actor. This phenomenon was mathematically formalized by Hamilton's inequality, $rb - c > 0$, where r is the coefficient of relatedness between the recipient and the actor, b is the additional reproductive benefit gained by the recipient, and c is the reproductive cost to the actor. Hamilton's rule predicts that cooperation will be favored by natural selection when the inequality is satisfied, and that cooperation is more likely to be directed toward relatives.

Kin selection can be partitioned into the categories of kin fidelity and kin choice, which differ in the mechanism by which they satisfy Hamilton's rule (Sachs *et al.*, 2004). Kin fidelity is contingent on the natural spatial distribution of related individuals (e.g., bacterial colonies). Cooperators do not actively direct cooperative actions toward kin, but toward physically close individuals who will likely be more closely related to the actor than the average member of the population. Many bacterial populations naturally exist in static environments, resulting in any cooperative behavior to be passively directed toward close relatives. Alternatively, if individuals exhibit a distinguishing phenotype that enables recognition of relatives, cooperative actions may be actively directed toward kin, even in unstructured environments.

The shared gene framework cannot be applied to those instances of cooperation between unrelated individuals or to cooperation between members of different species (Nowak, 2006). Evidence shows that relatedness is not an essential requirement for the evolution of cooperation and, particularly in the case of kin fidelity, may often be a spurious by-product of cooperation by other mechanisms (Kaushik and Nanjundiah, 2003; Smukalla *et al.*, 2008; Nowak *et al.*, 2010). Even kin choice may be achieved through the 'green beard' effect (Dawkins, 1976), which requires a single genetic locus to encode both the cooperative trait itself and a distinguishing feature (a 'green beard') by which to recognize and direct cooperative behavior toward other individuals carrying this locus. The green beard effect is also effective between nonrelatives who share a green beard gene(s). For example, flocculation in the yeast *S. cerevisiae* is induced by expression of the green beard gene *FLO1*, which causes cells to preferentially stick to other cells expressing *FLO1* regardless of genetic relatedness across the rest of the genome (Smukalla *et al.*, 2008). Similarly, the *csA* gene in the social amoeba *Dictyostelium discoideum* encodes a cell adhesion protein that interacts by homophilic binding to proteins anchored in the cell membrane of other cells, thereby facilitating preferential aggregation with other *csA*-encoding cells during fruiting body formation (Queller *et al.*, 2003).

To summarize, formal descriptions of the essential features of kin selection reveal that relatedness is optional and the essence of cooperation can be captured by any mechanism that promotes assortment between cooperating types (Godfrey-Smith, 2009). Although inclusive fitness theory is an empirically well-supported accounting method that is often invoked to explain the evolution of cooperation, it provides little insight into ecological mechanisms underpinning assortment (Doebeli, 2010).

Reciprocity

Reciprocal interactions between individuals can offset the cost of cooperation with fitness benefits gained at the same level, i.e., the level of the cooperating individuals themselves. Reciprocity, or 'reciprocal altruism' (Trivers, 1971), is classified as a mutually beneficial form of social interaction (**Table 1**) because both the actor and the recipient benefit from the cooperative interaction. While the evolution of a trait that directly benefits the actor may appear to be straightforward selection at the level of the individual, the challenge, as with all cooperation, is to explain how cooperation is maintained amongst the ever-present possibility of defection.

The paradox of cooperation is often examined within the framework of evolutionary game theory (Lewontin, 1961; Maynard Smith and Price, 1973), and its application to the 'Prisoner's Dilemma' game – a game that tests the consequences of cooperation and defection (Trivers, 1971). In the Prisoner's Dilemma game, defection will spread in a population made up of two 'players,' a cooperator and a defector, despite the cooperative strategy providing the best pay-off when both players cooperate. The Prisoner's Dilemma has been observed in many areas of ecology, including simple organisms such as viruses (Turner and Chao, 1999).

Reciprocity can evolve if there are repeated encounters between the same individuals (in an iterated Prisoner's Dilemma game), and if an individual has the ability to vary its strategy according to its partner's previous actions. The maintenance of a cooperative bacteriophage evolving at a low multiplicity of infection (ensuring clonal populations) during long-term selection experiments (Turner and Chao, 2003) can be interpreted as a player changing strategy to dominate the game (e.g., Chen *et al.*, 2012).

One successful game strategy is 'tit-for-tat,' in which an individual responds toward its partner with the same action the other player performed in the previous round (Axelrod and Hamilton, 1981). In *Pseudomonas aeruginosa* colonies growing on solid substrate, the costly secretion of pyoverdin, an iron chelator, is maintained in the population by tit-for-tat trafficking between contacting cells (Julou *et al.*, 2013). The local concentration varies according to the pyoverdin secreted by neighboring cells, feeding into a positive feedback loop that induces pyoverdin synthesis in the focal cell. Furthermore, this local exchange modulates the growth of individual cells thereby preventing a long sequence of retaliation because local patches of non-producers are outcompeted by the faster growth of producers.

Group Selection

Individually costly behaviors can be offset by benefits gained at levels above the individual – the level of the group. While cooperative actions may be selectively disadvantageous during competition between lower level entities within a group, they can be maintained by enhancing the competitive ability of the group in those instances where groups compete against groups. Darwin himself recognized that natural selection between groups might explain the evolution of self-sacrificial behavior among humans (Darwin, 1871). Michod and Roze (1999) even define cooperation in terms of the group-level fitness benefit: "an interaction that possibly decreases the fitness of the individual while increasing the fitness of the group".

The evolution of cooperation as a group-level adaptation has been (and still remains) one of the most debated areas in evolutionary biology, largely due to confusion over different modes of group selection. The debate was sparked in the 1960s when Wynne-Edwards (1962) argued that reproductive constraint evolved 'for the good of the group' because groups that do not exhibit restraint go extinct due to overexploitation of resources. The process of differential proliferation and extinction of groups leads to the evolution of cooperative behaviors that are adaptations of the group, rather than adaptations of the individual.

David Sloan Wilson's 'trait-group' model of group selection explicitly demonstrated that the cost of cooperation within groups could be offset by the differential productivity of groups (Wilson, 1975). However, Wilson's model was based on a different conception of the group, leading to a widespread misunderstanding of group selection. In Wilson's model the global population repeatedly separates into temporarily interacting 'trait-groups' with varying compositions of the group-beneficial cooperative trait. Despite the individual cost of cooperation, groups with a higher proportion of cooperators contribute more individuals to the total population than groups with a lower proportion of cooperators. The differences between this model of group selection, and one that requires differential reproduction of groups (*sensu* Wynne-Edwards and Wade) are illustrated in **Figure 1**. Progressively, group selection theory has developed into Multilevel Selection theory (Heisler and Damuth, 1987), which distinguishes between the type of group selection in which groups are part

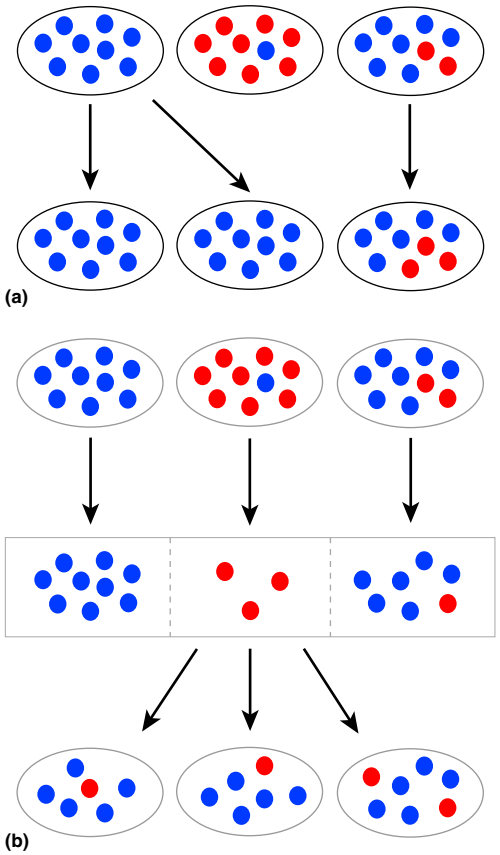

Figure 1 Two models of group selection. (a) Wynne-Edwards type of group selection. Selection is between groups via differential extinction and reproduction of groups, with well-defined groups and little gene flow between them (solid boundary lines). Blue circles represent cooperators, whereas red circles represent selfish types. Selfish types spread within groups, however groups with more cooperators leave more group offspring. (b) Trait-group model of group selection with arbitrarily defined groups (gray boundary lines). Groups with more cooperators make a higher contribution to a shared reproductive pool, from which new groups are formed. Reproduced from West, S.A., Griffin, A.S., Gardner, A., 2007. Social semantics: Altruism, cooperation, mutualism, strong reciprocity and group selection. Journal of Evolutionary Biology 20, 415–432, with permission from Wiley.

of the environment of individual, and the type in which groups themselves are units of selection (Hammerschmidt *et al.*, 2014).

The trait-group model of group selection can be alternatively conceptualized as individual selection with fitness-affecting interactions between neighbors – as is the case for kin selection. Group selection can effect the evolution of cooperation when variation between groups is increased relative to variation within groups – a situation that can be achieved by increasing the coefficient of relatedness, *r*, between interacting individuals (Frank, 1998). Indeed, it has since been argued that the two models are identical (Wade, 1985; Queller, 1992; Frank, 1998; Nowak *et al.*, 2010), although Traulsen (2010) has demonstrated that this mathematical equivalence is in fact only found in special cases. Similarly, reciprocity can drive assortative interactions between cooperators, decreasing the variation within groups of interacting individuals, and

increasing variation (and selection) between groups. In fact from a theoretic perspective, groups of a particular structure are unnecessary for the evolution of cooperation in those instances where the population is structured so that individuals interact with their neighbors (Maynard Smith, 1976; Godfrey-Smith, 2009). Cooperators can persist in a population if they are more likely to interact with each other than by chance (Godfrey-Smith, 2009). Therefore, the key principle common to the three classes of explanation for the evolution of cooperation is 'correlated interaction' between individuals (Godfrey-Smith, 2009). Preferential interactions among kin, reciprocity, and group structure are all different mechanisms for achieving correlation between traits expressed in a population.

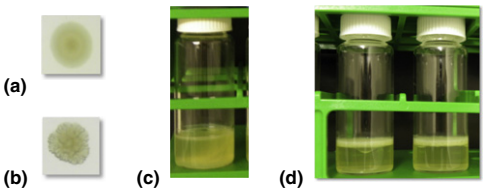

Figure 2 *Pseudomonas fluorescens* grown on solid and liquid media. (a) SM colony on solid agar. (b) WS colony on solid agar. (c) SM cells colonize the broth phase of liquid media in a microcosm. (d) WS cells form a visible mat at the air–liquid interface in a microcosm. SM and WS phenotypes (a,b) are heritable and correlate with both genotype and niche specificity (c,d). SM, smooth; WS, wrinkly spreader (Bantinaki *et al.*, 2007; Rainey and Travisano, 1998; Spiers *et al.*, 2002).

Examples of Bacterial Cooperation

Myxobacteria

The myxobacteria (to which the model species *Myxococcus xanthus* belongs) exhibit some of the most sophisticated cooperative interactions in the bacterial kingdom. Social swarming of *M. xanthus* allows the coordinated 'wolf-pack' predation of many other species of microbes, which they kill and degrade with costly extracellular digestive enzymes (Reichenbach, 1999). Furthermore, when they encounter starvation conditions, individuals aggregate into groups of ~100 000 cells and construct elevated fruiting bodies in which stress-resistant spores are formed and are capable of dispersing to unexploited resource patches. Only a portion (10%) of cells within the fruiting bodies differentiate into spores, while 30% of cells make up the exterior of the fruiting body, and the remaining cells undergo programmed cell death (Wireman and Dworkin, 1977; Dworkin, 1996), which is thought to provide nutrients to the other cell types. Developmental 'cheaters' evolved from an ancestral *M. xanthus* strain propagated in the laboratory under optimal growth conditions (nutrient-rich medium) suggest that this behavior is individually costly (or maladaptive in rich shaken laboratory culture), and an adaptation to fluctuating nutrient availability (Velicer *et al.*, 2000). When mixed with their ancestor, clones from several evolved lines cheated by being overrepresented in the spores of the fruiting body relative to their initial frequency in the mixture. Moreover, Fiegna and Velicer (2005) observed the re-evolution of social proficiency by an obligate cheater in a fluctuating environment with alternating cycles of starvation and growth. After four cycles the obligate cheater, which was introduced as a rare (1%) invader of a population of the marked ancestral strain, increased in frequency by re-evolving the ability to undergo social development.

Pseudomonas fluorescens

The evolution of cooperation has been observed in laboratory populations of *Pseudomonas fluorescens*, a free-living motile bacterium that is commonly found in the plant rhizosphere. The wild-type phenotype of the strain SBW25 is termed 'smooth' (SM) because of the appearance of its colony morphology when grown on solid agar plates (**Figure 2(a)**). In spatially structured 'microcosms' containing the ancestral SM genotype (**Figure 2(c)**), surface biofilms arise from single mutant cells that overproduce acetylated cellulose, which acts as a cell–cell glue (Spiers *et al.*, 2003). The failure of the mutant 'wrinkly spreader' (WS) cells (so called because of their distinctive colony morphology, **Figure 2(b)**) to separate at cell division leads to the formation of a 'mat' at the air–liquid interface (**Figure 2(d)**). Natural selection favors WS cells because they gain access to an abundance of oxygen denied to SM cells due to the vertical oxygen gradient that develops rapidly within the medium.

The WS phenotype meets the criteria of a cooperative trait outlined above (Chase, 1980). First, while WS cooperators invade SM populations by occupying a vacant niche, cellulose production by actors (WS cells) is costly relative to nonactors (SM cells) (Rainey and Rainey, 2003). Secondly, cellulose production increases the fitness of other individuals: SM cells not only increase in frequency in populations founded with WS, but SM are fitter in the presence of WS than in their absence (**Figure 3**; Rainey and Rainey, 2003). Therefore, cooperating WS collectives are inevitably short-lived. Selection continues to favor mutant SM types that cheat by no longer producing cellulose, yet reap the benefits of cooperation (access to oxygen). If the number of defecting SM cells increases to too high a frequency to maintain integrity of the mat, this emergent group phenotype is destroyed, i.e., the mat collapses.

A Cautionary Note on Microbial Sociobiology

It has become increasingly fashionable to caste all microbial interactions as inherently social, however cooperation is not an inevitable outcome of communal living. Nevertheless, concerns over the potential misclassification of cooperation in cases of incidental by-products has led to many descriptions of cooperation requiring that a cooperative behavior is selected to enhance the fitness of others, and can therefore only be a target for selection if there is a fitness feedback from the recipient to the actor. West *et al.* (2007) illustrate this point with two examples, both involving the excretion of waste products that bestow a fitness benefit upon (a) dung beetles, in the case of elephant waste products; and (b) waste-utilizing microbes, in the case of bacterial waste products. Under a very broad definition of cooperation, these examples might be considered

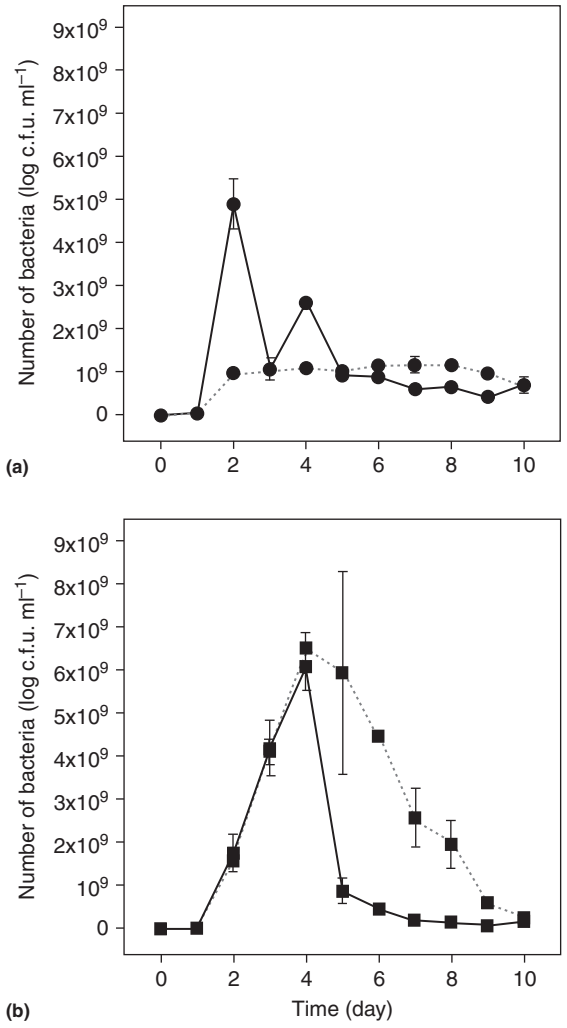

Figure 3 Evidence for cooperation in *Pseudomonas fluorescens*: population dynamics of WS and SM genotypes in the presence and absence of competition. (a) The effect of WS on the fitness of SM genotypes is the difference between dotted (absence of WS) and solid (presence of competing WS) lines. (b) The effect of SM genotypes on the fitness of WS genotypes is the difference between the dotted (absence of competition) and solid (presence of competing SM genotype) lines. SM, smooth; WS, wrinkly spreader. Reproduced with permission from Rainey, P.B., Rainey, K., 2003. Evolution of cooperation and conflict in experimental bacterial populations. Nature 425, 72–74.

'mutually beneficial cooperation,' because both the actors and recipients receive a benefit from the waste produced by the actors. To prevent the misclassification of biological phenomena such as by-products, the authors add the criterion that a cooperative behavior must be selected because of its beneficial effect on the recipient. However, under the definition of cooperation described above by Chase (1980), Velicer (2003), and many others, a cooperative behavior is costly relative to nonactors. The production of waste products by elephants and bacteria is not costly relative to those who do not produce waste; in fact waste disposal is individually beneficial, therefore these are not examples of cooperative interactions. Secondly, mutually beneficial interactions, by definition, benefit the actor, and therefore may originate and be maintained in a population because of the benefit incurred by actors. While nonactors may arise in the population and receive a benefit, it does not follow that the cooperative behavior was selected because of the benefit received by the recipients.

Syntrophy

Syntrophic (cross-feeding) interactions, which are due to the nutritional interdependence that underpins the symbiotic relationship between many species of bacteria, are common in the microbial world, yet they present no dilemma in terms of the evolution of cooperation because they are not costly.

The de novo evolution of syntrophy in bacteria was observed by Julian Adams *et al.* in experiments with *Escherichia coli* growing in an unstructured environment with a single limiting resource (glucose) (Helling *et al.*, 1987). The continuous culture evolved to become stably polymorphic after ~100 generations due to adaptations that allowed them to coexist by exploiting different niches. The less dominant strain (CV101) was maintained in the population because of adaptations that enabled it to utilize a metabolic by-product (acetate) excreted by the dominant strain (CV103) (Rosenzweig *et al.*, 1994). While the maintenance of CV101 was entirely dependent on the success of CV103, this mutually beneficial interaction is not cooperative because there is no obvious cost to the producer.

Cross-feeding interactions are common between different species in bacterial biofilm communities. The experimental work of Hansen *et al.* (2007) showed that simple mutations can lead to a stable symbiotic association between two unrelated soil-inhabiting bacteria, *Acinetobacter* sp. and *Pseudomonas putida*. When the two species were propagated in a spatially structured environment with benzyl alcohol as the sole carbon source, the persistence of *P. putida* was dependent on *Acinetobacter* for provision of a metabolizable form of carbon, benzoate. Mutations in the lipopolysaccharide (LPS) biosynthesis gene *wapH* gave rise to a 'rough' morphological variant of *P. putida*, which led to a more intimate and specialized association between the two species. No individually costly behavior underpinned the evolution and maintenance of this interaction between the two species; symbiotic relationships between species within bacterial biofilm communities are therefore not dependent on cooperation.

Public Goods

Public goods are extracellularly secreted compounds that are equally available to be used by the producer cell and all other ('public') cells in the population. By this definition, the production of public goods is a cooperative behavior because it is costly, and it increases the fitness of other cells in the population. However, some bacterial functions are 'leaky' – many bacteria unavoidably produce publicly available resources, yet this cooperative behavior can be automatic and based on selfish interests (Morris *et al.*, 2012). Confusion arises because there is a tendency to assign all extracellular products as public goods, however evidence is lacking.

Bacteriocins are extracellular toxins released by some bacteria that kill members of their own species, except those that

carry a linked immunity function. The production of bacteriocins is lethal to the small proportion of cells that do so, because the cells must lyse to release the molecule, and in so doing release nutrients that can be utilized by other cells in the population. In a series of elegant experiments, Chao and Levin (1981) sought to understand the evolutionary origins and maintenance colicin production, a bacteriocin produced by some strains of *E. coli* following terminal DNA damage (Salles *et al.*, 1987). In a well-mixed environment, a colicin-producing strain was able to invade a non-producing sensitive strain, but only when the initial frequency of producers in the population was higher than ~2%. Below this frequency, the colicin concentration was not sufficient to wipe out the sensitive population because the death rate of the producer was greater than the kill rate of the sensitive strain. The opposite was observed in a physically structured environment. When propagated on semisolid agar, the unstable equilibrium disappeared and the colicin-producing strain was able to invade from rare because the extra resources released from the lysed cells were disproportionately available to other producer cells within the colony. Colicin production must therefore have evolutionary origins in unstructured habitats that prevent the 'public' availability of the molecule.

Siderophores are small iron-scavenging molecules secreted by bacteria in iron-limiting environments, and are often considered 'public goods' without necessarily assessing both the cost of production and the availability of the molecule in the population. The generality of the conclusion that siderophore (pyoverdin) production in the bacterium *P. aeruginosa* is a cooperative public good (e.g., Griffin *et al.*, 2004) has recently been questioned on the basis that only under limited laboratory conditions can pyoverdin producers be considered cooperators, and non-producers 'cheaters.' Moreover, pyoverdin production can be personalized (i.e., it is not 'publicly' available) and there is inadequate evidence for a cost to pyoverdin production in the environment under which it evolved or is maintained outside of the laboratory. See Zhang and Rainey (2013), Kümmerli and Ross-Gillespie (2013), and Rainey *et al.* (2014) for further reading on this debate.

Cospeciation

MA Charleston, University of Tasmania, Hobart, TAS, Australia

Glossary

Codivergence The process in which a lineage diverges into two new phylogenetic lineages, be they species, populations, strains or genotypes, as a result of the host lineage also diverging into separate lineages.
Cospeciation The process in which a lineage speciates as a result of another speciation event: more specific than codivergence, it is concerned only with species.
Definitive host That host species of a parasite or pathogen that is required by the parasite or pathogen for its reproductive stage.
Duplication The coevolutionary event where a parasite or similarly dependent taxonomic unit speciates independently of its host species, and both new parasite species remain on that host.
Host With respect to a parasite or pathogen, a species that is infected or occupied by that parasite or pathogen as a major part of its life cycle (see parasite, pathogen, definitive host).
Lineage The path through evolutionary time of a species, disregarding any speciation events that may have occurred on that path. The simplest such path is that from one speciation event to the next speciation one, as represented on a phylogenetic tree as a single edge.
Lineage sorting The coevolutionary event where a parasite currently infecting a host species that has itself speciated, only persists on one nascent host species.
Loss When comparing dependent and independent evolutionary trees, the situation where a parasite is unexpectedly absent from a host species, either having undergone a linear sorting event, an extinction, or from having simply not been observed by chance.
Parasite A species that uses another species as an integral part of its life cycle.
Preferential host switching The observation that parasites tend, when infecting new host species, to switch to more closely related host than to more distantly related ones.
Species In the context of this article, a phylogenetically distinct group of individual organisms which have as a collection diverged from another such group.

Article Outline

This article will begin with some definitions, and then discuss some of the causes and effects of cospeciation in general. Next there are a few particular cases, with no claim that this is a comprehensive list. After that there is a brief overview of methods of detecting cospeciation, and a short summary.

A Few Examples

There are many examples of cospeciation that have been studied to a greater or lesser degree. Among 'coevolutionists' perhaps the most famous is the case of the pocket gophers and their obligate parasites, their chewing lice (Hafner and Nadler, 1988). This is one of the rather beautiful cases that support so-called Fahrenholz' Rule, which is that parasite phylogeny should mirror host phylogeny (Fahrenholz, 1913).

Another lovely case concerns the relationships between mealybugs and their primary endosymbionts, showing very high congruence over several genera of mealybugs (Downie and Gullan, 2005). In that system the host and symbiont trees share around three-quarters of their internal branches (clades): such a relationship has a vanishingly small probability under a null hypothesis of evolutionary independence, and these common clades correspond to hypothesized episodes of cospeciation, which must have been happening for long periods and dominating the (co)evolution of these species. The close phylogenetic congruence perhaps is not so surprising, given the obligate nature of the endosymbionts with their hosts, but one that is less obvious is the apparent codivergence of populations of Heliconius butterflies with their comimics, through a much more subtle link, Müllerian mimicry (Hoyal Cuthill and Charleston, 2012a).

Evidence of codivergence also can be found in many other interactions, such as the tri-trophic system of flies (Diptera) and their parasitic nematodes, together with their myrtle (Myrtaceae) plant hosts (Nelson *et al.*, 2014); for leaf hoppers and two sets of their own bacterial endosymbionts (Takiya *et al.*, 2006); for ectoparasites of gut flagellates in termites (Desai *et al.*, 2010).

Augustus De Morgan wrote in his Budget of Paradoxes (published in 1872, after his death) (de Morgan, 1872), that

> Great fleas have little fleas upon their backs to bite 'em,
> And little fleas have lesser fleas, and so ad infinitum.
> And the great fleas themselves, in turn, have greater fleas to go on;
> While these again have greater still, and greater still, and so on.

… and this idea has merit in the area of coevolutionary biology as well: it is natural that several levels of codivergence and cospeciation could in principle be uncovered through careful analysis of complex coevolving systems.

How Important Is Finding It?

Useful and interesting information emerges when we know that species or populations are codiverging – if we know such things, then we can say that, for example, two species speciated at approximately the same time. This is not quite as vacuous as it might first seem, because it means that we can lock together events on two phylogenetic trees (or estimates thereof) and then estimate relative evolutionary rates from their matched dates on the evolutionary timescale, for example.

This makes codivergence, where it is well supported by our inference methods, the equivalent in co-phylogenetics of a fossil record.

Once codivergence events are 'locked in' in this sense, then we can place other macroscopic scale coevolutionary events around them: duplication – a generic term that has come to mean a duplication of the *dependent* lineage such as a parasite, independently of the *independent* lineage such as a host.

Identifying cospeciation events has significant consequences for understanding coevolution, because it gives us a very good sense of the degree of dependence between groups of living organisms, such as between lentiviruses (including HIV) and their primate hosts. And it really is important to get those inferences right, because, for example, whether the apparently quite long association between lentiviruses and primates (Compton *et al.*, 2013) is dominated by codivergence or by one in which the viruses happen to match the host phylogeny because of other factors such as *preferential host switching* (PHS) (Charleston and Robertson, 2002; Mindell *et al.*, 1995; Siddall, 1995) has important consequences.

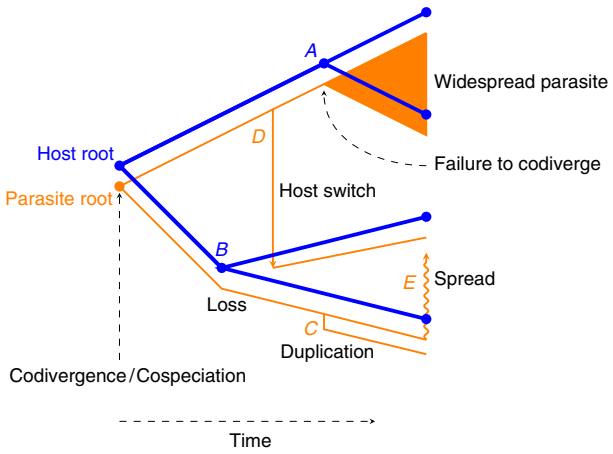

Figure 1 A simple system in which we see some coevolutionary events, including cospeciation, between some parasite species (orange tree) and some host species (blue tree). There is a cospeciation/codivergence event at the root of both trees. At host labelled A, the parasite is failing to codiverge with its host, and has not (yet) undergone speciation, perhaps because there is continued gene flow between the parasites infecting both host species even though the hosts are now genetically isolated. At B we see a loss event, also known as 'missing the boat' *(sensu* Paterson *et al.*, 2003): in this situation the parasite has failed to cospeciate and also failed to diverge, because it survives on only one of the new host lineages. Further down the tree at C we see a *duplication*, where the parasite has speciated independently of the host. The host switch is another case of not being cospeciation: the parasite has established on a new host species that is not the new sibling of its current host, by crossing the 'species barrier.' The last event is the 'spread' event, where a parasite establishes on a new host lineage but does not differentiate from the population on the original host.

Terminology

One of the most well-known kinds of diagram in biology is the *phylogeny*, or 'phylogenetic tree' or 'evolutionary tree.' In a phylogeny, *species*, or *operational taxonomic units* (OTUs) are represented as nodes or vertices, and the links between them are known as lineages. The known species are represented by leaf nodes (or simply 'leaves') in the tree, and hypothetical species are represented by internal nodes (see **Figure 1**). A single link between two nodes is called an edge or arc of the tree, and these represent the periods for which there are no phylogenetic divergences, at least, not marked on the tree.

It is (or was) common to talk about OTUs when creating phylogenies, but it is now more common to use phylogenetic *lineages* instead; this will be the usage here. A lineage in this sense is a group of individuals that is phylogenetically distinct from another such group. Thus a lineage (as with an OTU) can be a species, or a subspecies, or it could be a genetically isolated population, a strain, and so on.

Cospeciation is an idea that has been around for a long time. Clayton, Page, and others call it a process by which speciation in one lineage is accompanied by speciation in an associated, but unrelated, lineage (Johnson and Clayton, 2002; Page, 1991).

With this more generalized usage 'speciation' is a bit too restrictive, so we will speak here about *phylogenetic divergence*, or more simply just *divergence*, which means the splitting into two phylogenetically distinct lineages. The natural continuation of this decision in nomenclature is that we use *codivergence*, even though this article is called 'Cospeciation,' to mean the generalization of cospeciation to any phylogenetic lineages. Still, all the concepts described here apply to speciation and cospeciation as the dominant special cases.

Such a tree is often presented as having a defined *root*, that is, a (generally hypothetical) common ancestor of all the extant species represented by the leaves of the tree (see **Figure 1**). This root gives a sense of direction to the tree, which is necessary to this discussion of cospeciation (codivergence).

For convenience in this article we mainly refer to *hosts* and their *parasites*, because it is in such a context that the ideas of cospeciation (and codivergence) are most easily grasped. The exemplar case of this is the very well-studied gopher–louse system in which there is very strong evidence of coevolution and indeed of cospeciation, but such clean cases are comparatively rare (Hafner and Nadler, 1988). This should be treated as a simplification of the discussion with a view to clarity, but not of the underlying assumptions: it is of course possible that codivergence could occur with an intermediate host, for example, if that intermediate host is an instrumental vector for the parasite, and evidence for codivergence has been found in the Heliconius butterfly co-mimicry complex, driven only by Mullerian mimicry (Hoyal Cuthill and Charleston, 2012a).

Further, cospeciation in host–parasite systems is largely concerned with the *definitive* host of parasites, that is, those that are required for the reproductive phase, because it seems most likely that cospeciation will occur with the host with which parasites have this closest of links, rather than with intermediate hosts or perhaps vectors.

While we might consider genes as 'parasites' of their hosts (Dawkins, 1989), and in some sense species endemic to a given geographical area cospeciating as they undergo vicariant speciation with their range as it is fragmented, we will talk herein about the *dependent* lineages as parasites. The host–pathogen context is often distinguished from the host–parasite one, as there are some significant enough differences between the two situations: pathogens are frequently not as host-specific as parasites are with their definitive hosts, and often are much more motile, even being air-borne; however they share the same overall structure: one set of entities, the independent one, exerts a strong selective pressure on another set when it diverges. Another related set of problems concern the relationships between gene-trees and species trees, and between geographical regions and their endemic species. These scenarios are very similar in general principle to the host–parasite cophylogeny problem, so many of the methods and techniques that apply to hosts and parasites can be carried over to these other contexts.

Correspondingly this discussion will speak of *hosts*, not 'host species' or areas of endemism; this keeps the discussion relatively clean and manageable.

We will further avoid the whole 'Species Concept' question and restrict ourselves only to considering phylogenetic species, that is, those groups of organisms that can be differentiated by their phylogenetic history. Typically two species that are deemed 'phylogenetically distinct' in this sense have accumulated a certain level of divergence in their genetic makeup, for example a few percent difference in nucleotides in the coding genes known for the organisms in question. This avoids the difficulty of establishing whether viable hybrids might form between two lineages, and of gradual differentiation along a geographical range.

Thus we can now talk about *phylogenetic codivergence* or just *codivergence*, which is the process in which two ecologically linked lineages, such as a host species and one of its parasite species as with the now infamous gopher–louse system (Hafner and Nadler, 1988), or a mimicry complex such as the Heliconius butterflies (Hoyal Cuthill and Charleston, 2012a), diverge at the same approximate time, because of uni- or bi-directional influence of one speciation (divergence) event on the other.

How Does Cospeciation Happen?

Suppose we have a population of (for the sake of argument) furry, ground-dwelling creatures that live with plenty of gene flow across the population, over a wide plain, and which are parasitized by a species of fur-dwelling, skin eating ectoparasite that is highly host-specific, preferring only these hosts. Suppose further that the plain becomes broken by a crevasse, perhaps through severe lowering of the water table, and our furry creatures become isolated from each other, forming two sub-populations. Conditions on either side of the crevasse are slightly different from each other: perhaps one area is slightly warmer, favoring shorter, finer hair, and the other area, being cooler, presents an evolutionary advantage to our furry friends if they grow slightly longer, thicker fur. Over time, the slight difference in pressures will mean that the two populations will present different environments to their fur-eating ectoparasites, and will drive their selection also. The different selective pressures on the populations of parasites will lead to their divergence: after all, there is no longer any gene flow between the two so their own smaller populations may easily drift apart from each other. (Note that this is not an argument in favor of climate change driving diversification, as it is also likely that both populations will eventually die out from lack of water.) This toy example links biogeography through vicariant speciation of the furry hosts, to cospeciation of these hosts with their parasites.

In general, if there is population isolation between two nascent host lineages, and gene flow between the parasites of those hosts is severed – which is likely in this situation, then there may be genetic drift of the parasite lineages, and the parasites will then most likely diverge.

A note on timing is pertinent here: after population isolation we expect diversification in the host species, at which point, it then presents variation in the parasites' environment, and therefore there must be an inevitable delay in the initiation of the divergence in the parasite. Thus it is not expected that the host lineages diverge at exactly the same moment as do the hosts, and at any rate it is often the case that hosts, with their generally longer generation times and slower evolutionary rates will diverge from each other more slowly than will their parasites (Page, 1991). But at the scale at which we usually see phylogenetic (evolutionary) trees, the speciation time is close enough to be called contemporary.

Host specificity is of course another major component of cospeciation/codivergence, because without a strong tie to its host, a parasite experiences only weak pressure to co-evolve with it. If the relationship with the host is very tight, such as with the well-studied gopher–louse system described by Hafner and Nadler (Hafner and Nadler, 1988), then cospeciation is to be expected, particularly if the parasite maintains most of its life cycle in the same host species. Certainly this was the view of Fahrenholz (Fahrenholz, 1913), exemplified by the idea that 'parasite phylogeny mirrors host phylogeny.' On the other hand, if the parasite is not highly host specific then it is quite possible that divergence of the host will not have a strong influence on the parasite, and cospeciation will not occur.

Host specificity can be measured in various ways but a standard statistic is S_{TD} of Poulin and Mouillot (Poulin and Mouillot, 2003), which takes into account the mean taxonomic distance across a parasite's hosts. In general, host specificity is said to be high if a parasite shows a strong preference to a given host species, that is, is much more fit on that host species than on any other, and is low in the opposite situation. S_{TD} goes some way toward capturing the idea of 'fitness' for a host, by awarding a higher score to parasites whose hosts are very closely related to each other, than to parasites whose hosts are less related.

It is not likely that there is a simple global trend toward more host specificity or away from it (Poulin *et al.*, 2006), as every system is different, but investigating how it changes over time is still important to understanding how each host–parasite system is behaving, and it is to be hoped and expected that more such studies will shed light on cospeciation in more systems.

One common question next to consider is about dependence: Which species is dependent on which other species? Which one is 'the' host, and which is 'the' parasite? Sometimes it is not clear whether there is a strong dependence–independence relationship between the two groups of species, or whether the relationships is more mutually symbiotic. In the one extreme we expect no effect of speciation in one group on the speciation patterns in the other group, because the independent (host) phylogeny is truly independent of its parasites, which can be considered as merely along for the ride. In this situation there may be some coevolutionary effects by which for example the host's immune system is responsive to changes in its parasites, but this effect is not driving speciation in the host: certainly primates are not speciating in response to the diversification of lentiviruses.

At the other end of this spectrum we might find that the two ecologically linked groups are tightly coupled in a classically symmetric symbiotic relationship, by which divergence in either group commonly leads to divergence in the other. It is even possible, as we increase the sizes of phylogenies being considered for codivergence and other coevolutionary effects, that there could be regions in the phylogenies where both extremes of the spectrum are evident: for one clade the parasites might be completely dependent on the hosts, and for another, the relationship might be balanced.

One way we might find out where on this spectrum a given system lies is to simply attempt to map one phylogeny, X, into the other, Y, according to our chosen method of cophylogenetic analysis, and then to also do the reverse, mapping Y into X. If there is no difference between the measures of fit in the two results, then we cannot differentiate which is the dependent, and which is the independent; thus we can't reject the balanced relationship. However, a survey of over 100 published cophylogeny studies (described in Drinkwater and Charleston (2014b)) in this way shows, perhaps surprisingly, that there is apparently no clear differentiation between the two extremes of this spectrum: despite the explicit or implicit assumptions of dependence in the many studies involved, only a very few show any difference between the quality of the maps when mapped in both directions. One possible reason for this is that the datasets surveyed are simply not big enough to show significant differences in the mapping qualities from X to Y or from Y to X; another reason is that we have simply been unlucky in our choice of the systems to study: we may well have only chosen systems in which there is a strong suggestion of cospeciation already, and the way we recognize these systems is based on simple similarity between phylogenies. Whatever the cause, this is an interesting problem that deserves attention.

Failure to Codiverge

What does it mean to not cospeciate or codiverge?

While we are talking about codivergence we cannot miss out a discussion on what it means for a species or lineage not to codiverge with its host. If a species fails to codiverge when we would have expected it to, then there are a few possibilities (those numbered 1 and 2 as mentioned in Banks and Paterson, 2003 (Paterson *et al.*, 2003)):

1. the parasite species have in fact diverged, but are not distinguishable, in this sense being cryptic – they may be on the verge of divergence though;
2. the host lineage did not actually diverge, despite appearances to the contrary, so there was nothing for the parasite to codiverge with;
3. the host speciated and the parasite (or, recall, pathogen, gene, etc.) did not establish in both new host lineages, populating only one – this is known as 'missing the boat' (Paterson *et al.*, 2003);
4. the parasite populations on two nascent hosts continue to have gene flow between them, therefore maintaining as a single lineage.

This last event is known in the literature as a 'failure to diverge' event, though it should really be 'failure to codiverge' (species 'fail to diverge' almost all the time). 'Failure to codiverge' is one of three events that can lead to widespread associations of parasites with hosts. The second is sometimes called *incomplete host switch* (Clayton *et al.*, 2003) or *spread* (Hoyal Cuthill and Charleston, 2012b) – this makes particular sense in the context of those parasites or pathogens that are not particularly choosy about which host they infect.

Other Coevolutionary Events

It is not possible to talk about codivergence only, when considering the differences between evolutionary histories of linked groups of organisms. If the only event was codivergence, then the trees would be identical, and there would be rather little interest in the topic! Rather, we have several other macro-scale events to deal with: these are usually referred to in the literature as *duplication*, *loss*, and *host switching*.

We will refer to **Figure 1** once more for this part.

Duplication is where the parasite lineage diverges (e.g., speciates) independently of such an event in the host lineage. The terminology comes from the connection of the cophylogeny problem to the gene tree/species tree problem: it is common for genes to duplicate, giving rise to potentially very large gene families, while remaining functional, and not driving speciation in the 'host' organism in which they reside. An example of duplication is shown in **Figure 1** at point 'C.'

Loss is what happens when there is a parasite (pathogen, gene, etc., depending on the context) that is absent from its host, where an ancestor of the host did have (an ancestor of) the parasite (**Figure 1**, at 'B'). It can arise in several ways, and this presents challenges that are very hard to address without targeted coevolutionary studies. One way in which a loss can arise is through one of the cases where codivergence does not occur: number 3 in the list above (section 'Failure to Codiverge'), the host speciates, and the parasite only establishes on one of the two new host lineages.

The second case is where the parasite goes extinct: it did cospeciate with its host, but then after a period of successful infection, died out.

The last is due to sampling error: there may well have been cospeciation, with survival of the parasite to the present, but we simply failed to find it.

The difficulty that these three events present to analyses of coevolution is that they are indistinguishable, when we are only presented with host and parasite trees and their 'known' associations. It is simply not possible to determine which of these processes took place in order for the loss to be observed, and if we are faced with loss then we should spend time looking for other evidence of the loss event being due to extinction or sampling failure; and we should also accommodate the possibility of all these processes when drawing our conclusions, not just assume it is missing the boat (which is the default interpretation in most software).

Host switching has been the main culprit that makes the detection of cospeciation difficult. A host switch (as shown in **Figure 1, 'D'**) is when a parasite infects and establishes on a new host lineage. Another culprit is the 'spread' event, shown at 'E' in the figure, and dealing with it is also a challenge that has only recently seen significant progress (Drinkwater and Charleston, 2014a).

If there is no host switching then it is trivially simple to find where cospeciation could have taken place. However, permitting host switching in the coevolutionary system takes this problem from one that can be solved in an amount of time that is linear in the problem size, to one that is in a class of problems not known to have any polynomial time solution: it is NP-Complete (Ovadia *et al.*, 2011). Dealing with host switching in cophylogenetic studies has been the major challenge in recent years to detecting cospeciation and the other macro-scale coevolutionary events: the computational difficulty means that we cannot guarantee to find optimal solutions (i.e., to find all the cospeciation events), and so recent focus has been on developing faster heuristic methods for this (Conow *et al.*, 2010; Drinkwater and Charleston, 2014a,b).

Detecting Cospeciation/Codivergence

Cospeciation is a consequence of very tight coevolution, and it in turn has consequences. We can use these consequences to detect systems that are consistent with a history of cospeciation, even in situations where the degree of match between say host and parasite species is not very high: still there can be signals left in the parasite tree that can indicate cospeciation has been a significant factor in the coevolution of the system in which we are interested.

One consequence is, as Clay in 1951 noted, that the coevolution of the parasite (in Clays work, Mallophaga, chewing lice) led to "… related groups of birds being parasitized by related groups of lice" (Clay, 1951). Put another way, in general we expect if there is a history of cospeciation that the phylogenetic distance between pairs of parasites should be significantly correlated with the corresponding distances between their hosts. This is straightforward to detect and an approach based on the statistical congruence between distance matrices derived from host and parasite trees is implemented in ParaFit (Legendre *et al.*, 2002), and a simpler test was used by Hoyal Cuthill and Charleston in a study on Heliconius butterflies (Hoyal Cuthill and Charleston, 2012a).

Note that co-speciation implies a direct dependence relation, rather than via a third influence such as through common biogeography: the apparent congruence between phylogenies of Joshua trees (*Yucca brevifola*) and its two (sister) species of obligate pollinators *Tegeticula* spp. moths is unlikely to be cospeciation, as the moths appear to have diversified much more recently than their hosts (Smith *et al.*, 2008).

Apparent congruence can also be explained by PHS, where parasites tend to switch to hosts that are more closely related to their current host than to more distant ones (Charleston and Robertson, 2002; De Vienne *et al.*, 2007).

What confounds the detection of cospeciation? While there are some other systems that show significant congruence between the evolutionary histories of host and parasite (or host and pathogen, and other variants on this independent–dependent theme), other processes can either cover up apparent cospeciation, or mistakenly support it.

PHS was presented as a plausible explanation of how two phylogenies that were *not* undergoing codivergence could still appear to be codiverging, due to their high degree of congruence (Charleston and Robertson, 2002). Under PHS, parasites (in this case, lentiviruses) were observed on hosts that were statistically closer to each other on the primate phylogeny than they would be expected to be, if the host switching was random. It was noted in that paper that PHS could give rise to apparent congruence between the primate and lentivirus trees, even without a long history of codivergence. PHS and the tendency of parasites or pathogens to simply spread, without speciation, to closely related host species, has also been observed and goes part-way to explain the nature of host switch dynamics in general (Hoyal Cuthill and Charleston, 2012b).

Summary

In a sense the community of scientists interested in research in coevolution at the species level has been misled by the remarkable congruence between the gophers and their chewing lice (Hafner and Nadler, 1988). Since that important publication there have been many other studies seeking congruence, with reasonable confidence that there will be some, yet in fact the number of clear cases of cospeciation has been relatively few in comparison with those showing little indication of cospeciation.

Why Is It So Hard to Find Cospeciation?

Partly this comes from a lack of targeted studies of coevolution: reports in the scientific literature commonly have one half of the coevolutionary picture investigated quite well and the other be rather more sketchy, and there are very few studies that seek specifically to find host–parasite associations. Another confounding factor is that even in the presence of some cospeciation there may also be, and commonly is, some host switching, and it does not take very many host switches to

completely mask the congruence that a history of pure codivergence would yield.

There are many complicating factors: host–parasite associations are hard to define, as well as to uncover; parasite life cycles can be cryptic; and cophylogeny mapping is a computationally hard problem. Even small amounts of host switching can mask a history that has many cases of cospeciation.

While it is unlikely that a 'big push' to gain better data is to be expected any time soon though, useful data and better understanding continue to show gains and it is clear that a wealth of understanding of coevolution will come from studying cospeciation.

Darwin's Finches, the Galapagos, and Natural Laboratories of Evolution

FR Davis, Florida State University, Tallahassee, FL, USA

Introduction

Darwin's Finches, also known as the Galápagos finches, have achieved iconic status as exemplars of evolution. Darwin famously misidentified several of the finches he collected during his 5 weeks in the Galápagos, but eventually recognized their potential significance to the study of evolution. During the Age of Surveys, many naturalists followed Darwin to the Galápagos and collected numerous finches along with the fauna of the Galápagos. Most confined themselves to the taxonomy of finches, but a few drew conclusions about the ecology or evolution of the group. Darwin's finches emerged as an icon of evolution when David Lack published his study of the finches in 1947. Among others, E.O. Wilson and William Brown cited Lack's work with the finches as a potential model for character displacement. Peter and Rosemary Grant launched a long-term study of the finches on this premise, but over 40 years, their research in this 'natural laboratory' has extended to many aspects of the finches: evolution, genetics, hybridization, ecology, and conservation (Figure 1).

Darwin and the Finches

During the voyage of HMS Beagle, Charles Darwin himself collected specimens of the finches. However, he famously misidentified some of the finches, one as a blackbird and another as a grosbeak. Back in England, the ornithologist John Gould set Darwin straight and described the finches as a highly diverse group of closely related species. In the first edition of *The Voyage of Beagle* (1839), Darwin noted, "a nearly perfect gradation of structure in this one group can be traced in the form of the beak" (Darwin, 1839). Later in his account of the wildlife of the Galápagos, Darwin tentatively suggested that different finches may have been confined to different islands. However, Darwin had labeled his specimens 'Galápagos,' so he could not confirm such suspicions using his own collection. Both the captain and the crew of HMS Beagle collected finches while they conducted hydrogeographic surveys of most of the islands. Darwin and Gould drew on these collections to speculate that different finches occurred on different islands. In addition, Darwin attempted to place the finches he collected to specific islands based on his vague recollections and the other collections. Subsequent research has shown that Darwin's designations constituted educated guesses. However, when he published his suspected localities in *The Zoology of the Voyage of HMS Beagle*, they became inscribed in the ornithological record as later ornithologists at the British Museum relabeled some of the finches to conform to Darwin's conjectural localities (Sulloway, 1982, 1984).

Figure 1 *Geospiza magnirostris*, Plate 37 (Gould, 1839).

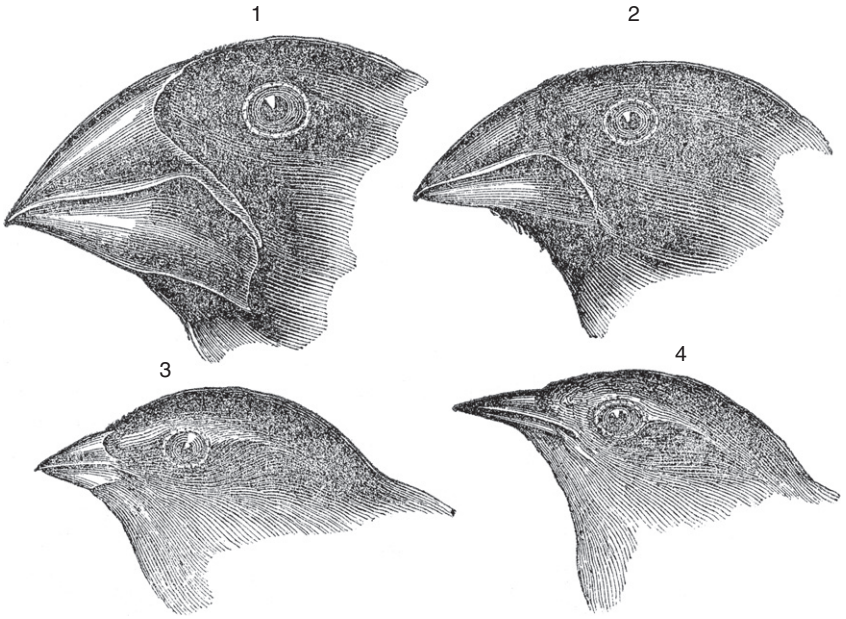

Figure 2 Galápagos Finches as illustrated in Darwin, Voyage of the Beagle, second ed., 1845.

Darwin's thinking about the finches expanded considerably before he published the second edition of the *Voyage of the Beagle*. He elaborated on the 'perfect gradation in the size of beaks' and he included a drawing to illustrate the heads of four of the finches that showed the range of bill size from the largest to the smallest as well as two of the species with intermediate bills (**Figure 2**).

Darwin (1845, p. 380) even speculated on the potential significance of the finches for biology: "Seeing this gradation and diversity of structure in one small, intimately related group of birds, one might really fancy that from an original paucity of birds in this archipelago, one species had been taken and modified for different ends." Such a statement strongly suggests that Darwin's view of evolution or transmutation had developed considerably during the 6 years between the first and second editions of *The Voyage of the Beagle*.

With the exception of the rather provocative statements in the second edition of the *Voyage of the Beagle*, Darwin did not include the finches in his subsequent writings on evolution, or anywhere else for that matter. He mentioned the Galápagos Islands six times in the *Origin of Species* and drew specific attention to the evolutionary significance of islands and animal and plant colonizers, but not the finches (Sulloway, 1982; van Wyhe, 2012). Despite Darwin's reticence on the subject, other naturalists strove to fill the remaining gaps in the natural history of finches beginning with the taxonomy of the closely related group (Donohue, 2011).

The Age of Surveys

Darwin introduced the ornithological community to the Galápagos finches, but his collections included only 31 finches and 64 birds in total from the Galápagos. He sought to obtain representative (or 'type') specimens of each animal (and plant) he encountered. Naturalists on subsequent expeditions to the archipelago sought to represent variations between the finches with larger collections.

In 1868, Habel collected 460 specimens, which Salvin described in 1876. The British Museum of Natural History became the repository of the collections of the 'Beagle' and Habel. In 1897, the ornithologist Robert Ridgway described the collections of the *Albatross* (1888) and George Baur (1891). The 'Albatross' collections remained at the United States National Museum (Smithsonian), Ridgway's home institution, while Baur's collection and that of the Webster-Harris expedition (3075 specimens) became part of the Rothschild collection, which was eventually acquired by the American Museum of Natural History in New York. The Hopkins-Stanford expedition amassed another large collection that Robert E. Snodgrass and Edmund Heller described in 1904. But an expedition by the California Academy of Sciences obtained the largest collection (8691 specimens) in 1905 and 1906. Harry S. Swarth published on this collection in 1929 and 1931 (Swarth, 1929, 1931).

Drawing in part on Baur's collections from the Galápagos, the Smithsonian ornithologist Robert Ridgway (1897) described the many forms of birds from the Galápagos. Unlike Baur, who sought to restrict the number of forms per island, Ridgway represented the other taxonomic extreme in designating numerous forms as full species. He believed that previous taxonomists had been too conservative in designating species. In all, Ridgway added 25 full species to the list of Darwin's finches, including 6 in the genus *Certhidea*, 12 in *Geospiza*, and 7 in *Camarhynchus*. Ridgway generally hesitated to make broader claims regarding the evolutionary significance

of the finches. Baur criticized Ridgway for arranging the different species of finches in a single continuous line to show the gradual connection between the different forms. Baur organized the finches into several parallel series, arguing that species remained true on different islands and never intergraded on the same island, which was consistent with his essential point that natural selection played no role in the development of the finches (Baur, 1897).

Other naturalists did make general claims regarding the evolution of the finches during the Age of Surveys. In one of the first ecological studies of the finches, Robert E. Snodgrass and Edmund Heller preserved the stomachs of 209 specimens of *Geospiza* between December 1898 and June 1899 with a plan to determine whether bill size correlated with food type. Snodgrass hypothesized if the various sizes and shapes of bills within the *Geospizae* were adaptations, then it would be possible to differentiate diets (seed size) by species. The two naturalists separated the seeds by size (they did not attempt to determine the plants whence the seeds came), but found no patterns of consumption. Thus, Snodgrass (1902) concluded: "The evidence, then, seems to be in favor of the general conclusion that *there is no correlation between the food and the size and shape of the bill*. If this is true, then we must look elsewhere for an explanation of the variation of the *Geospiza* bill." After enumerating the remarkable extent of finch collecting efforts, David Lack noted: "As a result of all these visits, Darwin's finches are more adequately represented by museum specimens than almost any other group of birds" (Lack, 1947). Robert Kohler has reframed this period in the history of biology as the 'Age of Survey' (Kohler, 2009).

Percy Lowe (1936) coined the term 'Darwin's Finches' in an address to the British Ornithologist's Union in 1935 to mark the centenary of Darwin's visit to the Galápagos. On the basis of his anatomical studies of finches, Lowe argued that Fringillidae was the appropriate family designation for the finches. To explain the diversity of finches, Lowe proposed that the group represented a hybrid swarm, but he called for actual breeding experiments because Lord Rothschild had already suggested that if the extensive collections in existence could not provide the information, none would.

David Lack

By the 1930s, ornithologists had reached general consensus regarding the systematics of Darwin's finches. From December 1938 to April 1939, the Oxford ornithologist David Lack led an expedition to the Galápagos to study three aspects of the biology of the finches: breeding behavior, ecology, and hybridization. Lack's careful study of the breeding behavior revealed that the finches were very similar to each other. Similarities in breeding behavior corroborated anatomical findings that suggested a close relationship between the species. Ecological studies revealed three aspects of finch natural history: the near absence of food competitors, almost complete absence of predators, and the existence of several islands that provide partial but not complete isolation for island forms. Each of these ecological factors influenced speciation. But Lack (1945, p. 135) concluded: "Differences between closely related species are nonadaptive except that bill characters serve in species recognition. The main genera show adaptive radiation." Lack (1940) also published a brief article on his findings in the journal *Nature*, and he again denied evolutionary agency. Sewall Wright's random drift provided a better explanatory framework.

With the publication of *Darwin's Finches* (1947), Lack revealed that his views on the ecology and evolution of the finches had changed since his earlier writings. He had accepted Geogii F. Gause's (1934) contention that no two species can occupy the same ecological niche in the same place as a consequence of natural selection. If two species did in fact live in the same habitat and ate the same types of food, competition would inevitably result, and one species would eliminate the other. Given that there were three species of ground finches (*Geospiza*) and at least two tree finches (*Camarhynchus*) living together in the same habitat on the Galapagos, Lack theorized that another factor prevented these species from competing.

Lack explained that geographical isolation appeared to be the critical factor in speciation. To bolster his case, Lack surveyed bird species and found that in every species that maintained continental and island populations, the island races differed from each other more strikingly than the continental races. Moreover, the more isolated an island was, the greater the degree of differentiation within the land birds. Thus, Lack (1947, p. 119) concluded: "The primary cause of geographical variation in birds would seem to be not adaptation, but isolation." Darwin's finches provided Lack's case in point. The islands that were the most isolated had the highest proportion of endemic forms, while more central islands had fewer distinct forms. Lack wrote: "Hence in Darwin's finches there is a marked correlation between the degree of isolation and the tendency to produce peculiar forms" (p. 119).

Lack also wondered about forms that were originally geographical races of the same species, which met later in the same region, remained distinct, and formed new species. How might these forms compete? Lack offered four possibilities: one much better adapted form swamps the other and exterminates it; one form has an advantage in the region where it meets another form, but the other has an advantage in an adjacent region; one form may have an advantage in a section of the original habitat and another in the rest; and one form proves better adapted to taking one food, and the other to obtaining other foods. Lack (1947) noted that the differences in food habits were often associated with marked differences in size, including the size of beak. Darwin's finches provided at least two cases of each type of ecological isolation. For example, *Geospiza conirostris* replaced *Geospiza scandens* on three outer (geographically remote) islands. *Geospiza scandens* bred in the same habitat with other ground finches but fed on *Opuntia*. *Geospiza magnirostris*, *Geospiza fortis*, and *Geospiza fuliginosa* occupied the same habitat but their foods were different, at least in part. Lack suspected a similar state of affairs for three species of tree finches, though their dietary preferences remained unknown (**Figure 3**).

Lack's earlier writings on the finches, though transcending the taxonomic studies of the Age of Surveys to make claims regarding evolutionary significance, seem to have been missing a theoretical framework with which he could integrate the data from his ecological studies of the breeding and feeding behavior of the finches with systematic data from the large collection of

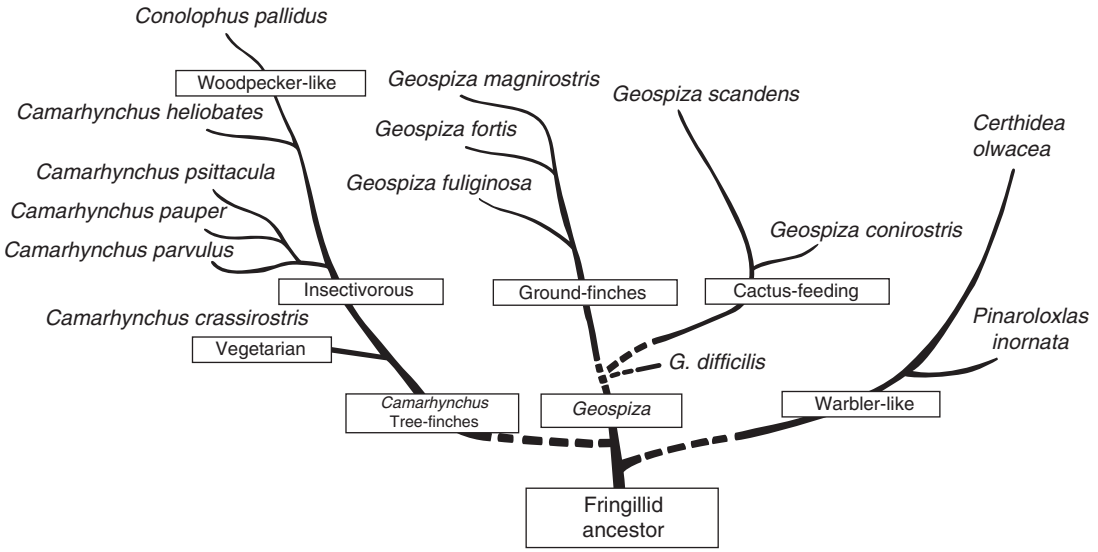

Figure 3 David Lack's tree showing his hypothesis about the evolutionary history of the finches. Reproduced from Lack, D., 1947. Darwin's Finches: An Essay on the General Biological Theory of Evolution. Cambridge: Cambridge University Press, with permission from Peter Lack on behalf of the David Lack Estate.

finches at the California Academy of Sciences. We have seen the influence of Gause's ecological niche concept for Lack's understanding of evolutionary patterns. Lack also cited Julian Huxley's (1942) writing on the modern synthesis and Ernst Mayr's (1942) *Systematics and the Origin of Species*. In this way, the unification of biology provided a new theoretical rigor that enriched Lack's *Darwin's Finches* (and countless biology textbooks).

In 1956, William Brown and E.O. Wilson identified Darwin's finches (*a la* Lack) as a striking case of character displacement. Citing Lack's data regarding *G. fortis* and *G. fuliginosa*, they noted that, on most islands where the two species occur together, the two species could be separated by the measurement of beak depth, and a random sample of this character resulted in two completely distinct distribution curves. However, a comparable sampling on the smaller islands of Daphne and Crossman revealed a single unimodal curve that fell between the curves of *fortis* and *fuliginosa* on the larger islands. Lack's careful analysis of beak to wing proportions revealed that *fortis* occurred on Daphne while the Crossman population was *fuliginosa*. Brown and Wilson (1956) accepted Lack's conclusion that each species had converged toward the other species, thereby filling the ecological vacuum created by its absence.

After two expeditions to the Galapagos, Robert Bowman (1963) argued that the major patterns of differentiation in Darwin's finches were related to adaptations for food getting. Bowman correlated the finches' beaks to various kinds of pliers (**Figure 4**). Although Darwin had confused the finches with similar continental families, Bowman deliberately compared the individual finches with continental families on the basis of the niches field by the different species. This group of songbirds represented no less than seven continental families, which Bowman illustrated with a chart that depicted 'ancestors of the Geospizinae' (**Figure 5**).

The key to the differentiation within the finches was the kind of food they consumed. In this and other respects, Bowman challenged the interpretations of David Lack, who had identified isolation and interspecific competition as the primary engine of adaptation among the finches. On the basis of the field observations and anatomical analyses of the muscular structures supporting the finch beaks, Bowman argued that the evolutionary pattern of the Galapagos finches hinged on differing vegetation between islands and related structural modifications of seeds and behavioral reactions of insects to escape widespread aridity with profound effects on feeding adaptations in the finches. In addition, predation (by Galapagos Hawks and Galapagos snakes) had been selective forces, which led to adaptive differences in plumage between genera, species, and even populations. Finally, Bowman (1961) pointed to the 'genetic constitution of ancestral colonists' as a constraint in the ability of finches to evolve to exploit all ecological niches rather than the presence of 'ecological equivalents.'

Peter and Rosemary Grant: Evolution in a Natural Laboratory

In 1971, Peter R. Grant embarked on a new research project. First, he sought to clarify whether population variation in the size of traits such as beaks was adaptive, as suggested without convincing evidence by Leigh Van Valen. From Lack he knew that Darwin's finches could shed light on this question. Second, following Brown and Wilson, Grant found evidence for character displacement lacking (i.e., the tendency for differences between ecologically similar species to be enhanced where they occur together as a result of natural selection minimizing competition between them). His decision to examine the related process of character release (changes in morphology and ecology of a species resulting from the absence of restraints from a competitor species) led him to the classic case of two species of Darwin's finches as

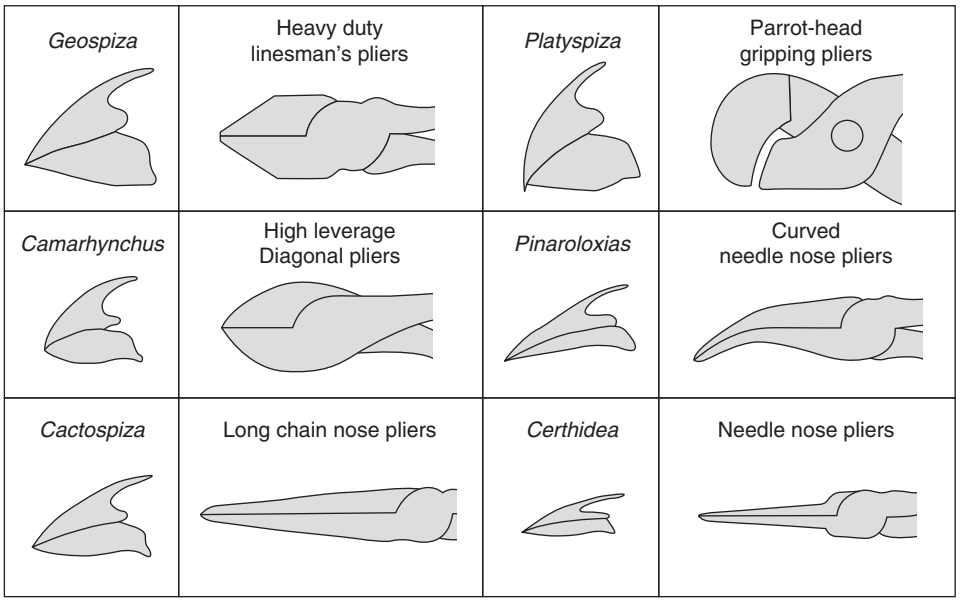

Figure 4 Comparison of shapes of bills with pliers. Reproduced from Bowman, R.I., 1963. Evolutionary patterns in Darwin's finches. Occasional Papers of the California Academy of Sciences 44, 107–140, with permission from California Academy of Sciences.

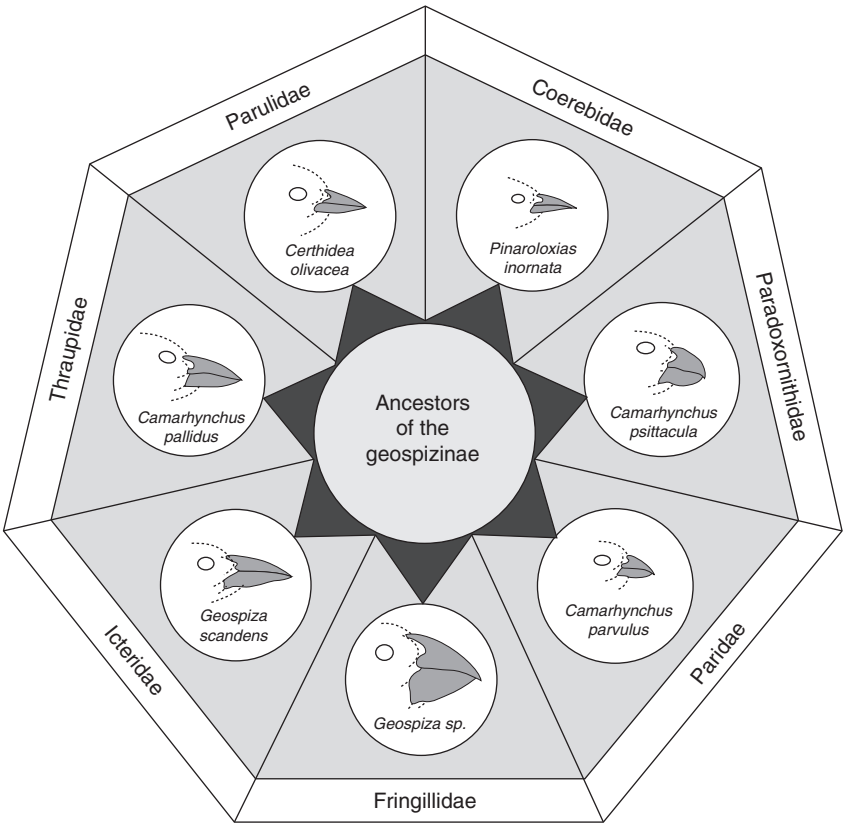

Figure 5 The pattern of adaptive radiation in Darwin's finches. Reproduced from Bowman, R.I., 1963. Evolutionary patterns in Darwin's finches. Occasional Papers of the California Academy of Sciences 44, 107–140, with permission from California Academy of Sciences.

described by Brown and Wilson (1956). Moreover, a graduate student had proposed a study of Darwin's finches on the basis of the conflicting conclusions of Lack and Bowman concerning the same material. Initially, Grant (1985) focused on the Medium Ground Finch (*G. fortis*) population on Daphne Major, the population of which was small enough so that he could uniquely color band every individual, and the birds were variable in both body size and bill shape.

On the basis of the Daphne Major population and through detailed analysis, Grant determined that, though ground finches (*Geospiza*) occurred together in nonrandom combinations, members of all pairs of coexisting species differed by at least 15% in at least one bill dimension with minimal overlap in frequency distributions. By evaluating the nature of the food supply (seed characteristics), Grant revealed a polymodal frequency distribution during the dry season, which in turn determined adaptive peaks. Grant's (1985) long-term study of the Medium Ground Finch (*G. fuliginosa*) and the Small Ground Finch (*G. fortis*) provided evidence of both character displacement (an evolutionary process) and differential colonization (an ecological process).

More generally, Grant asked why there were only 13 species of finches on the Galápagos, rather than twice that many or more. And why did the species range from 8 to 40 g, rather than from 5 to 100? Drawing on the evolutionary history of the finches, Grant suggested that isolation of the islands, ecological differences, and the passage of time all contributed to finch speciation from one to many, but limited ecological opportunity coupled with relatively limited time and the presence of other bird species all placed constraints on the continued diversification of finches.

A few years later, Grant, along with his wife and scientific collaborator, Rosemary, and graduate students, initiated a study of *G. conirostris* on Genovesa, one of the most isolated islands of the entire Galápagos archipelago. Over the course of 11 years, the Grants and their students examined the ecology, behavior, and genetics of the population predominantly through direct observation, because experimentation was limited by National Park regulations and the natural state of the population. Hence, they referred to the islands as a 'natural laboratory.' The Grants found that rainfall was the key environmental factor that influenced the population and its variation. During the 11 years, there were two major droughts and two *El Niño* years. In 1983, the plants, arthropods, and finches all reproduced throughout the prolonged period of rainfall brought about by *El Niño*. In 1985, during a drought, all reproduction ceased. Both events placed selective pressures on the finches and, more specifically, their beaks. Their observations (Grant and Grant, 1989) challenged long-held views that evolution occurs over the course of prolonged periods of time and the corollary that changes are generally imperceptible. In fact, using data from DNA, the Grants have calculated that it could take as little as 200 years for one finch species to evolve into a new species (Grant and Estes, 2009). Widely regarded as one of the most important studies in ecology and evolutionary biology (see Travis, 1990), the Grants' long-term study of Darwin's finches has demonstrated that evolution can be studied in real time. Given the right circumstances, scientists can study evolutionary change as it happens (Figure 6).

The Future and the Finches

In addition to revealing the ecology and evolution of Darwin's finches, the conservation of these geographically constrained birds has been a recurring theme in the Grants' work. Others have also recognized the need for conservation efforts. The Mangrove Finch (*Cactospiza heliobates*) was the last of finches to be described, and the entire population was restricted to some of the mangrove forests bordering Isabela and Fernandina, but the Grants determined that the latter population may no longer exist and the Isabela birds are under threat from an introduced wasp and habitat destruction (Grant and Grant, 1997). Critically endangered and limited to highland regions of Floreana, the Medium Tree Finch (*Camarhynchus pauper*) also suffers from habitat destruction as well as introduced predators and a parasite (O'Connor *et al.*, 2010). Local extinctions of wider ranging species such as the Warbler Finch (*Certhidea fusca*) on Floreana have also occurred (Grant *et al.*, 2005). Each of these cases offers a cautionary tale for the continued survival of Darwin's finches.

Conclusion

More than 150 years passed between Darwin's first suggestion that the Galápagos finches would serve as an excellent model for evolution in nature and the full realization of that prediction. After Darwin's initial confusion, John Gould described most of the species, but the complexity of speciation vexed biologists during the Age of Survey. Like Darwin, David Lack initially misinterpreted the significance of the finches, but he eventually re-characterized the finches as a model of adaptation by natural selection. The longitudinal studies conducted by Peter and Rosemary Grant (as well as numerous students and collaborators) revealed that in the right circumstances at natural laboratories like Genovesa and Daphne, it is possible to measure evolution as it occurs. Studies of the finches' conservation status suggest that rare and widespread species alike are threatened by anthropogenic change in the Galápagos. The development of Darwin's finches as an evolutionary icon began in a fog of confusion, but a long series of empirical and theoretical studies revealed and continues to provide rich insights into evolution and ecology.

Darwin–Wallace Theory of Evolution

J van Wyhe, National University of Singapore, Singapore

The Darwin–Wallace Theory of Evolution

The Darwin–Wallace theory of evolution is arguably the most important and widely influential in the entire history of science. It has resulted in one of the most revolutionary changes in human thinking in history with profound consequences for research in a wide swathe of areas including geology, paleontology, biology, taxonomy, philosophy, anthropology, psychology, literature, medicine, and theology.

The theory and its origins have therefore been written about, discussed, and debated more than any other. The story of its origins has been retold countless thousands of times over the past 150 years. Like any tale endlessly recounted, the story has considerably evolved in the telling. There are now more myths and legends about this topic and its principal players, Darwin and Wallace, than perhaps any other.

In order to understand the origins of the theory, it is necessary to understand the people and events in their original historical contexts. One of the most persistent myths is that evolution was the answer to an eternal question or mystery which scientists long sought to solve or discover. Nothing could be further from the truth.

The Age of the Earth

In Christian Europe, the world was traditionally held to be about 6000 years old based on interpretations of the Bible, which itself gave no dates or age for the earth. By the early nineteenth century the accepted age of the earth had changed through the work of many scholars studying mining, geology, and fossils. Although most of these scholars were devout Christians, from the continued investigation of the rocks, it came to be universally accepted that the world was extremely ancient.

With the discovery of ever more fossils, another dramatic fact about the history of the world was uncovered and became widely accepted. The history of life on earth had been progressive. The most primitive forms such as shells and ferns had preceded the more complex forms such as crustaceans and conifers. In later rocks reptiles appeared followed in the comparatively recent rocks by the first mammals, although of extinct types. Yet nowhere in the immense history of living things were any human fossils or artifacts found. Humans were clearly a far more recent species. This led some to believe that the creation stories in Genesis only referred to the most recent of many creations, the one that concerned us.

'Catastrophism'

At the beginning of the nineteenth century, the French comparative anatomist Georges Cuvier, through his detailed analyses of fossil bones such as the mammoth and the *Megatherium*, first proved an extremely controversial point. Extinction was a fact. Before this, many scholars held that the suggestion that species could go extinct was irreligious and impossible. Cuvier's excavations in the Paris basin showed that the further back in time one moved, the more different were the kinds of living things. Each era represented in the rocks was characterized by its own flora and fauna. These periods seemed to Cuvier to have been abruptly ended and followed by subsequent environments characterized by a new and unique flora and fauna. For someone who had lived through the French revolution, perhaps it is not surprising that Cuvier characterized these changes from era to era as revolutions. Cuvier's view is usually caricatured in recent accounts as an old-fashioned theory of 'catastrophism.' But it was extremely advanced at the time.

'Lamarckism'

In opposition to Cuvier's theory of extinction, the French naturalist Jean-Baptiste de Lamarck argued that unfamiliar fossil species had not gone extinct but had changed or evolved. For well more than a century now Lamarck's theory has almost always been misrepresented as evolution by the inheritance of acquired characteristics. This is a very inaccurate shorthand. The inheritance of acquired characteristics was not invented by Lamarck, it was not the core of his theory, and it was a very common belief amongst eighteenth- and nineteenth-century naturalists. Lamarck's theory was instead driven by a 'complexifying force' which drove species to become ever more advanced. Along the way Lamarck argued that inheritance of acquired characteristics allowed organisms to adapt to their particular environments. Cuvier so powerfully discredited Lamarck and his theory that for many years any type of evolution was considered unscientific.

More Species

Another great change was the number of species known to exist. This went from a few hundred known in Europe and the Mediterranean areas to countless thousands by the early nineteenth century. As European ships circled the globe, new species became known, from the porpoise and the dodo to the strange marsupial creatures of Australia. Systematists, like the great Swedish botanist Carl Linnaeus, created elaborate systems to arrange and sort them, and it was found that whole classes of organisms were closely related to one another through chains of similarity. Even more fundamentally, it was found that all groups fit as subgroups within larger ones, so that, for example, all species of wolves were classed with foxes, jackals, and dogs as canides. This pattern would later be explained by the Darwin–Wallace theory of branching evolution.

'Uniformitarianism'

Many histories incorrectly attribute the developments outlined so far, such as modern geology with its ancient earth and fossil

 doi:10.1016/B978-0-12-800049-6.00003-2

record, to the Scottish geologist Charles Lyell and his influential work *Principles of Geology* (1830–33). But this is another modern shorthand.

Lyell conducted extensive fieldwork. He examined the volcano Mount Etna in Italy and showed that it must have grown slowly over a vast period of time. Lyell argued that events that appeared sudden on a geological scale could be the result of a long sequence of less abrupt changes. This aspect of his theory is the one usually remembered as 'uniformitarianism,' and is held up as the key to Lyell's theory. A supposed debate between 'uniformitarians' and 'catastrophists' is often invoked. Yet this was not the issue at the time, and indeed Lyell was probably the only 'uniformitarian.' Lyell's fellow geologists had no problem with mundane causes explaining past events but they objected to his insistence that causes of the same (or uniform) intensity as those of the present were all that had ever existed.

In addition to his survey of geology, Lyell also discussed what is now called paleontology. He carefully surveyed the evidence for the successive appearance and disappearance of species in the geological record. Here too he tried to show that gradual natural processes were responsible. Because he believed that species could not change, they would eventually become extinct as their environments slowly changed beyond their limited ability to adapt. So, extinction was a gradual and piecemeal process. The question was starting to arise, where did the subsequent species come from? Lyell accepted that species introductions were probably as piecemeal as extinctions and hypothesized that new species somehow appeared in accordance with the new environments. He seemed to allow that supernatural creation was involved with the appearance of new species.

Just as the volumes of Lyell's *Principles of Geology* were coming out, a young English geologist working in South America was able to put some of Lyell's ideas about gradualism to the test. He was also to find Lyell's dodging of the question of where new species came from not entirely satisfactory. His name was Charles Darwin.

Darwin

Charles Robert Darwin (1809–82) was born in the small market town of Shrewsbury, England, to a wealthy upper middle-class family. His mother died when he was eight years old. There is no evidence that he suffered any unusual effects from this as was once believed. Darwin was raised by his elder sisters and maidservants.

He attended the nearby Shrewsbury Free Grammar School as a boarder from 1818 to 1825. In October 1825 he was sent to Edinburgh University with his elder brother Erasmus to study medicine with a view to becoming a physician. While in Edinburgh, Darwin investigated marine invertebrates with the guidance of Robert Grant, a gentleman naturalist. Darwin did not like the study of medicine and could not bear the sight of blood or suffering and so his father proposed the church as a respectable alternative. The advantage to becoming a country parson would be the freedom to pursue a growing interest in natural history. To become ordained in the Church of England it was necessary to first obtain a BA degree from an English university.

On 15 October 1827 Darwin was admitted a member of Christ's College, Cambridge (van Wyhe, 2014a). Darwin was never a model student, but he did mature into a passionate amateur naturalist. He began avidly collecting beetles. His name appeared in print when some of his records of insect captures were published in 1829.

Darwin became the devoted pupil of Professor of botany John Stevens Henslow (1796–1861). Through their close friendship Darwin learned a great deal about the practice of natural science. Darwin passed his BA examination in January 1831. Shortly thereafter he was taught the basics of field geology by Professor Adam Sedgwick during a tour of north Wales.

Voyage of the Beagle

Later in 1831 Henslow recommended Darwin for the post offered by Commander Robert FitzRoy for a naturalist to travel on a Royal Navy survey ship, HMS 'Beagle.' Contrary to recent fashion, Darwin was not on board as the captain's social companion, nor was the ship's surgeon the 'official naturalist' (van Wyhe, 2013b). Darwin was expected to investigate the natural history of the lands visited and this he did to a remarkable extent.

The 'Beagle' surveyed the coasts of the Southern half of South America and the Galapagos islands and returned home via the Pacific. The voyage lasted 5 years. Darwin spent most of these years investigating the geology and zoology of the lands he visited, especially South America, the Galapagos islands, and Pacific oceanic islands. He recorded many of his specimens and observations immediately in field notebooks (Chancellor and van Wyhe, 2009). Throughout the voyage Darwin shipped home specimens which soon earned him a reputation as a collector and observer of the first order. Later he recorded his experiences in a diary which became the basis of his famous book *Journal of Researches* (1839) now known as *Voyage of the Beagle* (Keynes, 2001; Darwin, 1839).

Darwin had the opportunity to witness all of the forces discussed by Lyell, such as erosion, earthquakes, and volcanic eruptions. Darwin made several very important discoveries about the geology of South America, volcanic islands, and the origins of coral reefs by building on Lyell's ideas.

Darwin also unearthed many fossil creatures in South America. He wondered why the fossils resembled the present inhabitants of that continent more than any other species. Where had the new species come from? If species were somehow created to fit their environments, as was then believed, why were tropical species different in Asia, Africa, and South America despite the similarity of climate?

The Galapagos

Only in the middle of the twentieth century did Darwin's visit to the Galapagos come to be seen as a pivotal moment in his life, described as the occasion for a eureka-like discovery of evolution. Darwin did not become an evolutionist on the Galapagos and neither the islands finches nor their now famous beaks prompted a revelation either (Sulloway, 1982;

van Wyhe, 2012). Only much later would the case of the Galapagos animals influence Darwin's thinking.

The Big Three

During the 'Beagle' voyage and after his return, Darwin was particularly struck by three types of puzzling evidence: the succession of allied fossil forms in the same locale, geographical distribution, and the species of the Galapagos (see Darwin, 1958, pp. 118–119). These three factors suggested to Darwin that species must evolve.

The species on the Galapagos, for example, were obviously similar to those of South America, yet their rocky island home bore no connection or resemblance to South America. It seemed to Darwin that stray migrants from South America had come to the Galapagos, after the islands rose from the sea as volcanoes, and then changed over time in isolation on the islands.

Darwin also used the experience and observations of farmers and breeders to reveal that the purported limits or barriers to species mutability was a belief without foundation. Darwin mingled with pigeon breeders to learn how they created extraordinary breeds by careful selective breeding (Secord, 1981).

In September 1838, Darwin read Thomas Malthus's *Essay on the Principle of Population* (1798). For many years it was claimed that Darwin's theory was therefore influenced by the politics or economics of Malthus's book. In fact Darwin noticed none of this but was instead struck by the implications of population growth potential in humans and other species.

Malthus argued that human population growth, unless somehow checked, would necessarily outstrip food production. The focus of this argument inspired Darwin. He realized that an enormous proportion of living things are always destroyed before they can reproduce. This must be true because every species would otherwise breed enough to fill the entire earth in a few hundred generations. Instead, populations remain roughly stable year after year. The only way this can be so is that most offspring (from pollen, to seeds, and eggs) do not survive long enough to reproduce.

Darwin embarked on a vast research program of reading and experimentation that would take many years to complete. In the meantime his primary occupation was the publication of his vast 'Beagle' collections. This would take more than 10 years.

From the 1960s it became widely believed that Darwin kept his theorizing a secret and delayed its publication because he was afraid of the reaction. A large literature emerged to propose reasons or causes for this extraordinary secrecy and 20-year delay. In fact both are modern legends. Darwin told his family, friends, and colleagues about his theory and his plans to publish a large book on it. Like all of his other book projects, the species theory took even longer than he originally imagined (van Wyhe, 2007, 2013a). Nevertheless, the 20 years of work on the theory was far less than the delay in publishing many of Darwin's other works.

Vestiges of Creation

In 1844 an extraordinary anonymous book appeared which became a Victorian sensation: *Vestiges of the natural history of creation* (Secord, 2000). The book was written by the Edinburgh publisher Robert Chambers. *Vestiges* argued that nature operated according to natural laws, and that a fundamental outcome of the way the laws worked was progress. In space, dust evolved to form solar systems, the earth itself evolved to make the planet more suitable for higher life forms and life itself evolved or 'developed.' Organisms produced offspring like themselves. But sometimes, according to an even higher natural law, they would produce an offspring of a higher type. Over time, this led to life progressing ever upwards. Invertebrates, fish, reptiles, mammals, and finally humans had all followed in succession, and *Vestiges* hinted that something higher would follow us. Although widely attacked by the scientific community, *Vestiges* convinced many that life evolved. One of these was a young man named Wallace.

Wallace

Alfred Russel Wallace (1823–1913) came from a rather humble background compared to Darwin's. Wallace's father, a solicitor by training, once had property sufficient to generate a gentleman's income of £500 per annum. But the family's financial circumstances declined so that by the time Wallace was born, they were living in a quiet cottage near Usk, on the Welsh borders. Nevertheless, Wallace was not working class as he is sometimes described by modern commentators.

When Wallace was six years old the family moved to Hertford, north of London, where he lived until he was 14. Here Wallace attended Hertford Free Grammar School which offered a classical education, almost identical to Darwin's at Shrewsbury. Wallace left school aged 14 in March 1837, shortly after Darwin returned from the 'Beagle' voyage. Wallace never attended university. In recent years it has been widely claimed, though erroneously, that Wallace was forced to leave school early for financial reasons.

Over the next decade Wallace pursued a series of jobs from land surveying to an assistant teacher in Leicester. In 1848 he set out with his friend and entomologist Henry Walter Bates to work as a specimen collector in the Amazon basin. In recent years it has become increasingly fashionable to claim that they set out to solve the problem of the origin of species. This is an apocryphal, even if romantic, story (van Wyhe, 2014b). Wallace returned to Britain in 1852 but tragically lost his personal collection in a shipwreck. Undaunted, he set out for another collecting expedition, this time to Southeast Asia, then sometimes called the *Malay Archipelago*.

Malay Archipelago

Over the next 8 years, Wallace and a team of assistants made dozens of expeditions to islands from Singapore to New Guinea and collected 125 000 specimens of insects, birds, mammals, and so forth. Wallace discovered hundreds of new species including the world's largest bee and rarest cat.

In 1855, while living in the province of Sarawak on the great island of Borneo, Wallace wrote his first theoretical paper on species: 'On the law which has regulated the introduction of new species' (Wallace, 1855). Wallace argued that: "Every species has come into existence coincident both in time and

space with a pre-existing closely allied species." Although a lucid analysis of the paleontological and biogeographical evidence of the time, the paper did not explicitly state that species evolve. Instead Wallace left this point to be inferred. Many modern readers, however, mistakenly assume that the essay openly declared evolution.

Wallace continued reading about geology and paleontology and jotting notes about how he believed species changed. As he collected more and more specimens and observed the change of animals from island to island, his ideas about life also evolved. He was convinced that species must be related genealogically – not just somehow created to suit their environments. But he was certainly not, as many modern commentators put it, searching for a 'mechanism' for how evolution works. This is a later manner of thinking.

In February 1858 Wallace was living on the island of Ternate in the Moluccas, the fabled spice islands, west of New Guinea, and then part of the Dutch East Indies. According to his later recollections, Wallace was suffering from a recurring bout of fever when he suddenly conceived of an explanation for the origin of new species. When he recovered, he wrote an essay entitled 'On the tendency of varieties to depart indefinitely from the original type.'

In this extraordinary essay Wallace reminded his readers of the well-known principle of the 'struggle for existence' which kept population numbers in check. Modern readers often misinterpret this initial discussion as if it were about natural selection, but this is a mistake. After establishing the point about how in the normal state of the natural world balance is maintained by the strong living and the weak dying, Wallace then made an analogy: just as there was a struggle for existence amongst individuals of a species, the same was true for varieties or races (essentially modern subspecies). As an environment gradually changed over time a species would become unsuited and die out. Among its daughter varieties, there might be one that happened to suit the new environment. This variety would then become the new species. It could never return back to the parental form as that was now inferior in the new environment. This process, if reiterated over a long time, would lead, as Wallace's title declared, "varieties to depart indefinitely from the original type."

It was a brilliant scientific essay and demonstrates Wallace's independent formulation of what Darwin called 'natural selection.' Nevertheless, historians of science have long commented on the many differences between Wallace's and Darwin's views. The essay is heavily influenced by Wallace's study of his copy of Lyell's *Principles of geology*. Years later Wallace recalled that he had been inspired by Malthus. This is certainly possible but should not be repeated incautiously as if a straightforward fact. Wallace made no mention of Malthus in his essay and only did so after reading Darwin who stressed the work of Malthus.

Darwin versus Wallace?

What happened next has been surrounded by confusion and conspiracy theories in recent decades. Wallace did not send his essay for publication. A few weeks after writing it he received an extremely encouraging letter from Darwin who praised Wallace's (1855) paper and mentioned that Charles Lyell also thought highly of it.

Wallace was inspired. If the Sarawak paper had impressed the great Lyell, perhaps the new Ternate essay would impress him too. Perhaps Wallace could even convince Lyell that his own principles actually supported, rather than contradicted, evolution. So Wallace sent his essay to Darwin, whom he knew to be preparing a large work on evolution, with the request that it be forwarded on to Lyell if sufficiently interesting.

For decades it was believed that Darwin might have lied about when he received Wallace's letter and essay. Based on this uncertainty some even claimed, without evidence, that Darwin might have plagiarized from Wallace. In fact, Darwin received Wallace's essay exactly when he said he did (see van Wyhe and Rookmaaker, 2012; van Wyhe, 2013a).

Darwin was by then 2 years away from completing and publishing his big book on species. Surprised by Wallace's essay, but very much the Victorian gentleman, Darwin immediately forwarded it to Lyell as requested. Darwin even proposed sending Wallace's essay for publication and giving up his own 20 years of priority in natural selection.

Concerned that their friend would lose his priority, Lyell and J.D. Hooker had extracts from Darwin's manuscripts written in 1844 and 1857, together with Wallace's essay, read before the Linnean Society of London on 1 July 1858. These documents were published together as a joint contribution in the Society's proceedings in August 1858 (Darwin and Wallace, 1858). Thus began the long series of events that are usually called the Darwinian revolution.

Since the 1960s there has been an increasing number of suggestions that something about the joint announcement was unfair to Wallace or that he has been otherwise unfairly treated or forgotten. The arrangement was perfectly correct according to the standards of the time. Wallace was both flattered and delighted when he found out about the arrangement. Indeed it was described in this way by all of the participants, their contemporaries and later commentators for over a century. Nevertheless the papers were very brief and easy to read as only a contribution to debates about varieties. Few and perhaps no converts to evolution were made by the joint presentation.

Darwin began to prepare a summary or abstract of his larger work for publication. This project too lengthened far beyond his original plan and eventually became the 500-page *On the origin of species* (1859). The book condensed Darwin's massive research program of 20 years into a single volume and all of the most likely objections were openly acknowledged and answered.

The book immediately became extremely controversial and discussed. Despite the fact that it argued against some of the most fundamental scientific views of the time, and for many was also considered religiously or morally unacceptable, the book almost single-handedly convinced the international scientific community to accept that evolution is a fact within 10–15 years.

As Darwin's book had this dramatic impact, the theory and its success were, from the beginning, attributed to Darwin. *On the origin of species* also included many components not present in Wallace's essay. These included the analogy of man's selective shaping of domesticated plants and animals, laws of

variation, transitional varieties, inherited instincts, family selection, hybridism, embryology, taxonomic classification, no inherent progress, sexual selection, vestigial organs as remnants, and natural dispersals rather than former land bridges. Wallace was amongst Darwin's foremost supporters. The theory was therefore commonly called 'Darwinism.' Wallace (1889) also promoted this view, including his own great book on the theory, second only to the *Origin of species*, called *Darwinism*.

After the work of Darwin, Wallace, and many others, the question of whether or not evolution occurred was never again scientifically in doubt, though natural selection and indeed inheritance, along with a number of other aspects of the theory remained problematic until the first few decades of the twentieth century when the so-called modern synthesis of evolution diminished such concerns. Indeed, it remained for generations of workers to work out the many details and profoundly important and complex implications.

Developmental Biases on Morphological Evolvability

Y Hu and RC Albertson, University of Massachusetts, Amherst, MA, USA

Conceptual Definition(s) of Evolvability

Evolvability, the ability of biological systems to evolve, is a relatively new concept in evolutionary biology, which has emerged as the field pivots away from a gene-centric view of evolutionary change and places renewed emphasis on the origin of phenotypic variation. Similar to many other biological concepts, the definition of evolvability has not been completely settled. Depending on the scale of interest, evolvability has overlapping yet different meanings (these are described in detail by Pigliucci, 2008). At the microevolutionary level, evolvability refers to "the ability of a population to respond to selection" (Flatt, 2005), which is largely equivalent to heritability. At the macroevolutionary level, evolvability may refer to the propensity to produce major evolutionary novelties, such as the turtle shell or bat wings. In between these two extremes, evolvability may be defined as any property of a genetic/developmental system that facilitates the emergence of new patterns of phenotypic variation.

Another conceptual difficulty of defining evolvability relates to whether one is referring to the 'rate' or 'direction' of evolutionary changes (Figure 1). When considering the rate of evolutionary change, evolvability depends on patterns of phenotypic covariation. For instance, a population that is characterized by a pattern of phenotypic covariation that is closely aligned with the vector of selection should, in theory, be able to evolve rapidly along this axis (Figure 1(a)). Alternatively, if selective pressures shift such that the vector of selection is perpendicular to the primary axis of phenotypic variation within a population, the evolutionary response should be slower. Thus, evolvability with respect to the rate (i.e., how fast/efficiently a population will respond to selection) depends on the pattern of phenotypic (co)variation within that population and the direction of the vector of selection.

In terms of the direction of evolutionary change, evolvability relates more to the level of phenotypic covariation, often referred to as phenotypic 'integration' (more on this below). Highly integrated trait complexes will show high levels of covariation among its component parts. Under this scenario it should be hard to change one aspect of the phenotype without simultaneously altering other aspects. Thus, evolution will be constrained such that movement in certain directions of phenotypic space should be relatively easy to achieve, whereas movement into other dimensions of shape–space should be more difficult, if not impossible (Figure 1(a)). A very different situation is expected to arise when suites of traits exhibit low levels of integration (Figure 1(b)), where the population is free to move along various phenotypic axes, depending on the direction of the vector of selection. Evolvability with respect to the direction of evolution will therefore be high in this situation.

Given these considerations, it is clear that evolvability is operationally context-dependent, and it is perhaps most appropriate to consider this phenomenon at the nexus between evolutionary constraint and opportunity (Klingenberg, 2008, 2010). A constrained, highly integrated phenotype may have limited opportunity to evolve in multiple dimensions, but

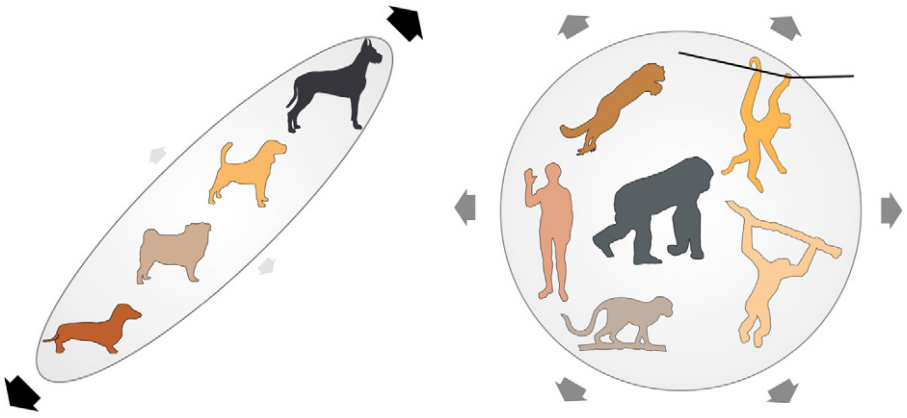

Figure 1 Illustration of how phenotypic covariation (integration) may bias evolution, using limb length as an example (adapted from Klingenberg, C.P., 2010. Evolution and development of shape: Integrating quantitative approaches. Nature Reviews. Genetics 11 (9), 623–635). (a) Among dogs, forelimb and hindlimb lengths covary, resulting in a 2-dimensional ellipsoid distribution of variation in phenotypic space. In this case, the population may respond efficiently to selection along the major axis (dark arrows; i.e., changes in both forelimb and hindlimb length), but it will not be able to respond as well to selection along other directions (small, light arrows; e.g., longer forelimb and shorter hindlimb). (b) Among primates, forelimb and hindlimb lengths are relatively independent to each other, resulting in a circular distribution of variation. In this case, the lineage may respond with equal efficiency to selection on any direction (e.g., longer hindlimb in leaping species, longer forelimbs in arm-swinging species, and equal limbs in quadrupedal species) and thus have maximized opportunity to occupy various regions of phenotypic space.

may respond rapidly to selection along one specific axis. Evolvability of this trait may therefore be considered high with respect to rate, but low with respect to direction. Alternatively, a phenotype with low levels of integration should be relatively less constrained to evolve in multiple directions (i.e., greater opportunity), but will evolve less efficiently along any one axis of variation. Here, evolvability would be considered low in terms of rate, but high in terms of direction. Thus, evolvability can be used as a term to describe the trade-off between the rate and direction of evolutionary response, which operationally is determined by the relative levels of 'constraint' and 'opportunity' that define the system (**Figure 1**).

It is now generally accepted, though still not widely considered, that evolvability in biological systems is strongly influenced by patterns of phenotypic (co)variation. Given this, a renewed effort in evolutionary biology is now underway to understand the mechanisms that determine these patterns, and the field of evolutionary developmental biology (evo-devo) is making significant inroads into this question (Hendrikse *et al.*, 2007).

Development Determines Evolvability

Genetic variation originates from mutation and recombination events in the genome, which are largely considered to be random phenomena. For the better part of the twentieth century, genetic variation has been considered to be the raw material upon which natural selection may act – i.e., the more genetic variation that exists in a population, the greater its potential to evolve. Yet selection does not operate on genes, rather it is the traits translated from the genomic blueprint that ultimately determine the fitness of an organism. The translation from genotype to phenotype is achieved over development, which can act as a 'filter' through which only a subset of the genetic variation will be expressed and thus visible to selection (Jamniczky *et al.*, 2010). For example, many important developmental processes are 'robust' such that little variation is evident in the system. The ultimate cause of robust development is not thought to be reduced genetic variation, but rather the self-regulatory properties of the molecular signaling network, including redundancy, modularity, and negative feedback within the system (Paulsen *et al.*, 2011 and references therein). Thus, the invariant nature of development may belie extensive nucleotide variation in the loci that encode members of the developmental network. It is for this reason that the penetrance of many genetic 'mutation' depends upon the genetic background into which they are introduced (Kitano, 2004).

Another important feature of developmental systems is that they interact with environmental factors, and thus the expression of genetic variation also depends on the external environment. The interaction between genes and the environment is broadly referred to as developmental plasticity, which is predicted to play an important role in promoting phenotypic evolution (West-Eberhard, 2005). Mechanistically, a plastic response may occur when a population encounters a novel environment, revealing cryptic (i.e., hidden) genetic variation that has accumulated over time under normal environmental conditions. This previously hidden genetic variation has the potential to produce new patterns or levels of phenotypic variation upon which natural selection may act (Gibson and Dworkin, 2004). While empirical evidence for such a process has largely been limited to laboratory models (Bateman, 1959; Dilda and Mackay, 2002; Polaczyk *et al.*, 1998), recent work on cavefish evolution provides an excellent example of this phenomenon within a natural system (Rohner *et al.*, 2013). *Astyanax mexicanus* is a species of freshwater fish commonly known as the Mexican tetra that is native to streams and rivers in northeastern parts of Mexico. In certain instances, populations of *A. mexicanus* have become trapped within caves, and have subsequently diverged from their surface-dwelling ancestors. In particular, cavefish have repeatedly lost their eyes and pigment. While much research has focused on understanding the genetic changes that have occurred within cavefish populations that have led to these dramatic shifts in phenotypes (Protas *et al.*, 2006, 2007, 2008; Gross *et al.*, 2009), a recent study by Rohner *et al.* (2013) has demonstrated that the first step in cavefish divergence may involve the release of heritable cryptic genetic variation. They focus on HSP90, which is a chaperone involved in protein folding and is very sensitive to environmental conditions. They show that when surface fish are exposed to a cave environment, a HSP90-related stress response is induced. In particular, they demonstrate that with this environmental shift the function of HSP90 is affected, which leads to a substantial increase in the variation of eye size (notably, other cave-specific phenotypes like pigmentation were unaffected). Thus, changes in the environment are sufficient to produce novel phenotypic variation without genetic mutations, and in the case of blind cavefish, this may have been the first step toward evolved eye loss.

This idea that development filters genetic variation is not new and roots from Waddington's classic concept of canalization (Waddington, 1957), wherein developmental systems exhibit varying degrees of robustness. A robust system is one in which the phenotypic outcome remains the same regardless of variations introduced by genetic mutations, or changes in the environment. Waddington conceptualized development as a marble rolling down a sculpted landscape. In this metaphor, the marble represents a cell or tissue, while the different 'valleys' it encounters along the way represent different developmental pathways. Canalized development would be characterized by a landscape with steep walls and narrow valleys such that there is little variation in the trajectory of development. Importantly, Waddington posited that this landscape could itself evolve by increasing or decreasing the width of the valleys encountered by each marble. In other words, development can evolve to either promote or restrict levels of phenotypic variation. For example, in *Astyanax*, pigmentation is less sensitive to environmental changes (i.e., is more canalized), whereas eye size is relatively more sensitive to the same shift in environment (i.e., is less canalized). The ways in which developmental systems can evolve to effect canalization are likely many, and this represents an active area of research. The common theme however is that these mechanisms act at the intersection between genotype and phenotype, and thus implicitly involve changes in the developmental program (Jamniczky *et al.*, 2010).

Phenotypic Integration and Modularity

Recent efforts to understand how development constrains variation have centered on the related concepts of phenotypic integration and modularity. Phenotypic integration refers to the relative degree to which sets of traits covary. Modularity is a term used to describe trait sets that exhibit a relatively high degree of correlation internally and low degree of correlation with other traits (Pigliucci and Preston, 2004; Klingenberg, 2008). The phenotypic consequence of modularity is that change in one trait will lead to corresponding changes in all other traits in the same module, but little or no change in traits in other modules. Consequently, variation within a module is typically biased/concentrated along certain axes in the phenotypic space that is determined by the pattern of covariation, and would be expected to constrain phenotypic evolution (**Figure 1**). Empirical support for these ideas can be found from a large-scale comparative study of shoulder girdle morphology and integration among mammals by Sears *et al.* (2013). Specifically, investigators found that, compared to placental mammals, marsupials possess a tightly integrated shoulder girdle. These data are consistent with the observation that girdle elements have evolved independently in placentals, but in marsupials they have evolved in a more coordinated manner. Thus, the evolution of the shoulder girdle in marsupials appears to be constrained, and this is coincident with and likely due to their unique reproductive strategy. In particular, marsupials have evolved a highly specialized pectoral girdle to enable a crawl from the reproductive tract to the teat early in life. Moreover, patterns of integration were found to be highly consistent across placental and marsupial mammals. In all this work highlights two attributes of integration: (1) It can impose long-term constraints that bias the production of phenotypic variation within a lineage (i.e., patterns are maintained across marsupial mammals); (2) Integration itself is a trait that can respond to selection (i.e., patterns vary between taxa at a larger scale). The evolvable nature of integration patterns implies that constraint imposed by development is not absolute, and that such processes vary over phylogeny.

Developmental constraints also vary over the course of ontogeny. Evidence supporting this idea can be found in recent studies on the 'phylotypic stage' of vertebrate facial development (e.g., Young *et al.*, 2014). Young *et al.* compared facial shape during embryonic development among multiple species of mammals, reptiles, and birds. They found that after the initial prominence outgrowth, embryonic facial shape converges as the frontonasal maxillary prominences fuse to form the primary palate. After this important process is complete, facial shape then diverges to take on species-specific geometries. Their data are consistent with an hourglass model of development, whereby morphological variation in the face is reduced during the middle/fusion stage compared to the early and late stages. In other words, although adult facial morphology varies dramatically among these lineages, their developmental trajectories are restricted through a bottleneck at the fusion stage. Formation of the primary palate is of critical importance to the survival of the animals, and is the result of the coordinated effects of myriad cellular activities that are under the control of numerous genes and pathways (Wilkie and Morriss-Kay, 2001; Dixon *et al.*, 2011). Variation in this process can have dramatic detrimental effects on the developing embryo (e.g., cleft palate in mammals), thus this stage of craniofacial development appears to be tightly coordinated and highly canalized. The observation that facial development is more variable after this stage implies relaxed constraint within a developmental system that is less susceptible to catastrophic breakdown.

How developmental constraints manifest themselves over ontogeny remains an open question, but integration/modularity are hypothesized to play an important role (Raff, 1996). For example, in the case of amniote facial development, the fusion stage may reflect a period characterized by relatively high levels of integration. Specifically, in order for the various prominences of the embryonic face to properly fuse there must be a high degree of cross talk between these multiple components (e.g., modules). Subsequent divergence in facial shape among amniote lineages may occur as a result of the embryo/face becoming more modularized. With less cross talk between modules, variation could arise within one component of the face without impacting other regions.

'Constraint' in Developmental Systems Is Necessary for Evolution

Note that the word 'constraint' does not necessarily mean that development is an obstacle for evolutionary processes. Rather, theory suggests that constrained variation is actually necessary for the evolution of complex character networks. In their now classic paper, Wagner and Altenberg (1996) used the infinite monkey analogy to illustrate this idea, in which a monkey is given either a pencil or a typewriter to reproduce a verse of Shakespeare. In this scenario, the monkey's behavior is random and analogous to genetic mutations, Shakespeare's text represents an adaptive phenotype/direction of selection, and the pencil and typewriter represent two different developmental systems that translate the random behavior of the monkey. The monkey with a typewriter has a far better probability of reproducing a verse of Shakespeare compared to a monkey with a pencil, since the monkey is constrained by the typewriter to produce letters, and thus has a greater chance to achieve an adaptive phenotype. However, this is only true when the axis of selection is along a Shakespearean axis. If we were to consider selection along other directions, say toward the reproduction of a pencil sketch of Michelangelo, then the pencil would represent a more 'adaptive' developmental system. Thus, it is the environment that influences the direction of selection, and consequently the degree to which a developmental constraint may be considered adaptive. An important outstanding question is how do developmental mechanisms themselves change over time. That is, how easily may a typewriter evolve into a pencil?

Future

How does development bias evolution? How does constraint vary over ontogeny? How do constraints themselves evolve? All of these questions underscore the importance of development when studying the origin of phenotypic variation. Hallgrímsson proposed the palimpsest model as a conceptual

guide/framework for such studies (Hallgrímsson *et al.*, 2009). A palimpsest is an ancient page/script that could be erased and reused. However, with each use the previous text won't be completely washed away, and would leave some trace on the page. Development is a similarly hierarchical process in that each developmental event will add on and reorganize the phenotype established from previous events. The final outcome (e.g., adult phenotype, which is often the topic of evolutionary investigations) is therefore the product of multiple layers of developmental processes superimposed upon each other (Figure 2). Consequently, investigating adult morphology alone cannot inform a comprehensive understanding of developmental constraints. Concerted efforts are therefore needed to dissect the palimpsest, and examine the specific genetic, molecular, and developmental networks that are acting within each layer. We also need to gain a better understanding of the extent to which each layer influences subsequent layers over ontogeny, as well as how these mechanisms interact with the environment. These are lofty goals, but necessary to achieve a holistic understanding of how development translates/filters genetic variation into phenotype.

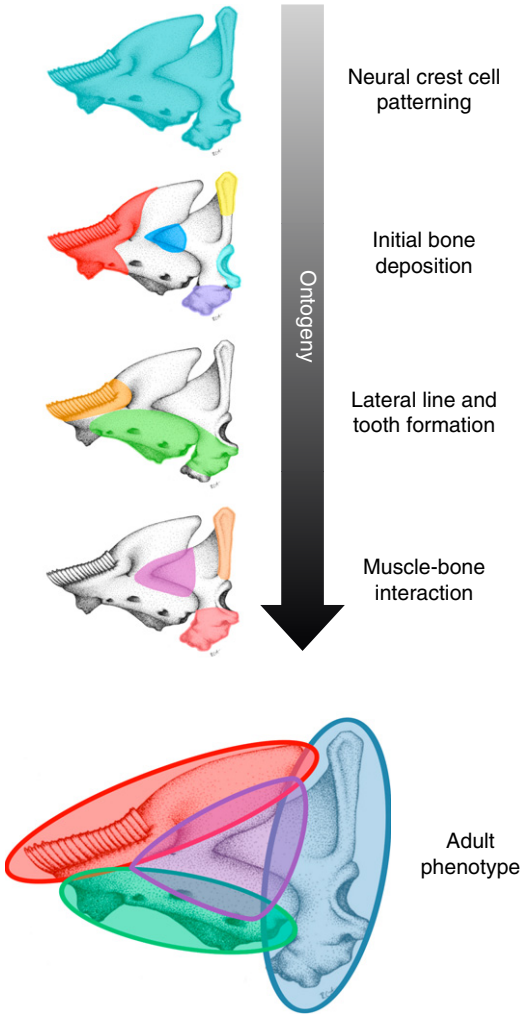

Figure 2 Illustration of a proposed palimpsest model for the cichlid mandible (adapted from Hallgrímsson, B., Jamniczky, H., Young, N. M., *et al.*, 2009. Deciphering the palimpsest: Studying the relationship between morphological integration and phenotypic covariation. Evolutionary Biology 36 (4), 355–376). Various developmental events influence the shape of the jaw at different stages over ontogeny. Each event affects certain regions of the jaw, and has the potential to establish different patterns of integration at different stages. The pattern of covariation observed in the adult is therefore the result of a complex interplay between events over development. A change at any one stage in terms of either the pattern or strength of phenotypic covariation will affect the pattern of integration observed in the adult.

To this end, there are several methods that may prove to be especially helpful. This is by no means an exhaustive list, but rather one that highlights what we feel are promising directions in the field. Classic forward genetics (mapping techniques) would be very useful as an unbiased search for genes and epistatic interactions involved in specific developmental processes (e.g., Albertson *et al.*, 2005; Roberts *et al.*, 2011). Revealing epistatic interactions among loci could be especially informative, because they show how different loci interact, and if the genetic effects are acting at different developmental stages these insights could provide an inroad toward interactions between different layers of the palimpsest. Mapping studies targeting different/multiple stages of ontogeny should also be useful in understanding how different regions of the genome affect phenotype at different developmental stages. Notably, new methods have also recently been established that allow investigators to more explicitly examine the genetic basis for phenotypic integration via forward genetics (e.g., Pavlicev *et al.*, 2011; Parsons *et al.*, 2012; Hu *et al.*, 2014). Induced laboratory mutants (e.g., reverse genetics) are another potentially valuable resource with which to dissect the basis for developmental constraint. Here, instead of characterizing the role for a particular gene in phenotypic development, investigators could use mutant animals to examine how genetic changes translate to shifts in patterns of phenotypic covariation (e.g., Hallgrímsson *et al.*, 2009). Finally, because developmental constraints are unlikely to manifest the same way in divergent lineages, it will be important to explore these ideas in multiple systems and across different phylogenetic levels. We anticipate this to be an especially rich area of future research, which should help to reveal the full range of influence that development has on the production of phenotypic variation, as well as identify any common themes and first principles with respect to the role of development in phenotypic evolution.

Developmental-Genetic Toolkit for Evolutionary Developmental Biology

I Schneider, Universidade Federal do Para, Instituto de Ciencias Biologicas, Belem, Brazil
C Amemiya, Benaroya Research Institute, Seattle, WA, USA

Glossary

Ectopic Occurring in an abnormal position or in an unusual manner or form.
Homeobox A highly conserved 180-base-long sequence present in genes encoding Hox proteins. Importantly, *Hox* genes are not the only genes that encode a homeobox; this important motif exists in many other transcription factor genes that are not found in Hox clusters.
Homeodomain A 60-amino acid DNA-binding domain encoded by the homeobox.
Homeotic Adjective of the term homeosis, which describes a mutation that causes one body part to assume the identity of another.
Homologous Genes or structures that share common ancestry or evolutionary origin.
Tetrapod The superclass comprising the first four-limbed vertebrates and their descendants, including the living and extinct amphibians, reptiles, mammals, and birds.

Introduction

A striking characteristic of our planet is its diversity of animal life. From the most varied landscapes, ranging from the deep ocean to deserts, rainforests and mountaintops, vertebrate and invertebrate life abounds, showcasing a vast array of forms. It has long been the quest of naturalists to describe the patterns within the animal kingdom. Nineteenth-century comparative anatomists realized that behind the manifest variation of forms in living creatures, there was order. For example, creatures as dissimilar as bats and whales share a fundamental anatomical blueprint, or body plan (Valentine, 2004).

Charles Darwin's theory of evolution provided the explanation for the existence of this basic body plan: it was present in, and inherited from, the common ancestor of all animal species, and then subsequently modified to produce the various shapes seen in extant and extinct species. Soon after the mechanisms of heredity were elucidated, evolutionary biologists began working on what would become the modern evolutionary synthesis. In the decades that followed, the primary concern of evolutionary biologists became understanding how genes, allele frequencies at a population level, and natural selection combined to explain the arrival of new species, while neglecting a central question: how do new forms arise? Thus, evolutionists attempted to explain the survival of the fittest, without addressing the mechanisms behind the making of the fittest (Carroll, 2006; Müller, 2008).

To address this quandary, it was necessary for biologists to turn their attention to the process that actually builds animal bodies, namely embryonic development. By performing mutagenesis screens on animal models that were easy to breed in the laboratory, underwent rapid development, and produced abundant offspring, scientists revealed for the first time that genes were required to build bodies. This approach paved the way to the discovery of the developmental-genetic toolkit, namely the genes that controlled development, pattern formation, and identity of body parts. And then came the biggest surprise: these genes were deeply conserved across phyla and were shown to set up the body plans of every animal examined, from flies to humans.

The Discovery of the Homeobox Genes

Mutations in genes controlling development often give rise to defective tissues or structures and developmental arrest. Nevertheless, on occasion an unusual mutant results in a phenotype that does not fall in one of the aforementioned categories. In the *bithorax* mutant, the fruit fly, *Drosophila melanogaster*, develops an additional set of wings (Lewis, 1978), and in the *antennapedia* mutant, legs in place of the antennas (Wakimoto and Kaufman, 1981). These abnormalities were exceptional because the genetic change did not result in a breakdown of embryonic development; it instead transformed the identity of body parts. Additional aberrant flies such as *bithorax* and *antennapedia*, where body parts were made in the wrong places, became collectively known as homeotic mutants (Lewis, 1994).

The search for the genes responsible for homeotic mutants led to many surprising findings. First, the homeotic genes were located on the same chromosomal region in the fruit fly. Second, the genes were clustered in such a manner that genes involved in the formation of anterior structures were on one end and genes directing posterior structures on the other end of the cluster. Third, the order of the genes in the chromosome roughly matched the order of the body structures they influenced. And finally, the homeotic genes (which became known as *Hox* genes) all shared a conserved DNA sequence, the homeobox, that encoded a 60-amino acid 'homeodomain' predicted to function in DNA binding. Altogether, these findings offered for the first time an explanation for how a complex organism is built: a set of genes encoding DNA-binding proteins regulate genetic targets that will organize the formation of body parts in the developing embryo (Slack, 1984). As astonishing and elegant as it was, the discovery of *Hox* genes and its role in fly development represented, of course, an explanation for how an insect builds its body. However, the search for *Hox* genes across metazoa produced the next set of surprising findings that revolutionized developmental biology, and later, evolutionary biology (**Figure 1**).

When researchers set out to find *Hox* genes in other organisms, not only did they discover an abundance of them,

 doi:10.1016/B978-0-12-800049-6.00128-1

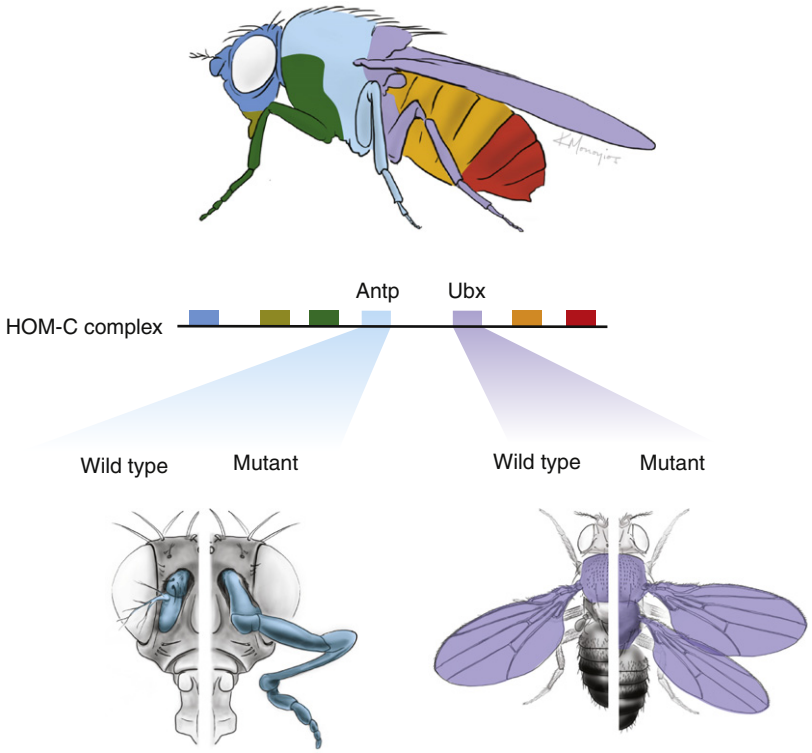

Figure 1 The fruit fly homeobox gene cluster. Top: Genes in the *Drosophila melanogaster* homeobox cluster (HOM-C) are color coded to match the corresponding body segment it controls. Bottom: Alterations to the *Antp* and *Ubx* genes result in changes in corresponding body parts, resulting in an ectopic leg in the place of an antenna or an extra set of wings, respectively. Illustration by K. Monoyios.

there were poignant similarities to the ones previously identified in fruit flies. *Hox* genes in mice were also grouped in the genome, except there were four clusters instead of one, and the position of a *Hox* gene within a cluster and its respective expression pattern along the body axis were relatively compatible (Duboule, 1994; Graham *et al.*, 1989). The outcome of studies on *Hox* genes in flies and mice was a new vision of development and evolution, one in which the bodies of all metazoans were being shaped over 600 million years of evolution. Further research on the developmental-genetic toolkit identified many more genes and showed that their use was not restricted to organizing the main body axis: body structures developed as modules with their own set of toolkit genes.

The Expanded Toolkit: Genes for Body Parts

The eyeless mutation in fruit flies is caused by a defect in the *ey* gene and is characterized by partial or complete loss of eyes. The *ey* gene is, therefore, crucial to the development of the fly's compound eyes. When researchers first isolated the DNA encoding *ey*, two features were particularly exciting: *ey* encodes a DNA-binding protein carrying a homeodomain and it had clear mammalian counterparts. The human version, called *Pax6*, is a gene required for proper development of the iris and the mouse counterpart was called *Small eye* or *Sey*, as mouse mutants for this gene displayed reduction or absence of eyes (Quiring *et al.*, 1994). Therefore, homologous genes in mice and flies were involved in the development of the compound and the camera-type eye, two structures considered at the time to have evolved independently. Researchers suspected that *ey* might have the qualities of a 'master' control gene, and could be capable of guiding the formation of the eye. They hypothesized that, as in homeotic mutants, ectopic *ey* expression might result in ectopic eyes. To test this, *ey* gene expression was induced on the embryonic precursors of wings, legs, and antennas, and the outcome was, as predicted, ectopic eyes. Remarkably, the mouse *Sey* gene, known today as *Pax6*, was also capable of inducing ectopic compound eyes in the fly (Halder *et al.*, 1995). In fact, the association of *Pax* genes and eyes is so profound that in jellyfish, eye development is dependent on *PaxB*, a member of the *Pax2/5/8* subfamily (Kozmik *et al.*, 2003), and the jellyfish *PaxB* gene can also induce ectopic eyes in flies (Suga *et al.*, 2010).

As in the case of the eye, other body parts also develop under control of the developmental-genetic toolkit. In land vertebrates, or tetrapods, the limb originates as four outgrowths on the body wall that will form the fore and hind limbs. Many genes that guide limb growth and patterning also act in similar ways to regulate fin development in fishes. Even *Hox* genes, which specify identity along the head–tail axis, are deployed to specify identity of the different parts of limbs and fins (Schneider and Shubin, 2013). The *Tbox* genes *Tbx4* and *Tbx5* represent a particularly striking example of limb toolkit genes deeply rooted in the metazoan phylogenetic tree. During development, *Tbx5* is expressed in the forelimb and the *Tbx4* gene in the hind limbs, where both are required for limb bud initiation, as mice lacking any one of these genes fail to

develop limbs (Naiche and Papaioannou, 2003; Rallis *et al.*, 2003). Yet, *Tbx4* and *Tbx5* arose by duplication of an ancestral gene named *Tbx4/5*. The lancelet, a cephalochordate also known as amphioxus, is a marine invertebrate that lacks paired appendages and possesses the *Tbx4/5* gene. Remarkably, when the single lancelet *Tbx4/5* gene is expressed in mice that lack the *Tbx4* or *Tbx5* genes, it can promote limb development (Minguillon *et al.*, 2009).

The homeobox gene *tinman* is another outstanding example of a conserved toolkit gene for a body part. Geneticists have discovered that *tinman*, named after the Wizard of Oz character that lacked a heart, is required for heart development in fruit flies. As was the case for many other homeobox genes, *tinman* turned out to have a genetic equivalent in vertebrates, including mammals (Bodmer and Venkatesh, 1998; Harvey *et al.*, 2002). The mammalian version, known as *Nkx2.5*, is also crucial for heart development, as mice lacking this gene display severe heart malformations (Tanaka *et al.*, 1999).

In sum, the findings considered above and many others not addressed here point to the origin of an ancestral developmental-genetic toolkit for body parts. Homologous genes are used to build appendages, eyes, and hearts in species as disparate as mice and flies, whose evolutionary lineages have diverged over half-a-billion years ago. We will next discuss how modifications to such genes may contribute to the diverse morphologies seen in organisms alive and extinct.

Tinkering with the Toolkit Genes and the Origin of New Forms

In our previous sections we examined examples of profoundly conserved toolkit gene function. With all of these deeply conserved genes shared by animals as distantly related as flies and mice, how does diversity arise? Here we discuss studies that highlight how the location, time, and intensity in which a gene is expressed can have a profound effect on development and, consequently, on morphology.

During his visit to the Galapagos Islands, Charles Darwin studied the wide variety of finches inhabiting the archipelago. The finch species varied with respect to beak morphology: some species have long, thin beaks while others, deep and broad beaks. Darwin proposed that these different birds were descendants of a continental species that colonized the archipelago. But what is the mechanism behind the emergence of various forms of beaks among birds of the Galapagos? For some time, biologists speculated that gradual accumulation of mutations in several genes might have been responsible for modifying beak shapes. More than a century after Darwin's trip to Galapagos, researchers found that the thickness of the beaks of Galapagos finches was strongly correlated with the activity of *Bmp4*, a gene encoding a growth factor of the bone morphogenetic protein family. *Bmp4* is expressed in the developing finch beak and the deeper and broader the beak, the greater is the expression of *Bmp4*. To demonstrate that the intensity of *Bmp4* gene expression was responsible for the thickness and width of the beak, researchers artificially increased expression of this gene in chicken embryos. The result was chicks with deep and broad beaks, resembling those seen in Galapago's finches (Abzhanov *et al.*, 2004). This remarkable discovery paved the way for a new overarching hypothesis: could *Bmp4* be involved in craniofacial variation in other animals? When researchers investigated variation in jaw shape in cichlid fishes, they found it was associated with *Bmp4* expression. Furthermore, experimentally modulating *Bmp4* in zebrafish yielded jaw shapes reminiscent of cichlids (Albertson and Kocher, 2006). Collectively, these studies support a fundamental role for BMP4 in vertebrate craniofacial evolution and illustrate how changes in regulation of a toolkit gene can produce phenotypic variation.

Another prime example of nodulation of gene expression associated to morphological variation is pelvis loss in stickleback fish. The reduction or complete loss of hind limbs is a relatively common occurrence among vertebrates. In many aquatic mammals such as manatees, hind limbs are vestigial. In marine stickleback fish, pelvic fins are modified into spike-shaped spines, which protect the fish from predators. By contrast, freshwater sticklebacks have very reduced or absent pelvic fins. The gene associated with the reduction of the pelvic fins turned out to be *Pitx1*, a gene encoding a transcription factor that works in concert with *Tbx4* during hind limb outgrowth (see above). By analyzing its sequence, researchers found no difference between the *Pitx1* gene of freshwater and marine sticklebacks, however, the expression pattern during pelvic fin development was reduced in the freshwater species (Shapiro *et al.*, 2004). It was later shown that the mutation did not alter the gene itself, but rather a region that controls expression of the gene in the developing pelvic fins (Chan *et al.*, 2010) (**Figure 2**).

As previously discussed, homeotic mutations can produce spectacular phenotypes with body parts developing in abnormal positions. Nevertheless, homeotic transformations may occasionally lead to morphological innovation. Crustaceans are subdivided into different groups according to the types of appendages they display in each segment. In some crustaceans, appendages in all segments look similar and are used for locomotion. In others, such as lobsters, modified thoracic appendages called maxillipeds serve as additional feeding appendages, as they are morphologically similar to mouthparts. One *Hox* gene, *Ultrabithorax* (*Ubx*), had long been suspected of playing a role in determining the identity of crustacean appendages, as its anterior expression is invariably absent from the jaw-like maxilliped appendages. Researchers had long known that *Hox* genes are often causally linked to the identity of the body parts in which they are expressed. It was hypothesized that an expansion of *Ubx* expression into the body segments that form maxilliped appendages could result in their transformation into a thoracic-like appendage used for locomotion. This could explain why in some crustaceans, like brine shrimp, no maxillipeds are observed and all appendages look alike. To test this idea, researchers studied *Ubx* gene expression in the *Parhyale hawaiiensis*, a crustacean that has a single pair of maxillipeds. By experimentally reducing *Ubx* expression in *Parhyale*, walking legs were transformed into maxilliped-like legs, as in lobsters (Liubicich *et al.*, 2009). Conversely, expressing *Ubx* ectopically in anterior appendages led to homeotic maxilliped to leg transformations, resembling the morphology seen in brine shrimps (Pavlopoulos *et al.*, 2009).

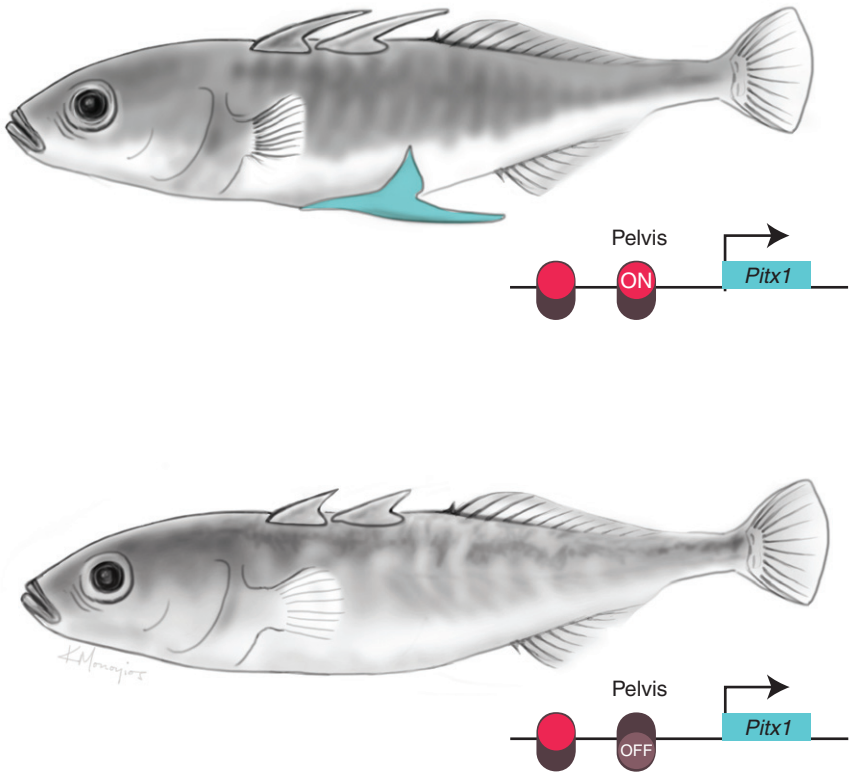

Figure 2 *Pitx1* and pelvic fin loss in freshwater sticklebacks. Top: In marine sticklebacks, *Pitx1* expression in the developing pelvis is controlled by a specific regulatory region. Bottom: A mutation in this regulatory region in freshwater sticklebacks results in the lack of *Pitx1* expression during pelvic development and in reduced or absent pelvic fins. Illustration by K. Monoyios.

The Developmental-Genetic Toolkit and the Hourglass Model

The developmental toolkit genes that set up head–tail segment identity, control eye and appendage development, and regulate craniofacial morphology have many common attributes. Many are DNA-binding proteins that directly modulate downstream genetic targets. Others, like *Bmp4*, are secreted proteins that bind to receptors in the target cells and subsequently bring about changes in gene expression. When the expression pattern or activity of a toolkit gene is altered, profound phenotypic consequences ensue: an entire body part may be produced in the wrong location, or have its serial identity changed, or it may not form altogether. Yet another shared attribute of these and many other toolkit genes is related to when, during development, they become active.

During early development of both vertebrates and invertebrates, there is a high degree of variation in embryonic form and developmental process. Different life histories and adaptive strategies translate into a great deal of divergence, at least until mid-development. Then, embryos reach what various researchers call the 'phylotypic' period, when embryos converge into a stage where they share a basic body plan (Wagner, 2014). After the phylotypic stage, embryos of different species will follow distinct ontogenetic paths that will lead to the adult organism. The observation that disparate embryos converge on a phylotypic period only to diverge as development proceeds became known as the Hourglass Model (Duboule, 1994; Raff, 1996).

The phylotypic period seems to be largely resistant to variation, as pharmacological perturbations during this developmental stage often lead to systemic malformations and developmental arrest (Galis and Metz, 2001). Interestingly, it is during this conserved phylotypic period that many toolkit genes (*Pax6*, *Nkx2.5*) and gene families (*Hox*, *Tbx*, *Bmp*, etc.) are deployed to assemble the basic body plan. In the following section we will survey new tools and approaches that have allowed us to examine, among other things, how regulatory changes in toolkit genes may have contributed to morphological innovation at a macroevolutionary scale.

The Future of Experimental EvoDevo

The recent emergence of high throughput and inexpensive DNA sequencing techniques and computer algorithms to assemble and assimilate the data are revolutionizing many fields in biological sciences, including evolutionary biology. This greatly enhanced capacity for DNA sequencing has created the opportunity for broadening the range of sequenced genomes to include species other than those of medical or economical relevance. For instance, recent genome sequencing efforts have focused on sampling branches of the phylogenetic tree that inform important macroevolutionary events and/or that have not yet been assessed. For example, sequencing of key vertebrate species such as the sea lamprey, chimera, and coelacanth are revealing much information about what it takes to be a

vertebrate as well as the kinds of genetic innovations that have been acquired along the way (Smith *et al.*, 2013; Venkatesh *et al.*, 2014; Amemiya *et al.*, 2014). The pace of genomic sequencing is staggering and efforts are underway to sequence representative genomes of every major animal group (Genome, 2009).

In addition, high throughput sequencing enables the study of the near complete collection of genes expressed in given tissues, so-called transcriptomes. As a result, our ability to compare gene expression profiles between different cells, tissues, or species has expanded profoundly. In fact, recent studies comparing cross-species genome-wide expression of orthologous genes during development have shown that the most conserved expression profile is found at mid-embryonic stages in both invertebrates and vertebrates, supporting the hourglass model in both (Irie and Kuratani, 2014).

In summary, we have described the basic tenets of the developmental-genetic toolkit for evolutionary developmental biology. This toolkit provides a framework for which to carry out empirical investigations into the presumed changes that organisms have undergone throughout their histories. Finally, the recent infusion of high throughput DNA sequencing is helping to drive the field by expanding the developmental-genetic toolkit. This, in turn, is facilitating novel investigations into all manners of evolutionary problems and in all manner of organisms, something not possible just a few years ago.

Developmental Mechanisms Controlling Cell Fate, Evolution of

DC Lyons, Duke University, Durham, NC, USA
M Srivastava, Harvard University, Cambridge, MA, USA
DQ Matus, Stony Brook University, Stony Brook, NY, USA

Glossary

Epidermal growth factor (EGF) Secreted growth factor that binds to an EGF receptor.
Epithelial to mesenchymal transition (EMT) Cellular behavior where individual cells lose epithelial characteristics such as adhesion and cell–cell polarity and adopt a mesenchymal phenotype.
Equivalence group Set of cells arising from the same lineage that have equal potential to respond to neighboring inductive cues.
Gene regulatory networks (GRNs) Set of genes and the control elements (*cis*-regulatory elements) that control a specific cell biological process.
Metazoa It is another name for the animal kingdom.
Primary mesenchyme cells (PMCs) Embryonic echinoderm cells located in the vegetal plate that will undergo EMT and ingress giving rise to mesoderm.
Vulval precursor cells (VPCs) Set of ectodermally derived cells that can give rise to the adult nematode vulva, or egg-laying organ.

Introduction

The field of evolutionary developmental biology has matured substantially from its earliest days in the pre-genomic era. We have begun to generate answers to many important outstanding evo-devo questions, and today there are few limits on the questions that can be asked, or the organisms in which to ask them. There are many reasons for this. First, decades of intensive study in a few distantly related 'model' organisms such as the fly, roundworm, and mouse have uncovered an astonishing level of detail about the genetic control of cell function, explaining how their cells build disparate body plans. These studies provide an intellectual framework to generate specific hypotheses about how additional body plans (or cell types, tissues, or processes) may have evolved. Second, a number of new tools are available for perturbing gene function and visualizing cellular behavior, making it possible to investigate the mechanistic basis of development in almost any group of animals (Moczek *et al.*, 2015). Third, the fields of systematics and phylogenetics have established the branching order of most of the major and minor nodes of the animal tree (Aguinaldo *et al.*, 1997; Dunn *et al.*, 2008; Halanych *et al.*, 1995; Hejnol *et al.*, 2009; Moroz *et al.*, 2014; Ryan *et al.*, 2013), a requirement for assessing similarities and differences in animal development in an evolutionary framework (**Figure 1(a)**).

Data from many different organisms and developmental processes clearly shows that complex gene regulatory networks (GRNs) control embryonic development (Davidson *et al.*, 2002; Maduro, 2006; Rottinger *et al.*, 2012). These GRNs ultimately specify the identity and behavior of cells (such as proliferation, migration, shape changes) that determine the adult body plan. This article will focus on the evolution of mechanisms for cell fate specification, a field that has its roots in classical embryology (e.g., Conklin, 1905; Driesch, 1892; Roux, 1888). In that era, any cell or organelle that exhibited a phenomenon of interest was worthy of study, so that, as E.B. Wilson wrote "the problems of evolution have been reduced to problems of the cell" (Wilson, 1911). Today, we are able to be more reductionist, thanks to both our ability to rapidly generate transcriptome data and the increasing ease of functional studies. This allows researchers to characterize the underlying GRNs that, in combination with inductive signaling pathways, specify cell fate. These approaches have expanded our ability to generate comparisons from between homologous cells and cell types to more disparate structures and processes based on changes in gene regulatory network architecture.

Here, we review data on three different aspects of metazoan cell specification (**Figure 1(b)**). The first deals with the behavior of an 'equivalence group' in nematodes. We describe powerful techniques developed in the model nematode, *Caenorhabditis elegans*, which have been used to understand how a group of initially equivalent cells are able to acquire distinct fates through induction from other tissues. These data have been leveraged to study related nematodes, uncovering cryptic variation governing fate specification in a homologous group of cells. A second aspect of specification that we will discuss is the emergence of a novel cell type: the sea urchin skeletogenic mesoderm. A detailed GRN has been established for this cell type, making it possible to compare the network across echinoderms to reveal how this unique cell type arose during evolution. Our third section focuses on the decision between cell differentiation and stemness in the context of adult tissue and how the underlying mechanisms vary over the course of animal evolution. The lessons learned from mature developmental systems are combined with data from emerging models in each case study. In this way we gain a better understanding of the evolution of cell fate specification strategies by examining taxa across the metazoan tree, revealing the 'experiments' that have already occurred over the course of animal evolution. To that end, we begin our discussion of cell fate specification using a study group that allows for functional manipulation of homologous cells at single cell resolution, the rhabditid nematode vulva.

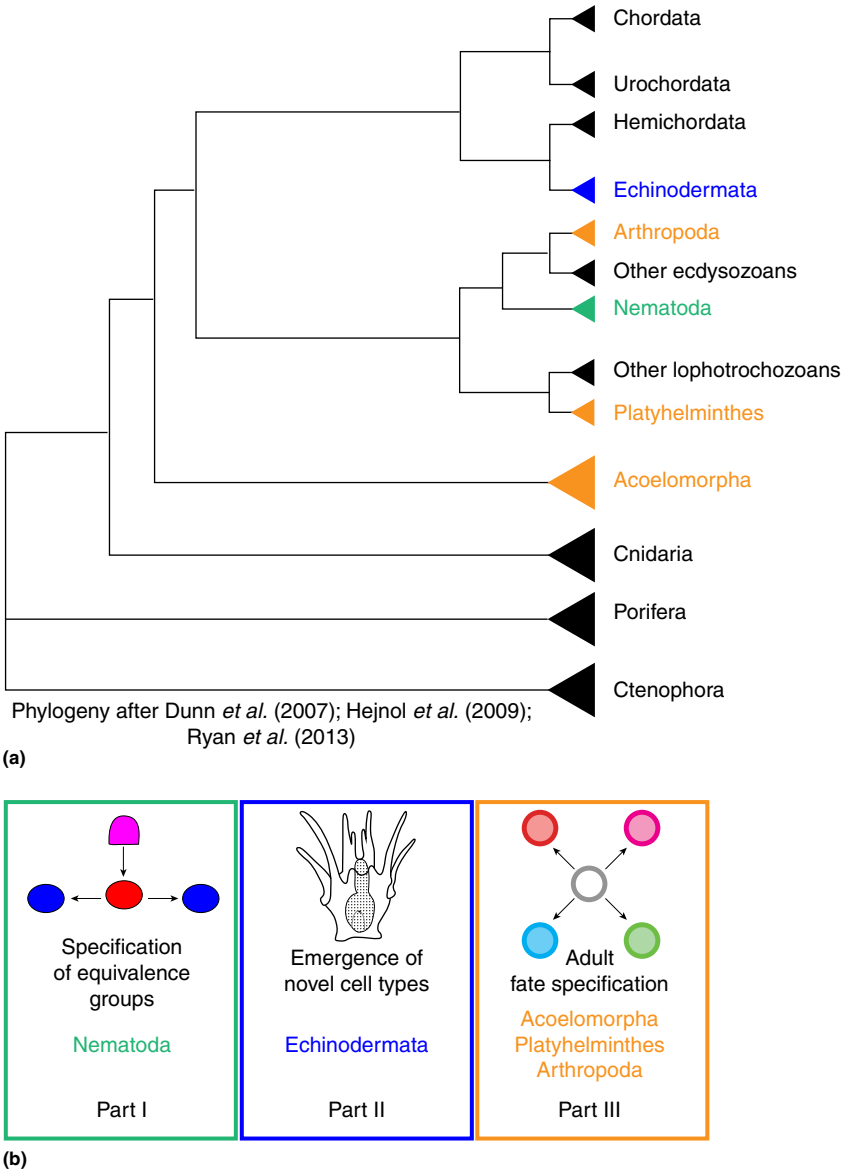

Figure 1 Phylogenetic relationships of animals discussed in this article. (a) Cladogram represents taxonomic relationships. Phylogeny based on recent phylogenomic studies (Dunn *et al.*, 2008; Hejnol *et al.*, 2009; Moroz *et al.*, 2014; Ryan *et al.*, 2013). Colored lineages match taxonomic groups discussed in (b) in each section of this article.

Part I: Competency, Equivalence Groups, and Cryptic Variation

Evolution of Equivalence Groups

A fundamental feature of metazoan cell fate acquisition is the establishment of competency, or the ability of a group of lineage-related cells to respond to inductive signaling. When multiple cells are capable of responding to the same signaling system they are said to form an 'equivalence group' (Kimble, 1981). The discovery of most equivalence groups stems from the ability to map cell lineage patterns during embryogenesis, and thus equivalence groups have been identified in organisms with stereotyped development where individual cells can be both followed over developmental time and destroyed using targeted ablation (e.g., transparent, fast-developing animals, see Table 1). Due to space limitations, in this article, we will focus on the best-studied equivalence group, the rhabditid nematode vulva, or egg-laying apparatus, and refer readers to Table 1 for investigating competence groups in other taxa.

The Rhabditid Nematode Vulva: An Evo-devo Model for Cell Fate Specification

Equivalence groups were first described in nematodes (Kimble, 1981), and due to a wealth of experimental and genetic tools available in *C. elegans*, we have the best molecular understanding of how they function. The most thoroughly characterized equivalence group is the six ectodermal cells (P3.p–P8.p) that

will give rise to the adult vulva (Sternberg, 2005). These six vulval precursor cells (VPCs), born in the first larval stage, are all able to generate vulval fates, but under normal (wild-type) conditions only the three inner cells, (P5–7.p) are induced to become vulval cells, adopting either a 1° fate (P6.p) or a 2° fate (P5.p and P7.p). The remaining three cells adopt a default 3° fate and fuse with the epidermis; thus the final pattern is depicted as '3° 3° 2° 1° 2° 3°' (**Figure 2(a)**).

Researchers have spent the past three decades using a variety of experimental and molecular genetic approaches to decode the mechanisms that regulate the fate of these six cells (Sternberg, 2005). Briefly, the VPCs are initially patterned by the expression of a central class Hox5 gene (LIN-39) during the L1 larval stage. Later, in the L3 stage, an EGF signal (LIN-3), secreted by the gonadal anchor cell (AC), which is dorsally situated to the VPCs, induces the 1° fate of P6.p. Upon adopting the 1° fate, P6.p expresses Notch ligands (three delta orthologs, *apx-1*, *lag-2*, and *dsl-1*) (Chen and Greenwald, 2004). Delta ligands activate the Notch receptor (LIN-12) in the neighboring P5.p and P7.p cells which induces the 2° fate. The Wnt pathway functions during VPC specification in a maintenance role to prevent the acquisition of a 3° fate and epidermal fusion (Braendle and Felix, 2008; Eisenmann *et al.*, 1998; Gleason *et al.*, 2002; Myers and Greenwald, 2007).

Comparative work in other nematodes has identified the same signal transduction pathways (Wnt/Notch/EGF) that are used during *C. elegans* VPC specification, although to varying degrees in a taxon-specific fashion (**Figure 2(b)**). For example, data from forward-genetic screens and use of mitogen-activated protein kinase enzyme (MEK) inhibitors in *Oscheius tipulae* has identified a role for EGF/MAPK signaling in VPC induction (Dichtel-Danjoy and Félix, 2004). The initial forward genetic screens to identify vulval development mutants in the diplogastrid nematode *Pristionchus pacificus* led to an unexpected result – rather than a reliance on EGF and Notch/Delta signaling as in *C. elegans*, vulval induction in *P. pacificus* utilizes redundant Wnt signaling from two spatially distinct signaling centers (Tian *et al.*, 2008; Zheng *et al.*, 2005). With many nematode genomes now sequenced and the potential for precise genome engineering offered by new technologies such as CRISPR-Cas9 (Witte *et al.*, 2015) it should now be possible to determine the identity of the signaling pathways that are required to induce VPC fates in different nematode species.

Cryptic Evolution and Developmental System Drift

Not only can we observe striking examples of evolutionary flexibility in signaling pathway usage during nematode VPC induction between related species, but recent work both in *C. elegans* (Barkoulas *et al.*, 2013) and *P. pacificus* (Kienle and

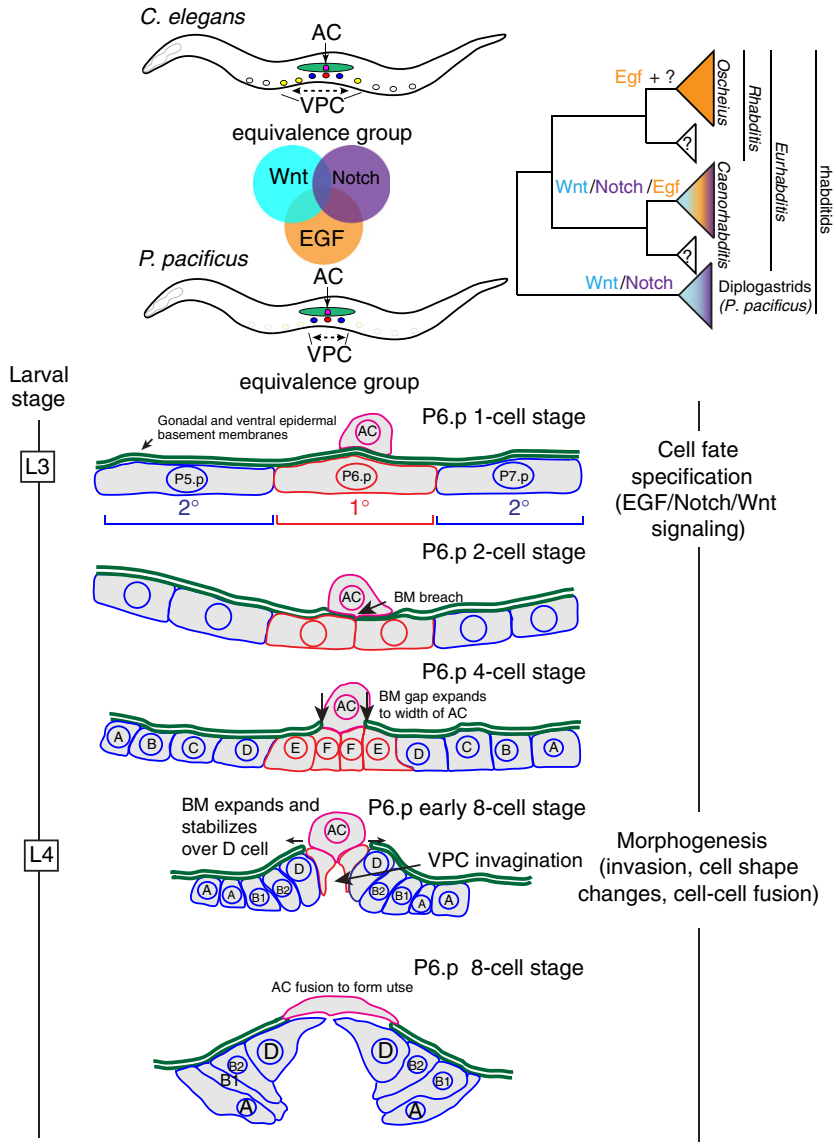

Figure 2 Evolution and development of the rhabditid nematode vulval precursor cell (VPC) equivalence group. (a) Schematics depict VPC fate specification in *C. elegans* (top) and *P. pacificus* (bottom). VPC colors refer to fate (primary, red; secondary, blue; tertiary, yellow (*C. elegans* only)). Venn diagram depicts the contribution of three signaling pathways in VPC specification and corresponds to the colored gradient used in the rhabditid nematode phylogeny shown in (b; phylogeny based on Kiontke *et al.*, 2007). Based on previous research, a role for EGF (orange) signaling (via MEK) has been identified in VPC specification in *Oscheius tipulae*. *P. pacificus* utilizes contributions from both the Wnt (light blue) and Notch (purple) pathway to specify VPC fate, while *C. elegans* receives contributions from all three pathways. It is unknown what signaling pathways specify fate in other rhabditid nematodes (denoted with '?'). (c) Schematic of *C. elegans* uterine–vulval cell specification and morphogenesis (stages defined by division of P6.p and its daughters (e.g., 1-cell stage, 2-cell stage, etc.), with each individual VPC designated by the specific letters, (A)–(F); modified from Matus, D.Q., Chang, E., Makohon-Moore, S.C., *et al.*, 2014. Cell division and targeted cell cycle arrest opens and stabilizes basement membrane gaps. Nature Communications 5, 4184.

Sommer, 2013) highlights cryptic variation that occurs in VPC fate specification within species between natural wild isolates. For example, the Sommer group recently showed that a single *cis*-regulatory change in the conserved Notch ligand, *apx-1*/Delta (one of three Delta ligands redundantly used in 2° fate specification in *C. elegans*) led to gain of a HAIRY binding site in the reference strain of *P. pacificus* (PS312/CA) originally isolated from Pasadena, California. The presence of this HAIRY binding site results in repression of transcription of *apx-1*/Delta in the 1°-fated P6.p cell in PS312/CA. However, most other wild isolates lack this HAIRY binding site and express *apx-1*/Delta in P6.p. Expression of *apx-1* is sufficient to induce 2° fate in the absence of induction from the gonad (Kienle and Sommer, 2013). Their elegant experiments reveal cryptic variation in a core developmental pathway, as a single *cis*-regulatory change can result in the abolition of Notch/Delta signaling as a patterning system in *Pristionchus* VPC specification, and provides a plausible explanation for the diversity in signaling systems that pattern homologous vulval cells between nematode species.

Cell Fate Specification Leads to Differentiation and Morphogenesis

Once the VPCs are properly specified, they execute lineage specific morphogenetic behaviors required to form the adult vulva, including cell division, invagination, and cell fusion (**Figure 1(c)**). *Caenorhabditis elegans* anchor cell (AC) invasion has become a powerful model to understand the genetic control of cell invasive behavior (Matus *et al.*, 2010; Sherwood *et al.*, 2005). Recent work has investigated AC invasion in related nematode species, identifying conserved features: there is only a single AC in all species examined and the AC is required to breach the basement membrane to initiate the uterine–vulval connection (Matus *et al.*, 2014). Following AC invasion, the basement membrane gap expands outward, likely due to forces generated from cell division of the underlying VPCs (Ihara *et al.*, 2011; Matus *et al.*, 2014). The size of this basement membrane gap is tightly regulated, as in all species examined the edges of the gap are stabilized by the same vulval cell, the innermost 2° fated VPC, the D cell. Strikingly, the D cell is the only cell in all nematodes examined to date that never divides (Kiontke *et al.*, 2007). Cell cycle exit of the D cell allows for localization of the extracellular matrix adhesion protein, integrin, to the basal surface of the D cell in response to an increase in the basement membrane component, laminin, at the edges of the basement membrane gap, stabilizing gap expansion (Matus *et al.*, 2014; **Figure 1(c)**). Thus, comparative studies in nematode uterine–vulval development have identified a new mechanism to stabilize basement membrane gaps, a cell biological process that occurs in both developmental contexts and disease pathogenesis (Matus *et al.*, 2014). Connecting cell specification strategies to the cell biology of morphogenetic behaviors across nematode evolution will be informative, especially identifying whether a similar amount of cryptic variation exists between species in executing morphogenetic behaviors as it appears to during cell fate specification.

Part II: Evolution of a Novel Cell Type – Echinoderm Larval Skeleton

The previous section focused on identifying evolutionary changes that alter specification strategies of a homologous group of cells. It is also critical to examine changes in cell fate specification that lead to the origin of new cell types, as they can offer insight into the evolution of novel structures and morphology. To illustrate this point we discuss the echinoderm pluteus larva, which has been a model for developmental, evolutionary, and ecological studies for over a century (Ettensohn, 2009; Lyons *et al.*, 2014; McClay, 2011; Raff and Byrne, 2006; Vaughn and Strathmann, 2008).

The phylum Echinodermata consists of five extant classes: crinoids (sea lilies), asteroids (sea stars), ophiuroids (brittle stars), holothuroids (sea cucumbers), and echinoids (sea urchins, sand dollars). Crinoids are the earliest-branching class, and among the remaining four classes, sea stars and brittle stars are more closely related, forming a clade that is sister to a clade comprised of sea urchins and sea cucumbers (Cannon *et al.*, 2014; Reich *et al.*, 2015; Telford *et al.*, 2014). Members of all five classes develop through an indirect life cycle that includes a planktonic, bilaterally symmetric larva, and a benthic, pentaradial adult. All echinoderms share a homologous calcite endoskeleton at the adult stage, but only ophiuroids and echinoids possess a larval calcite skeleton in the larval stage (**Figure 3(a)**). The skeletonized ophiuroid and echinoid pluteus larva is considered to be a derived form, having evolved from an ancestral auricularia-type larva, shared by the other echinoderm classes (Cannon *et al.*, 2014; Reich *et al.*, 2015; Telford *et al.*, 2014), and their closest out-group, the hemichordates (Rottinger and Lowe, 2012; **Figure 3(a)**). This suggests that the sea urchin and brittle star larval skeleton evolved independently by convergent evolution (or alternatively was lost by crinoids, asteroids, and holothuroids, which is less parsimonious). The development of the sea urchin larval skeleton provides an entry point into understanding how the pluteus skeleton evolved in these two lineages.

The Primary Mesenchyme Cells Build the Pluteus Skeleton in Sea Urchins

The sea urchin skeletogenic lineage arises during cleavage stages as the result of asymmetric cell divisions of vegetal pole blastomeres (Ettensohn, 2009; McClay, 2011). Progeny of these cells undergo an epithelial-to-mesenchymal transition (EMT) and crawl into the blastocoel (the fluid-filled central region of the blastula stage embryo). Once inside the blastocoel, these cells are referred to as primary mesenchyme cells (PMCs). The PMCs then migrate in response to cues coming from the ectoderm/endoderm boundary (Adomako-Ankomah and Ettensohn, 2014; McIntyre *et al.*, 2013, 2014). Although the micromere lineage is autonomously specified at birth (Okazaki, 1975; Oliveri *et al.*, 2008), and will even make skeletal elements *in vitro* (Okazaki, 1975), the pattern of the resulting skeleton is dictated by localized cues emanating from the overlying ectoderm (Armstrong and McClay, 1994; Duloquin *et al.*, 2007; McIntyre *et al.*, 2013; Piacentino *et al.*, 2015; Rottinger *et al.*, 2008). During gastrulation stages, the PMCs fuse to one another and the syncytium forms a ring next to the posterior ectoderm. Soon after ring formation, two aggregates or ventrolateral clusters of PMCs form, where skeletogenesis will begin in response to induction by vascular endothelial growth factor (VEGF) signaling (Adomako-Ankomah and Ettensohn, 2013, 2014; Duloquin *et al.*, 2007; **Figures 3(b)** and **3(c)**). Ventrolateral clusters, expressing the VEGF receptor (**Figure 3(g)**) form directly under signaling centers in the ectoderm expressing the VEGF ligand, where posterior ectoderm and the ciliary band territory intersect (**Figure 3(b)**; McIntyre *et al.*, 2013). When VEGF signaling from the ectoderm is impaired, skeletal patterning within the mesodermal PMCs is perturbed (Adomako-Ankomah and Ettensohn, 2013, 2014; Duloquin *et al.*, 2007). Within the ventrolateral clusters, the PMCs secrete the rudiment of the skeleton, called the triradiate (**Figure 3(d)**). Each prong of the triradiate then grows in a unique and characteristic way to build the mature pluteus skeleton (**Figure 3(e)**; Lyons *et al.*, 2014). The PMC lineage has been used as a model for building GRNs to explain fate specification (Ettensohn, 2013; Oliveri

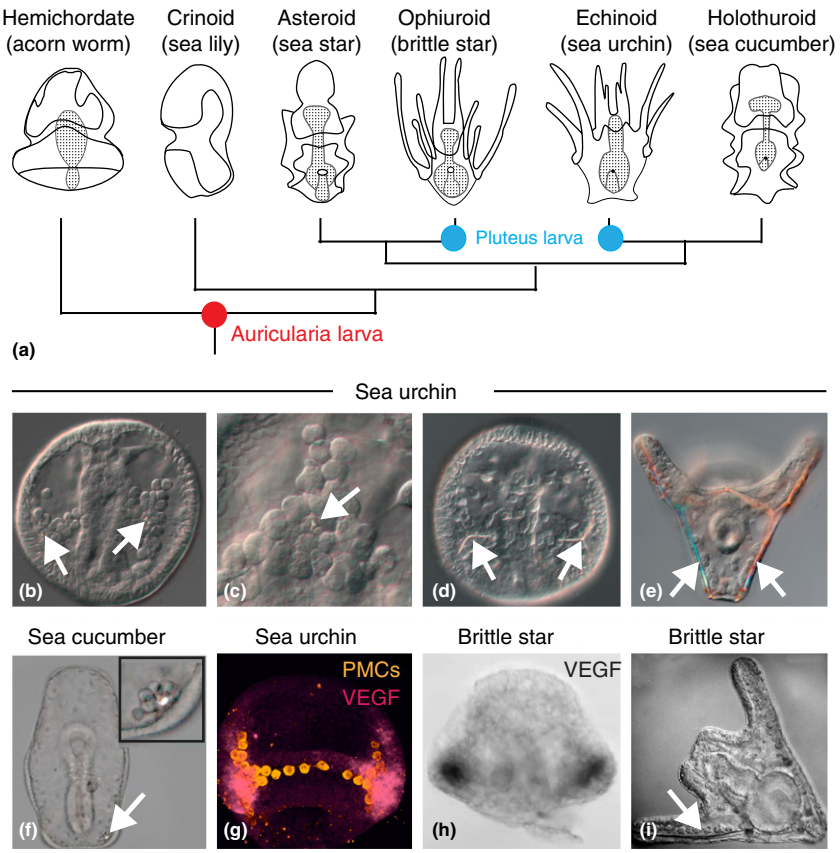

Figure 3 Evolution of larval skeletogenesis in echinoderms. (a) Cladogram showing the evolutionary relationship of echinoderm classes, and their closest outgroup, hemichordates. The auricularia larval form is considered ancestral for echinoderms, making the evolution of the pluteus larva in sea urchins and brittle stars an example of convergence. et al., 2008). This detailed knowledge of PMC specification can be used to ask many evolutionary questions, including how the larval skeleton evolved in echinoids, and what role genes required for PMC specification play in clades that lack a larval skeleton (Hinman and Cheatle Jarvela, 2014).

Co-Option of Adult Skeletogenesis for Larval Skeleton Formation

Genes expressed after metamorphosis, during adult skeletogenesis, appear to have been heterochronically shifted into embryonic stages and expressed in the sea urchin PMC skeletogenic lineage (Gao and Davidson, 2008). Using the sea urchin PMC GRN as a starting point, Gao and Davidson (2008) compared the genetic circuitry upstream of the larval and adult skeleton to identify the points at which the programs overlap, and at which they diverge. They found that whereas the transcription factors *ets1*, *alx1*, and *hex* are expressed in both the micromere lineage and the adult rudiment in sea urchins, *tbr* is expressed only in the PMC lineage. *ets1*, *alx*, and *hex* are also expressed in the rudiment of adult sea stars, but *tbr* is not. These data suggest that the *alx/ets1/hex* node of echinoderm adult skeletogenesis is ancient, and was co-opted for larval skeletogenesis in the sea urchin lineage. *tbr*, which is necessary for larval skeletogenesis, but not adult skeletogenesis, was an independent acquisition into the micromere lineage.

What Can Out-Groups Tell Us About the Evolution of the Sea Urchin Pluteus?

Sea cucumbers are the echinoderm class most closely related to sea urchins and sand dollars (Cannon *et al.*, 2014; Reich *et al.*,

2015; Telford *et al.*, 2014), but they lack a larval skeleton. However, a small spine or spicule granule has been observed in the larvae of some sea cucumber species, but it never grows into a triradiate, or makes arms, as occurs during the development of the sea urchin pluteus skeleton. Recent work has investigated the morphological and molecular basis of granule formation in the sea cucumber *Parastichopus* (**Figure 3(f)**; McCauley *et al.*, 2012). In this species, the granule is made by cells that enter the blastocoel early, and these cells go on to form a dorsal cluster underneath the posterior-dorsal ectoderm. *Parastichopus alx1* is expressed in cells at the vegetal pole, and in the cells that enter the blastocoel early and make the dorsal cluster and spicule granule. Knockdown of *Parastichopus alx1* abolishes the dorsal cluster, and the spicule, suggesting that, as in sea urchins, *alx1* is necessary for specifying cells capable of making skeleton material. In the sea cucumber *Holothuria*, *ets1/2* is expressed in mesodermal cells, including a patch of posterior-dorsal cells that might be the mesodermal cells that secrete the larval spicule granule in that species (Koga *et al.*, 2010). These data suggest that sea cucumber mesodermal cells express some of the same genes when making a spicule granule, as the sea urchin PMCs express when making the pluteus skeleton. Koga *et al.* (2010) propose that ancestrally, *ets1/2* had two functions: one specifying larval mesoderm that was non-skeletogenic, and a second specifying adult skeletogenesis. In the echinoid lineage, the *ets1/2* transcription factor gained the ability to upregulate the skeletogenic program in the larval mesoderm.

In fact, many genes associated with the sea urchin PMC lineage are expressed in the larval mesoderm of species that do not make larval skeletons, such as the sea stars (Koga *et al.*, 2010; McCauley *et al.*, 2010; Morino *et al.*, 2012). These studies support the idea that the genes involved in skeletogenic mesoderm in sea urchins were likely expressed in the larval mesoderm of the echinoderm common ancestor and then later became able to promote skeletogenic cell fate by subtle changes in gene regulation, such as downstream gene target switching (Koga *et al.*, 2010).

Convergent Evolution of the Pluteus in Brittle Stars?

How similar is the development of the larval skeleton between sea urchins and brittle stars? Unlike sea urchins, the brittle star skeletogenic lineage does not arise from a noticeable asymmetric cell division at 4th cleavage (Primus, 2005). Instead, the skeletogenic cells, similarly called PMCs, become obvious inside the blastocoel before gastrulation and form bilateral rudiments of the larval skeleton (Yamashita, 1985). The behavior of the brittle star PMCs suggests that they might also migrate in response to signals from the ectoderm. In fact, in the brittle star *Amphipholis* Morino *et al.* (2012) found that homologs of VEGF are expressed in bilateral patches of ectoderm (**Figure 3(h)**), very much like the pattern in urchins; VEGFR is likewise expressed in adjacent ventrolateral PMC clusters. As in sea urchins (Adomako-Ankomah and Ettensohn, 2013; McIntyre *et al.*, 2013), the expression of brittle star VEGF becomes restricted to lateral ectodermal patches.

This remarkable similarity in expression patterns of VEGF and VEGFR between sea urchins and *Amphipholis* demonstrates that there are fundamental similarities in how the two groups make their larval skeleton. More work on brittle stars will be necessary before we fully understand how deep the similarities go, on a cellular or molecular level. For example, *Amphipholis* (Koga *et al.*, 2010) also expresses the *ets1/2* gene in its PMCs, and a transcriptome of *Ophiocoma* gastrula-stage embryos (Vaughn *et al.* 2012) revealed that many homologs of genes involved in sea urchin PMC specification and skeletogenesis are expressed in this brittle star species. Studies of both the transcripts and proteins made by *Ophiocoma* show that the skeletogenic tool kit is similar, but not identical, to that in sea urchins (Seaver and Livingston, 2015; Vaughn *et al.*, 2012).

The fact that in both sea urchins and brittle stars members of the VEGF signaling pathway are expressed in analogous territories (VEGF ligand in the ectoderm, and VEGF receptor in the PMCs) suggests that communication between mesoderm and ectoderm was critical for the evolution of the pluteus in both echinoderm lineages. Whether sea cucumber or sea star skeletogenic cells are responding to cues from the ectoderm during the larval stage remains to be answered. The expression of *vegf* and *vegfr* has been examined in sea stars (Morino *et al.*, 2012), and no transcripts for either gene were detected by *in situ* hybridization or qPCR during early larval stages. Yet later, *vegf* (expressed in the ectoderm), and *vegfr* (expressed in the mesoderm), were associated with the rudiments of the adult skeleton. Thus VEGF signaling might have been heterochronically activated during larval stages, in ectoderm and mesoderm, in sea urchins and brittle stars independently. How this occurred poses a fascinating open question for future investigations. In order to understand the evolution of a novel cell type, we will need to hone in on the conversation between these two tissues.

Part III: Cell Fate Specification in Adult Animals

Specification of cell fate from undifferentiated cells is essential to the maintenance of adult form, as adult tissue can be lost during homeostatic turnover or due to damage. Some animals (e.g., planarians), have pluripotent adult stem cells that can acquire many distinct cell fates, whereas other animals (e.g., vertebrates) possess lineage-restricted stem cells. Very little is understood about how the mechanisms that underlie stem cell pluripotency and subsequent fate specification compare across these diverse species, but recent studies in previously understudied animals have revealed valuable insight.

Differentiation in Lineage-Restricted Adult Stem Cells

Adult mammals have the capacity to continually replace tissues that are lost to homeostatic turnover or to injury. Pools of lineage-restricted stem cells that are maintained throughout adulthood provide new cells. These include hematopoietic stem cells in the bone marrow, which generate myeloid and lymphoid lineages of blood cells; slow-cycling cells of the intestinal crypt that make transit amplifying cells to replace secretory and digestive cells of the gut; and stem cells located in the bulge regenerate hair follicles (Clevers, 2013; Fuchs and

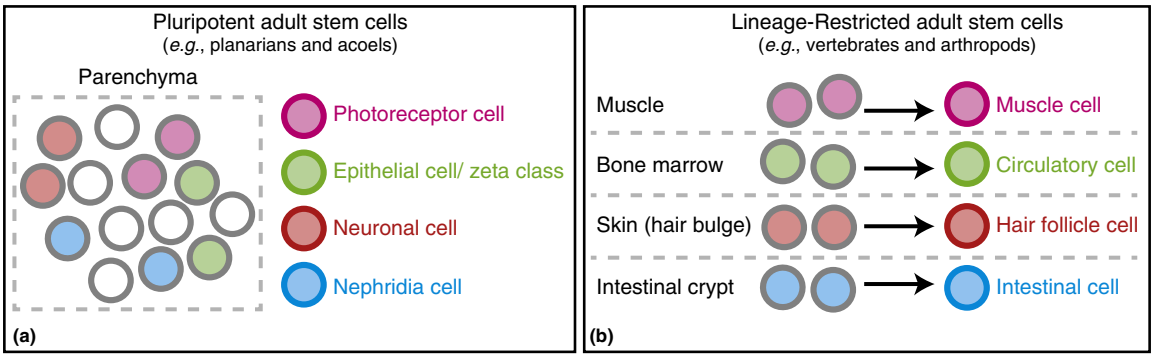

Figure 4 Schematic representation of cell fate specification from planarian adult pluripotent stem cells and lineage-restricted stem cells in vertebrates. (a) Planarian stem cells (neoblasts) are a broadly distributed population of cells that include progenitors that have become committed to specific lineages. The clonogenic-neoblasts (white circles with grey outlines) and progenitors (colored circles with grey outlines) are not separated spatially, but terminally differentiated cell types (colored circles with colored outlines) incorporate into tissues at specific positions in the adult body. Clonogenic-neoblasts are presumed to give rise to the committed progenitors, but this has not been shown directly. (b) Vertebrate organs harbor lineage-restricted stem cells (colored circles with grey outlines) that generate terminally differentiated cells (colored circles with colored outlines) for the specific tissue. These stem cells are spatially restricted to their tissue of origin.

Nowak, 2008; Seita and Weissman, 2010; **Figure 4**). These independent stem cell populations express distinct molecular markers and acquire their restricted cell fates under the control of different factors depending on their varied tissue contexts.

In contrast to blood, intestinal crypts, or hair, which are unique to vertebrates, muscle is present in all bilaterian animals, providing an opportunity to compare specification mechanisms across species. Vertebrates have quiescent stem cells called satellite cells that express *Pax7* protein, may or may not express *Pax3*, and may have sequestered mRNA for the myogenic factor *Myf5* (reviewed in Cerletti *et al.*, 2008; Motohashi and Asakura, 2014). Upon injury, these cells respond to signals from their niche, i.e., the surrounding microenvironment, by dividing asymmetrically to produce a myoblast. This cell downregulates *Pax7* expression, upregulates the expression of *Desmin* and *MyoD*, proliferates, and, with increasing expression of other myogenic factors such as *MRF* and *Myogenin*, differentiates into a muscle fiber.

A recent study on muscle regeneration in a new arthropod model system provides the first opportunity to compare regenerative mechanisms across distantly related bilaterian phyla. Whereas *Drosophila*, the classic model arthropod, cannot regenerate limbs, the crustacean *Parhyale hawaiiensis* is able to regrow its appendages upon amputation. The *Parhyale* ortholog of vertebrate *Pax3* and *Pax7*, *Pax3/7*, labels cells that are present adjacent to muscle fibers and morphologically resemble vertebrate satellite cells (Konstantinides and Averof, 2014). Transgenically-labeled satellite cells were isolated, and upon transplantation into host limbs, contributed to newly formed muscle fibers in regenerating limbs. This finding suggests that arthropod and vertebrate muscles regenerate in a very similar manner, using lineage-restricted stem cells that are labeled by an evolutionarily conserved marker, *Pax3/7* (**Figures 1** and **4**). Moving forward, it will be fruitful to investigate more broadly in cell types besides muscle, commonalities between lineage-restricted stem cells, which are present in many animal phyla, including the early branching non-bilaterians (e.g., ctenophores, cnidarians) (Alie *et al.*, 2011; Plickert *et al.*, 2012).

Specification in Pluripotent Adult Stem Cells

Adult planarians show amazing regenerative abilities. They can regenerate virtually any missing tissue through the activity of a large population of parenchymal cells called neoblasts, which are required for regeneration (Reddien *et al.*, 2005; **Figure 4**). Based on their shared expression of homologs of *piwi*, neoblasts were considered to be a homogeneous population. Single neoblasts transplanted into irradiated animals expand clonally (thus referred to as clonogenic- or c-neoblasts), differentiate into all tissue types of the adult animal, and restore the regenerative capacity of their hosts (Wagner *et al.*, 2011). It is unknown what proportion of the total neoblast population is clonogenic.

Studies of regeneration in planarians of specific organs, such as nephridia and eyes, revealed that transcription factors that are expressed in and required for the regrowth of these structures, also label a small number of *piwi*+ cells (**Figure 4**). These cells are thought to be committed progenitors that begin to express a tissue-specific marker (*Sp6-9*, *Dlx*, *Six1/2*, and *Eya* for pigment cups of the eye; *Six1/2-2*, *Eya*, *Osr*, *POU2/3*, and *Sall* for nephridia), lose *piwi* expression, and become terminally differentiated (Lapan and Reddien, 2011; Scimone *et al.*, 2011). Several progenitor classes for different neuronal lineages have also been recently identified (Cowles *et al.*, 2013; Scimone *et al.*, 2014). Clustering of neoblasts, based on the expression of 96 genes in single cells, revealed progenitor lineages that differentiate into the gut and epidermis (van Wolfswinkel *et al.*, 2014). Thus, neoblasts represent a dynamic population of stem cells that differentiate into varied cell types, presenting a great opportunity to understand the mechanisms of fate specification in adults.

It is unknown whether the mode of adult cell fate specification uncovered in planarians is broadly conserved among animals. Acoel worms diverged from planarians 550 mya and likely represent the earliest-diverging lineage of animals with bilateral symmetry (Hejnol *et al.*, 2009; Philippe *et al.*, 2011; Srivastava *et al.*, 2014). Acoels also have a population of proliferative cells that resemble planarian neoblasts based on

morphology, expression of *piwi*, and sensitivity to radiation (De Mulder *et al.*, 2009). A recent study in *Hofstenia miamia*, a new model acoel species, revealed that expression of *piwi* in neoblasts is required for regeneration (Srivastava *et al.*, 2014). Additionally, Wnt and Bmp signaling pathways are required for correctly regenerating tissues along the anterior–posterior and dorsal–ventral axes respectively in *Hofstenia*, suggesting that the decisions upstream of fate specification are also shared between acoels and planarians. *Hofstenia* is amenable to mechanistic studies of differentiation within the neoblast population which, combined with similar studies in planarians, could inform us on whether fate specification in adult pluripotent stem cells is evolutionarily conserved or independently-evolved.

Many other regenerative animal species have putative pluripotent adult stem cells that express piwi (e.g., sponges, cnidarians, annelids, and ascidians) (Alie *et al.*, 2011; Brown *et al.*, 2009; Funayama *et al.*, 2010; Giani *et al.*, 2011; Juliano *et al.*, 2014; Plickert *et al.*, 2012; Rinkevich *et al.*, 2013), but fate specification mechanisms in these species are currently unknown.

The Evolution of Stem Cell Fate Specification

Given that both lineage-restricted and pluripotent modes of adult stem cells are broadly distributed across animal phylogeny, it is unclear which mode represents the ancestral condition (**Figure 1**). For example, ctenophores and sponges, the two earliest-diverging animal lineages, feature lineage-restricted and pluripotent stem cells respectively (Alie *et al.*, 2011; Funayama *et al.*, 2010).

Fate specification mechanisms may be conserved, regardless of the source of undifferentiated cells. Small populations of lineage-committed progenitors within the total neoblast population in planarians could be analogous to the lineage-restricted pools of stem cells in vertebrates and crustaceans. If the satellite-like cells in *Parhyale* and vertebrates maintain stemness and differentiate into muscle fibers via the same molecular mechanisms, then one would infer that these mechanisms appeared in the bilaterian ancestor. Planarians also evolved from this same ancestor, and one might hypothesize that a subset of neoblasts that are committed to differentiate into muscle would resemble satellite cells, for example requiring the expression of a *Pax3/7* homolog. One *Pax3/7* homolog reported thus far from planarians is required for the formation of progenitors for *dopa-beta-hydroxylase*+ cells of the nervous system (Scimone *et al.*, 2014). Recently reported MyoD-expressing *piwi*+ cells may represent planarian muscle progenitors (Cowles *et al.*, 2013; Scimone *et al.*, 2014). Thus, a detailed investigation of muscle progenitors within the neoblast population is needed to illuminate this hypothesis.

An alternative explanation for shared mechanisms underlying lineage-committed progenitors could be independent co-option of developmental pathways in the adult. For example, *Pax3* and *Pax7* expressing cells form muscle during mouse embryonic development (Relaix *et al.*, 2005), and if these transcription factors are conserved regulators of muscle cell fate in other animals as well (e.g., in arthropods and flatworms), then their role in adult muscle progenitors would reflect a hard-wired control over downstream genes that mediate muscle cell function. Investigating the details of how *Pax3/Pax7* are regulated to hold progenitor cells in a paused state, and subsequently to release them to acquire muscle fate in distantly related species, will be crucial to understanding the overlap between developmental versus adult muscle specification.

Studies of fate specification in adults not only inform how animal body plans are maintained, but how adult stem cells are regulated. Emerging model systems such as planarians, acoels, and crustaceans offer opportunities for mechanistic investigations of fate specification in a variety of cell types in the context of pluripotent and lineage-restricted adult stem cells. In addition to cell-intrinsic control of fate specification, it will be important to compare niche signals, which are essential regulators of vertebrate adult stem cells.

Conclusions and Future Directions

This is an exciting time to be investigating the molecular basis of cell fate specification in an evolutionary context. We are fortunate to have a wealth of data generated by traditional model systems that provides a framework for empirical testing. The ease of adapting CRISPR/Cas9 to both induce mutations in genes of interest as well as introduce GFP and other fluorescent markers into endogenous loci is enabling researchers to move beyond the descriptive approaches that dominated the field of evo-devo for the past two decades. These new genome engineering techniques will allow us to directly test gene function and visualize cellular behaviors in nearly any taxon of choice. These molecular approaches are critical if we are to understand how alterations in cell fate specification strategies result in evolutionary change. Whether they are represented by cryptic variation in the formation of homologous cell types and tissues, changes in GRNs that result in the formation of novel cell types, or changes in the molecular cascades that maintain the balance between stemness and differentiation in response to injury or environmental stress in adults, the next decade should see huge leaps forward in our understanding of the evolution of cell fate specification in multicellular organisms.

Developmental Paleontology and Paleo-Evo-Devo

C Haug and JT Haug, LMU Munich, Munich, Germany

Glossary

Ambulacral field Part of the plate system of an echinoderm bearing the tube feet.
Cambrian Earliest geological age during which animal life is known with certainty.
Cycloneuralia Group of worm-shaped animals which are characterized by an anterior nerve ring; it includes Nematoda, Nematomorpha, Priapulida, Kinorrhyncha, and Loricifera.
Disparity Morphological diversity.
Doushantuo Geological formation in China, dating shortly before the Cambrian.
Eryoneicus Larva of polychelid lobster, adapted to long-term pelagic life.
Heterochrony Evolutionary shift in developmental timing.
Metamorphosis Short phase during post-embryonic ontogeny with rapid and drastic change in morphology.
Metanauplius Early larva of (eu-)crustaceans, subsequently adding segments and appendages.
Monophyletic group Group including all species descending from the same stem species, including the latter.
Ontogeny Individual development of an organism.
Orsten Special fossil preservation type, in the strict sense limited to early Paleozoic deposits; three-dimensional uncompressed preservation, including finest details down to the sub-micrometer range.
Otolith Small stones in the static organ, for example, of fishes, with growth lines often used to determine the age of the organism.
Phyllosoma Larva of achelate lobsters with a very thin, leaf-shaped body.
Phylogram Diagram of relationship, following traditional phylogenetic systematics, additionally giving a relative timing of the species splitting events.
Plesiomorphic Ancestral trait inherited from the stem species.
Precambrian Geological age before the Cambrian.
Proximal endite Median sclerotization in the body-appendage membrane in crustaceans, important for further evolution within crustaceans.
Spinicaudata Group within branchiopod crustaceans, with two large shield valves showing growth lines.
Taxonomy Discipline of naming and classifying species.
Viviparous Giving birth to living offspring (in contrast to, e.g., laying eggs).

Developmental paleontology is a scientific discipline that focuses on the ontogeny, i.e., the individual development of extinct organisms. A primary goal of paleo-evo-devo, which is an expansion of developmental paleontology, is to set developmental information from extinct organisms into an evolutionary context. To achieve this goal, paleo-evo-devo scientists investigate two specific questions:

1. How did ontogenetic patterns change through time?
2. How did changes of ontogenetic patterns contribute to evolutionary patterns in general?

Paleo-evo-devo research differs in its approach from traditional evo-devo research on extant organisms in certain aspects. For example, traditional evo-devo studies on extant taxa often rely heavily on modern genetic tools, while paleo-evo-devo studies tend to rely more on morphological comparisons of structures of various developmental stages and ontogenetic sequences.

In the following, we will first explain why a paleo-evo-devo approach is not only an interesting amendment of 'normal' paleontological or evo-devo studies, but also is absolutely crucial for the understanding of evolution. In the second part, we present how paleo-evo-devo studies are practically performed, especially in the light of an often scarce-appearing dataset. As we are zoologists and work on animals, we restrict our examples to these. However, paleo-evo-devo studies can also be performed on other groups of organisms, for example, on plants or unicellular organisms such as foraminiferans (e.g., Brummer *et al.*, 1986; Boyce, 2010; Gerrienne and Gonez, 2011). Therefore, several aspects of what is discussed below can also be transferred to nonanimal groups.

Why Is a Developmental Paleontological and Paleo-Evo-Devo Approach Necessary?

We here discuss five reasons why a developmental paleontological and paleo-evo-devo perspective is an important component of modern synthetic research.

Taxonomy

A comparably underestimated value of developmental paleontology, and not straightforward to recognize, is its taxonomic significance. If two fossil specimens differ morphologically, it is important to differentiate if these two morphs represent different species or simply different developmental stages of the same species (or other possible intraspecific morphs such as sexes, seasonal morphs, and castes). This issue also played an important role in the initial identification of some modern species, for example, many aberrant larval stages of crustaceans were originally described as separate species (and even higher categories; Harvey *et al.*, 2002).

 doi:10.1016/B978-0-12-800049-6.00138-4

The most prominent examples of such ontogeny-confounded taxonomic issues can be found in dinosaurs. Horner and co-workers have proposed that supposed separate species among Marginocephalia (= Pachycephalosauria or dome-headed dinosaurs + Ceratopsia or horned dinosaurs) indeed represent different growth stages of a single species (Horner and Goodwin, 2009; Scannella and Horner, 2010; see also below). Although these interpretations remain controversial (see e.g., Longrich and Field, 2012; Maiorino *et al.*, 2013), they raise a significant question: how should one place 'morphological differences' among fossils in a biological context? This issue has also been raised in arthropod groups (e.g., Haug *et al.*, 2012).

Furthermore, it should be noted that it is also possible that supposed larval stages in the fossil record may well represent separate dwarf species (example in extant animals: Worsaae *et al.*, 2012).

These taxonomic issues have several potentially significant implications:

a. An important aspect raised by Horner and co-workers is that of diversity. If several supposed species are in fact representatives of a single species, the species richness and diversity of a fossil community have been lower than originally anticipated. What is however not lowered through such a shift in the interpretation is the disparity of a community. If supposed conspecific morphs in fact represent different species, the diversity would in fact be higher.

b. Certain species may not differ recognizably as adults, but have quite differing larval stages or ontogenetic sequences (examples in De Beer, 1958). Hence, these developmental stages can contribute characters for recognizing two species as separate ones (see also discussion in Haug *et al.*, 2012). Generally it is thought that early stages are more similar between different species and later stages more distinct morphologically (e.g., Haeckel, 1866; Høeg and Møller, 2006). Yet, quite the opposite might play a major role here.

c. Flawed taxonomy also has the potential to confound phylogenetic reconstructions. If developmental stages of a single species are included into a phylogenetic analysis as separate terminals this will lead to significant artifacts. Conspecific but morphologically differing stages will not be resolved as a monophyletic group in the tree (see Wolfe and Hegna, 2014). Hence, a single species will occupy numerous different positions in a single tree. This will not only make the whole topology meaningless, but also obscure character evolution entirely. The same problem also applies to the opposite: if separate species are treated as conspecific morphs they are automatically forced to represent a monophyletic unit, although some of these may in fact be closer related to other species. Hence only a careful a priori discussion before the phylogenetic analysis will lead to meaningful results.

d. Biogeographical insights can also suffer heavily from taxonomic and phylogenetic artifacts if different developmental stages are misidentified. Such a scenario might be the case within certain representatives of Pachycephalosauria. According to the phylogeny reconstructed by Snively and Cox (2008), closely related species occur on different continents, i.e., in Asia and North America. This interpretation leads to a scenario which requires several migrations of the populations. However, when the skull morphology of the co-occurring species is considered, these assumed separate species could also represent different developmental stages of the same species (Horner and Goodwin, 2009; **Figure 1**). Hence, significantly less migration events are necessary to explain this phylogenetic pattern.

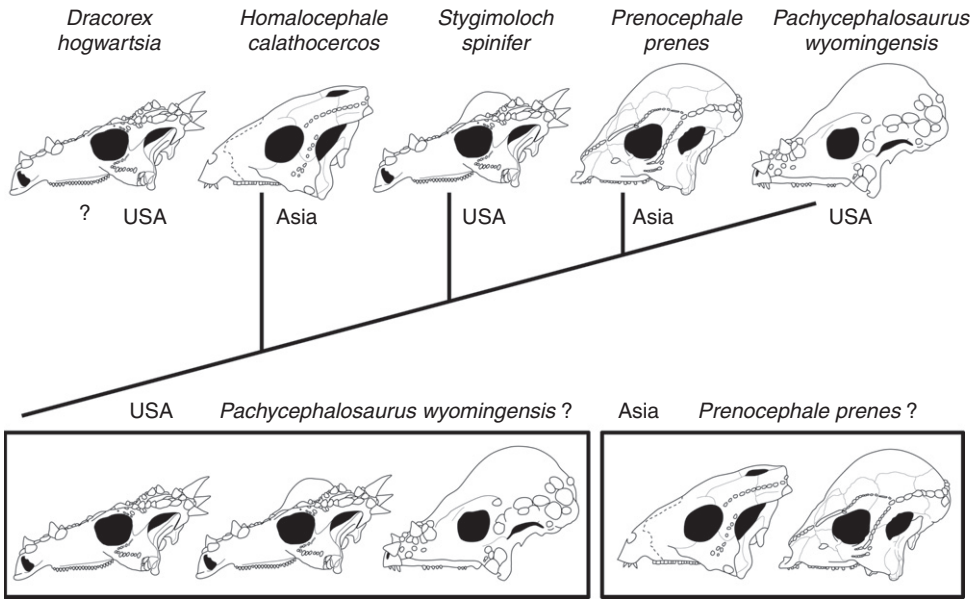

Figure 1 Dome-headed dinosaurs (Pachycephalosauria) as an example for taxonomic, phylogenetic, and biogeographic challenges. According to the simplified phylogeny (top; after Snively and Cox, 2008), several migration events between Asia and North America need to be assumed for these species. However, if some species represent ontogenetic stages of another one, the distribution of the fossils is much easier to explain.

Minimum Ages

A very important aspect of developmental paleontology is that it provides minimum ages for modern developmental patterns. In most cases, minimum ages for developmental patterns are based on phylogenetic inference. While the latter can be comparably reliable, minimum age calculations rely on the assumption that development has remained comparable in the early and modern representatives of a lineage. Fossil data can be used to test such an assumption or also to reject it.

The fossil record of crustaceans, in particular, highlights the insights that can be obtained from the fossil record concerning the earliest appearance of modern larval morphotypes. The oldest known crustacean larva, *Wujicaris muelleri* from the lower Cambrian of China (520 million years old), already represents a modern morphotype, similar to larvae of barnacles (**Figure 2(a)**; Zhang *et al.*, 2010). Therefore, fossil evidence suggests that this larval type, called metanauplius, has evolved more than half a billion years ago.

The fossil record also provides evidence for modern-type larvae in some highly specialized crustacean ingroups. For example, the lithographic limestones of southern Germany (150 million years old) have produced the oldest example of a modern-type larva of mantis shrimps (Stomatopoda; but also now extinct morphotypes, see below), which already possesses all characteristics seen in living stomatopod larvae (**Figure 2 (b)**; Haug *et al.*, 2008).

Additionally, thousands of larval specimens of achelatan lobsters (slipper and spiny lobsters) have been found in the Solnhofen limestones (**Figure 2(c)**; e.g., Polz 1972, 1973, 1984; Haug *et al.*, 2011), the so-called phyllosoma larvae. These larvae are among the most aberrant-appearing larval forms of all

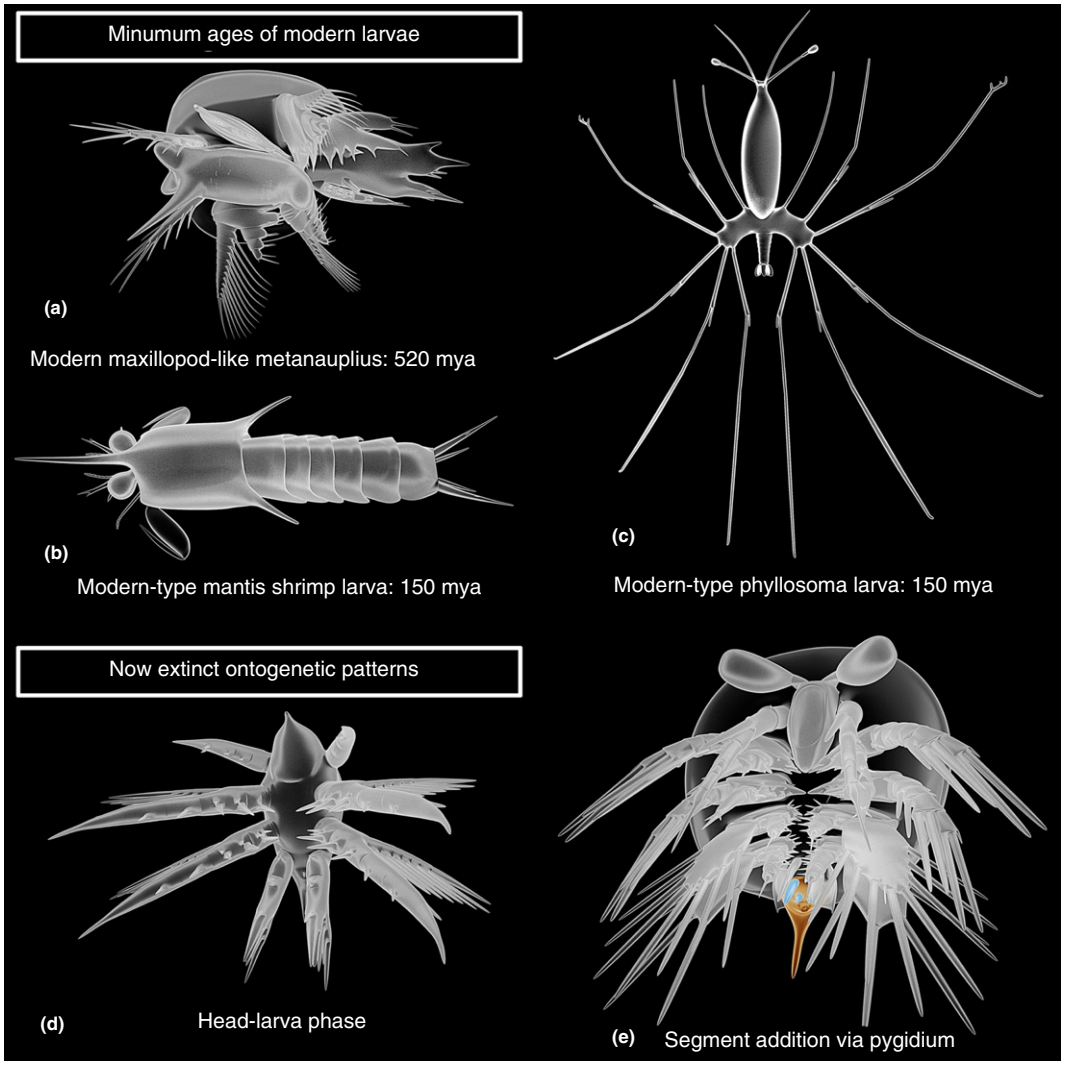

Figure 2 Minimum ages of modern larval morphotypes (a–c) and developmental patterns no longer existing today (d, e). (a) Oldest known crustacean larva, *Wujicaris muelleri* from the lower Cambrian of China (520 million years old), already closely resembling modern larval morphology. (b) Modern-type mantis shrimp larva from the Upper Jurassic Solnhofen limestones (150 million years old). (c) Modern-type phyllosoma larva from the Solnhofen limestones. (d) Head larva of early crustacean, *Martinssonia elongata* from the middle Cambrian Orsten of Sweden (505 million years old). (e) Larva of early crustacean, *Henningsmoenicaris scutula* from Swedish Orsten, with segment addition via pygidium (orange, with limb buds in blue).

crustaceans. The body is leaf-like (name!), flat and translucent; the appendages are very elongate and slender; distally they possess a sub-chelate claw for grasping jellyfish or comb-jellies. Phyllosoma larvae can reach astonishing sizes of up to 150 mm. As in the previous example, fossil phyllosoma larvae look very much like the modern ones. Therefore, the highly specialized larvae of this group had already evolved 150 million years ago.

Ancestral, but Now Extinct Patterns

Fossil developmental data can also reveal ancestral developmental patterns that are now extinct. These extinct patterns may bridge very differing developmental patterns in modern groups that otherwise would remain seemingly unrelated.

As above, several examples of these now extinct developmental patterns can be found among crustacean fossils, some of them in the middle Cambrian Orsten from Sweden (505 million years old; e.g., Maas *et al.*, 2006). One example is the head larva. Early crustaceans such as *Martinssonia elongata* hatched as head larva with four pairs of legs (**Figure 2(d)**), while modern crustaceans hatch with only three pairs (see above). Additionally, the segment number at hatching was retained in early crustaceans for several molts while modern crustaceans add segments subsequently at each molt (e.g., Müller and Walossek, 1986; Walossek, 1993; Haug *et al.*, 2009a; Haug *et al.*, 2010a,b).

Another now extinct developmental pattern present in early crustaceans, trilobites, agnostines, and possibly a number of other early euarthropods is the mode of segment addition via a pygidium (e.g., Haug *et al.*, 2010a). While in modern crustaceans segments bud off an undifferentiated posterior budding zone, the pygidium (e.g., in *Henningsmoenicaris scutula*; **Figure 2(e)**) is a posterior body area with a dorsal shield and well identifiable segmental markings. From this area the segments bud off anteriorly.

Further examples of now extinct developmental patterns can be inferred from crustacean larvae found in the Solnhofen and other Mesozoic limestones. As mentioned above, achelatan lobsters and mantis shrimps are both represented in these deposits with modern as well as ancestral-appearing larvae. In achelatan lobsters, a number of larval forms in these limestones combine phyllosoma and post-phyllosoma characters in very different combinations (**Figure 3(a–c)**; Haug *et al.*, 2009b, 2013; Haug and Haug, 2013). Such character combinations are unknown from any modern achelatan lobster.

For the evolution of developmental patterns in achelatan lobsters, three scenarios were offered by Haug and co-authors, which are probably all represented in the material:

1. Some of the fossil larvae could represent intermediate stages between modern-type phyllosoma and post-phyllosoma stages, but which were evolutionary skipped in modern forms (condensation).

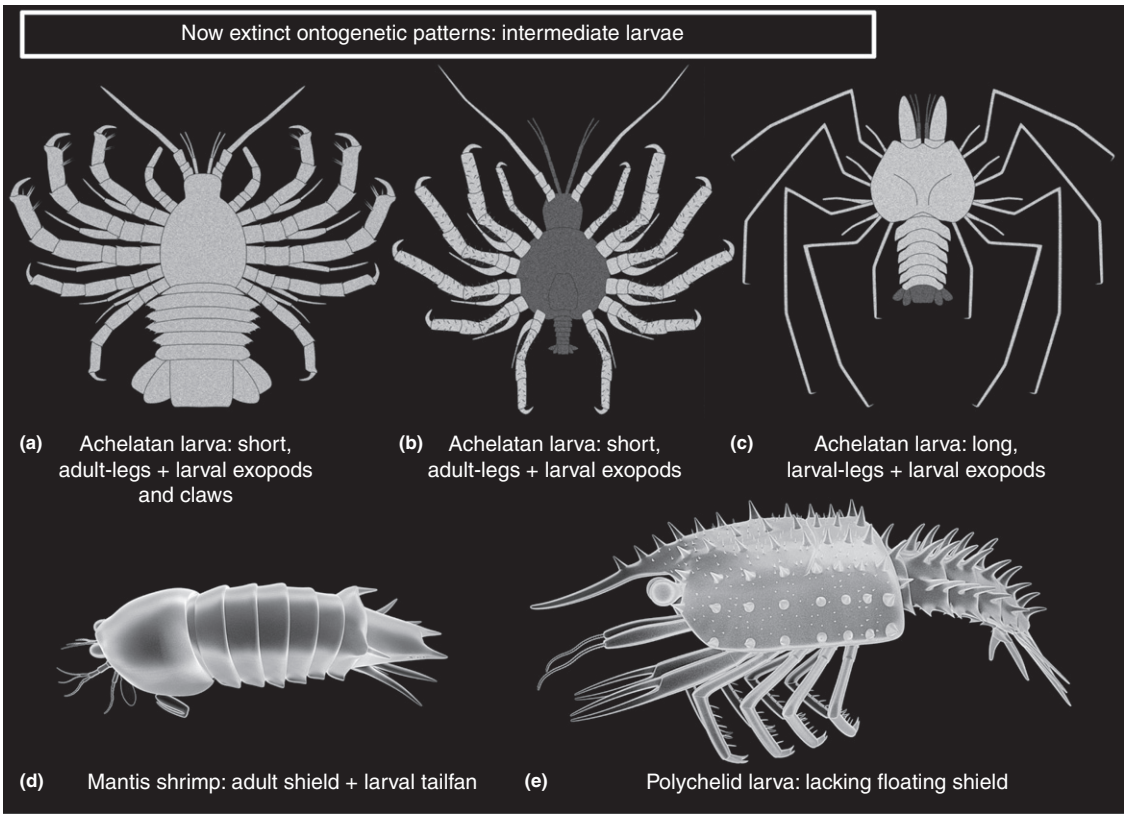

Figure 3 Developmental patterns no longer existing today, continued. (a–c) Different types of achelatan larvae with a mixture of typical phyllosoma and post-phyllosoma characters from the Upper Jurassic Solnhofen limestones (150 million years old). (d) Late larva of the mantis shrimp, *Spinosculda ehrlichi* from the Solnhofen limestones. (e) Larva of a polychelid lobster from Upper Cretaceous Lebanese limestones (90 million years old).

2. Some of the fossil larvae could be evolutionary early 'proto-phyllosomes' which did not yet possess all specifications modern-type phyllosoma larvae have.
3. Some of the fossil larvae could represent paedomorphic species, so they would have retained larval characters into the 'post-larval' phase.

The ancestral-appearing mantis shrimps larval type found in the Solnhofen limestones differs from the co-occurring modern type in its relatively advanced morphology at a still rather small body size (**Figure 3(d)**). While still retaining the larval tail fan, it already possesses the short adult head shield. Other features characteristic for modern-type stomatopod larvae are lacking, such as the long spines on the shield. As also other developmental stages of the stomatopod species with this ancestral larval type have been discovered (Haug *et al.*, 2009), it appears that the ontogeny of this species did not comprise a drastic metamorphosis as in modern species, but rather happened more gradually.

Another crustacean group from Mesozoic limestones in which an ancestral developmental pattern occurred, which is no longer present today, is polychelidan lobsters. Today, polychelidan adults and larvae both live in the deep sea. In the Mesozoic, however, representatives of this group lived in much shallower areas. This change of the habitat resulted in morphological changes in the larvae: while modern polychelidan larvae, also called eryoneicus larvae, are large, blind, and possess an extremely blown-up spinose shield, fossil larvae from Cretaceous limestones of Lebanon (ca. 95 mya) have eyes and relatively normal-sized, though spinose shield, but are in total also quite large (**Figure 3(e)**). In comparison with the supposedly more ancestral developmental pattern of certain polychelidan species from the Solnhofen limestones, these fossil data suggest that modern polychelidan larvae likely evolved through the stepwise acquisition of specialized morphological characters (Haug *et al.*, 2015).

Evolution of Body Organization

In paleo-evo-devo, as well as in an evo-devo approach with extant organisms, developmental patterns are used to explain the evolution of new features of body organization. The advantage of incorporating a paleo-evo-devo approach is that extinct developmental patterns can also be included into analyses. Such ancient datasets are especially valuable for groups in which large radiation events occurred many millions of years ago.

One example is the evolution of echinoderms (sea urchins, sea stars, sea cucumbers, etc.). Certain fossil representatives exhibit a very specific developmental pattern, which can be deduced from the plate arrangement in adult specimens (Sumrall and Wray, 2007; Sumrall, 2008). At first, a pair of lateral ambulacral fields is developed, followed by one anterior ambulacral field. Then, the two lateral fields divide into two fields each, resulting in five fields in total. With this pattern as starting point, the evolution of the very diverse forms of body organization in the different fossil echinoderm groups can be deduced. If the development of the anterior field is inhibited, only four ambulacral fields develop. The inhibition of the split of the lateral fields leads to three ambulacral fields. If anterior field and the lateral split are inhibited, only two fields develop. Finally, if the development of the lateral fields is inhibited, the result is only one ambulacral field. With this, a complete range of adult forms of body organization can be deduced from one ancient developmental pattern.

Evolutionary Scenarios

When evolutionary scenarios are reconstructed based exclusively on adult specimens, evolutionary 'novelties' often appear to have evolved abruptly. However, developmental information from fossils often makes it clear that these 'novelties' could have arisen through slight changes in developmental timing. As a result, fossil data often make it possible to reconstruct a much finer graded evolutionary scenario.

An example of this can be found in the early evolution of crustaceans, where fossil data have demonstrated that changes in developmental timing have driven morphological evolution. A very important morphological structure in crustaceans is the proximal endite, an exclusively median sclerotization in the body-appendage joint membrane, which contributes to the feeding apparatus. In certain appendages of certain crustaceans, the proximal endite is transformed into a coxa, a large and prominent structure, which forms a closed ring and often bears a median shovel-like extension. Data from the fossil record suggest that the evolutionary transformation of this structure occurred through small changes in the timing of its appearance during ontogeny. In the earliest crustaceans, the proximal endite is not present in early ontogenetic stages (**Figure 4(a)**) and remains small in later stages (**Figure 4(b)**). However, the proximal endite appears earlier in ontogeny later in crustacean evolution (**Figure 4(c)**). As a result, the proximal endite has more time to grow larger in later ontogenetic stages than in earlier crustaceans (**Figure 4(d)**). The repetitive occurrence of such a heterochronic pattern finally leads to the development of a coxa (**Figure 4(e)**; for more details, see Müller and Walossek, 1985; Haug *et al.*, 2010a,b).

Another example of a finely graded evolutionary scenario, in which the necessity to include fossil data becomes evident, occurs in achelate lobsters. The antenna of modern achelate lobsters show two distinct morphologies: a very long and slim antenna in spiny lobsters (**Figure 4(f)**), and a shovel-like, stout antenna in slipper lobsters. Fossil representatives, however, appear to exhibit intermediate antenna morphologies, especially when developmental stages are examined. For example, *Cancrinos claviger* from the Solnhofen limestones (**Figure 4(g)**) begins its development with a spiny-lobster-like antenna (**Figure 4(h)**) which then develops a broader proximal, set-off component (**Figure 4(i)**) and finally loses the thin distal component (**Figure 4(j)**; Haug *et al.*, 2009b). In this case, antenna development in a fossil achelate lobster recapitulates the evolution of antennal form within the group.

How Is a Study in Developmental Paleontology and Paleo-Evo-Devo Performed?

Largely Post-Embryonic Ontogeny

In general, developmental paleontological studies are based on post-embryonic stages, or stages occurring after the animal

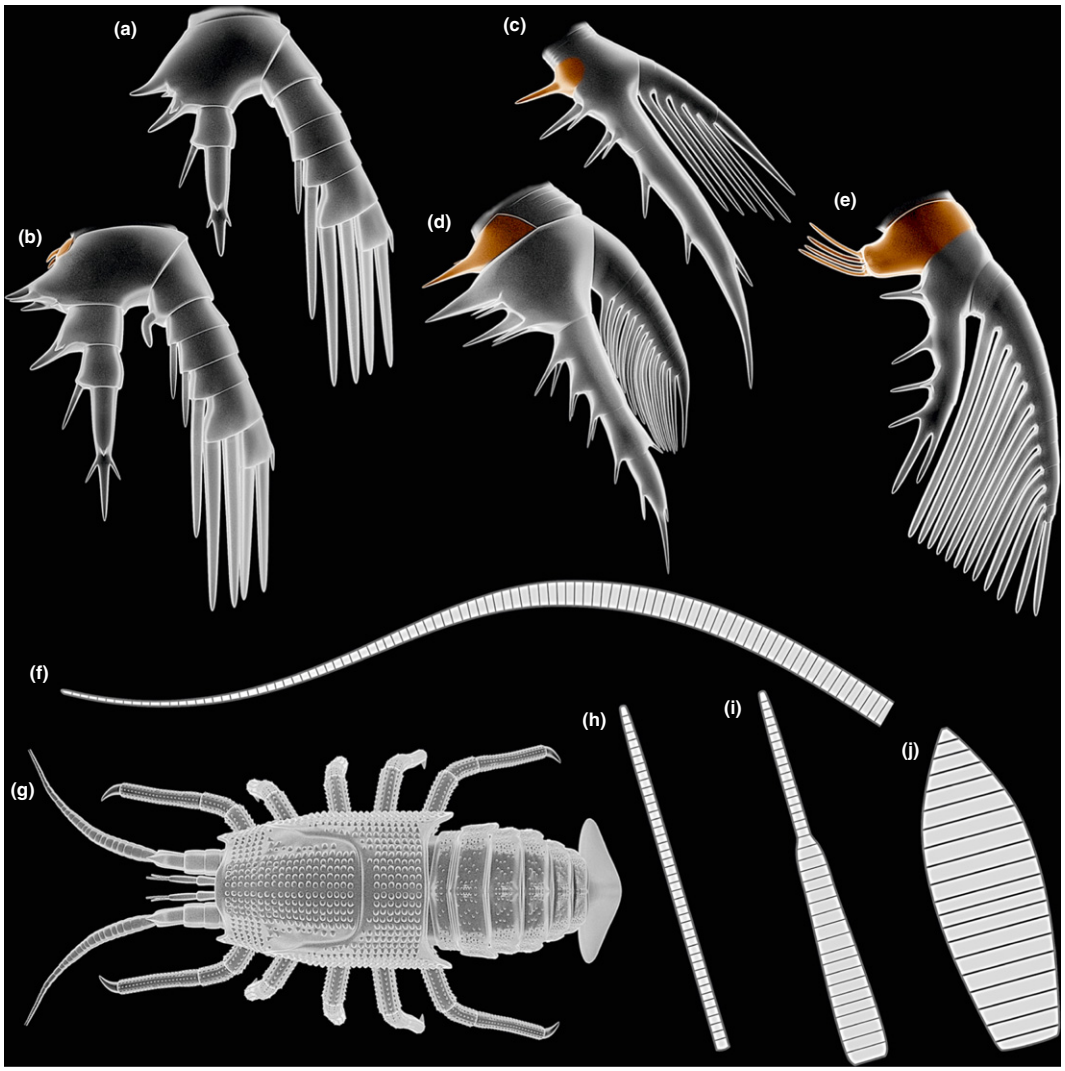

Figure 4 Evolutionary scenarios. (a–e) Evolution of the crustacean coxa as a specialization of the proximal endite, exemplified on the (second) antenna of half a billion years old Orsten crustaceans. (a) Young ontogenetic stage in the early crustacean *Henningsmoenicaris scutula*, still without proximal endite. (b) Later stage of *H. scutula*; proximal endite present (orange), but remains small also in this later stage. (c) Young ontogenetic stage of *Martinssonia elongata*, which is closer related to modern crustaceans (Eucrustacea) than *H. scutula*; the proximal endite (orange) appears here earlier in the ontogeny than in the earliest crustaceans. (d) Later stage of *M. elongata*; the proximal endite (orange) has grown larger than in similar stage of the earliest crustaceans. (e) Putative adult of *Skara anulata*, a eucrustacean; the repetitive occurrence of heterochronic events finally led to the development of a coxa (orange). (f–j) Evolution of the antenna within achelate lobsters. (f) Very long and slim antenna in spiny lobsters. (g) Reconstruction of a late juvenile of *Cancrinos claviger*, Solnhofen limestones. (h) Spiny-lobster-like antenna in early developmental stage of *C. claviger*. (i) Antenna in later ontogenetic stage of *C. claviger* with a broader proximal, set-off part. (j) Antenna in still later ontogenetic stage of *C. claviger* with thin distal part lost.

is born or has hatched from the egg. The reason is simply that embryonic stages are usually relatively small and very soft, which lowers their preservation potential and makes them difficult to find.

However, there are numerous exceptions to this rule. Viviparous species have the potential to preserve embryos within the mother when the latter becomes fossilized. Well-known examples come from vertebrate fossils, such as adult marine reptiles with late embryos preserved within the body, or nests with dinosaur and pterosaur eggs (e.g., Carpenter *et al.*, 1994; Carpenter, 1999; Caldwell and Lee, 2001; Norell *et al.*, 2001; Cheng *et al.*, 2004; Chiappe *et al.*, 2004).

Additionally, isolated invertebrate fossil embryos have also been preserved in late Precambrian and Cambrian strata as a result of Doushantuo and Orsten-type preservation (e.g., Chen and Chi, 2005; Donoghue and Dong, 2005; Donoghue *et al.*, 2006a,b, and references therein). The systematic position of these specimens is often difficult to assign; a notable exception is the embryo of a cycloneuralian worm, assigned to different species of *Markuelia* (e.g., Donoghue *et al.*, 2006a,b; Haug *et al.*, 2009c; Zhang *et al.*, 2011; Duan *et al.*, 2012). Such fossils appear to be highly restricted to a specific preservational window. Nevertheless, the preservation can be so intricate that even the finest details such as pores or tiny hairs are still

present. Hence, such fossils are immediately comparable to their modern counterparts.

However, even if only an older animal is preserved, information can sometimes be gleaned about earlier developmental stages. Certain animals such as molluscs or brachiopods may, for example, preserve aspects of the embryonic shell (see below) at older stages of development. Yet, one has to admit that such a late embryonic shell is presumably more or less identical to the early larval shell and will therefore mainly provide post-embryonic information. Thus, in most cases the study of ontogeny in fossil organisms is restricted to the post-embryonic and in most cases post-larval ontogeny (ambiguous term, see Anger, 2006) or juvenile development.

How to Obtain Such Data

Data for developmental paleontological studies are commonly obtained using two approaches, which can be combined:

a) Development at a single stage can be investigated using isolated, preserved specimens.
b) Ontogenetic sequences can be reconstructed from numerous specimens representing different developmental stages.

Single specimens with ontogenetic information

The adult forms of certain groups of animals, such as shell-bearing organisms (molluscs), preserve information about their ontogeny. In these animals, information about earlier ontogenetic stages can be preserved in the most proximal area of the shell. Interestingly, these late embryonic or larval shells can possess a completely different morphology than the adult shell, for example, a twist in the other direction in snails (for a recent summary, see Nützel, 2014 and references therein).

The adult shell can also provide ontogenetic information in ammonites, an exclusively fossil mollusc group. To access this information, the shell is sectioned and changes of the shape of the sutures inside the shell or of the whorl expansion rate can be detected (e.g., Landman *et al.*, 1996; Ubukata *et al.*, 2008; De Baets *et al.*, 2012).

Arthropods usually shed their exoskeleton while growing. Due to this process of molting, information concerning earlier developmental stages is lost as growth continues. However, there are exceptions to this rule. For example, spinicaudatan crustaceans retain their post-larval shield valves instead of shedding them during each molt. Hence, they show growth lines that can be used to investigate developmental evolution (e.g., Wang, 1989; Olempska, 2004).

Adult legs can also provide developmental information in certain arthropods. Numerous arthropods grow by posterior addition of segments, which subsequently develop their equipment such as legs to achieve the final adult morphology. Therefore, anterior segments are further developed than posterior ones. As a consequence, a single older specimen gives insight into its earlier development. Such well preserved specimens are also present in the fossil record, for example, in crustaceans of the Cambrian Orsten (e.g., Walossek, 1993; Zhang *et al.*, 2007).

Ontogenetic information can also be deduced from single adult specimens in echinoderms. Each single plate in the adult has growth lines that can be used to generate developmental data. Additionally, the mode of plate addition can to a certain degree be deduced from the pattern of plate arrangement in the adult (Sumrall, 2008).

In vertebrates, structures such as bones and teeth can store developmental data from earlier stages, and these structures are commonly preserved in the fossil record. For example, the internal structure of the bones and teeth can give insight into the speed of growth (e.g., Starck and Chinsamy, 2002; Chinsamy-Turan, 2005; Woodward *et al.*, 2011). In addition, otoliths are often an important source for ontogenetic data in fish. Otoliths are small stones inside the fish balance organ, which are used to sense gravity. They grow together with the fish (though there may be a more direct correlation with the metabolic rate instead of growth itself; e.g., Woydack and Morales-Nin, 2001), assembling prominent growth lines which can be mined for developmental information.

Ontogenetic sequences from several specimens

Scientists incorporating paleo-evo-devo approaches commonly use several conspecific specimens of different ontogenetic stages to construct ontogenetic sequences for fossil taxa. In the best case, these developmental sequences are relatively complete and ontogenetic changes can be clearly detected. There are indeed some rather complete ontogenetic sequences preserved in the fossil record, for example, among crustaceans in Orsten-type preservation (e.g., Müller and Walossek, 1988; Walossek, 1993; Maas *et al.*, 2003; Haug *et al.*, 2010a) or in lithographic limestones (e.g., Polz, 1972, 1973, 1999; Bravi *et al.*, 2014), echinoderms (e.g., Sumrall *et al.*, 2006, 2013), amphibians (e.g., Schoch, 1992; Schoch and Fröbisch, 2006), or dinosaurs (e.g., Horner and Goodwin, 2006, 2009).

However, in many cases huge gaps in the developmental sequences make it difficult to determine if specimens represent different developmental stages of the same species or if they belong to different species. There are a number of cases in which representatives of previously separately described species are now assumed to be different ontogenetic stages of the same species (e.g., Horner and Goodwin, 2009; Scannella and Horner, 2010; Haug *et al.*, 2012). The most prominent example is the still ongoing discussion about the horned dinosaurs *Triceratops horridus* and *Torosaurus latus*. Some paleontologists provided evidence that the first species is a juvenile form of the latter (Scannella and Horner, 2010), while others see these presumed developmental characters as clear species differences (Longrich and Field, 2012). However, these uncertainties need to be solved before an evolutionary scenario can be reconstructed.

Evolutionary Scenarios

We have explained how fossil developmental data can be collected, but have not yet addressed how to reconstruct an evolutionary scenario using paleo-evo-devo approaches. To reconstruct how the transformation from one developmental pattern to another took place, ontogenetic data from both

extant and fossil representatives need to be included. This is not a trivial undertaking, and most analyses to date have included ontogenetic data from either extant or fossil taxa, but not both.

The basis for the reconstruction of an evolutionary scenario is a relatively well-resolved phylogram ('diagram of relationships'; see discussion in Haug *et al.*, 2012). Developmental information can either be directly included into the phylogenetic analysis that constructs the phylogram, or the developmental patterns for each monophyletic group (species or larger unit) can be mapped onto an already existing phylogram. The latter may result in a reevaluation of the phylogeny, which means that the mapping has to be repeated based on the new phylogeny hypothesis.

By plotting developmental data onto the phylogram, researchers can identify developmental patterns that are ancestral and derived, and thereby hypothesize the direction of evolution. The inclusion of fossil developmental data is especially crucial to this process, as these may provide ancestral conditions no longer present in the modern fauna (although fossils also often possess modern character conditions). Here we discuss an example of this in achelate lobsters (slipper and spiny lobsters). In modern representatives of this group, animals hatch as flat, swimming, so-called phyllosoma larva with very tiny tails. At the end of the phyllosoma phase, the larva changes drastically within a very short time (metamorphosis) into an almost adult-appearing, ground-living lobster with a very pronounced tail. As this developmental pattern characterizes both slipper lobsters and spiny lobsters, the general assumption was that this pattern of development was present in the last common ancestor of these two groups. However, recent investigations on fossil ontogenies of achelate lobsters made clear that the condition in modern representatives must have evolved convergently as different fossil in-group representatives show a much less metamorphic pattern (Haug and Haug, 2013; Haug *et al.*, 2013). This is a striking example of the type of errors that can occur when fossil developmental data are not incorporated into phylogenetic and evolutionary analyses.

Interactions of Paleo-Evo-Devo and 'Neo'-Evo-Devo

One central question remains: How can we effectively integrate paleo-evo-devo and modern evo-devo approaches into one combined, more holistic approach? A few such enterprises have been successfully undertaken already (e.g., Ortega-Hernández and Brena, 2012; Garwood *et al.*, 2014). Yet, additional steps will be necessary before an even closer integration of the two fields will become possible.

As we pointed out above, paleo-evo-devo is often restricted to studies of post-embryonic development. In contrast, modern evo-devo is almost entirely restricted to studies of embryonic development. This is especially apparent in arthropods, where all common model organisms have a highly derived ontogenetic pattern, lacking dispersal larval stages. Hence, future studies on extant organisms need to be extended more into post-embryonic development to provide data for comparisons between fossil and extant organisms. Using this approach, the external and internal morphology, for example, of the muscles (e.g., Briggs *et al.*, 2005; Haug *et al.*, 2014), nervous system (e.g., Ma *et al.*, 2012; Tanaka *et al.*, 2013), or circulatory system (Ma *et al.*, 2014) of these organisms should be investigated. We expect that the resulting studies will provide exciting new insights into the evolution of developmental patterns.

Developmental Plasticity and Phenotypic Evolution

GK Davis and MA Wund, Bryn Mawr College, Bryn Mawr, PA, USA; and The College of New Jersey, Ewing, NJ, USA

Glossary

Baldwin effect The effect that occurs when a population encounters a novel environment and preexisting plasticity allows for the appearance of novel phenotypes. Selection then acts on these novel variants, influencing, over generational time, the direction of evolutionary change.

Cryptic genetic variation Genetic variation that is unexpressed due to genetic canalization, but which can be exposed to selection in the case of particular changes in genetic background or environmental conditions.

Developmental instability/developmental noise Stochastic perturbations of development independent of specific environmental or genetic variation, typically measured as a deviation from bilateral symmetry.

Developmental plasticity A form of phenotypic plasticity in which the differences in phenotype arise during ontogeny. This type of plasticity is often, though not always, irreversible.

Environmental canalization The developmental process by which a phenotypic trait is buffered against environmental variation, manifesting as a 'fixed' trait or flattened reaction norm.

Epigenetic A mitotically or meiotically heritable change in phenotype or gene function that does not involve a change in DNA sequence. This contemporary usage is distinct from the term as coined by C. H. Waddington and also differs from contemporary uses that focus on functionally significant changes in chromatin structure regardless of heritability. See Bird (2007) for discussion.

Genetic accommodation Changes in allele frequency due to selection on the regulation, form, or side effects of a novel trait. The phenomenon includes both selection on environmentally induced traits (in this case subsuming the second half of the Baldwin effect) or traits induced by novel mutations.

Genetic assimilation A form of genetic accommodation in which selection results in environmental canalization or the loss of plasticity.

Genetic canalization The developmental process by which a phenotypic trait is buffered against genetic variation, manifesting as overlapping reaction norms for different genotypes.

GxE A genotype-by-environment interaction, or genetic variation that responds differently to some aspect of the environment, resulting in reaction norms with different slopes.

Phenotypic plasticity The ability of genetically identical organisms to adopt different phenotypes in response to different environmental conditions. Such responses may or may not be adaptive.

Polyphenism A form of developmental plasticity in which alternative phenotypes, known as 'morphs,' are discrete and typically exhibit a suite of phenotypic differences.

Reaction norm A graphic representation of the phenotypic response (i.e., the value of a particular trait) of a genotype to a range of values for a particular environmental variable.

What is Developmental Plasticity?

The term 'developmental plasticity' refers to the ability of genetically identical organisms to develop different phenotypes in response to different environmental conditions. In practice, developmental plasticity is inferred when one observes different phenotypes developing from genetically similar if not identical organisms, and the observed phenotypic variation is associated with some aspect of the environment rather than with existing genetic variation. Such phenotypic variation can manifest as differences in almost any aspect of the phenotype, including those of morphology, physiology, behavior, or life history, as long as the differences result from a developmental or ontogenetic response to a change in the environment. Such responses tend to be irreversible for an individual organism, but not always. Developmental plasticity is thus a type of 'phenotypic plasticity,' a broader term that refers to the environmentally induced production of alternative phenotypes at any point in the life cycle of an organism. The predator-cued defensive 'helmets' of some cladocerans or the courtship song sung by a male sparrow that possesses the requisite neuroanatomy – both develop or are learned during ontogeny and are thus examples of developmental plasticity (**Figures 1(a)** and **1(b)**; Marler, 1999; Nottebohm, 2005; Tollrian and Dodson, 1999). In contrast, the predator-cued apparent death of an American opossum or the background-inspired camouflage of an octopus, both of which can be reversed and invoked at any time (Gabrielsen and Smith, 1985; Hanlon, 2007), are examples of nondevelopmental phenotypic plasticity (**Figures 1(e)** and **1(f)**); sometimes referred to as 'labile plasticity' (Gomulkiewicz and Kirkpatrick, 1992) or 'activational plasticity' (Snell-Rood, 2013). Although useful conceptually, in practice the developmental versus nondevelopmental distinction can be problematic, as it is often difficult to decide when 'development' ends and 'physiology' begins (Fusco and Minelli, 2010).

Under the right historical circumstances, developmental plasticity can afford populations and individuals the ability to adapt to changing environmental circumstances on short, nonevolutionary timescales. Such 'adaptive developmental plasticity' evolves when (1) a population possesses heritable variation in a developmental response to an environmental

 doi:10.1016/B978-0-12-800049-6.00135-9

cue and (2) some responses in the population confer greater reproductive success than other responses. Implicit here is the notion that not all developmental plasticity is adaptive. Indeed, developmental plasticity can be selectively neutral or even maladaptive, especially when it first appears in a population as a result of *de novo* mutations or exposure to a novel environment. Furthermore, developmental plasticity, whether adaptive, neutral, or maladaptive, is often considered to be distinct from 'developmental instability' or 'developmental noise,' which results from stochastic perturbations of development (Waddington, 1957, p. 40; also see Bradshaw, 1965). This latter type of phenotypic variation, observed for a single genotype in a single environment, can be induced by environmental stressors and is typically measured as a deviation from bilateral symmetry, as both sides of an individual develop with the same genotype and in the same macroenvironment (Klingenberg, 2003; Nijhout and Davidowitz, 2003; Palmer, 1994). Unlike developmental plasticity, however, environmentally induced developmental instability results when the environment's influence on development is directionless and effectively random with regard to effects on the resulting phenotype.

A helpful way to visualize developmental plasticity is the 'reaction norm.' First drawn by German zoologist Richard Woltereck (1909), a reaction norm or 'phenotypic curve' was later interpreted as the response of a genotype to a range of values for a particular environmental variable, such as temperature or nutrition, producing a range of values for a particular phenotypic trait (**Figure 2**). In other words, reaction norms illustrate how the environment modulates the phenotypic expression of the genotype (see Sarkar, 2004 for a history of reaction norms). In the case where the environment has little influence on the phenotype – that is, there is limited plasticity – the reaction norm is relatively flat (**Figure 2(a)**). The proximate cause of this flattening is developmental buffering against environmental variation, a process referred to as 'canalization' by Waddington (1942) or 'autoregulation' by Schmalhausen (1949), which itself is the result of a history of stabilizing selection (but see de Visser *et al.*, 2003; Flatt, 2005). For Waddington, however, it is worth noting that canalization included the stable production of the phenotype in the face of not only environmental, but also genetic, variation (i.e., mutations). Thus, strictly speaking, a single flat reaction norm, as the function of a single genotype, reflects only 'environmental canalization' as opposed to 'genetic canalization' (*sensu* Stearns *et al.*, 1995). In contrast, any reaction norm with a significant slope indicates plasticity, even if the reaction norm exhibits curvature and the slope changes as the environment changes. Plasticity can thus take many forms depending on the magnitude and shape of the reaction norm, including responses that are continuous and discrete (**Figure 2**, compare (b) and (c)). When a discrete response is adaptive, developmental, and irreversible, it is often referred to as a 'polyphenism,' with the alternative phenotypes, referred to as 'morphs,' typically exhibiting a correlated suite of phenotypic traits (Mayr, 1963; Michener, 1961; Moran, 1992; see **Figures 1(a)** and **1(d)**).

For a single genotype to produce a reliable, coherent reaction norm, regardless of whether it is environmentally canalized or plastic, requires that the phenotypic trait in question exhibit sufficient developmental stability (i.e., minimal variation at a particular value along the environmental axis). Note that this requirement for developmental stability is not the same as a requirement for genetic canalization; without genetic canalization, reaction norms exhibit greater inter-norm variation among genotypes, whereas reaction norms subject to genetic canalization exhibit limited inter-norm variation with greater overlap (**Figure 2**, compare (d) and (e); Stearns and Kawecki, 1994).

Although developmental plasticity had been discussed in adaptative terms as early as 1914 (Nilsson-Ehle, 1914), Synthesis biologists of the 1930s and 1940s – with some exceptions, notably Waddington (1942) and Schmalhausen (1949) – tended to treat the role of plasticity in evolution only cursorily, as they preferentially focused on phenotypic variation that was due to additive genetic variation and therefore subject to natural selection. Similarly, early geneticists interested in development focused on the role of genes in this process and thus tended to disregard environmentally influenced variation as noise (for a review of the history of views on plasticity, see Sarkar, 2004; Schlichting and Pigliucci, 1998, pp. 29–50; West-Eberhard, 2003, pp. 1–20). Both of these viewpoints changed slowly but steadily in the second half of the twentieth century, with the result that we are now witnessing a surge of interest in multiple aspects of developmental plasticity, including its evolution, its consequences for evolution more generally, the proximate mechanisms that generate it and how these can be altered by natural selection.

The Evolution of Plasticity

Dynamic responsiveness is a hallmark of life itself; indeed, adaptive conditional responses of behavior, physiology, and even morphology are common. This observation, along with the results of early experiments in which plasticity was modified by artificial selection, led Bradshaw (1965) to argue that plasticity is under genetic control and as such is subject to natural selection. Bradshaw went on to discuss the types of conditions under which plasticity would evolve, identifying scenarios in which plants would experience persistent variation in their environments. This work inspired the development of theoretical models for the evolution of plasticity, most dealing with life history traits, beginning in the 1970s and proliferating in the 1980s. Subsequent empirical explorations attempted to test the resulting predictions as to how and under what conditions adaptive phenotypic plasticity evolves.

How Does Plasticity Evolve?

Although few doubted that adaptive plasticity was the product of evolution by natural selection, from 1985 to 1995 there was considerable debate regarding whether phenotypic plasticity is the direct target of selection, or if, instead, plasticity is simply an emergent byproduct of selection for distinct, alternative traits in different environments (Gavrilets and Scheiner, 1993; Scheiner, 1993a,b; Via, 1993; Via *et al.*, 1995). The answer to this question has implications both for predicting evolutionary dynamics as well as for understanding the genetic underpinnings of plasticity. In particular, if plasticity

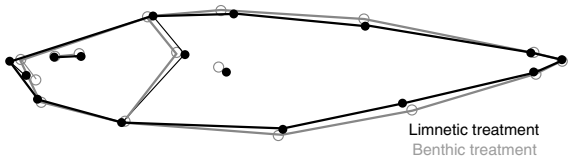
(c)



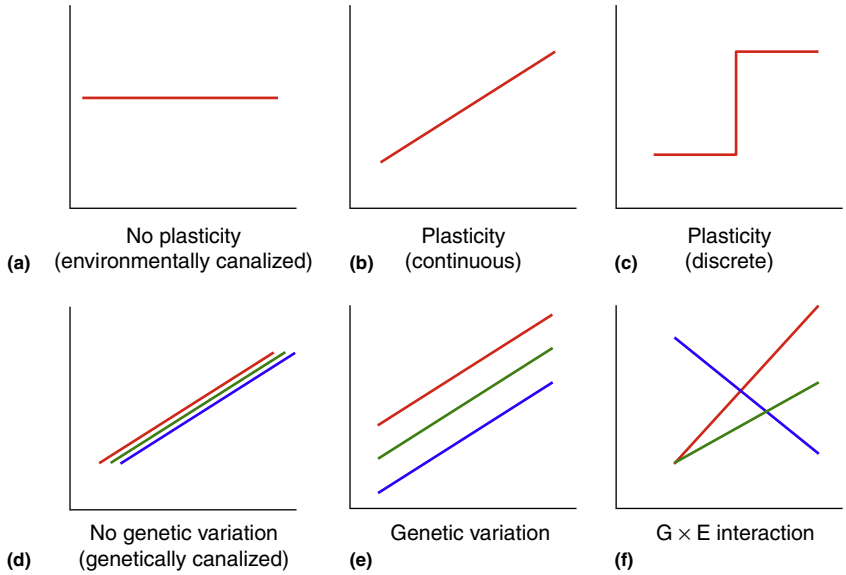


Figure 2 Some examples of reaction norms. In all cases, the *y*-axis represents a phenotype or trait value while the *x*-axis represents the value of some environmental variable. (a–c) Individual single-genotype reaction norms showing no plasticity (*monophenic*) (a), continuous plasticity (b), and discrete plasticity (*polyphenic* response) (c). Note that the term 'reaction norm' is often reserved for a continuous response (e.g., Stearns, 1989) and in this sense would not apply to (c). (d–f) Multiple single-genotype plastic reaction norms showing no genetic variation (reaction norms overlapping) (d), genetic variation, but no variation in the shape or magnitude of the response (e), significant genotype-by-environment interaction, representing heritable variation in the response (g). Although idealized single-genotype reaction norms are shown here, in practice reaction norms are estimated by plotting trait means for closely related families.

is indeed the direct target of selection, then there must exist specific genes that regulate the magnitude or shape of the plastic response that are distinct from the genes that control the development of the trait in alternative environments (Via *et al.*, 1995).

Another way to make the point would be to say that, in order for plasticity to be a target of selection, there must first be heritable variation in the plastic response itself, independent of the heritable variation in mean response across environments. In classical quantitative genetics, the proximate sources of phenotypic variation are partitioned as $V_P = V_G + V_E + V_{GxE}$ where the population's phenotypic variance (V_P) results from contributing genetic variance (V_G), environmental variance (V_E), and variance due to genotype-by-environment interaction (V_{GxE}). For plasticity to be subject to selection, it is not enough that $V_G > 0$ (**Figure 2(e)**), since this does not represent variation in the plastic response (i.e., the slopes of the reaction norms are the same). Instead, for plasticity to be subject to selection requires a significant genotype-by-environment interaction ($V_{GxE} > 0$) (Scheiner, 1993a; Scheiner and Lyman, 1989; Via

Figure 1 Some examples of phenotypic plasticity. (a) Two individuals of a single clone of the Asian and African water flea, *Daphnia lumholtzi*, exposed (left) and not exposed (right) to chemical cues from predaceous fish. The sharp helmet and extended tail spine of the induced morph protect the water flea from fish predators. (b) Sonograms sung by male swamp sparrows after exposure to the stereotyped song as juveniles (normal) and after no exposure (isolate). (c) For a given body size, stickleback fish raised in a limnetic environment have longer and more closely spaced gill rakers than those raised in the benthic environment (gill raker shown in inset). The average body shapes of limnetic-raised fish and benthic-raised fish also differ significantly, as depicted by wireframe graphs (deformations are exaggerated 4x to illustrate differences). (d) Genetically identical wingless and winged female aphids that developed under uncrowded or crowded conditions, respectively. (e and f) Two examples of nondevelopmental and reversible phenotypic plasticity: an opossum playing dead, an involuntary physiological response to a potential predator (e) and *Octopus vulgaris* sequentially showing a deimatic threat display and camouflage (left and right, respectively), dynamic changes that can take place in less than 1 s (f). Other well-known examples of developmental plasticity include seasonal polyphenism in butterflies (Brakefield and Frankino, 2009), horn plasticity in beetles (Emlen *et al.*, 2007; Moczek *et al.*, 2014), caste polyphenism in social insects (Miura, 2005), phase polyphenism in locusts (Simpson and Sword, 2009), cannibalistic larval polyphenism in both tiger salamanders (Collins and Cheek, 1983) and spadefoot toads (Pfennig, 1990), and environmental sex determination in reptiles (Janzen and Phillips, 2006). *Daphnia lumholtzi* images reproduced from Agrawal, A.A., 2001. and Lande, 1985), which has the effect of producing reaction norms that are not parallel and may even have opposing responses to the environment (**Figure 2(f)**). Although required for selection to shape plasticity, a $V_{GxE} > 0$ on its own does not suggest that plasticity itself is a direct target of selection.

Quantitative genetics experiments have demonstrated widespread heritable variation in plastic responses (i.e., significant 'GxE'; e.g., Danielson-François *et al.*, 2006; Gutteling *et al.*, 2007; and papers reviewed by Windig *et al.*, 2004). Furthermore, artificial selection experiments clearly demonstrate that direct selection on the magnitude of plasticity can lead to evolutionary responses, independently of changes in trait means (e.g., Czesak *et al.*, 2006; Garland and Kelly, 2006; Scheiner, 2002). As such, it is now generally accepted that phenotypic plasticity can indeed be a direct target of natural selection, and that the degree of flexibility of a trait is not necessarily genetically correlated to its environment-specific development, although selection on trait values in one environment may lead to changes in the slopes of reaction norms across environments (Scheiner, 2002; Suzuki and Nijhout, 2006). Numerous examples of reaction norm evolution in natural populations have also emerged, complementing work done on model systems in the laboratory (e.g., Baythavong and Stanton, 2010; Lee *et al.*, 2011; Scoville and Pfrender, 2010). Furthermore, the emergence of evolutionary developmental biology ('evo-devo') and advances in molecular biology have led to plausible models for the nature of so-called 'plasticity genes' and how they might work (Pigliucci, 2005). Applying this integrative biological approach, we now understand plasticity as resulting from any one of several mechanisms, including differential gene expression along an environmental gradient (Aubin-Horth and Renn, 2009), changes in enzyme activity under varying conditions, or the destabilization of posttranslational buffering mechanisms such as the activity of heat shock proteins and other chaperones (Rohner *et al.*, 2013; Rutherford and Lindquist, 1998; Queitsch *et al.*, 2002). Current work aims to further our understanding of how proximate mechanisms first detect environmental cues and then subsequently translate them into adaptive plastic responses, as well as how such complex developmental genetic systems evolved in the first place.

When Does Plasticity Evolve?

Environmental heterogeneity is common, and plasticity seems like an excellent strategy to handle it. So why do organisms sometimes confront a changing environment with a fixed (i.e., environmentally canalized) phenotype? In other words, under what circumstances do we expect a plastic versus fixed trait to evolve? There are at least two important answers to this question. The first is that the benefits of a plastic response might be outweighed by its cost, a price ultimately paid in reproductive success (DeWitt *et al.*, 1998; Relyea, 2002; Callahan *et al.*, 2008). The second is that plasticity is only favored by selection when environments vary predictably and frequently enough to make the ability to produce alternative phenotypes advantageous (reviewed in Schlichting and Pigliucci, 1998).

While it is conceptually intuitive that a plastic response might incur more cost than a fixed, jack-of-all-trades phenotype, efforts to empirically demonstrate the costs of plasticity have met with mixed results (DeWitt *et al.*, 1998; Murren *et al.*, 2015). Such equivocal evidence for the theoretical prediction of plasticity costs may be due, in part, to a tendency among investigators to conflate what is meant by the 'costs,' as opposed to the 'limits,' of plasticity. 'Costs' typically refer to the energetic and functional demands of producing alternative traits, including the physiological and developmental machinery required to detect an environmental cue and mount an appropriate response, which detrimentally affect reproductive success across the entire environmental range. 'Limits,' on the other hand, refer to constraints that prevent a plastic response from generating an optimal trait value for a given environment, such as developmental lag times, unreliable environmental cues, and reduced phenotypic integration that might make it difficult to simultaneously alter more than one or a few aspects of the phenotype (Auld *et al.*, 2010; DeWitt *et al.*, 1998). Such limits also come with costs in terms of reproductive success, but these costs are distinct from the 'costs of plasticity' described above and instead are costs that result from producing a suboptimal trait in a given environment, referred to as the 'costs of phenotype' (*sensu* Callahan *et al.*, 2008; Murren *et al.*, 2015). After reviewing the literature through this lens, Murren *et al.* (2015) conclude that, in most cases, it is in fact the limits of plasticity and their resulting costs of phenotype, as opposed to the costs of plasticity itself, that act as the predominant constraints on plasticity evolution.

One important class of limits of plasticity concerns environmental cues. In the case of adaptive plasticity, the environmental cue that triggers a plastic response may not be the same as the environmental challenge for which the response is an adaptation. This can be advantageous, as in cases where there is a developmental time lag associated with mounting an adaptive response. Here, a time delay between the environmental cue (e.g., a shortened photoperiod) and the environmental challenge (e.g., the cold temperatures of winter) can provide a sufficiently early warning for the adaptive plastic response to manifest on time (Nijhout, 2003). On the other hand, the distinction between environmental cue versus challenge also means that a plastic response can only be consistently adaptive if the cue that triggers the response reliably predicts the appearance of particular environmental conditions (Schlichting and Smith, 2002; David *et al.*, 2004). Thus, in the case of a novel plastic response (either mutationally or environmentally induced), plastic genetic variation will be consistently adaptive and hence favored by selection only if the environmental cue is reliably associated with the appropriate environmental challenge. Also predictive of whether or not selection will favor plasticity over a fixed response is the timescale at which the environment varies relative to generation time, a metric known as 'environmental grain' (Levins, 1968). In fine-grained environments in which the environment varies on timescales shorter than a typical lifespan, a fixed strategy might be favored if the lag time required for trait production is too long to be useful, particularly if environmental cues are also unreliable. In especially coarse-grained environments in which multiple generations pass between changes in the environment, we might also expect fixed

phenotypes because environmental change may be too rare for selection to favor plasticity (reviewed in Schlichting and Smith, 2002). Of course, predicting whether and how plasticity will evolve depends upon the nature of the trait in question. Activational responses (*sensu* Snell-Rood, 2013), such as rapid and reversible changes in behavior or physiology, might be expected to evolve in fine-grained environments, because they can immediately respond to new conditions. In contrast, developmentally plastic responses, whether irreversible or slowly reversible, may only evolve in somewhat less fine- or even course-grained environments due to a typically longer time lag between the detection of an environmental cue and the production of the altered phenotype.

Evolutionary Consequences of Plasticity

In addition to questions concerning the proximate mechanisms and evolutionary origins of developmental plasticity, we can also ask how preexisting developmental plasticity (and phenotypic plasticity more generally) might affect the course of evolution. Research on this question has suggested at least three major ways that plasticity might impact the evolutionary process (reviewed in Wund, 2012). In general, for populations that possess it, plasticity will potentially (1) improve viability in novel environments, (2) alter the rate at which a population responds to selective pressures, and (3) constrain the form of those responses (Ghalambor *et al.*, 2007; Price *et al.*, 2003; Schlichting, 2004; West-Eberhard, 2003).

While potentially counterintuitive, the idea that environmentally induced phenotypic variation might impact the evolution of inherited traits can be traced back to at least the late nineteenth century, when Morgan (1896), Osborn (1896), and Baldwin (1896, 1902) independently conceived of what has come to be known as the 'Baldwin effect' (coined by Simpson, 1953; see Crispo, 2007). When a population encounters a novel environment, either through migration or *in situ* change, plasticity may allow for the appearance of novel phenotypes. If at least some of these novel phenotypes are sufficiently adaptive, the population may remain viable until mutation and recombination can supply natural selection with beneficial genetic variants. It is possible, for example, to imagine that when facing a new environment, preexisting plasticity could place at least some members of a population on the slope of a new fitness peak. Assuming the appropriate genetic variation is or becomes available, natural selection could subsequently push the population toward the fitness maximum, either by changing mean trait values (e.g., the elevation, but not the slope, of the reaction norm) or the regulation of the plastic response (e.g., the slope of the reaction norm) (**Figures 1(a)** and **1(b)** in Crispo, 2007; Ghalambor *et al.*, 2007; Price *et al.*, 2003). It is in this basic sense that plasticity can both 'buy time' for adaptive evolution to take place while also affecting the rate of response to natural selection by providing an immediate (within generation) shift in phenotypic variation.

By revealing specific patterns of variation to selection or even influencing how individuals interact with their environment – as is the case, for example, with behavioral plasticity – the form of the plasticity (i.e., the magnitude and shape of the reaction norm) also constrains the types of adaptations that can evolve. Mary Jane West-Eberhard (2003) coined the term 'genetic accommodation' to describe evolutionary changes in the form, regulation, and integration of traits that adaptively 'accommodate' novel developmental variants, whether they result from novel mutations or a plastic response to a novel environment. The second step of the Baldwin effect, wherein environmentally induced adaptive variants are improved by natural selection, is an example of the latter and thus a type of genetic accommodation (Crispo, 2007; West-Eberhard, 2003). In terms of lasting effects on the course of evolution, the important point here is that the resulting adaptation initially arose as a plastic variant.

Another form of genetic accommodation that also depends on plasticity but instead results in the loss of plasticity was described and referred to as 'genetic assimilation' by Waddington (1957, 1961) and 'stabilizing selection' by Schmalhausen (1949). Like the Baldwin effect, genetic assimilation begins with an exposure to a novel environment that induces an adaptive response in virtue of preexisting but unexpressed plasticity, followed by selection. In the case of genetic assimilation, however, selection for this alternative phenotype necessarily results in a change in the regulation of the plasticity and this change is specifically in the direction of canalization, so that the alternative trait is expressed even if the environmental cue is no longer present (i.e., the reaction norm is flattened). In other words, plasticity has been lost (Pigliucci *et al.*, 2006).

Sometimes the phenotypic variation released by a novel environment is bolstered due to a history of stabilizing (or canalizing) selection. Indeed, canalized development – specifically, genetically canalized development – can lead to the buildup of unexpressed genetic variation because it is invisible to selection. A change in the environment might then release previously 'cryptic genetic variation,' exposing it as selectable phenotypic variation (Gibson and Dworkin, 2004; Le Rouzic and Carlborg, 2008; Paaby and Rockman, 2014; Palmer, 2012; Schlichting, 2008). This 'de-canalization' can occur when novel environmental conditions overwhelm or otherwise disrupt canalizing mechanisms during development – for example, through altered gene expression or changes in the activity of chaperone proteins (Hayden *et al.*, 2011; Iwasaki *et al.*, 2013; Queitsch *et al.*, 2002; Rohner *et al.*, 2013; Rutherford and Lindquist, 1998; Sangster *et al.*, 2008). This storage and subsequent release of cryptic genetic variation could potentially lead to rapid responses to selection where previously little additive genetic variation was observed (Le Rouzic and Carlborg, 2008; Paaby and Rockman, 2014). On the other hand, plasticity can also retard evolutionary change; if multiple genotypes can produce equally and highly adaptive phenotypes, then selection will be unable to distinguish among them and little or no evolutionary change will occur (Ghalambor *et al.*, 2007; Price *et al.*, 2003).

In addition to the microevolutionary effects already described, plasticity may also have macroevolutionary consequences (Pfennig *et al.*, 2010; Schlichting, 2004; West-Eberhard, 2003). By allowing populations to persist in different forms in alternative environments, plasticity may promote reproductive isolation and hence speciation. Plasticity may even foster adaptive radiation due the combined effects of population

persistence, genetic accommodation, and its role in speciation (West-Eberhard, 2005; Pfennig *et al.*, 2010). Whether we consider the micro- or macroevolutionary effects of plasticity, common to all of these processes is the fact that the environment has two interrelated roles: on the one hand it affects the expression of phenotypic variation, on the other it acts as the selective agent upon that variation. This interplay can lead to complex evolutionary dynamics (Wund, 2012).

Although hypotheses concerning the role played by plasticity in evolution remain controversial, a number of important books and reviews (e.g., Jablonka and Lamb, 2005; Pigliucci, 2001; Price *et al.*, 2003; Schlichting and Pigliucci, 1998; West-Eberhard, 2003) have spawned a renewed interest and motivation to evaluate them. A number of models demonstrate the capacity for plasticity to promote responses to selection (Behera and Nanjundiah, 2004; Chevin and Lande, 2011; Lande, 2009; Thibert-Plante and Hendry, 2011) and empirical evidence for this claim has been mounting quickly (reviewed in Schlichting and Wund, 2014). A role for genetic accommodation, for example, has been demonstrated in a number of instances: adaptation to novel predators (Scoville and Pfrender, 2010), the repeated colonization of freshwater by marine copepods (Lee *et al.*, 2011), and the evolution of eye reduction in cave fish (Rohner *et al.*, 2013). A recent study has even implicated genetic accommodation in the initial colonization of land by the ancestors of tetrapod vertebrates by examining the effects of terrestrialization on an extant analogue of stem tetrapods (Standen *et al.*, 2014). The release of cryptic genetic variation has also been demonstrated in several natural systems (Ledón-Rettig *et al.*, 2010; McGuigan *et al.*, 2011; Purchase and Moreau, 2012; Rohner *et al.*, 2013). With respect to impacts on macroevolutionary processes, plasticity has been implicated in originating novel traits (Ledón-Rettig *et al.*, 2008; Moczek *et al.*, 2011), promoting adaptive radiation (Pfennig and McGee, 2010; Wund *et al.*, 2008; Wund *et al.*, 2012) and facilitating speciation (Savolainen *et al.*, 2006).

Mechanisms of Plasticity

Our understanding of how adaptive developmental plasticity both evolves and affects the process of evolution will undoubtedly be informed by a deeper understanding of its genetic, epigenetic, and developmental basis. Although recent technological advances promise continued progress in this area, important insights can still be gained by applying classical techniques such as hormone manipulation and artificial selection (though see Zera, 2007). At least two species of the ant genus *Pheidole*, for example, possess a 'supersoldier' subcaste, which is induced by nutrition mediated by juvenile hormone. Application of a juvenile hormone analog, however, can induce supersoldiers in *Pheidole* species that do not normally produce supersoldiers, suggesting that an ancestral developmental potential for this plastic response was retained and this latent plasticity in turn facilitated parallel evolution of the subcaste (Rajakumar *et al.*, 2012).

Developmental investigations that follow artificial selection can also shed light on the mechanisms that underlie phenomena such the Baldwin effect and genetic assimilation. Suzuki and Nijhout (2006), for example, performed selection in two different lines, each starting with the same mutant stock of tobacco hornworms, which are normally black but become partially green as 5th instar larvae when heat shocked as 4th instars. In the green line, they selected for a greener color when heat shocked, while in the black line they selected for retention of the black color when heat shocked. In a control lineage they did not select after heat shock. After 13 generations, heat shocked larvae of the green line were completely green and heat shocked larvae of the black line were completely black. More interesting, however, were the resulting reaction norms. Rather than assimilating, the green line showed a stronger plastic response to increasing temperature in the form of a steeper, more polyphenic reaction norm relative to the unselected line. This constitutes evidence for the Baldwin effect and genetic accommodation in that phenotypes closer to the optimum were initially produced by a preexisting plastic response to a new environment (heat shock) and those variants (greener larvae) were then selected, with the result that even greener larvae were produced by modifying the plastic response through changes in the frequency of modifying alleles (Braendle and Flatt, 2006; Crispo, 2007; Suzuki and Nijhout, 2006). Here it is important to note that Suzuki and Nijhout did not select for increased plasticity per se; instead, increased plasticity resulted from selection in a single environment (i.e., 4th instar heat shock). In contrast, the black line showed a reaction norm that was both lower in elevation and environmentally canalized (i.e., flat), consistent with genetic assimilation if one takes the 'novel' environment to be the absence of 4th instar heat shock, assimilation having occurred after larvae remain completely black even in the presence of heat shock, where previously being black required the absence of heat shock (Crispo, 2007; Suzuki and Nijhout, 2006).

From a developmental perspective, the most interesting results came from follow-up experiments aimed at elucidating the mechanism of the genetic accommodation and assimilation. In the case of the green line, the more discrete response resulted from higher titers of juvenile hormone in response to heat, either through increased production or reduced degradation. In the case of the black line, the loss of plasticity appears to be due to reduced sensitivity to juvenile hormone under heat shock (Suzuki and Nijhout, 2006). It is important to emphasize that this loss of sensitivity occurs in 'response' to heat shock. Underlying this evolutionary 'loss' of outward phenotypic plasticity is thus an 'increase' in plasticity – in this case changes in hormone sensitivity in response to temperature – a theoretical possibility raised previously in a cautionary note about assuming too much about the nature of canalization (Frankino and Raff, 2004).

More recent advances in our ability to describe transcriptomes and the establishment of model systems for studying plasticity have fueled rapid progress toward understanding the details of alternate developmental trajectories and the nature of environmentally controlled developmental switches (*sensu* Stearns, 1989). In a number of polyphenisms, for example, transcriptomic approaches have identified differences in gene expression between morphs (e.g., Gallot *et al.*, 2012; Grozinger *et al.*, 2007; Wang *et al.*, 2014; Warren *et al.*, 2014), in some cases providing candidate genes that respond specifically to inducing cues (Colbourne *et al.*, 2011; Ishikawa

et al., 2012; Kijimoto *et al.*, 2014; Le Trionnaire *et al.*, 2012) or allowing comparisons with analogous genetic polymorphisms (Brisson *et al.*, 2007). Emerging model systems, particularly among insects (Simpson *et al.*, 2011; Whitman and Ananthakrishnan, 2009), have additionally allowed us to go beyond correlation and test the potential roles played by particular genes, pathways or hormones in generating plasticity. Examples include phenomena as diverse as the specification of caste in honeybees (Kucharski *et al.*, 2008; Li-Byarlay *et al.*, 2013; Patel *et al.*, 2007), horn polyphenism in beetles (Emlen *et al.*, 2012; Kijimoto *et al.*, 2012; Snell-Rood and Moczek, 2012), the wing polyphenism of planthoppers (Xu *et al.*, 2015), the wing and reproductive polyphenisms of the pea aphid (Brisson, 2010; Le Trionnaire *et al.*, 2008), and the phase polyphenism of locusts (Ernst *et al.*, 2015), to name just a few.

Increasingly, 'epigenetic' modifications of chromatin appear to play a key role in the mechanism of plasticity through effects on gene function. Cytosine methylation at CpG dinucleotides in particular is common yet variable among social bees, wasps and ants (Kronforst *et al.*, 2008), and the honeybee, pea aphid, and two locusts have been shown to possess functional DNA methylation systems (Walsh *et al.*, 2010; Wang *et al.*, 2006, 2014). The latter four species also possess an intriguing bimodal distribution of genes showing high versus low levels of CpG methylation (either inferred by the ratio of observed to expected CpG sites or examined directly) in contrast to the unimodal distribution found in other insects that do not exhibit polyphenism (Elango *et al.*, 2009; Falckenhayn *et al.*, 2013; Lyko *et al.*, 2010; Walsh *et al.*, 2010; Wang *et al.*, 2014). Some studies suggest that genes exhibiting caste- or morph-biased expression are hypomethylated, which may make sense if these CpG sites need to be available for *de novo* methylation, which in turn allows for the developmental specification or differentiation of castes or morphs (Elango *et al.*, 2009; Hunt *et al.*, 2010; Srinivasan and Brisson, 2012; though see Lyko *et al.*, 2010). This idea is consistent with the fact that interfering with *de novo* DNA methylation in the honeybee causes would-be workers instead to adopt a queen-like fate (Kucharski *et al.*, 2008).

Direct examination of the methylation status of cytosines by methylation-sensitive restriction enzymes or bisulfite sequencing additionally allows one to detect genes that are methylated differently in tissue from different morphs, as adults or during development (Bonasio *et al.*, 2012; Foret *et al.*, 2012; Lyko *et al.*, 2010; Wang *et al.*, 2014; Weiner *et al.*, 2013). In two species of ants with different degrees of caste polyphenism, the extent of differential methylation correlates with both the degree of caste differentiation in the two species, as well as the onset of caste differentiation during development (Bonasio *et al.*, 2012). Interestingly, this study, as well as another study of the brains of honeybee workers and queens, detected a correlation between CpG methylation and RNA splicing sites, raising the possibility that methylation could foster plasticity by regulating alternative splicing (Lyko *et al.*, 2010; Bonasio *et al.*, 2012). In support of this, interfering with *de novo* DNA methylation has been shown to alter patterns of exon skipping and intron retention in the honeybee (Li-Byarlay *et al.*, 2013) and phase-biased alternative splicing of 45 transcripts has been demonstrated in the migratory locust (Wang *et al.*, 2014). This work will undoubtedly continue to improve our understanding of how morph-biased epigenetic modifications, of both DNA and histones (e.g., Simola *et al.*, 2013), mediate the ability of the environment to shape the ontogeny of alternate phenotypes.

Future Directions and Implications

The role of developmental plasticity in phenotypic evolution continues to be an active area of investigation. Ongoing problems include establishing the relative importance of the various processes described above, asking in particular how common and important the release of cryptic genetic variation is in natural populations and whether adaptive evolution by genetic accommodation is the exception or the rule (Pfennig *et al.*, 2010; Schlichting and Wund, 2014). Answers to these questions in turn have important implications for human health and well-being as we increasingly expose ourselves to conditions well outside the range of our evolutionary history, opening the doors for a mismatch between historically adaptive environmentally cued phenotypes and actual environmental conditions (Bateson *et al.*, 2004; Gluckman *et al.*, 2011a, 2011b). Outdated 'nature versus nurture' debates are also being replaced by more nuanced understandings of the complex interactions among genetics, development, and the environment, and a recognition of how the environmental conditions experienced by one generation may affect disease susceptibility in the next (Gluckman *et al.*, 2007; Whitelaw and Whitelaw, 2008). As we learn more about these processes, as well as nongenetic systems of inheritance such as epigenetic inheritance and cultural transmission (Day and Bonduriansky, 2011; Jablonka and Lamb, 2005; Jablonka and Raz, 2009), some have argued that the Modern Evolutionary Synthesis requires an extension, one that moves us away from a strictly mutation-selection-response view of evolutionary change, if we are ever to grasp fully the complexity of phenotypic evolution (Jablonka and Lamb, 2005; Laland *et al.*, 2014; Moczek, 2012; Pigliucci, 2007; Pigliucci and Müller, 2010).

Directed Evolution, History of

MA Ulett, Duke University, Durham, NC, USA

Directed Evolution

Is evolution the consequence of environmental circumstances alone? Or do factors internal to the organism cause evolution to proceed in certain directions? For the past two centuries, biologists have sought answers to these related questions. Charles Darwin's theory of evolution by undirected variation and natural selection suggested little or no directionality to the evolutionary process. Given Darwin's popularity, many people might assume that theories of directed evolution are outdated, false theories of a bygone era. While some biologists over the past 150 years have argued that evolution is predominantly nondirectional, many evolutionists have articulated theories and research projects that describe evolution as directed of limited. These modern theories of directed evolution began in the work of Jean Baptiste Lamarck in the early nineteenth century, gained prominence as theories of 'orthogenesis' at the turn of the twentieth century, and continue today as a part of the field of evolutionary developmental biology. Throughout this long history, theorists postulated a wide range of innate tendencies, internal factors, evolutionary laws, and developmental mechanisms that could account for evolutionary directionality. And, while theories about the specific factors causing directed evolution have changed over time, broad trends and long-term outcomes of morphological evolution have dominated the explanatory goals and empirical studies of people explaining apparent trajectories in evolution.

The term 'directed evolution' arose in the late nineteenth century, though its core ideas existed earlier. Put simply, 'directed evolution' denotes evolution taking place along certain trajectories (that is, in particular directions) due to constraints on the production of new morphological features. Thus, theories of directed evolution describe the developing organism as limiting or constraining the outcomes of evolution in certain respects. During earlier periods of history, evolutionists focused on the directionality of or trajectories in evolution quite broadly. In the past few decades, however, they have begun to utilize developmental and genetic analysis to accurately explain evolutionary constraints.

Four points clarify the scientific meaning of the term 'directed evolution.' First, something or some condition in the natural world must cause evolutionary directionality. Put differently, theories of directed evolution do not explain directionality as an accidental, random occurrence. Second, evolution proceeding in a limited direction does not mean that it has an end-goal or ultimate purpose. Therefore, directed evolution is not necessarily teleological; directionality can stem merely from conditions or factors that constrain the course of evolution. Third, theories of theistic evolution – evolution guided by a supreme being – were predominantly directional in nature, yet the scientific community rejected them because theistic evolutionary ideas failed to generate testable hypotheses. Fourth, cultural notions of 'progress' have infused the language of directed evolution throughout history, especially in the nineteenth century. Even today, many people either state directly or imply that both human history and evolution are inherently progressive. Even still, the question of evolutionary directionality is a problem that has been, and continues to be, examined using rigorous scientific methods. Because of these various cultural influences on the idea of directed evolution, understanding the history of scientific theories of directed evolution requires investigating only theories based on scientific naturalism and rigorous empirical evidence.

Variation and Teleology

In *Philosophie Zoologique*, the French biologist Lamarck (1809) proposed an evolutionary explanation for all life on Earth, a central component of which was inherent directionality. While thinkers before him had argued that some species could change over time, Lamarck provided a clear theoretical foundation for how that process occurred. He based this theory on two fundamental principles. First, he argued that organisms become more complex or perfect over time, meaning they become better suited to their conditions of existence. Following in the footsteps of physicists like Isaac Newton, who sought fundamental laws of nature to explain natural phenomena, Lamarck contended that evolution toward perfection was one such law. He argued that new, simple organisms constantly arise spontaneously from inorganic matter, a process that supplies the Earth with the raw material of evolution; the oldest organisms (humans) are the most complex and perfectly adapted to the world. The second principle held that characters an organism acquired during its life would be passed on to future generations; this was known as the 'inheritance of acquired characters.' While the inheritance of acquired characters was not a new concept, Lamarck used the idea to explain evolutionary change over time at the broadest scale – the entire history of life on Earth – which was an unprecedented and ambitious application of the theory. Both of these fundamental features of Lamarck's theory – the principle of perfection and the inheritance of acquired characters – had a lasting and major influence on subsequent theories of evolution. Inherent in the first, however, was the fundamental notion that evolution was inherently directional and progressive.

Fifty years after Lamarck's book, Darwin (1859) published *On the Origin of Species*, which changed the landscape of evolutionary theory dramatically and called into question the inherent directionality of evolution. Importantly, Darwin's theory differed from its predecessors because he described variation as multifarious, or taking place in a wide number of directions. Even though Darwin did not view variation as completely random, his argument that variation was nondirected was an important conceptual move. Based on his understanding of variation, Darwin argued that evolutionary

change was primarily driven by differential survival and reproduction caused by the conditions of existence. In a sense, Darwin recast teleology in evolution as adaptation caused by selection, as opposed to evolution toward a predetermined goal or perfection. Even still, the language of progressive evolution – for example, 'advanced,' 'higher,' 'developed' – persisted throughout Darwin's work. Despite this, Darwin's theory of evolution by natural selection and multifarious variation became the theory against which proponents of directed evolution argued.

Orthogenesis and Nomogenesis

Even though support for the idea of evolution toward perfection waned in the mid to late nineteenth century, theories of evolutionary directionality gained considerable support. These ideas took shape under the name 'orthogenesis,' meaning evolution in specific directions due to limitations on the production of variation. The German biologist Wilhelm Haacke proposed the word 'orthogenesis' in 1893 based on the Greek term 'ortho' meaning 'in a line,' and 'genesis' meaning 'origin.' Like 'directed evolution,' the term 'orthogenesis' came to refer to both the phenomenon itself, of evolution in a particular direction, and the wide range of theories proposed by prominent biologists to account for this phenomenon. Haacke, for example, argued that the material of heredity was crystalline. New variation in nature would follow the crystalline pattern of the hereditary material, and only proceed in certain limited directions. The Swiss-German zoologist Theodor Eimer supported orthogenesis vocally, usually in opposition to the neo-Darwinian biologist August Weismann. Eimer (1890) argued that the developmental process – in which an organism transforms from an embryo into an adult – structures and limits the types of new features that can arise. Based on this idea that development limits variation, Eimer claimed that evolution is 'definitely directed,' because variation produces the raw material required for evolution. According to Eimer, because development produces variation only along limited trajectories, evolution can only proceed along the trajectories created in development. Like other supporters of directed evolution, such as Edward Drinker Cope, Henry Fairfield Osborn, and Othenio Abel, Eimer argued that orthogenesis could account for a wide range of empirical observations that followers of Darwin and Lamarck struggled to account for, such as patterns of directionality in the fossil record, overspecialization of parts, and patterns of variation.

The Soviet biogeographer and taxonomist Leo Berg developed a theory of evolution in the 1910s (see e.g., Berg, 1969) called 'nomogenesis,' or evolution according to law. Although not the most influential theory in the history of biology, Berg's nomogenesis nevertheless exemplified theories of directed evolution around this time in important ways. Much like Lamarck and Eimer before him, Berg argued that evolution proceeds in defined directions because evolution operates according to natural laws. He claimed that the origin and change of evolutionary variation were strongly constrained by morphological forms along certain trajectories. Berg argued against what he claimed to be the Darwinian ideas that variation was random and that evolution proceeded simply according to environmental circumstances. Strongly anti-Darwinian, Berg also criticized the idea of descent with modification, emphasizing evidence from the fossil record and studies of extant animals that showed evolution as fundamentally convergent, not divergent. Like Berg, many orthogenesists directly opposed the neo-Darwinian conception of multifarious variation and adaptation to local conditions as the primary mode of evolutionary change. While most did not deny outright the operation of natural selection as a cause of evolution, they focused instead on ideas and evidence that showed morphological evolution to be a highly ordered and constrained process, proceeding almost always in definite directions.

The Evolutionary Synthesis and Beyond

In the mid-twentieth century in Britain and the United States, biologists from a wide range of disciplines (zoology, paleontology, cytology, botany, etc.) rallied around the confluence of Mendelian genetics and Darwin's theory of natural selection. This modern evolutionary synthesis brought an intense focus on gradual, genetic changes or adaptations to local conditions, often at the level of populations of organisms; and, thus, support for orthogenesis waned. In Germany and elsewhere, however, directed evolution remained a vibrant part of evolutionary theorizing. The German paleontologist Otto Schindewolf used extensive evidence from paleontology to showcase directionality in the evolutionary history of life on earth. His theory to explain directed evolution, called 'typostrophism,' described evolution as a cyclical, three-part process. In each of these phases of evolution, Schindewolf discussed the evolution of entire taxonomic groups, related by a common ancestor (see e.g., Schindewolf and Reif, 1993). In the first phase, a group of species evolves rapidly into multiple different morphological forms, all based around a common architecture called a 'body plan.' In the second phase, the morphologically distinct organisms in the group evolve along similar lines – that is, directions – for a long period of time. Schindewolf argued that these trajectories result from internal factors or developmental processes that constrain organismal evolution. In the final phase of evolution, the entire group of species went into decline, with many or most going extinct due to maladaptive features. His theory nicely explained gigantism, overspecialization, evolutionary directionality, and mass extinction, highlighting sets of evidence that were difficult to account for in the modern evolutionary synthesis framework.

Evo Devo and Devo Evo

In the 1970s and 1980s, developmental, molecular, and evolutionary biologists, alongside paleontologists, focused on the question of how developmental and evolutionary phenomena are causally related. Modern theories of directed evolution emerged as one component of the complex and related interdisciplinary research programs today known as evolutionary developmental biology (evo devo) and developmental evolution (devo evo). These research areas built off of work like Gould's (1977) *Ontogeny and Phylogeny*, and that

of others who, like Gould, were dissatisfied with the explanatory sufficiency of the approach from the modern synthesis. An important workshop in Berlin in 1981, chaired by developmental biologist John Tyler Bonner, clarified two important considerations that have become central to modern attempts to understand the apparent directionality in evolution (see Alberch and Bonner, 1982). First, conference attendees argued that the ways in which genes regulate development is a major contributor to the trajectories and directionality in evolution. Second, the developmental process constrains the conditions under which selection can operate. These conceptual advancements resulted in a view of evolution as deeply constrained and contingent on development. Soon thereafter, in 1985, an important paper further articulated several foundational ideas concerning directed evolution, and defined 'developmental constraints' as 'a bias in the production of variant phenotypes or a limitation on phenotypic variability caused by the structure, character, composition, or dynamics of the developing system' (Maynard Smith *et al.*, 1985, p. 266). This definition specified features of the developmental process that could constrain or direct evolution, thereby identifying concrete causes of directionality in evolution. Furthermore, this article distinguished developmental constraints from constraints of history, physics, or selection. Set out in this way, the idea that the genetics and mechanisms of development guide and limit evolution became an important and coherent research project for future generations.

Throughout the 1980s and 1990s, investigators from various disciplines further studied the relationship between evolution and development. Evo devo tended to focus on the role of evolution in development, and devo evo emphasized ways that development influenced or constrained evolution. Both areas of research – with their associated theories and study of directed evolution – became important parts of the emerging trend toward interdisciplinarity in the biological sciences. Devo evo especially emphasized ways in which the regulation of gene activity in the developing organism structures and limits the production of new variation, and constrains evolution. The discovery of homeobox genes, which regulate the patterns of anatomical development, and studies showing the similarity of regulatory genes across all metazoans have dramatically shaped our understanding of the limits to morphological evolution. Through careful analysis of these deep genetic homologies, developmental geneticists and evolutionists have come to understand the networks of regulatory genes shared across all organisms with a common body plan.

Evolutionary Directionality

Theories explaining evolutionary directionality have persisted throughout the past two centuries of evolutionary thinking, beginning in the work of Lamarck and continuing today as a part of evo devo and devo evo. While the proposed cause of directionality has changed over time – from progress toward perfection and laws of evolution in the nineteenth century to gene regulatory networks and deep homology in the twentieth and twenty-first centuries – the theories of directed evolution represent an important part of the history of evolutionary theory. While early hypothesized causes of directed evolution were vague, or inconsistent with our modern understanding of developmental constraints, orthogenesists nevertheless asked a set of questions that biologists are still trying to answer today. Orthogenesists identified directionality as a real phenomenon and something worth investigating carefully. Throughout this history, the question of the explanatory relationship between directed evolution and natural selection based on environmental circumstances has arisen time and time again. While most orthogenesists viewed natural selection as operating in a limited capacity, they also positioned their ideas as explicitly against the neo-Darwinian view. Supporters of evo devo and devo evo argue for a much larger role for natural selection in evolutionary causation generally, though directionality caused by developmental constraints also features importantly in these subfields. Consequently, supporters of directed evolution today uphold developmental constraints and inherent limitations to phenotypic variation as one part of the complex set of factors causing evolutionary phenomena.

Glossary

Ancient DNA DNA obtained from fossils or museum specimens. It is usually very fragmented and contains chemical modifications that tend to accrue after the expiration of the individual.

Diffusion approximation A continuous approximation to a process that undergoes discrete changes in state over discrete periods of time. It is based on the assumption that only very small changes happen in any particular time step. In the case of the Wright–Fisher process, neutral drift may only cause very small allele frequency changes at a specific generation, so long as the population size is large. The diffusion approximation maps the discrete time and allele frequencies onto a continuous scale, which simplifies the mathematics of the system.

Identity-by-descent (IBD) Continuous stretches of DNA sequence that contain sites with the same allele, because they were all inherited from a common ancestor without being broken up by recombination. Long segments of IBD are a hallmark of recent selective sweeps.

Linkage disequilibrium Nonrandom association between alleles at different loci. It can be caused by low-local rates of recombination along a chromosome, specific forms of population structure and/or selection.

Introduction

Natural selection is the process by which particular traits become more or less abundant in a population, as a consequence of their effects on survival and reproduction. A major branch of population genetics involves the study of the genetic variants that code for beneficial or deleterious traits, and how those variants rise or fall in frequency throughout time.

A new variant that enters a population (e.g., by mutation) can be harmful, beneficial, or neutral. If it is harmful, then negative selection will act to remove it from the population because it causes a fitness disadvantage. If the variant is beneficial, then positive selection will act to increase its frequency in the population because it confers a fitness advantage. This increase in fitness may manifest itself, for example, through a larger number of viable offspring in those individuals that carry the mutation. A neutral variant (neither harmful nor beneficial) may also remain in the population for some time, and even reach fixation (become present in all individuals in the population), merely due to chance.

In this article, we will study natural selection and its effects on genetic variation. We will focus on the process of positive natural selection, because this can result in the appearance of new adaptive phenotypes. Two key questions in population genetics are how long it takes for a beneficial variant to fix in a population and what the probability of fixation is. In order to study these questions, biologists have historically modeled the frequency trajectory of neutral and beneficial alleles using the 'Wright–Fisher' model, which we will briefly explain below (see Ewens, 2004 for an extensive treatment of this model). Then, we will survey different types of selection in the context of linkage and recombination, including 'hard sweeps,' 'soft sweeps,' and 'adaptive introgression.' Finally, we will explain how particular signatures left by selection on the genome can help us detect selected genes, both in humans and other organisms. Whenever possible, we will attempt to illustrate theoretical ideas with concrete examples from the biological literature.

The Dynamics of Selection

To understand the dynamics of natural selection in a population, we will first begin by assuming this population is infinitely large. This abstraction allows us to ignore the stochastic sampling of alleles that occurs in each generation (see 'Genetic drift and the Wright–Fisher Model' below) and concentrate only on the effects of fitness differences on the composition of a population. Here, we will focus on viability selection, meaning selection operating on the ability of individuals to survive until they can reproduce rather than on their fertility. We will also restrict ourselves to the case of an additive locus. If A is the advantageous allele, that means that the relative fitnesses of the three possible genotypes, aa, Aa, and AA, are $w_{aa}=1$, $w_{Aa}=1+s$, and $w_{AA}=1+2s$, respectively. These relative fitnesses express the viabilities of each genotype, relative to the other two. Here, s is the selection coefficient, which determines how advantageous a particular genotype is, relative to the aa genotype.

Let us see what happens in one generation of selection favoring the A allele. Suppose the allele frequencies in the parents are f_A and f_a, that the size of the population remains constant across generations, and that parents mate at random. In that case, the frequency of offspring containing each of the three genotypes in the next generation will be in Hardy–Weinberg equilibrium: $f_{aa}=f_a^2$, $f_{Aa}=2f_Af_a$, and $f_{AA}=f_A^2$. However, not all of these offspring survive to adulthood, as selection will remove some individuals before they get to successfully reproduce. In fact, the three types of zygotes will eventually reproduce in the ratio $w_{aa}:w_{Aa}:w_{AA}$. Therefore, the

 doi:10.1016/B978-0-12-800049-6.00028-7

ratio of reproducing adults will be $f_a^2 w_{aa}$: $2f_A f_a w_{Aa}$: $f_A^2 w_{AA}$. We can transform each of these terms into relative frequencies by dividing by their sum, which yields that:

$$f'_{aa} = f_a^2 w_{aa}/w_{\text{sum}}$$
$$f'_{Aa} = 2f_A f_a w_{Aa}/w_{\text{sum}}$$
$$f'_{AA} = f_A^2 w_{AA}/w_{\text{sum}}$$

where

$$w_{\text{sum}} = f_a^2 w_{aa} + 2f_A f_a w_{Aa} + f_A^2 w_A$$

To obtain the allele frequencies in this new generation, we need to account for the number of copies of each allele in each genotype:

$$f'_a = f'_{aa} + (1/2)f'_{Aa} = (f_a^2 w_{aa} + f_A f_a w_{Aa})/w_{\text{sum}}$$
$$f'_A = f'_{AA} + (1/2)f'_{Aa} = (f_A^2 w_{AA} + f_A f_a w_{Aa})/w_{\text{sum}}$$

Finally, we can quantify the net change in allele frequencies in a generation by taking the difference between the allele frequencies in the new and the old generations:

$$\Delta f_A = f'_A - f_A = f_A f_a [f_A(w_{AA} - w_{Aa}) + f_a(w_{Aa} - w_{aa})]/w_{\text{sum}}$$

We can also express this difference in terms of the selection coefficient:

$$\Delta f_A = f_A f_a s/(1 + 2f_A s)$$

Thus, we see that if the selection coefficient is positive, the frequency differential will also be positive and the allele frequency of the A allele will increase. Furthermore, the most rapid change will occur at intermediate frequencies, when $f_A f_a$ is largest.

If a new advantageous allele appears in an infinite population, it is guaranteed to rise to high frequencies, but it will only asymptotically reach fixation, as the population is infinite. The speed at which it reaches asymptotic fixation will not only depend on the selection strength, but also on the dominance relationship between the two alleles (Figure 1). While we have focused above on an additive case, it is also possible that the advantageous allele could be dominant or recessive

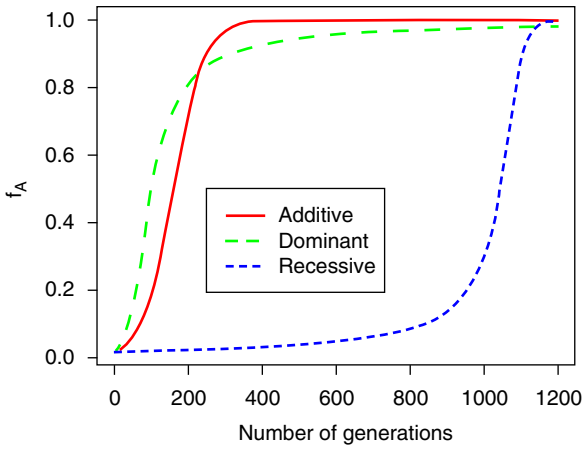

Figure 1 The change in the frequency of an advantageous allele when it is additive, dominant or recessive. Here the selection difference between *aa* and *AA* is 5%.

(Figure 1). For further details about the dynamics of selection, we refer the reader to more extensive treatments of this topic in Crow and Kimura (1970), Hartl and Clark (1997), and Nielsen and Slatkin (2013).

The Interplay between Selection and Drift

Evolution in finite populations is stochastic. At each generation, individuals undergo meiosis, and only a proportion of the gametes make it to the next generation. Additionally, not all individual zygotes survive to adulthood and reproduce. While a selective advantage may influence which genes are passed on to the next generation, there is always some probability that even nonselected genes rise in frequency, just by chance. This stochastic effect on allele frequencies is known as 'genetic drift.' We have gotten away with ignoring drift so far, because we assumed our population was almost infinitely large, but we will now turn to studying it in detail, as well as its effect on selection.

One way to analyze the frequency changes of a mutation due to drift is by means of the Wright–Fisher model (Figure 2). This model assumes that a population of individuals has a constant size N and is randomly mating; furthermore, it assumes that generations do not overlap. At each locus, only two alleles exist. We can visualize this model by imagining that we put all the alleles at a particular locus into a bag. Then, the frequency of an allele will be the number of copies of that allele divided by $2N$ because each individual has two chromosomes. In a two-allele model, the frequency of the two alleles will always add to one, so we need only track the frequency of one allele over time (Figure 2). At the next generation, we sample 'with replacement' from the bag of alleles from generation t in order to create a new generation of N individuals. The allele frequencies may increase or decrease, depending on how many individuals inherit each allele at generation $t+1$. One can show that the probability of eventual fixation for a new neutral mutation is $1/(2N)$. Conversely, the probability of its eventual extinction (removal from the population) is $1 - 1/(2N)$.

When we introduce selection into the Wright–Fisher model, the probability of fixation not only depends on the size of the population, but also on the strength of selection. If there is no mutation, either one of the two alleles at the site will eventually reach complete fixation, while the other will go extinct forever. However, the selected allele is not guaranteed to be the fixed allele. Kimura (1957) used a diffusion approximation to derive the probability of eventual fixation of A in an additive selection model, when the current frequency of A is p and the selection coefficients for the three possible genotypes (AA, Aa, and aa) are defined as in the previous section. He obtained the following equation:

$$p[A \text{ fixes}] = (1-\exp(-4Nsp))/(1-\exp(-4Ns))$$

This function is plotted in Figures 3(a) and 3(b), for different s and p. We see that, as we would expect, the fixation probability increases as the selection strength increases and also strongly depends on the current frequency of the allele. Even with a relatively high selection strength, newly arising alleles ($p=1/(2N)$) have a very low chance of fixation as they are much more likely to be lost by stochastic fluctuations.

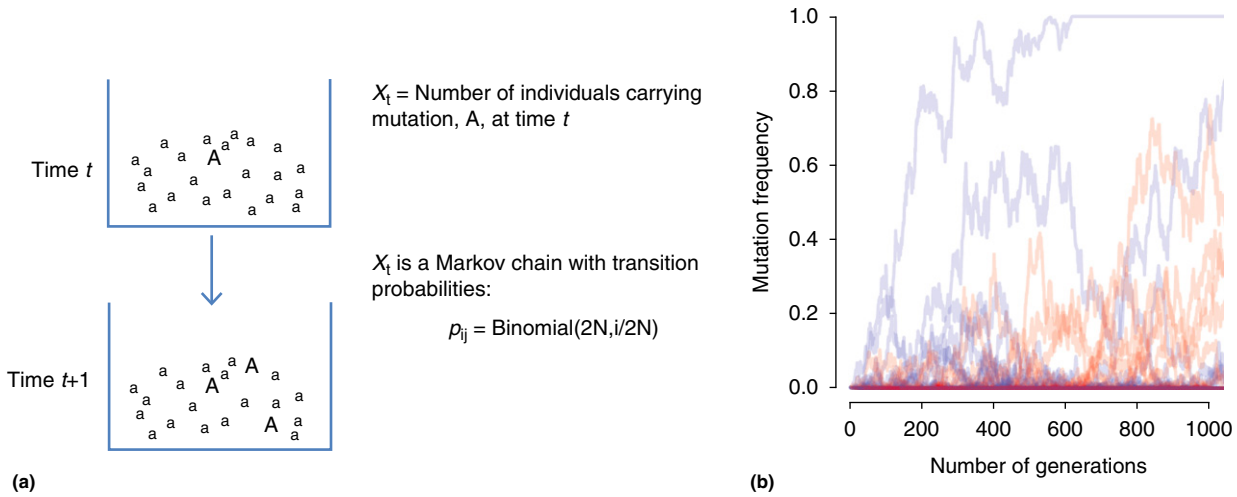

Figure 2 The Wright–Fisher model. (a) Schematic illustrating the Wright–Fisher model as random sampling with replacement from a population of alleles at time t to create the population at time $t+1$. X_t is a random variable defined as the number of chromosomes carrying the mutation A at time t. We use the Wright–Fisher model to simulate allele frequencies over time. (b) Example trajectories of a neutral Wright–Fisher model, the y-axis is the frequency of the allele in the population; the x-axis is time in generations. 2000 mutations were simulated, starting with one allele in the population, and were spaced uniformly in the time interval from 1 to 1000 generations, approximately two mutations per generation. The population size N is 500. We show example trajectories, evolving through 1000 generations. Notice that most mutations that arise over time are later lost from the population.

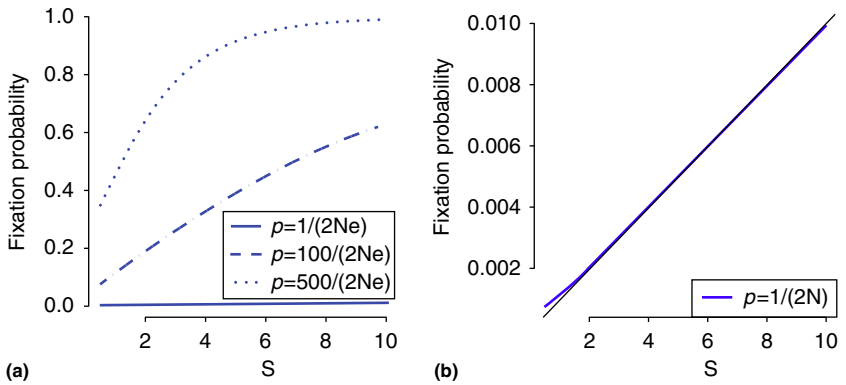

Figure 3 Fixation probabilities: Theoretical results from the diffusion approximation of the Wright–Fisher model. The panels are the probabilities of fixation as a function of the selection strength, $S=2Ns$, for different initial frequencies p. On the right is a zoom-in of the solid curve where $p=1/(2N)$, and the overlaid black line is the approximation $2s=S/N$, discussed in the text when $S\gg1$. The leftmost point on the curve of the zoom-in is $S=0.5$ and fixation probability $=0.0008$, the 'weakly advantageous' regime discussed in the text. By comparison, the neutral fixation probability is $1/(2N)=0.0005$. These functions can be obtained from formulas derived by Kimura and Ohta (1969), using a diffusion approximation to the Wright–Fisher model.

There is an approximation we can make for the case of a newly arising mutant A in a population made up entirely of a (i.e., when $p=1/(2N)$). If selection acts in favor of A ($s>0$) and $2Ns$ is much larger than 1, an allele will have a higher probability of fixation than under neutrality. In that case, the denominator will be approximately one, while the numerator will approximately equal $2s$, and so the probability that A eventually fixes will be close to $2s$ (**Figures 3(b)** and **4(a)**). When this occurs, we say that A is 'strongly advantageous.' However, in the case where the population or the selection coefficient are small (in particular, when $0<2Ns<=1$), then the probability of fixation will be only slightly larger than the neutral fixation probability ($1/(2N)$) (**Figure 3(b)**, right panel and **Figure 4(b)**) and we say that A is 'weakly advantageous.' An important determinant of whether a new mutant allele fixes in a population is whether it can make it past the initial low frequencies at which stochastic sampling (due to a low copy number) makes it highly probable that the allele goes extinct merely by chance, even when advantageous. For example, **Figure 4(d)** shows that the proportion of alleles that eventually go extinct is high, even when selection is strong ($s=0.1$) and the population is fairly large ($N=200$).

The time of fixation differs under the two regimes of weak and strong selection. When selection is strong and the population size is large, this time is approximately equal to the theoretical time at which an allele would get close to fixation in an infinitely sized population, where genetic drift does not affect the trajectory at all (**Figure 4(a)**). However, when the

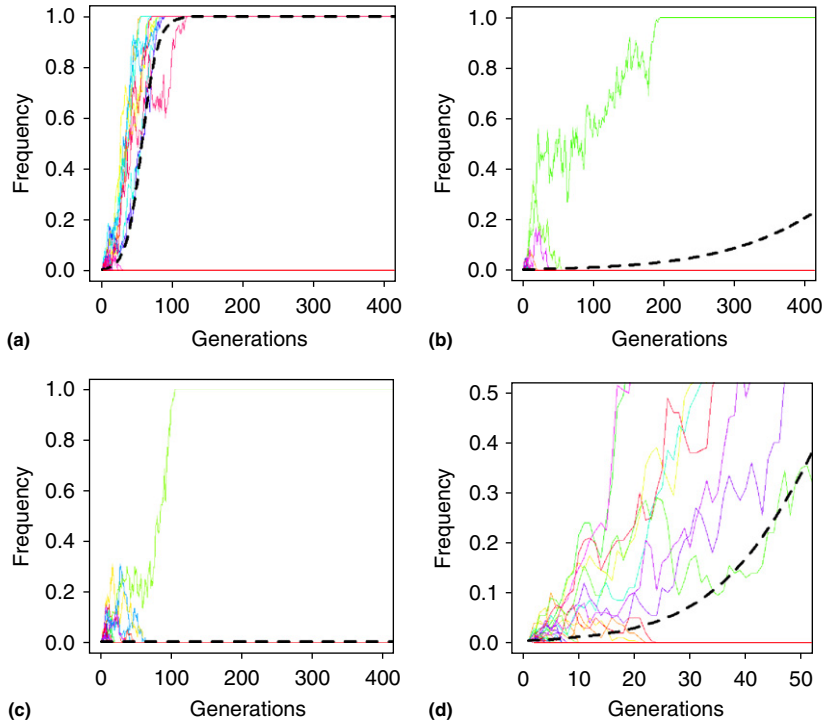

Figure 4 Examples of frequency trajectories of a newly arisen allele in finite populations. In each panel, we simulated 200 populations with size $2N=200$, and plotted the frequency trajectory of a new allele in each population. We also plotted the deterministic trajectory of an allele in an infinitely large population, where drift plays no role, and so there are no stochastic forces in the population (black dashed line). (a) Strongly advantageous allele ($s=0.1$). (b) Weakly advantageous allele ($s=0.01$). (c) Neutral allele ($s=0$). (d) Even under strong selection ($s=0.1$), alleles that fail to rapidly reach intermediate frequencies will likely go extinct.

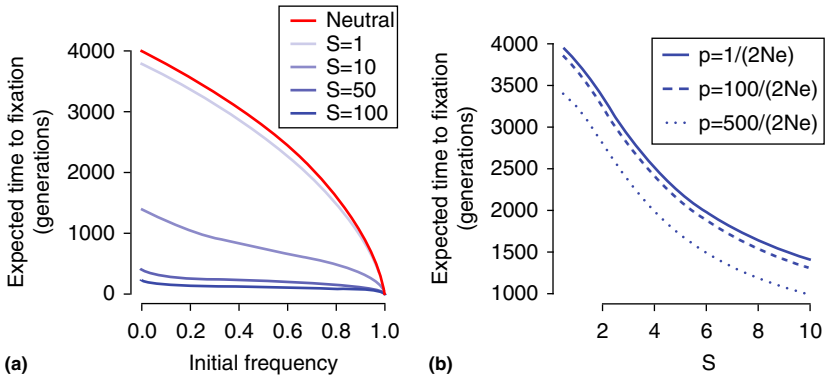

Figure 5 Expected time to fixation. Theoretical results from the diffusion approximation of the Wright–Fisher model. The panels are the predicted mean time to fixation of an allele, assuming a population size, N, of 1000. On the top left is the expected time is plotted as a function of the initial frequency. Curves are plotted for different scaled selection strengths, $S=2Ns$. The red curve is the neutral model prediction ($S=0$). The expected fixation time decreases as the selection strength increases or the initial frequency increases. The panel on the right is the same function plotted as a function of selection strength S, for three different initial frequencies, p.

population size is small relative to the selection coefficient, genetic drift will be a major determinant of the allele trajectory. In the few occasions in which the allele may manage to reach intermediate frequencies, genetic drift will contribute to push the allele to fixation faster. This will happen approximately at the speed at which neutral alleles fix, which is $2N$ generations (Figures 4(b) and 4(c)). In Figures 5(a) and 5(b), we plot the expected time to fixation of an allele under different selection regimes, as a function of the current frequency of the allele (left panel) and the selection strength (right panel).

Genetic Hitchhiking and Selective Sweeps

An additional assumption that we have been making for the Wright–Fisher model is that loci are independent and exist in

Figure 6 Different ways in which a beneficial mutation and its linked neutral variants may rise in frequency in a population. Each of the rectangles is a chromosomal segment that may undergo recombination. The green stars denote linked neutral variants, while the red, blue, and purple stars denote beneficial variants.

isolation, with each one changing frequency independently each generation. In reality, genes exist within chromosomes, and only over time will recombination uncouple allele frequencies between different sites. This creates an additional layer of complexity, but, as we will see later on, it also provides another way to detect positive selection along the genome.

Let us again imagine a new strongly beneficial allele that appears in a population for the first time. This time, however, we will keep in mind that the mutant sits on a chromosome with other genes that may have different alleles in different individuals (Figure 6(a)). As the allele rises in frequency, it also carries along with it the neutral variants that are physically linked to it in the same chromosome. At the same time, recombination works to break apart the chromosomes. If the selected allele rises in frequency fast enough, recombination may not have enough time to randomly shuffle the neutral alleles in the local neighborhood of the selected variant. Thus, the set of neutral variants that were originally linked to the beneficial mutant – its original 'haplotype' – will 'hitchhike' along with it (Maynard Smith and Haigh, 1974), replacing

other haplotypes that do not carry the mutant. This phenomenon will produce a recognizable footprint in the distribution of haplotypes in the population (**Figure 6(a)**) and is called a 'selective sweep.'

New Models: Soft Sweeps, Polygenic Selection, and Adaptive Introgression

While selective sweeps from new mutations (also called 'hard sweeps') are somewhat easy to detect (see section below) and appear to be prevalent in fruit flies (Sattath *et al.*, 2011) only a few examples of this phenomenon have so far been found in humans (Barreiro *et al.*, 2008; Pickrell *et al.*, 2009; Hernandez *et al.*, 2011, but see Enard *et al.*, 2014). This has prompted theoreticians to come up with alternative models by which positive selection may act, and to understand how they shape patterns of variation at linked variants (Hermisson and Pennings, 2005; Pritchard *et al.*, 2010; Messer, 2013; Messer and Petrov, 2013).

One of these models is called a 'partial sweep' and posits that sometimes a beneficial allele may not completely fix in the population, but remain at intermediate frequencies (Coop and Ralph, 2012; Voight *et al.*, 2006; Pritchard *et al.*, 2010; **Figure 6(b)**). Another model is called a 'soft sweep from standing variation' and posits that sometimes selection may not immediately act on a beneficial variant, which will therefore drift neutrally (or possibly subject to negative selection) for some time. Once the allele begins to be beneficial and rise in frequency, different copies of it will be linked to different alleles at nearby genes. This will generate a different pattern than the one observed during or after a selective sweep (Orr *et al.*, 2001; Hermisson and Pennings, 2005; **Figure 6(c)**). Additionally, if the mutation rate is high, different copies of the beneficial allele may arise in different haplotype backgrounds, before any particular copy has had a chance to fix. Selection may jointly favor these multiple copies, and so the distribution of haplotypes after selection may not look as uniform as in the case of a hard sweep. This is called a 'soft sweep from *de novo* mutation' (Pennings *et al.*, 2006a,b; Messer, 2013; Messer and Petrov, 2013; **Figure 6(d)**). Finally, the model of 'polygenic adaptation' posits that selection for a trait may act by subtly increasing the frequencies of alleles in different genes in coordination (Barton, 2000; Pritchard *et al.*, 2010; Berg *et al.*, 2014). In this case, no single locus may show a strong signature of a sweep (**Figure 6(e)**).

In recent years, there has also been increasing evidence in favor of selection acting by means of 'adaptive introgression' (Hedrick *et al.*, 2013; Racimo *et al.*, 2015). In this scenario, an advantageous mutation is passed on, via interbreeding, from one population or species to another, and afterwards is pushed to high frequencies by selection in the recipient population (**Figure 6(f)**). A striking example is the gene *EPAS1*, which is involved in the human response to hypoxia at high altitudes. A particular haplotype of this gene is uniquely found at an elevated frequency in Tibetans, while almost absent everywhere else in the world (Yi *et al.*, 2010; Huerta-Sanchez *et al.*, 2014). Moreover, the Tibetan haplotype is extremely different from other present-day human variants of the gene. Using ancient DNA sequences obtained from human fossil remains (Meyer *et al.*, 2012), Huerta-Sánchez *et al.* (2014) recently found that the haplotype is closest to the Denisovans, an extinct group of hominins that likely interbred with the ancestors of Tibetans.

Tests of Selection on Real Data

The Site-Frequency Spectrum

When studying natural populations, researchers often take the counts of all polymorphisms segregating in the population at a particular allele frequency, and build a histogram (**Figure 7**). This histogram is called the site-frequency spectrum (SFS). Under neutrality, if one assumes an infinite sites model of mutation (where each mutation creates a new biallelic site never before seen in the population), the expected number of polymorphic sites where the derived allele appears in i out of n chromosomes sampled is equal to θ/i. Here, $\theta = 4Nu$ is the per generation mutation rate (u) scaled by the population size (Fu, 1995). Departures from this expectation can be useful to infer both demography and selection.

Computing the SFS in a particular genomic region is a powerful tool for detecting departures from neutrality. However, the mutation rate parameter θ is often unknown, and so in practice the SFS is usually calculated from data as the proportion of polymorphic sites with a particular allele frequency, rather than the absolute number of such sites.

Figure 7 shows a schematic plot of an SFS for a sample of size 20 (10 diploid individuals) for a set of neutral mutations (in gray), a set of positively selected mutations (in red), a set of negatively selected mutations (in blue) and a set of neutral mutations subject to a selective sweep (in orange). Mutations that are positively selected tend to reach high frequencies more often than do neutral mutations. In contrast, negative selection pushes mutations toward low frequencies. Consequently, in the negative selection scenario, we see relatively more rare mutations and a deficit of high-frequency mutations compared to the neutral case. Finally, during a selective sweep, mutations that are near a selected site will hitchhike to high frequency if they are initially linked to the beneficial variant, while those that are not linked to it will be pushed to low frequencies. In this last case, we will see an excess of both low-frequency and high-frequency variants, relative to the neutral scenario.

There are two ways that the SFS can be used to study selection in real data. In one case, the SFS is computed over all sites that are putatively under selection in the genome. For instance, Boyko *et al.* (2008) examined the SFS of non-synonymous mutations in humans, which are putatively subject to both negative and positive selection. They then used population genetic theory to obtain estimates of the distribution of selection coefficients that would be consistent with the observed SFS in coding regions. Using the extensive functional genomics annotations available for humans, Racimo and Schraiber (2014) extended this work to estimate the distribution of negative selection coefficients genome-wide. This distribution can be informative to researchers interested in understanding the prevalence and intensity of selection throughout the genome.

Another advantage of the SFS is that it is useful for detecting particular regions of the genome that have recently experienced selection. In particular, the SFS can be used to look for the signature that the hitchhiking effect leaves on

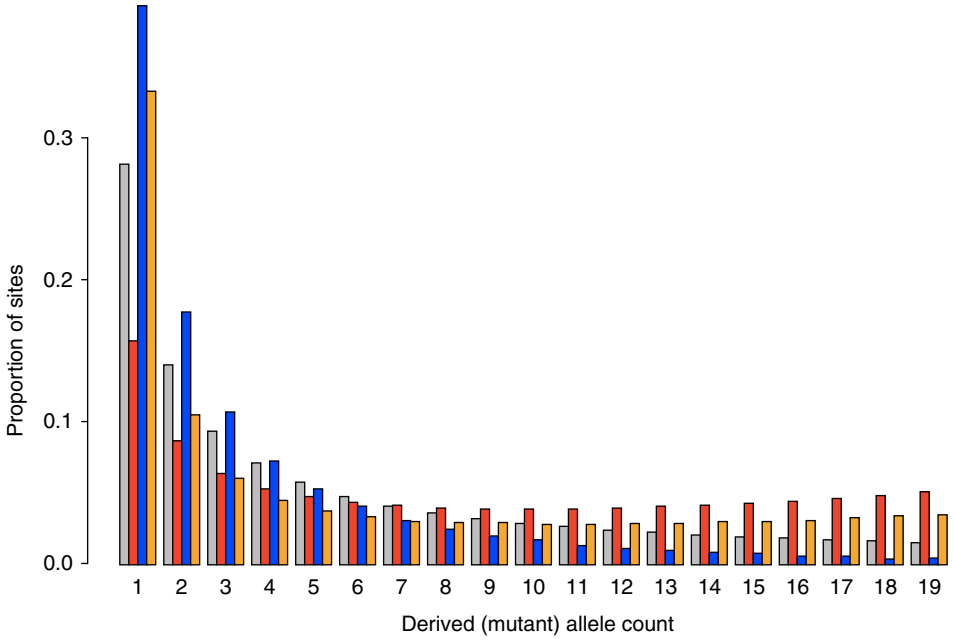

Figure 7 Representative site-frequency spectra (SFS) for a sample of size 20, under different selection regimes. The gray bars are a neutral SFS, the red bars are an SFS for positively selected sites, the blue bars are an SFS for negatively selected sites, and the orange bars are an SFS for sites that are affected by selective sweeps. The general shapes of the spectra are based on a figure from Nielsen, R., Williamson, S., Kim, Y., *et al.*, 2005. Genomic scans for selective sweeps using SNP data. Genome Research 15, 1566–1575.

neutral variation. In most cases, some test statistic summarizing the SFS is computed in sliding windows along the genome, and extreme departures from the neutral expectation of this statistic are used to identify regions under selection. The quintessential summary statistic of the SFS is Tajima's D (Tajima, 1989). Tajima's D compares two estimates of θ that are derived from the SFS: $\hat{\Theta}_\pi$ and $\hat{\Theta}_W$. Both are weighted averages over entries in the SFS, but $\hat{\Theta}_\pi$ gives more weight to middle frequencies, whereas $\hat{\Theta}_W$ weights all frequencies equally. Hence, Tajima (1989) defined a statistic called 'D,' which is proportional to $\hat{\Theta}_\pi - \hat{\Theta}_W$; under neutrality, $\hat{\Theta}_\pi$ should be equal to $\hat{\Theta}_W$, making Tajima's D equal to 0. A positive value of D indicates an excess of middle frequency alleles while a negative value of D indicates a deficit of middle frequency alleles.

A selective sweep will result in a negative value of this statistic. This is because alleles that are linked to the selected site will be dragged to high frequency along with the selected site, while alleles that are not linked to the selected site will be pushed to low frequencies. Hence, there will be a deficit of middle frequency alleles, resulting in a negative value of *D*. Unfortunately, historical demographic events, including bottlenecks, can also produce a negative value of *D*. Thus, to determine if the SFS in a region is actually shaped by hitchhiking, as opposed to other demographic forces, it is important to perform simulations under a demographic model that recapitulates the recent history of the species under study.

Haplotype Lengths

In addition to shaping the local SFS, genetic hitchhiking will cause patterns of haplotype sharing that are unexpected under neutrality. In particular, because a strong selective sweep occurs rapidly relative to neutral dynamics, there is less time for recombination to disrupt the haplotype upon which the selected site arose. Thus, haplotypes surrounding selected sites that recently fixed will be on average longer than haplotypes arising due to neutrality. In other words, the scale of linkage disequilibrium surrounding a recent selective sweep will be much larger.

Several test statistics exist to test for unusually long, high-frequency haplotypes. Among the first to be introduced was the Extended Haplotype Homozygosity (EHH) statistic (Sabeti *et al.*, 2002). Sabeti *et al.* (2002) applied EHH to genetic data from regions encompassing two genes thought to confer malaria resistance in humans: *G6PD* and *CD40L*. In both cases, they found that EHH was significantly higher than expected under neutrality. In later work, Bersaglieri *et al.* (2004) used EHH to show that lactase persistence was shaped by strong positive selection in some populations.

Because EHH was originally applied only to small regions, it did not provide a single test statistic that could be applied in a genome-wide scan. To remedy this problem, Voight *et al.* (2006) developed the integrated Haplotype Homozygosity (iHH) score. Roughly, iHH is expected to be higher in regions that underwent recent strong selection, because it captures the signal of higher identity-by-descent that is expected to be observed in a sample of selected haplotypes, but not in a sample of haplotypes evolving neutrally. Using iHH, Voight *et al.* (2006) found evidence of natural selection at several loci in humans, including *LCT*. This gene codes for the lactase enzyme and is thought to have allowed particular populations of humans to be able to digest milk as adults. This ability is hypothesized to have been especially advantageous during the origins of agriculture.

Population Differentiation

In many cases, selection acts as a response to a local environmental stress. In these cases, looking at patterns of population differentiation along the genome can serve to detect regions that experienced recent positive selection. Because positive selection can drive alleles to high frequency much faster than under neutrality, many approaches rely on looking for unusual differences in allele frequencies among populations. These methods are often fundamentally based on Wright's fixation index, F_{ST}. As commonly applied to genomic data, F_{ST} is calculated as the difference in heterozygosity (the proportion of sites that are heterozygous) as measured between and within populations, normalized by the between population heterozygosity. High values of F_{ST} indicate that there are substantial allele frequencies differences between populations, while low values indicate that the populations are close to randomly mating, as if they were a single population. By searching for genomic regions with particularly high F_{ST} relative to the genome-wide background, it is possible to find candidate regions of local adaptation between populations.

In a large-scale study, Coop *et al.* (2009) applied this approach to human genomic data. They found three common patterns of geographic differentiation: non-African sweeps (e.g., the *KITLG* variant conferring lighter skin color, which is at near fixation in all non-African populations), West Eurasian sweeps (e.g., the *SLC24A5* variant conferring lighter skin color, which is at high frequency only in west Eurasians), and East Asian sweeps (e.g., a variant of the *MC1R* gene of unknown consequence, which differentiates the Han Chinese from the French and Yoruba populations). Based on the prevalence of these patterns, they concluded that humans experienced novel selective pressures after expanding out of Africa.

When computed between two populations, F_{ST} alone cannot directly reveal which of the populations was the one that experienced selection. However, it is possible to leverage information from triplets of populations to determine this. This approach was used by Yi *et al.* (2010) to define the population branch statistic (PBS). Using PBS, they found evidence of recent, strong selection in the *EPAS1* locus in Tibetans when compared to the Han Chinese, while using a Danish population as a third outgroup. The selected variant of the gene is thought to confer an adaptation to high altitudes to Tibetans, making them less likely to suffer from hypoxia in their native mountainous environment.

Allele Frequency Time Series

All previously discussed methods of detecting selection explore patterns of variation in extant populations to infer the past action of selection. With the advent of high throughput sequencing, ancient DNA (aDNA) has made it possible to assay historical allele frequencies to look directly at selection in action. Using the theoretical framework of Bollback *et al.* (2008), Ludwig *et al.* (2009) found direct evidence that loci influencing coat color in horses evolved under natural selection, and estimated selection coefficients. More recently, using ancient DNA from several archeological sites in Europe, Mathieson *et al.* (2015) showed that several loci were subject to strong natural selection in Europeans, although most of the genome showed patterns of allele frequency changes consistent with neutral processes.

Conclusion

Evolution routinely carves seemingly designed adaptations out of the random starting material provided by mutation. Using mathematical models, it is possible to understand the dynamics and timescales of natural selection, as well as to look for its signature in genetic data. One of the most important lessons from the study of selection in finite populations is that even strongly beneficial alleles will frequently be lost very quickly. However, alleles that manage to survive their initial genetic drift at low frequency will rise to fixation by natural selection, leaving characteristic signatures of genetic variation within and between populations.

By examining the patterns of variation left by selectively favored alleles, we can elucidate the processes by which organisms adapt to their environment. Strongly selected, *de novo* mutations will drive one large haplotype to fixation. The signature of such mutants should be easy to detect in data on the basis of linked allele frequencies or haplotype lengths. On the other hand, other modes of adaptation, including soft and partial sweeps, will leave more diffuse, difficult to recognize signatures in the data. Nonetheless, new tools and models, including access to ancient DNA, may allow us to characterize the prevalence of each mode of adaptation in different species.

Dispersal Biogeography

JM Waters, University of Otago, Dunedin, New Zealand
CI Fraser, Australian National University, Canberra, ACT, Australia

Glossary

Colonization The biological process by which dispersing species become established in new areas.
Dispersal The movement of an individual away from its place of birth.
Dispersal biogeography An explanation for the geographical distribution of organisms based on processes of dispersal.
Invasion The expansion of a species into a new area.
Last glacial maximum (LGM) The time during the last glacial period when ice sheets were most extensive, roughly twenty thousand years ago.
Oceanic island An island that does not sit on continental shelf, typically volcanic in origin.
Phylogeography The study of geographic distributions of genetic lineages and processes that shape them.
Rafting The dispersal of organisms as, or in association with, floating material.
Refugia Geographical areas in which populations of glacially impacted organisms persisted during glacial periods.
Vicariance A biologically passive explanation for the geographical distribution of organisms, typically invoking geological processes.

Dispersal Biogeography

There are numerous factors potentially promoting organismal dispersal, including the avoidance of environmental change (Levin *et al.*, 1984) and opportunities for genetic diversification (Hamilton and May, 1977). Dispersal has been recognized as a key process underpinning biological distributions since the nineteenth century, when natural historians such as Darwin and Wallace proposed that many widespread species had likely dispersed long distances from regions of origin. These researchers also recognized that overwater dispersal events have played a particularly important role in establishing distinctive oceanic island biotas (Darwin, 1845, 1872; Wallace, 1876). Their proposed examples of dispersal included the suggested African origin for humans (Darwin, 1871) and circumpolar dispersal of southern freshwater fishes (Darwin, 1872; McDowall, 1970, 1978) – hypotheses subsequently corroborated by molecular evidence (Burridge *et al.*, 2012; Cann *et al.*, 1987). Indeed, human history provides many excellent examples of long-distance dispersal, even on recent timescales (Oppenheimer, 2012).

The acceptance of plate tectonic theory in the latter half of the twentieth century provided potential vicariant (nonbiological) explanations for many biological distributions. While there are indeed numerous cases in which biologically passive earth-history processes (rather than dispersal) have apparently led to biogeographic isolation of particular taxa (e.g., Burridge *et al.*, 2006; Knowlton and Weigt, 1998; Riddle *et al.*, 2000; Sanmartin and Ronquist, 2004), this focus on geological processes seemingly led some biogeographers to an extreme view of vicariance as the sole permissible explanation for biological distributions (Craw *et al.*, 1999; Croizat *et al.*, 1974; Nelson, 1974; Nelson and Platnick, 1981).

Over the last three decades, the incorporation of molecular data, along with a range of new technological and analytical approaches, have enhanced understanding of genealogical relationships among organisms, populations, and species, and have enabled dispersal events to be characterized. In particular, these studies have strengthened scientific understanding of biological dispersal processes and their role in promoting population connectivity and range expansion (de Queiroz, 2005; Gillespie *et al.*, 2012; Hewitt, 2000; Yoder and Nowak, 2006). Here we review evidence for biological dispersal and highlight key areas of dispersal research.

Dispersal as a Predictable Process: Evidence from Life History, Ecology, Biogeography, and Genetics

Although some early biogeographers dismissed dispersal as an untestable and therefore unimportant phenomenon (e.g., Croizat *et al.*, 1974; Platnick and Nelson, 1978), others recognized that, despite the difficulty in demonstrating its occurrence, it was surely a critical driver of many species' distributions (Carlquist, 1981). Today there is increasing recognition that dispersal is an important evolutionary biogeographic process that is often highly predictable based on ecological, life history, and abiotic data (Gillespie *et al.*, 2012). Indeed, over recent decades, population-genetic studies have provided compelling evidence of the key role of dispersal as a process that connects isolated populations and facilitates range expansion. Comparative studies and meta-analyses have repeatedly demonstrated that life history and ecology are strong predictors of gene flow between populations, with dispersive taxa typically showing low genetic structure relative to nondispersive taxa (Allibone and Wallis, 1993; Bohonak, 1999; Govindaraju, 1988; Nikula *et al.*, 2011; Ward *et al.*, 1994; but see Waters *et al.*, 2013). Additionally, taxa capable of long-distance dispersal (e.g., flighted insects, diadromous fishes, rafting invertebrates) often have substantially broader geographic ranges than those with more limited dispersal ability (e.g., flightless insects, freshwater-limited fishes, nonrafting invertebrates) (e.g., Beck and Kitching, 2007; Donald *et al.*, 2005; Fraser *et al.*, 2010; Lester *et al.*, 2007; McCulloch *et al.*, 2010; McDowall, 2002; Rundle *et al.*, 2002). Ecologically linked taxa, such as host–parasite and substrate–epifauna

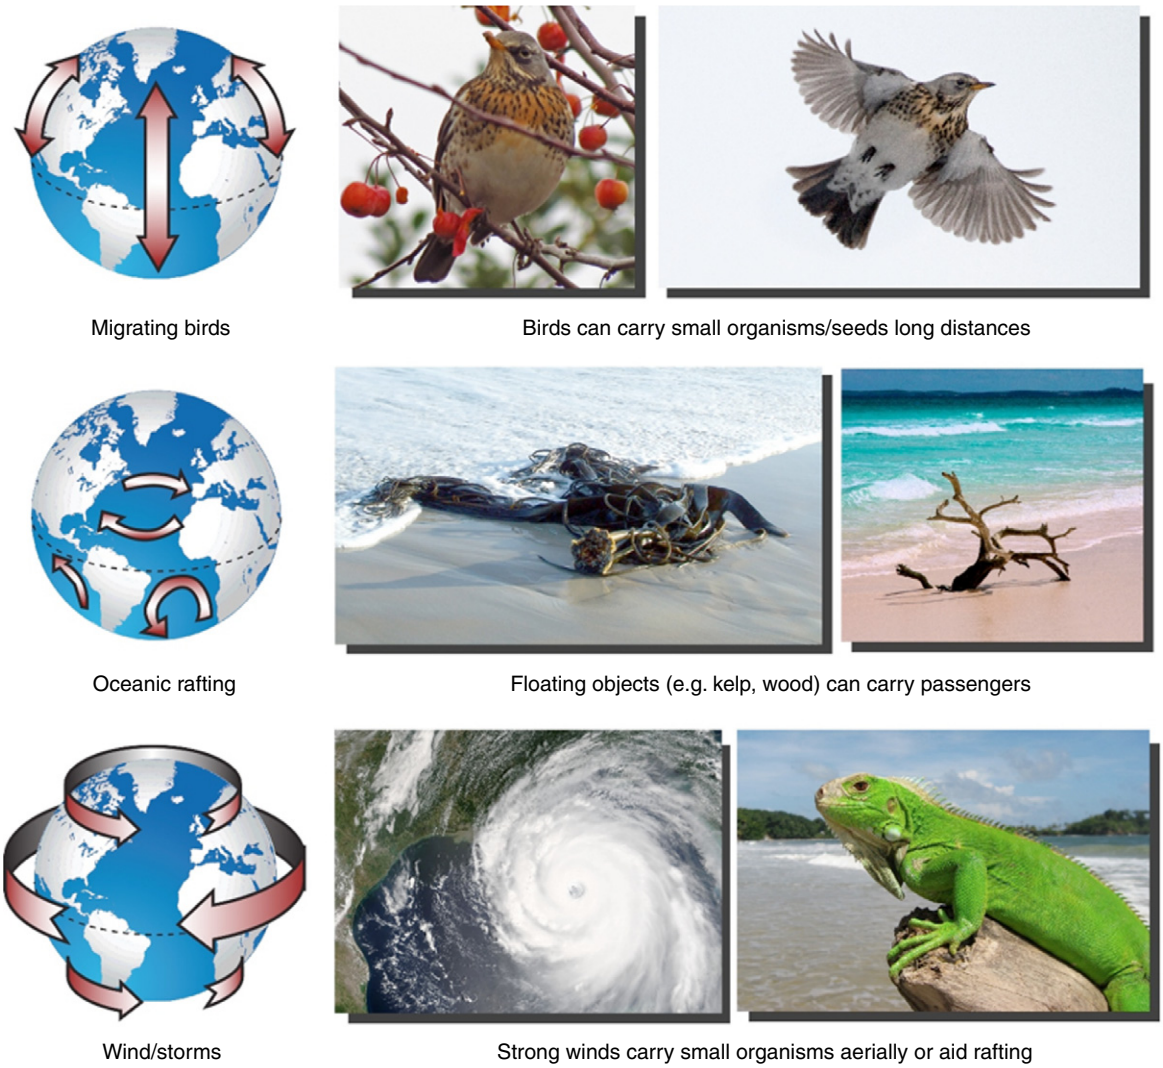

Figure 1 Dispersal of organisms can be mediated by wind, oceanic rafting, and the movement of animals. Migrating birds, for example, can carry seeds, insects, and other small organisms long distances, generally moving north–south or vice versa. Transoceanic dispersal of terrestrial or shallow water marine organisms can be facilitated by rafting on buoyant objects such as kelp, wood, and pumice, and generally follows the paths of ocean currents. Strong winds, such as the easterly equatorial winds and the westerly mid-latitude winds, can transport small organisms aerially or influence rafting events at sea; for example, green iguanas (*Iguana iguana*) were able to colonize a Caribbean island by rafting on driftwood in the path of a hurricane (Censky *et al.*, 1998). Photographs, from left to right, top to bottom, with credits in parentheses: the migratory bird *Turdus pilaris* ingesting seeds (T. Reynolds) and in flight (J. Strzelecki); the buoyant bull kelp *Durvillaea antarctica*, which can transport intertidal organisms across oceans (C. Fraser), and driftwood (Wlavallee); hurricane Katrina (J. Schmaltz, NASA) and a Caribbean iguana on driftwood (Plyco/dreamstime.com).

associations, often show similar dispersal histories (Fraser and Waters, 2013; Nikula *et al.*, 2010). Source and sink regions for dispersal are often predictable based on abiotic features such as glacial refugia (Fraser *et al.*, 2012; Hewitt, 2000), prevailing winds and storm tracks (Gillespie *et al.*, 2012; Monzón-Argüello *et al.*, 2012), and oceanographic features (Ali and Huber, 2010; Collins *et al.*, 2010; **Figure 1**).

Types of Dispersal

Dispersal can be broadly characterized by frequency and distance, with different types generating a range of distinctive genetic signatures. Dispersal that is 'leptokurtic' (with most individuals moving only small distances, but with rare long-distance dispersal), for instance, generates relatively patchy genetic patterns, relative to 'stepping stone' (where individuals only disperse between neighboring populations) (Ibrahim *et al.*, 1996). Genetic signatures of past range changes can be observed thousands of years after the changes occurred, as density-blocking by founders (the first lineages to recolonize an area) can limit the genetic diversity of recolonized versus refugial populations (Hewitt, 1993; Ibrahim *et al.*, 1996; Waters *et al.*, 2013).

Dispersal can also be classified as active or passive. Active dispersal events involve organisms moving to new regions through independent locomotion, such as flight. Passive long-distance dispersal events involve assistance and are usually

achieved via anemochory (dispersal with wind), hydrochory (disperal with water), or epi-/endo-zoochory (dispersal on/in animals) (Nathan *et al.*, 2008). Examples of direct evidence for these various modes of dispersal are provided below.

Transoceanic Dispersal and Island Colonization

Overwater dispersal has played a key role facilitating colonization of oceanic islands (Gillespie and Roderick, 2002), promoting distinctive and rapid radiations (with founder speciation) across geologically dynamic island archipelagos such as Hawaii (Fleischer *et al.*, 1998; Funk and Wagner, 1995; Mendelson and Shaw, 2005; Percy *et al.*, 2008; Shaw, 1996), the Galapagos (Parent *et al.*, 2008; Sequeira *et al.*, 2000), and the Canary islands (Emerson *et al.*, 2000; Juan *et al.*, 2000, 1995).

Long-distance dispersal also appears to have been a key process underpinning the evolution of 'continental' island biotas such as those of New Zealand, New Caledonia, and Madagascar. In New Zealand, a combination of molecular dating (e.g., Burridge *et al.*, 2012; Wallis and Trewick, 2009), geological and paleontological analysis (see Landis *et al.*, 2008; Waters and Craw, 2006) implies that most of the country's extant plant and animal lineages likely established following Oligocene inundation, probably via dispersal from the Australian region. Geological evidence similarly suggests New Caledonia emerged following the Eocene, with subsequent arrival of most of its biota via overwater dispersal (Grandcolas *et al.*, 2008; Neall and Trewick, 2008; Swenson *et al.*, 2014), and there is mounting support for transoceanic dispersal of many terrestrial vertebrates from Africa to Madagascar (Ali and Huber, 2010; Yoder and Nowak, 2006). Even many ratite birds, whose distributions have traditionally been assumed to be solely the result of vicariance, are now thought to have dispersed among landmasses since the breakup of Gondwana (Mitchell *et al.*, 2014).

Wind/Storm Dispersal

Strong winds have been shown to assist dispersal of small organisms such as insects (Compton, 2002) and plant seeds (Horn *et al.*, 2001). Indeed, long-distance, transoceanic aerial dispersal of plant propagules has been inferred to explain connectivity among Southern Hemisphere landmasses separated by thousands of kilometers of ocean (Muñoz *et al.*, 2004). Wind directions and strengths – and therefore dispersal sources and sinks – are often predictable according to geographic region; for example, storms in the north Pacific will normally transport organisms from east to west (Gillespie *et al.*, 2012).

Whereas most wind-assisted dispersal events are of small, easily airborne organisms, the extremely strong winds associated with storms such as hurricanes can also result in long-distance dispersal of larger organisms. For example, in the mid-1990s green iguanas (*Iguana iguana*) (**Figure 1**) colonized a Caribbean island (Anguilla) from a source population more than 200 km away (Censky *et al.*, 1998). The iguanas were first found amongst beached driftwood, shortly after several large hurricanes had passed through the region, and are inferred to have rafted between islands on uprooted trees driven by the strong storm winds (Censky *et al.*, 1998). Iguanas were not previously found on Anguilla.

Dispersal at Sea

Oceanic rafting events have been demonstrated for a range of terrestrial organisms including insects (Heatwole and Levins, 1972), mammals (e.g., rabbit on kelp: Prescott, 1959), and reptiles (e.g., iguanas: Censky *et al.*, 1998). Rafting can also explain the broad distributions of many coastal and marine species that lack inherent dispersal capacity, such as small, slow-moving, or sedentary organisms that brood their offspring or have short-lived larval phases (Donald *et al.*, 2005; Fraser *et al.*, 2011; Haye *et al.*, 2012; Johannesson, 1988; Nikula *et al.*, 2010; Thiel and Gutow, 2005b). Organisms can make use of a range of floating substrata for rafting, including macroalgae, pumice, wood, and man-made objects (see review by Thiel and Gutow, 2005a). The direction and distance of rafting events is driven by ocean currents and winds (**Figure 1**), whereas duration is influenced by the buoyancy and rate of deterioration/consumption of the floating substrate.

Dispersal with Animals

Small organisms such as plant propagules (Wheelwright and Gordon, 1982), insects (McClure, 1990), fungi (Johnson, 1996), parasites, and bacteria (Scott *et al.*, 2001) can be dispersed via the movement of animals. Migrating animals, in particular, can take passengers long distances (Gillespie *et al.*, 2012). Some seeds and parasites can be carried internally (epizoochory; e.g., fruit seeds, liver flukes), whereas others attach externally (endozoochory; e.g., barbed seeds, ticks, mites, moss, and fungal spores) (e.g., seeds: Costa *et al.*, 2014). Migrating birds tend to travel latitudinally (north to south and vice versa), resulting in primarily latitudinal transport of passengers (Gillespie *et al.*, 2012; **Figure 1**).

Dispersal Routes

Dispersal routes are often predictable based on particular oceanographic or geological features. Consistent ocean currents, for instance, may connect isolated populations in predictable ways (Ali and Huber, 2010; Nikula *et al.*, 2010; Gillespie *et al.*, 2012). Similarly, landbridge connections between previously isolated landmasses (e.g., Beringia, Panama) can represent clear pathways for parallel dispersal and range expansion events.

Past and Future Dispersal

Future dispersal trends can be predicted based on climate models, with anticipated range shifts toward the poles or to higher elevations (Chen *et al.*, 2011; Davis and Shaw, 2001; Walther *et al.*, 2002). Large range changes are, however, dependent on a species' ability to disperse, so will vary among taxa. Range changes can often be achieved by local propagule

dispersal, or by small movements of individuals at the edges of ranges, and by rare chance events that shift some individuals longer distances across barriers such as mountains or oceans. For example, intertidal shores of the subantarctic were scoured by sea ice at the last glacial maximum (LGM), causing local extinction of many coastal marine species, but recolonization of these shores by a wide range of species occurred after the ice receded, facilitated by long-distance dispersal, for example, via rafting with floating kelp (Fraser *et al.*, 2009; Macaya and Zuccarello, 2010; Nikula *et al.*, 2010).

Future analyses based on multidisciplinary approaches (e.g., oceanographic modeling and genetics) and emerging technologies (e.g., forensic genetics and remote sensing) promise to further enhance the scientific understanding of biological dispersal.

Distance-Based Phylogenetic Inference

F Pardi and O Gascuel, Institut de Biologie Computationnelle, LIRMM UMR, CNRS & Université de Montpellier, Montpellier, France

Glossary

Additive distances A collection of pairwise distances δ_{ij} is additive if there exists a phylogenetic tree whose branch lengths determine distances between leaves coinciding with the δ_{ij}.

Branch lengths The branches in a phylogenetic tree usually have lengths representing the amount of evolutionary change that has occurred between the taxa at their endpoints. When the tree represents the evolution of a set of biological sequences, branch lengths are usually measured in terms of expected number of substitutions per site.

Computational complexity A measure of how a resource (typically time or memory) employed by an algorithm scales with the input data. An algorithm has complexity $O(f(n))$ if the resources grow at most proportionally to $f(n)$, a function of the input size n.

Distance matrix A square matrix, i.e., a table with an equal number of rows and columns corresponding to a set of taxa, where the entry in column i and row j, denoted δ_{ij} represents an estimate of the evolutionary distance between the i-th and the j-th taxon. The matrix is symmetric (i.e., $\delta_{ij}=\delta_{ji}$) and the elements on its diagonal are zero ($\delta_{ii}=0$).

Evolutionary distance A measure of the amount of change or divergence that has occurred between two taxa. When taxa are represented by biological sequences, 'change' is usually taken as the occurrence of substitutions along the evolutionary path connecting the sequences.

Least squares (LS) A general principle from regression analysis to adjust the parameters of a model function to best fit some observed data. In distance-based reconstruction, it is used to fit the branch lengths of a phylogeny to a set of distance estimates. Least squares methods aim to minimize a quadratic function of the differences between the distance estimates and the additive distances determined by the branch lengths. For 'ordinary least squares' (OLS) the goal is to minimize the sum of the squared differences, while for 'weighted least squares' (WLS) this sum is weighted by terms reflecting the variances of the distance estimates.

Minimum evolution (ME) A general distance-based principle, analogous to parsimony, to measure the plausibility of a phylogenetic tree whose branch lengths have been fitted to the data, typically by least squares (see above). If we define the length of a tree as the sum of its branch lengths, then shorter trees are deemed to be more plausible than longer ones.

Molecular clock The assumption of a constant substitution rate across a phylogeny, implying that branch lengths are directly proportional to time.

Molecular phylogenetics The study and reconstruction of phylogenies representing the evolution of molecular sequences, such as those of DNA or proteins.

Nearest neighbor interchange (NNI) A rearrangement of a tree topology swapping the position of two subtrees separated by exactly three branches. For example, one NNI can transform tree ((A,B),(C,D)) into ((A,C),(B,D)) or into ((A,D),(B,C)).

Sequence profile A table describing the general form of a collection of aligned sequences. For each site, the profile specifies the frequency of each possible character (including gaps) at that position.

Statistical consistency In statistics, a method of estimation is statistically consistent if it is guaranteed to converge, with probability 1, toward the correct value of the parameter, as the size of the input sample tends to infinity. In molecular phylogenetics, the central parameter is often taken to be the topology τ of the correct phylogenetic tree, so a method is said to be statistically consistent if the probability of reconstructing a tree of topology τ converges to 1 as the input sequence alignment becomes longer and longer.

Substitution model A probabilistic model describing the occurrence of substitutions in a DNA or protein sequence. Substitutions models are used to estimate the evolutionary distances between pairs of molecular sequences.

Subtree pruning and regrafting (SPR) A rearrangement of a tree topology, which removes a subtree (a clade) and reinserts it elsewhere in the tree topology.

Tree topology The discrete, structural information contained in a phylogenetic tree, besides branch length information.

Ultrametric distances The pairwise distances δ_{ij} are ultrametric if they are additive with respect to a tree whose leaves are all at the same distance from the root. In molecular phylogenetics, distances are approximately ultrametric only when the molecular clock assumption holds.

Introduction

Distance-based phylogenetic reconstruction rests on two steps. First, for each pair of taxa estimate the amount of change that has occurred along the evolutionary path connecting them. Such measure of change is called an 'evolutionary distance,' and in the case of biological (DNA or protein) sequences, it is proportional to the number of substitutions that have taken place in the two lineages since the last common ancestor of the two sequences. Tree inference is then based on these estimates – the goal being to find the tree that best accounts for the estimated distances.

 doi:10.1016/B978-0-12-800049-6.00206-7

Using pairwise distances or similarities between taxa is arguably the oldest approach to investigate systematic relationships by means of a computer (Sneath, 1957; Sokal and Michener, 1958). Early work saw a very clear distinction between, on the one hand, hierarchical clustering techniques for taxonomic classification (Sokal and Sneath, 1963), and, on the other hand, optimization-based methods directly aimed at phylogenetic reconstruction (Cavalli-Sforza and Edwards, 1967; Fitch and Margoliash, 1967). These two lines of work eventually converged in the 1980s, leading to the hugely popular neighbor joining (NJ) method (Saitou and Nei, 1987) – which combined algorithmic ideas from classification (e.g., UPGMA, Sokal and Michener, 1958; ADDTREE, Sattath and Tversky, 1977) to optimization principles from phylogenetics (e.g., ME, Kidd and Sgaramella-Zonta, 1971; OLS, Cavalli-Sforza and Edwards, 1967; see below). From NJ onwards, phylogenetics has witnessed a renaissance of distance-based methods, often related to, or inspired by NJ (e.g., FastME, Desper and Gascuel, 2002; FastNJ, Elias and Lagergren, 2009; FastTree, Price *et al.*, 2009).

These methods are still widely used for their computational efficiency, an advantage that makes them particularly suited for the reconstruction of very large phylogenies, or large collections of phylogenies (e.g., for bootstrapping), or to provide a basis for progressive multiple sequence alignments (Larkin *et al.*, 2007), or even to construct initial trees for more sophisticated inference approaches such as those based on maximum likelihood (ML) (Guindon and Gascuel, 2003). More generally, using estimated distances between biological sequences is an obvious answer to cope with the massive datasets generated by the modern, ever faster and cheaper sequencing techniques – as testified by the ongoing success of NJ, which to date remains the most cited algorithm in phylogenetics.

In this article, we outline the main ideas that underlie the methodology for distance-based phylogenetics. We start by explaining the importance of estimating distances that reflect the number of changes that have actually occurred between two taxa, rather than the (smaller) number of differences between them. After describing concisely the task of estimating evolutionary distances, the main focus here is on the methods for tree inference proper, that is, to reconstruct a tree that fits well the estimated distances.

Preliminaries

A phylogenetic tree T over a set of taxa X has two components. First, a tree topology τ, i.e., an unrooted tree with no degree-two nodes, whose leaves are labeled by (and represent) the taxa in X, and whose internal nodes represent putative ancestors of these taxa. The second component consists of positive branch lengths $b(e)$ for every branch e in τ, which represent a measure of evolutionary change occurred along e.

Every phylogenetic tree T determines a collection of *tree distances* d_{ij}^T between the taxa $i,j \in X = \{1,2,\ldots,n\}$ labeling its leaves. They are defined by:

$$d_{ij}^T = \sum_{e \in \tau_{ij}} b(e)$$

where τ_{ij} denotes the set of branches between i and j in τ. In other words, the tree distance d_{ij}^T is the length of the path connecting i and j in T.

Now suppose that, for each pair of taxa $i,j \in X = \{1,2,\ldots,n\}$, an estimate δ_{ij} of their evolutionary distance is obtained. We say that the δ_{ij} are *additive*, if $\delta_{ij} = d_{ij}^T$ for all $i,j \in X$, for some phylogenetic tree T over X. Importantly, when such a tree exists, it is unique (Zaretskii, 1965; Simões Pereira, 1969; Buneman, 1971). Moreover, as we shall see in the following, it is algorithmically easy to reconstruct tree T from its tree distances d_{ij}^T. These observations provide the fundamental idea underlying distance-based methods: if we manage to obtain precise estimates of the distances d_{ij}^T for the phylogenetic tree we seek, then reconstructing this tree is easy.

The word additive comes from the fact that if we could observe a taxon i as it evolves into k at an intermediate stage, and then eventually into j, then the true evolutionary distances between i,j,k must satisfy

$$d_{ij} = d_{ik} + d_{kj} \qquad [1]$$

Distance Estimation

The first, fundamental component of a distance-based method is the definition of 'evolutionary distance.' It is important to understand that not any measure of distance can be adopted for phylogenetic reconstruction: the key requirement is that the parameters that we set out to estimate must be additive in the sense specified above. This ensures that, as the data become more and more abundant and the distance estimates more and more accurate, these estimates will determine the correct phylogenetic tree (Atteson, 1999).

As a consequence, in molecular phylogenetics, where the data are collections of DNA or protein sequences, simply counting the number of differences between each pair of sequences is not acceptable, because of the possibility of multiple substitutions at the same site (see Figure 1). The number of differences, or mismatches, between sequences is sometimes referred to as their 'uncorrected distance.'

A much better approach is to define the distances as (proportional to) the number of substitutions that have occurred between the two sequences, which clearly leads to an additive measure. As this number is unobservable, the general approach is to estimate it using nucleotide or amino acid substitution models. Note that uncorrected distances do not

```
i: GAATACTCAAA
   ||.|.|.|.||
k: GACTGCCCGAA
   ||.|||.||.|
j: GATTGCTCGGA
```

Figure 1 Uncorrected distances are not additive. We assume that i, k and j are realizations of the same sequence at three successive times. If distances were defined as the number of differences, we would have $d_{ij}=4<d_{ik}+d_{kj}=7$, contradicting eqn [1], and showing that the distances would not be additive. Note that both d_{ij} and $d_{ik}+d_{kj}$ potentially underestimate the number of substitutions occurred between i and j.

account for unobserved changes – such as multiple substitutions at the same site – and therefore underestimate this number (see Figure 1). We will now describe, in very general terms, the ML approach to solve this estimation problem. The interested reader is referred to more advanced textbooks (e.g., Felsenstein, 2004; Yang, 2006) for a detailed treatment of distance estimation.

Substitution models allow us to calculate a substitution probability matrix $P(d)=(p_{xy}(d))$, where x and y denote nucleotides, amino acids or other biological characters, and $p_{xy}(d)$ denotes the probability that an x becomes a y after evolving along a branch of length d. Note that d is not expressed in units of time. Instead, the rate of substitution models is usually scaled so that d equals the expected number of substitutions per site along a branch of that length. Also recall that π_x denotes the stationary probability of x. It can be defined as $\pi_x = \lim_{d\to\infty} p_{yx}(d)$, and is sometimes estimated using the frequency of x in the sequences being analyzed.

The evolutionary distance between two sequences x and y is estimated on the basis of a pairwise alignment of these two sequences. Denote by x_i and y_i the i-th aligned character of x and y, respectively. Assuming that the substitution model is time-reversible, the likelihood is given by:

$$L(d) = \prod_{i=1}^{m} \pi_{x_i} p_{x_i y_i}(d)$$

where the product is over the m aligned sites. Then, the ML estimate of the distance between x and y is the value of d that maximizes $L(d)$ above, and can be obtained numerically or analytically, depending on the model.

For illustration, we consider the simplest model of nucleotide substitution, the JC model (Jukes and Cantor, 1969). For this model, we have, $\pi_A=\pi_C=\pi_G=\pi_T=1/4$ and, assuming $x\neq y$,

$$p_{xx}(d) = \frac{1}{4}\left(1+3e^{-\frac{4}{3}d}\right), \quad p_{xy}(d) = \frac{1}{4}\left(1-e^{-\frac{4}{3}d}\right)$$

The likelihood is then given by:

$$L(d) = \frac{1}{4^{2m}}\left(1-e^{-\frac{4}{3}d}\right)^{m_{\neq}}\left(1+3e^{-\frac{4}{3}d}\right)^{m-m_{\neq}}$$

where $m_{\neq}$ is the number of mismatches. It is then easy to calculate that $L(\delta)$ is maximized for

$$\delta = -\frac{3}{4}\ln\left(1-\frac{4}{3}\frac{m_{\neq}}{m}\right)$$

That is, the distance estimate δ between the two sequences is a simple, strictly increasing function of the proportion of mismatches – the uncorrected distance we mentioned above. Note that $\delta \geq m_{\neq}/m$, corresponding to the fact that there are more substitutions than observed differences.

Other models cause the ML estimates of the distances to be functions of multiple features of the pairwise alignment, so strictly speaking it is not always accurate to describe distance estimates as transformations of the uncorrected distances. As ML distance estimation is the same as ML phylogenetic reconstruction of a two-taxon tree, the numerical techniques for distance estimation are largely the same as those employed for ML branch length optimization.

Tree Reconstruction

We organize our brief survey of tree reconstruction methods around three well-defined components. Any choice with respect to them defines a possible distance-based method.

C1 Branch Length Estimation: a method to assign lengths to the branches of any fixed tree topology, so that the resulting tree distances are as close as possible to the estimated distances δ_{ij}. This is usually achieved using least squares techniques from regression analysis (Cavalli-Sforza and Edwards, 1967; Fitch and Margoliash, 1967).

C2 What to Optimize: a criterion assigning a score to all the trees of different topologies that can be obtained with component C1, reflecting the biological plausibility of a phylogenetic reconstruction given the estimated distances. An obvious choice for this is the least squares criterion used to assign branch lengths, but as we describe below a lot of recent methodology is based on a different criterion, 'minimum evolution' (ME) (Kidd and Sgaramella-Zonta, 1971). Some methods (e.g., ADDTREE; Sattath and Tversky, 1977) directly optimize topological criteria, and thus bypass C1.

C3 How to Optimize: an algorithm to seek the optimal tree with respect to the criterion in C2. Since this is a computationally hard optimization problem, algorithms are usually heuristic, and based on simple but effective ideas such as stepwise addition, iterative agglomeration, or hill climbing (Swofford *et al.*, 1990; Felsenstein, 2004).

In the following, we start by surveying the methodology for C1 (Section Least Squares Branch Length Estimation). Then we describe one of the most popular criteria for C2, ME (Section Optimization Criteria: ME), which is at the foundation of what is still the best known distance-based method, NJ. We illustrate this algorithm along with other approaches that are based on the same ideas (Section NJ and Related Algorithms). Finally, we briefly describe a few promising approaches which, strictly speaking, are not distance-based methods, but which share with them several ideas and the same emphasis on computational efficiency (Section Beyond Distances).

Least Squares Branch Length Estimation

Given the estimated distances δ_{ij} for all $i,j\in X$, the goal of least squares phylogenetic reconstruction (Cavalli-Sforza and Edwards, 1967; Fitch and Margoliash, 1967) is to find a phylogenetic tree T that minimizes the gap between the estimates δ_{ij} and the tree distances d_{ij}^T, measured in terms of a quadratic function $Q(T)$ of the residuals $\delta_{ij}-d_{ij}^T$. Different statistically motivated choices for $Q(T)$ are possible, and are detailed below. While many versions of this problem have been proven computationally hard (Day, 1987), here we focus on the simpler problem of assigning branch lengths to a tree of fixed topology τ. As we show below, exact, analytic, and polynomially computable solutions are available for this task.

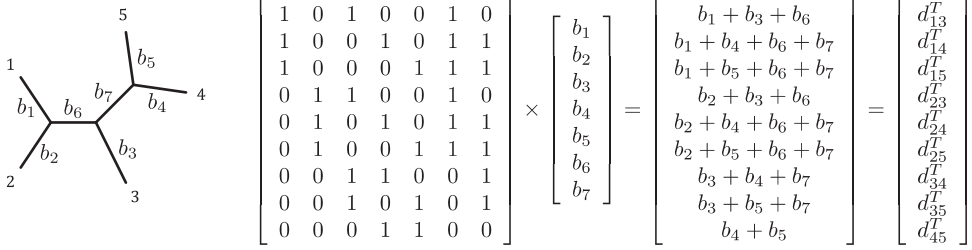

Figure 2 The usefulness of the topological matrix. The tree distances for the 5-taxon tree on the left are expressed here as $A_\tau \boldsymbol{b} = \boldsymbol{d^T}$.

The method of least squares was first introduced in phylogenetics in the mid-1960s. The proposed objective function was

$$Q(T) = \sum_{i<j} w_{ij}\left(\delta_{ij} - d_{ij}^T\right)^2$$

with $w_{ij}=1$ (Cavalli-Sforza and Edwards, 1967) and $w_{ij} = 1/\delta_{ij}^2$ (Fitch and Margoliash, 1967). The former is often referred to as 'ordinary least squares' (OLS), and both approaches are particular cases of 'weighted least squares' (WLS), where various choices are possible for w_{ij}. From a statistical standpoint, the weight w_{ij} represents the degree of confidence that we can attach to the distance estimate δ_{ij}: ideally w_{ij} should be inversely proportional to the variance of δ_{ij}, but in practice setting the weights is a delicate art, because the variances are difficult to evaluate. One particular choice on which we will come back a few times in the following is that of 'balanced' weights – with w_{ij} proportional to $2^{-|\tau_{ij}|}$ ($|\tau_{ij}|$ denotes the number of edges on the path between i and j in τ) – which assigns less confidence to the distances between topologically distant taxa.

WLS approaches ignore the correlations between the distance estimates δ_{ij}, δ_{kl} for different pairs of taxa, which may be significant when the paths τ_{ij} and τ_{kl} share many branches. In order to take these correlations into account, 'generalized least squares' (GLS) (Chakraborty, 1977; Bulmer, 1991) minimizes

$$Q(T) = \sum_{i<j}\sum_{k<l} w_{ij,kl}\left(\delta_{ij} - d_{ij}^T\right)\left(\delta_{kl} - d_{kl}^T\right)$$

where the $w_{ij,kl}$ should be set as the entries of the inverse of the variance–covariance matrix for the distance estimates δ_{ij}. Just as OLS is a particular case of WLS, WLS is a particular case of GLS, obtained by setting $w_{ij,kl}=0$ whenever $\{i,j\} \neq \{k,l\}$. In practice GLS is rarely used for phylogenetic inference, because of the difficulty of evaluating the covariances, and because of its higher computational costs relative to those of OLS and WLS.

The branch lengths that are optimal with respect to the $Q(T)$ criteria above can be simply expressed in matrix notation. To this end, let $\boldsymbol{\delta} = (\delta_{ij})$ denote the distance estimates and $\boldsymbol{d^T} = (d_{ij}^T)$ the tree distances for a tree T, in vector form. Moreover, we represent any topology τ with a binary matrix $A_\tau = (a_{ij,e})$ – whose rows correspond to pairs of taxa $\{i,j\}$ and whose columns correspond to branches of τ – defined by setting $a_{ij,e}=1$ if e is on the path between i and j in τ, and 0 otherwise. Given these notations, we can write

$$\boldsymbol{d^T} = A_\tau \boldsymbol{b}$$

where $\boldsymbol{b} = (b(e))$ denotes the branch lengths of T in vector form. See **Figure 2** for an example illustrating these notations.

The objective functions of OLS, WLS, and GLS can then be written concisely in matrix form:

$$Q(T) = (\boldsymbol{\delta} - A_\tau \boldsymbol{b})^t W (\boldsymbol{\delta} - A_\tau \boldsymbol{b})$$

where $W = (w_{ij,kl})$ contains the GLS weights and the superscript t denotes the matrix transpose. When W is diagonal, the identity matrix, WLS and OLS are obtained, respectively. The branch lengths for τ that minimize $Q(T)$ can then be expressed as:

$$\boldsymbol{b} = \left(A_\tau^t W A_\tau\right)^{-1} A_\tau^t W \boldsymbol{\delta} \qquad [2]$$

The matrix calculations in eqn [2] are computationally expensive, but a number of properties of the matrices involved can be exploited to speed up the solution (Gascuel, 1997a; Bryant and Waddell, 1998). For WLS, computational complexity is dominated by the matrix inversion – or equivalently by linear system resolution – which standard algorithms achieve in $O(n^3)$ time, where we recall that $n = |X|$ denotes the number of taxa. For OLS, the complexity can be reduces further to $O(n^2)$. In fact, the OLS branch lengths can be expressed with simple combinatorial formulae (Vach, 1989, Rzhetsky and Nei, 1993). More recently it was discovered that similar formulae exist for WLS with balanced weights (Desper and Gascuel, 2004), and in fact for a whole new class of special cases of WLS, those with 'multiplicative weights' (Mihaescu and Pachter, 2008).

We conclude by remarking that none of the approaches described above guarantees that the assigned branch lengths are all positive. Least squares branch length estimates are sometimes negative, which does not correspond to any biological reality. Constraining branch lengths to be nonnegative leads to nonnegative least-squares (NNLS) regression (Lawson and Hanson, 1974), an approach that however further increases computational costs.

Optimization Criteria: ME

Once a way to assign branch lengths to any fixed topology has been determined, the next question (C2) is how to measure the plausibility of the trees we obtain. One possibility is to adopt the same least squares criterion $Q(T)$ used for branch lengths, implying that a tree topology is considered plausible if its tree distances can be fitted very closely to the estimated distances. This approach is known to perform best when negative branch lengths are disallowed (Kuhner and Felsenstein, 1994), a constraint that can be imposed in popular

programs such as FITCH (Felsenstein, 1997) and PAUP* (Swofford, 2003).

A different approach – ME – scores a tree using the sum $L(T)$ of the fitted branch lengths: the shorter the tree, the better. The intuition underlying ME is the same as that of maximum parsimony for character-based tree reconstruction: similarly to the general principle that simple explanations are preferable to complex ones, in phylogenetics shorter trees are often considered more plausible than longer ones.

ME can deal with negative branch lengths in a variety of ways: they can be simply excluded from the sum in $L(T)$ (Swofford *et al.*, 1990), or $L(T)$ can be defined as the sum of the absolute values of the branch lengths (Kidd and Sgaramella-Zonta, 1971). To date, the most common approach is to define $L(T)$ as the sum of all branch lengths, irrespective of their sign (Saitou and Imanishi, 1989; Rzhetsky and Nei, 1993), which would seem to favor negative branch lengths, but in practice works quite well.

The first theoretical foundation of ME was provided by Rzhetsky and Nei, who showed that, if the distance estimates are unbiased, and branch lengths are assigned with OLS, then the mathematical expectation of $L(T)$ is minimized for the correct tree topology (Rzhetsky and Nei, 1993). This means that, when the distance estimates equal the tree distances for a tree T – that is when $\boldsymbol{\delta} = \boldsymbol{d}^T$ – then the optimal tree with respect to OLS + ME is T itself. Note that in the following we will use the short form 'C1 + C2' to denote the optimization principle based on a particular choice for components C1 and C2 (see above).

If we assume that $\boldsymbol{\delta}$ converges to $\boldsymbol{d}^T$ as more and more data are available, the result above implies that OLS + ME is 'statistically consistent' – meaning that the probability of reconstructing T (within any given approximation) converges to 1 – which is an essential property of any phylogenetic inference method. Unfortunately ME does not always have this property (Gascuel *et al.*, 2001) – an observation that casts serious doubts on the general applicability of the ME principle in phylogenetics. To date, statistical consistency has been proven to hold for all instances of WLS + ME with multiplicative weights (Pardi and Gascuel, 2012).

One special case of this is WLS + ME with balanced weights, which is also known as BME (Pauplin, 2000; Desper and Gascuel, 2002, 2004). This optimization principle has several interesting mathematical features (Semple and Steel, 2004), including the fact that for fully resolved trees its objective function can be expressed very concisely – and elegantly – as a function of the estimated distances:

$$L(T) = \sum_{i<j} 2^{1-|\tau_{ij}|}\delta_{ij} \qquad [3]$$

BME is of key importance to interpret some of the most central methods in distance-based phylogenetics, including NJ, as we explain below.

NJ and Related Algorithms

NJ is an agglomerative clustering algorithm, that is, it constructs a tree in a bottom-up fashion by alternating the following two steps until the tree is complete:

'Selection step': based on the distances between taxa, choose two 'active' taxa i and j to agglomerate. That is, connect them to a new taxon (ij) representing their direct common ancestor. (Initially all taxa are 'active.')

'Reduction step': remove i and j from the list of active taxa, and define new distances between the new active taxon (ij) and all remaining active taxa.

The two steps above are common to all agglomerative algorithms. For NJ, there are a number of equivalent (Gascuel, 1994) ways to specify the two steps above (Saitou and Nei, 1987; Studier and Keppler, 1988). Here we describe the most efficient computationally (Studier and Keppler, 1988). In the selection step, NJ agglomerates the taxa i and j that minimize

$$q_{ij} = (r-2)\delta_{ij} - \sum_{k=1}^{r}\delta_{ik} - \sum_{k=1}^{r}\delta_{jk} \qquad [4]$$

where the sums run on the set of remaining active taxa, and r is their number. As for the reduction step, the new distance between (ij) and any other taxon k is defined by

$$\delta_{(ij)k} = \frac{1}{2}\left(\delta_{ik} + \delta_{jk} - \delta_{ij}\right)$$

A third step, defining branch lengths for the reconstructed tree, is also usually described for NJ, but here we omit it for simplicity.

Different choices for the two steps above lead to other well-known agglomerative algorithms: single-linkage clustering (Sneath, 1957), average-linkage clustering, also known as UPGMA (Sokal and Michener, 1958), WPGMA (Sokal and Sneath, 1963), ADDTREE (Sattath and Tversky, 1977), UNJ (Gascuel, 1997a), and BIONJ (Gascuel, 1997b). The last method is a special case of the MVR approach (Gascuel, 2000a), which adapts the reduction step above so as to account for the variances and covariances of the distance estimates δ_{ij}. It is similar in spirit to another agglomerative algorithm, Weighbor (Bruno *et al.*, 2000), which also modifies the selection criterion, and uses a different formula (Bulmer, 1991) to evaluate the variances of the distances.

Of the algorithms above, the fastest are single-linkage clustering, UPGMA and WPGMA, as they manage to construct a tree in $O(n^2)$ time (Sibson, 1973; Murtagh, 1984; Gronau and Moran, 2007). However, they are only accurate when the distances are approximately ultrametric (see Glossary), and thus they are little used for phylogenetic inference, where the molecular clock is the exception rather than the rule. Apart from ADDTREE and MVR, which have a time complexity of $O(n^4)$, all other agglomerative algorithms mentioned above reconstruct a tree in $O(n^3)$ time. This includes NJ, where each of the n-3 selection steps is carried out in $O(r^2) = O(n^2)$ time via precalculation of the sums $\sum_{k=1}^{r}\delta_{ik}$ (Studier and Keppler, 1988). One of the reasons for the continued success of NJ is the fact that it has long been considered to achieve a very good tradeoff between reconstruction accuracy and running times.

Recently, a lot of work has gone into crafting computationally efficient implementations of NJ, both in terms of running time and memory usage. These include QuickTree (Howe *et al.*, 2002), QuickJoin (Mailund and Pedersen, 2004), the bucket-based method of Zaslavsky and Tatusova (2008), NINJA (Wheeler, 2009), RapidNJ, and ERapidNJ

(Simonsen *et al.*, 2011). A general idea is to speed up the selection of the pair of taxa that minimizes q_{ij} in eqn [4], by limiting the search to a subset of pairs guaranteed to contain the best pair. Moreover, external (disk) memory is used to cope with large datasets (standard implementations can only deal with a few thousand taxa because of internal memory limitations). Although the worst-case time complexity remains $O(n^3)$ these approaches permit a dramatic improvement in efficiency, allowing the reconstruction of trees with more than 50 000 taxa in a few hours on a normal PC (Wheeler, 2009; Simonsen *et al.*, 2011).

Even faster NJ-like algorithms can be obtained by employing heuristics – instead of exact algorithms – to select the pair of taxa to join on the basis of q_{ij}. These include FastNJ (Elias and Lagergren, 2009) and RelaxedNJ (Evans *et al.*, 2006), which is implemented in Clearcut (Sheneman *et al.*, 2006). In the case of FastNJ, the taxa to join are selected among a list of $O(n)$ pairs, implying a running time of $O(n^2)$. For both methods, some loss of accuracy is to be expected, as in general these approaches do not reconstruct the same tree as NJ. Despite this, like NJ, these methods are statistically consistent, as they are guaranteed to reconstruct a tree T when the input distances are additive with respect to T, or nearly additive (Atteson, 1999; Elias and Lagergren, 2009).

A question that puzzled phylogeneticists for some time is whether NJ is related to any of the optimization criteria we discussed above. It was often suggested that "NJ has some relation to OLS and some to ME, without being definable as an approximate algorithm for either" (Felsenstein, 2004). These connections come from the fact that the original selection criterion q_{ij} can be obtained as a sum of OLS estimates for a certain subset of branch lengths (Saitou and Nei, 1987; Gascuel, 1994). However, if the good performance of NJ were due to its relation to OLS + ME, then we would expect that better (shorter) trees with respect to this criterion would also be phylogenetically more accurate than NJ trees, something that is actually contradicted by experience (Saitou and Imanishi, 1989; Kumar, 1996; Gascuel, 2000b; Desper and Gascuel, 2002).

More recently, it was shown that the real optimization criterion behind NJ is BME (Desper and Gascuel, 2005; Gascuel and Steel, 2006). To briefly illustrate this, we note that the formula $L(T)$ in eqn [3] (which only applies to bifurcating trees) can be generalized to unresolved trees by replacing $2^{1-|\tau_{ij}|}$ by a factor $p(i \to j)$ expressing the probability of ending up in j when following a suitably defined random walk starting at i. The resulting generalized BME formula can then be seen as the guiding principle behind the selection step in NJ: at each of these steps, the agglomeration performed by NJ is the one that results in the tree with the smallest BME length.

Motivated by the observation that NJ can be seen as a greedy algorithm for BME, other methods guided by BME have been proposed (Desper and Gascuel, 2002; Catanzaro *et al.*, 2012). These methods differ from NJ in their choice for component C3, that is, the algorithm to seek the BME-optimal tree. FastME (Desper and Gascuel, 2002; Lefort *et al.*, 2015) implements heuristics including stepwise addition to construct an initial tree, and common tree topology rearrangements (NNI, SPR) to perform a local search in tree space. Although the running time of FastME is comparable to that of NJ, its reconstruction accuracy is superior (Desper and Gascuel, 2002, 2004; Vinh and von Haeseler, 2005), thus confirming the suitability of BME as an optimization principle in distance-based phylogenetics.

Beyond Distances

An important computational bottleneck of all the methods we presented so far is that they require the initial estimation and storage of distances for all pairs of taxa, which takes $O(\ell n^2)$ time – assuming that distances are estimated from sequences of length ℓ – and $O(n^2)$ memory. It is intuitive, however, that not all distances are necessary to reconstruct a phylogeny, meaning that these bounds can be improved. Some distances – those with large variances – may even be misleading for tree inference. Moreover, for large datasets with hundreds of thousands taxa, reducing memory usage may be a necessity: just storing the entire distance matrix for 100 K taxa typically requires 20 GB of memory, which may be problematic for many users.

In the last few years a number of approaches have been proposed to bypass the bottleneck above. The most widely used is FastTree (Price *et al.*, 2009), whose strategy to construct an initial tree is inspired by NJ, but with two fundamental differences – one aimed at improving reconstruction accuracy, and the other for computational efficiency. We now briefly describe the main distinctive points of FastTree, as they underlie its good performance and thus its popularity.

The first difference with NJ and other classical distance-based methods is that FastTree stores 'sequence profiles' for the active taxa (see Glossary) – instead of a distance matrix – and only computes the distance between two profiles if the corresponding pair is a candidate for joining. After each agglomeration, the sequence profile for the new node joining i and j is computed as the arithmetic average of the profiles for i and j. The pair of taxa to join is selected on the basis of a distance-based criterion formally similar to eqn [4], but where distances are uncorrected and defined on the basis of the profiles stored for the active taxa. The second difference consists of maintaining a list of $O(\sqrt{n})$ 'top-hits' for each taxon (i.e., putative closest neighbors), which is combined to the strategies of FastNJ (Elias and Lagergren, 2009) and RelaxedNJ (Evans *et al.*, 2006) to reduce the pairs of taxa to consider for agglomeration: at the end of its execution FastTree will only have considered $O(n^{1.5}\log n)$ pairs – as opposed to $O(n^3)$ for NJ, and $O(n^2)$ for FastNJ. The NJ-like reconstruction of an initial tree – with a claimed complexity of $O(\ell n^{1.5}\log n)$ time and $O(\ell n + n^{1.5})$ memory – is then followed by a local search based on common tree topology rearrangements (NNI, SPR), using techniques similar to those implemented in FastME (Desper and Gascuel, 2002).

FastTree is faster and more memory-efficient than the distance-based methods discussed so far, and it can easily cope with datasets with hundreds of thousands of sequences. Given the central role of sequence profiles, it can be argued that FastTree is not a distance-based method. It shares ideas with with character-based methods such as parsimony, benefitting in particular from information about ancestral sequences – something that is not available to purely distance-based methodology.

Other methods that arguably lie beyond the frontier of distance methods – but which share with them several ideas and the same emphasis on computational efficiency – have recently been proposed by Brown, Truszkowski, and collaborators (Truszkowski *et al.*, 2012; Brown and Truszkowski, 2012). Particularly promising as a basis for future methodology is LSHTree (Brown and Truszkowski, 2012), which like NJ proceeds in a bottom-up fashion by joining subtrees – although not necessarily at their roots. To do so, it uses 'locality-sensitive hashing' exploiting ancestral sequence reconstructions, to rapidly find candidate pairs of close sequences to join. Just as FastTree, the running time of LSHTree is sub-quadratic.

Conclusion

Despite the simplicity of their approach, and the loss of information that is necessarily entailed by summarizing sequence data into a numerical matrix, distance-based methods are not just computationally efficient, but also remarkably accurate. The reconstruction accuracy of distance-based methods has been the subject of many simulation studies in the past (e.g., Saitou and Imanishi, 1989; Kuhner and Felsenstein, 1994; Kumar, 1996; Gascuel, 2000b; Nakhleh *et al.*, 2002; Desper and Gascuel, 2004). The general idea of these studies is to generate sequences using standard substitution models and known model trees, and then compare the trees reconstructed by a number of competing methods to the model trees employed to generate the sequences. From these works it transpires that although not comparable to that of likelihood-based methods, the reconstruction accuracy of distance-based methods is competitive with that of maximum parsimony (MP) with MP superior for trees with short branches, and inferior when the effect of multiple substitutions at the same site becomes important. The reason for this is largely intuitive: while distance-based methods naturally account (or 'correct') for multiple substitutions in the way they estimate distances, MP does not even model branch lengths, leading to serious problems such as statistical inconsistency in extreme cases (Felsenstein, 1978). Another important conclusion that empirical studies have helped to reach is the importance of improving the tree reconstructed initially, via topological rearrangements such as NNI and SPR (e.g., Vinh and von Haeseler, 2005). This is why most modern tree reconstruction methods include this important step, as we have seen for FastME (Desper and Gascuel, 2002) and FastTree (Price *et al.*, 2009) in a distance-based context.

Another important advantage of distance-based methods is their versatility: they can be employed not just with sequence data, but in every context where pairwise comparisons are possible. For example, they have been used to infer phylogenies from morphological characters (Sokal and Michener, 1958), immunological data (Sarich and Wilson, 1967), gene frequencies (Cavalli-Sforza and Edwards, 1967), DNA–DNA hybridization data (Sibley and Ahlquist, 1984), and more recently from gene content (Snel *et al.*, 1999) or gene order (Wang *et al.*, 2006) within genomes. Another area where distance methods may prove useful is phylogenomics, where large collections of genomic alignments may be summarized into multiple distance matrices. Their combined analysis may provide an efficient alternative to traditional supertree and supermatrix approaches (Lapointe and Cucumel, 1997; Criscuolo *et al.*, 2006).

Divergence and Diversification, Quantitative Genetics of

JC Uyeda, University of Idaho, Moscow, ID, USA

Glossary

Adaptive landscape G.G. Simpson's phenotypic adaptive landscape which can be conceptualized as a surface describing the relationship between a population's mean values for a set of continuous traits and relative fitness (cf. Wright's adaptive landscape, in which population fitness is a function of allele frequencies).

Additive genetic variation The variance in breeding values (mean genetic values of offspring for a given population) for a quantitative trait in a population. Additive genetic variation is the component of genetic variation that leads to resemblance between parents to offspring and is therefore most relevant for evolutionary change.

Brownian motion A simple continuous-time stochastic model often used to model quantitative trait evolution. The model describes the random movement of trait means through phenotypic space.

Constraints hypothesis The hypothesis that patterns of divergence among lineages are constrained by the amount and structure of genetic variation within populations, with divergence being limited by genetic constraints along certain axes of trait space.

Correlational selection Selection that favors combinations of traits rather than acting on traits independently.

Demographic constraints A demographic constraint is an inability for a population to maintain a viable population size while approaching an adaptive peak. Thus, a demographic constraint on adaptation occurs when the population becomes extinct before the peak is reached, despite some additive genetic variation in the direction of selection.

Diversifying selection Natural selection that drives divergence and increases phenotypic variation among populations or lineages.

Evolvability A measure of the amount of additive genetic variation in a trait or along an axis of multivariate trait space. Formally, evolvability is the additive genetic coefficient of variation (Houle, 1992).

Genetic constraints Insufficient genetic variation in the direction of selection to produce an evolutionary response. An absolute genetic constraint exists if no genetic variation exists along a certain axis of trait space.

Key innovations Novel traits that allow or trigger diversification and/or divergence of phenotypes and often accompany adaptive radiations and the colonization of novel niches.

M-matrix A matrix describing the variance and covariance of mutational effects of new mutants affecting a set of phenotypic traits in a population.

Phenotypic integration A term used to describe the state of having a set of correlated phenotypic traits, generally integrated together as a functional unit. Phenotypic de-integration then represents the loss of genetic correlations that allows traits to evolve independently from one another in the population.

Qst A measure of population differentiation that describes the partitioning of quantitative genetic variation in continuous traits within and among populations.

Stabilizing selection Natural selection that favors intermediate values and selects against extreme values.

Wright's F-statistic A measure of population differentiation that describes the partitioning of genetic variation within and among populations.

Introduction

Disentangling the evolutionary processes that shape the divergence and diversification of lineages requires an understanding of the inheritance of quantitative traits. While quantitative genetics provides a powerful and effective framework for understanding short-term response to selection and genetic drift (Lande, 1979; Lande and Arnold, 1983), it is less clear how the complex interplay between selection, standing genetic variation, mutation, migration, and demographic stochasticity results in realized patterns of divergence and diversification among lineages over longer evolutionary timescales (Arnold *et al.*, 2001). This article examines to what extent the properties of quantitative genetic variation within populations can inform our understanding of the evolutionary processes influencing lineage divergence and diversification over 'macroevolutionary' time. Our goal is not to predict the exact course of evolution in natural populations over such scales, as this is likely infeasible; instead, we seek to understand whether and how the variational properties in evolving populations bias or constrain divergence and diversification.

As described in previous articles, the structure of genetic variation within populations can be summarized for quantitative traits by the genetic variance–covariance matrix (the G-matrix, Lande, 1979). The G-matrix describes the set of genetic constraints present in a population (Arnold, 1992). The amount of additive genetic variation for a given phenotypic trait determines a population's response to selection (Lande, 1979; Lande and Arnold, 1983) and the rate at which variation among lineages accumulates in response to genetic drift (Lande, 1976). Furthermore, the genetic covariation between traits resulting from pleiotropy and linkage disequilibrium determines correlated responses to selection that can skew the trajectory away from the direction of selection (Lande, 1979; Schluter, 1996).

 doi:10.1016/B978-0-12-800049-6.00060-3

The G-matrix is therefore a key parameter for predicting patterns of evolution for specific evolutionary models and, more generally, for understanding whether genetic constraints bias patterns of divergence among lineages. Furthermore, when phenotypic traits are tied to reproductive or ecological isolation, quantitative genetic variation may influence the process of speciation and help explain disparate patterns of diversification across lineages. Here we address the effect of quantitative genetic variation on among-lineage evolutionary patterns at three distinct levels: (1) Can the observed divergence patterns among lineages be attributed to a specific evolutionary process (e.g., drift or selection)? (2) Does the structure of genetic variation bias patterns of phenotypic divergence across lineages? (3) Does the amount of genetic variation within or among populations affect speciation and diversification?

Is Divergence Among Populations the Result of Drift or Selection?

The quantitative genetic model of genetic drift provides a neutral model of phenotypic evolution (Lande, 1976; Lynch, 1990) in much the same manner as Kimura provided a neutral expectation for molecular evolution (Kimura, 1968; Kimura, 1983). Just as Kimura's model allows for tests of selection from gene sequences, the neutral model of quantitative genetics generates predictions for patterns of divergence expected under genetic drift. Significant deviations from this expected pattern provide a useful tool for detecting adaptive trait differentiation and determining the nature of selection.

A neutral expectation for phenotypic divergence of a single character under genetic drift can be obtained by first assuming constant genetic variation. Each generation drift erodes genetic variation, while mutation (and, potentially, migration) increases genetic variation, resulting in mutation–drift equilibrium (Phillips *et al.*, 2001). Assuming that the effective population size remains constant, genetic drift is expected to shift the phenotypic mean of the population each generation at a rate proportional to the additive genetic variation in the population, and inversely proportional to effective population size (N_e, Lande, 1976). Under such a model of drift, divergence among lineages is expected to evolve via Brownian motion and the variance among replicate population's mean phenotypes is expected to increase linearly with time. One can also relax the assumption of constant genetic variation, since the amount of genetic variation itself is expected to depend on N_e. Specifically, Lynch and Hill (1986) showed that at mutation–drift equilibrium, genetic variance is expected to approximately equal $2\,V_m N_e$, where V_m is the mutational variance added each generation. Under these assumptions, effective population size cancels out when predicting divergence among replicate populations, and variance increases at a rate proportional only to the mutational variance.

These models allow rough estimates for the amount of divergence expected under neutrality in typical natural populations. Lynch (1990) and later Estes and Arnold (2007) showed that most macroevolutionary divergence between species occurs at a rate that is substantially slower than what is expected under genetic drift. Comparing across a wide range of paleontological divergence estimates, Lynch (1990) found that only hominid divergence in cranial capacity fell within the range predicted by genetic drift. Of course, this does not indicate that hominid cranial capacity is a neutrally evolving trait, but rather shows that most macroevolutionary divergence is considerably slower than predictions from genetic drift, indicating that stabilizing selection is prevalent in nature (but see Hansen and Houle, 2004). This observation is consistent with the paleontological observation of stasis (Eldredge and Gould, 1972; Gingerich, 1983; Estes and Arnold, 2007; Uyeda *et al.*, 2011), or little-to-no accumulation of evolutionary change over long timescales (whereas genetic drift predicts steady increase in divergence over time).

Similarly, neutral expectations for patterns of divergence for multiple, covarying traits can be modeled under drift as a multivariate Brownian motion process. Estimates of the G-matrix and effective population sizes can be used to generate predictions for the amount of divergence among lineages. This provides a null expectation for the amount of divergence that is consistent with genetic drift (Rogers *et al.*, 2002; Marroig and Cheverud, 2004). In addition to predicting the amount of expected divergence among populations, it is also possible to test whether correlations among lineages' multivariate trait values reflect within-population genetic covariance between traits (McGuigan *et al.*, 2005). Building on these methods, Hohenlohe and Arnold (2008) developed a phylogenetic comparative approach for testing whether among-species patterns of divergence are consistent with expectations under genetic drift, as well as evaluating whether the pattern of covariation is consistent with within-population structure. This latter question is discussed in more detail in the Section Does Genetic Architecture Bias the Direction of Evolution (or Vice Versa)?

Frequently, it is difficult to obtain reliable estimates of relevant parameters (e.g., effective population size, time since divergence) to make specific predictions about the amount of divergence under drift. Furthermore, the assumptions necessary to make direct predictions are frequently violated in natural populations (e.g., no migration). Studies below the species level in natural populations commonly encounter complex population histories of gene flow, population fission, and fusion. These processes greatly complicate direct prediction of expectations under genetic drift using quantitative genetic models. An alternative approach is to compare the amount of phenotypic divergence to divergence at putatively neutrally evolving genetic loci (Wright, 1951; Lande, 1992; Spitze, 1993). This approach compares Wright's F-statistic for a neutral genetic locus with an analogous quantity for a quantitative trait (Qst). Both quantities describe how variation is partitioned within and among populations. A value of 0 is indicative of no divergence among populations in allele frequencies, while the theoretical maximum value of 1 would indicate that all variation is partitioned between populations (with no variation shared between populations). Under the neutral model, Qst is expected to behave as a single neutrally evolving molecular locus (Whitlock, 2008). Assessing significance of a given value of Qst can be obtained by comparing its value to the distribution of Fst for neutrally evolving loci (Whitlock, 2008; Whitlock and Guillaume, 2009). A Qst significantly higher than Fst would indicate a phenotypic trait

under diversifying selection, while a Qst significantly lower than Fst would indicate stabilizing selection. Multivariate extensions of Qst–Fst tests allow exploration of the relationship between orientation and direction of divergence in quantitative traits within and among populations (Kremer *et al.*, 1997; Chenoweth *et al.*, 2008).

Empirical studies reveal that at the relatively short timescales of population differentiation, it is quite common for phenotypic traits to exhibit diversifying selection (Merilä and Crnokrak, 2001; Leinonen *et al.*, 2013). Given that the traits under study are often assumed to be ecologically relevant, it is perhaps unsurprising that these traits evolve and adapt to local conditions faster than neutral expectation. However, note that this is in contrast to macroevolutionary comparisons of trait divergence relative to neutrality that were discussed above, which typically show rates of phenotypic divergence slower than predicted under drift. This disparity likely reflects a difference in timescales. By analyzing a large database of divergence estimates collected from generational to macroevolutionary timescales, Estes and Arnold (2007) showed that empirical estimates of phenotypic divergence in body-size related traits across a large range of taxa are generally larger than neutral expectation at microevolutionary and population divergence timescales. However, at longer timescales divergence lags behind neutral expectation. These differences underscore that traits such as body size are not likely to evolve neutrally for very long, but rather, have long-term dynamics driven by the evolution of adaptive landscape (Hansen, 2012).

Does Genetic Architecture Bias the Direction of Evolution (or Vice Versa)?

Under most circumstances, complex phenotypic traits that are closely tied to organismal fitness are not expected to be selectively neutral. A more interesting question is whether within-population genetic variance and covariance biases the pattern of phenotypic divergence among lineages. This so-called constraints hypothesis posits that the pattern of divergence among lineages will reflect the evolutionary constraints present within populations (Schluter, 1996).

Schluter (1996) conjectured that divergence among lineages proceeds, at least temporarily, along 'lines of least resistance' in phenotypic space. In particular, he posited that the 'genetic line of least resistance' – or the combination of traits with the most available genetic variation in a population – would bias divergence to occur primarily in this direction. Mathematically, this axis is described by the leading eigenvector of the G-matrix, or g_{max} . The hypothesis may be viewed from two sides. First, it may be viewed as a hypothesis about genetic constraints, in which divergence is limited because of low levels of genetic variation, particularly along multivariate axes of trait variation (**Figures 1(a)** and **(b)**; Arnold, 1992; Blows and Hoffmann, 2005; Walsh and Blows, 2009). On the other side of the coin, one may view genetic covariance among traits as not limiting divergence, but rather by positively channeling divergence along lines of least resistance (**Figure 1(c)**; Lande, 1979; Gould, 1989; Brakefield, 2006; Eroukhmanoff, 2009; Agrawal and Stinchcombe, 2009). Patterns of divergence among lineages can be described in a manner analogous to within-population divergence, via the divergence matrix (D-matrix, a variance–covariance matrix of phylogenetically-weighted lineage-specific phenotypic means; Lande, 1979; Blows and Higgie, 2003). Schluter's model predicts that the D-matrix and the G-matrix will be proportional, providing a test for whether the genetic architecture of populations affects the structure of phenotypic diversification. Indeed, under both drift and selection, genetic covariance will bias both divergence generated by genetic drift and the short-term selection response of covarying traits (**Figures 1(a)–(d)**).

Empirical tests of the constraints hypothesis commonly find a relationship between multivariate axes of high genetic variance and divergence (Schluter, 1996; Mitchell-Olds, 1996; Chenoweth *et al.*, 2010; Hohenlohe and Arnold, 2008; Hansen and Houle, 2008; Blows and Higgie, 2003; Bégin and Roff, 2004; McGuigan *et al.*, 2005; Bolstad *et al.*, 2014). A smaller but still notable number of studies report a lack of a relationship (Merilä and Björklund, 1999; Chenoweth *et al.*, 2008; Kimmel *et al.*, 2012). Even so, a number of statistical and methodological issues have yet to be fully addressed. Bolstad *et al.* (2014) argue that the majority of these statistical issues will weaken the observed relationship between g_{max} and divergence, and that few studies can be claimed to convincingly demonstrate a lack of effects of genetic constraints on patterns of divergence. Furthermore, a strict alignment between d_{max} (the leading eigenvector of the D-matrix) and g_{max} is not necessary to validate the more general hypothesis that genetic constraints bias long-term evolutionary trends, as phenotypic differentiation may occur along one of many axes with higher than average genetic variance and evolvability (Hansen and Voje, 2011; Bolstad *et al.*, 2014).

Of course, G-matrices themselves evolve over time (Turelli *et al.*, 1988; Roff, 2000; Steppan *et al.*, 2002). However, the G-matrix must be relatively constant over the timeframe of divergence in order to make quantitative predictions. While it is a certainty that the G-matrix will evolve over time, the overall structure of genetic constraints may often remain relatively constant over the timescales of interest (Bégin and Roff, 2004). However, exceptions do occur, and some closely related populations or species have diverged substantially in g_{max} (Berger *et al.*, 2013). Ultimately, the constancy of the G-matrix over long timescales is an open empirical question.

The constraints hypothesis suggests that lineages are constantly chasing their adaptive optima, or under weak selection. Otherwise, biases induced by trait covariance are expected to be temporary so long as the constraints are not 'absolute constraints' (all eigenvalues of the G-matrix are nonzero) and populations are given sufficient time to reach an adaptive peak. In fact, many studies find an abundance of genetic variation along all axes of variation (Mezey and Houle, 2005; Walsh and Blows, 2009). Strong directional selection is also frequently observed (Hereford *et al.*, 2004; Siepielski *et al.*, 2009; Kingsolver and Diamond, 2011). In combination, these two patterns predict near instantaneous adaptation to adaptive peaks (relative to macroevolutionary time) and would seem to suggest limited potential for genetic constraints to shape divergence (Hansen and Houle, 2004). Naively, these patterns suggest that among-lineage patterns of divergence may be driven primarily by the dynamics of adaptive peaks over time,

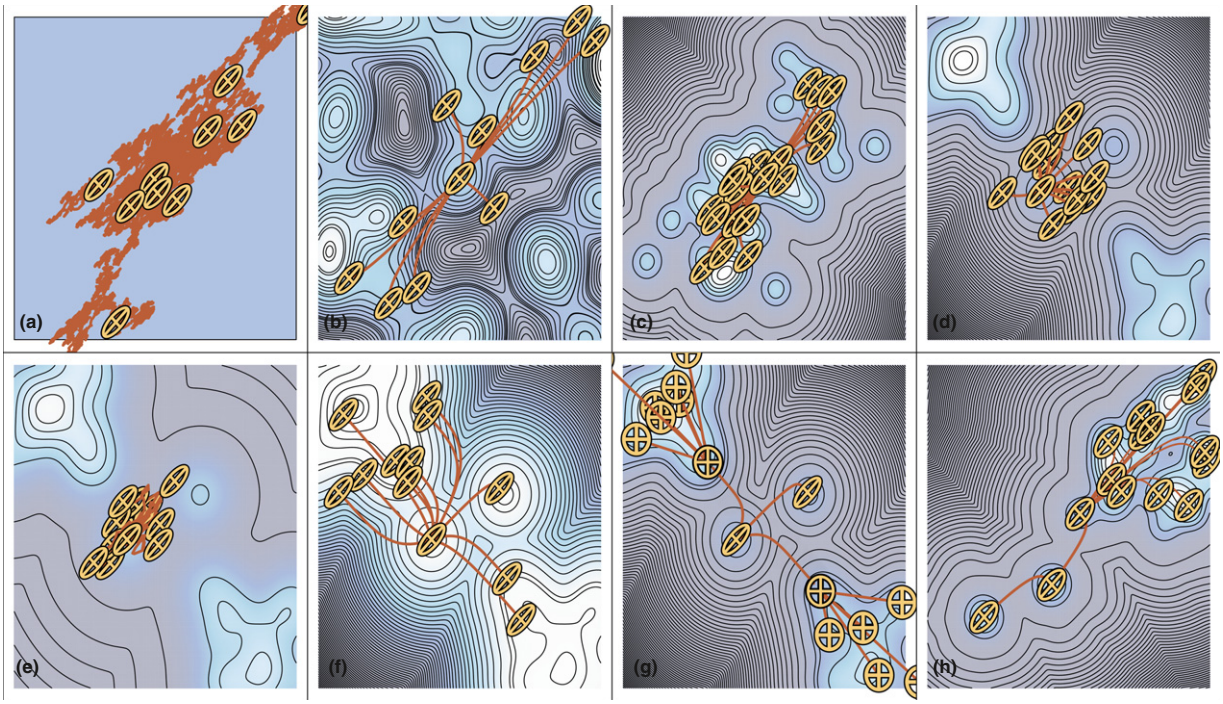

Figure 1 Conceptual figure depicting scenarios depicting the relationship between the adaptive landscape and the G-matrix. The G-matrix is indicated by the orange ellipses, which represent the 95% confidence interval for the bivariate distribution of genetic values in the population. X- and Y-axes indicate mean values for two phenotypic traits, while the contour lines and color indicates mean fitness of the population. Note that we cannot depict spatially or temporally varying adaptive landscapes in only two dimensions. Hence, we show here adaptive peaks varying across a landscape, but in a given population, we assume a single adaptive peak. Trajectories therefore illustrate paths between the ancestral adaptive peak (center) and novel adaptive peaks in surrounding regions. (a) Genetic drift – A flat adaptive landscape allows diverging species to freely explore phenotypic space. Divergence is biased along genetic lines of least resistance. (b) Randomly oriented adaptive peaks – In this scenario, no region of the adaptive landscape is favored over any other. However, peaks along g_{max} are reached more quickly, leading to greater divergence along this axis. Nevertheless, given sufficient time for selection, all peaks will reach their optimum. Thus, the correspondence between g_{max} and d_{max} erodes over time. Nevertheless, if demographic constraints prevent species from reaching distant peaks along constrained axes of variation, a correspondence between g_{max} and d_{max} may remain. (c) Positive constraints – This scenario depicts so-called 'positive constraints,' where the correlation between traits channels variation in directions likely to be adaptive in novel habitats. (d) Negative constraints – This scenario depicts an ill-formed G-matrix. High fitness 'adaptive ranges' are located nearby, but approach to these peaks is slow, and combined with demographic constraints, prevents populations from colonizing these areas of phenotypic space. Scenarios (e)–(h) depict different types of ecological release and key innovations leading to an increase in phenotypic divergence. (e) Decrease in stabilizing selection – In accordance with the hypothesis of Yoder *et al.*, 2010, stabilizing selection can decrease the valleys between adaptive peaks and thus allow lineages to traverse to novel adaptive peaks. However, this occurs at a slower rate due to weaker selection favoring novel peaks. This scenario comes to resemble genetic drift. (f) Increase in absolute fitness – Demographic constraints may prevent species from reaching distant peaks. Therefore, an increase in absolute fitness in accordance with ecological release can allow lineages to traverse fitness valleys to new adaptive peaks without risking extinction. In this scenario, relative fitness remains the same, and thus divergence proceeds at the same rate as in (d), but with a relaxation of demographic constraints. (g) Loss of phenotypic integration – Key innovations are thought to allow the rapid differentiation of species into novel regions of phenotypic space. Here a loss of genetic constraints and phenotypic integration allows lineages to more rapidly colonize novel adaptive peaks which were always present and accessible, but could not be reached due to genetic constraints. (h) Novel area of phenotypic space – This type of key innovation can result simply from a shift in the mean that allows access to novel habitats with an abundance of adaptive peaks. This is typical when, for example, a species invades a novel niche or is introduced to a novel bioregion.

with most populations residing close to their adaptive optima. If we accept this view, the primary determinant of evolutionary divergence among lineages is the long-term dynamics of adaptive peaks themselves with the specifics of genetic architecture playing little role in the pattern of divergence (Simpson, 1944; Arnold *et al.*, 2001; Hansen, 2012). Alternatively, the trajectory of evolution may still be biased by the G-matrix if the landscape has multiple peaks, and local peaks in certain directions of phenotypic space are favored over others, leading to biased exploration of the adaptive landscape (Hine and Blows, 2006; McGuigan and Blows, 2007).

What, then, explains the commonly observed relationship between the G-matrix and the D-matrix? The dual observation of abundant genetic variation in most measured directions and the existence of strong directional selection is not a death blow to the constraints hypothesis. Multivariate genetic constraints with unmeasured traits experiencing stabilizing selection may limit adaptation while simultaneously allowing limited but rapid short-term evolutionary responses (Walsh and Blows, 2009; Hansen, 2012; Bolstad *et al.*, 2014). This latter pattern is widely observed for phenotypic divergence across timescales, which find that although divergence is often quite rapid in the short

term, it is bounded and does not accumulate until much longer, million-year timescales (Uyeda *et al.*, 2011). Such a pattern may arise by considering the concept of 'conditional evolvability' (Hansen and Houle, 2008), which is defined as the amount of available genetic variation along the vector of selection that is uncorrelated to variation along perpendicular axes (i.e., the amount of evolutionary change possible in a given direction without change in other traits). Because only a small subset of traits are typically measured, this may mean that conditional evolvabilities are considerably lower than evolvabilities measured in natural populations (Bolstad *et al.*, 2014). Furthermore, genetic constraints need not be absolute if populations are constrained by finite population sizes. If populations are maladapted and off their fitness optima, they may incur demographic costs and decrease in population size. Even temporary lags resulting from insufficient genetic variation could impose 'demographic constraints' on adaptation, preventing colonization of peaks along axes of low evolvability despite an absence of absolute genetic constraints (Gomulkiewicz and Houle, 2009).

Alternatively, alignment between the G-matrix and the D-matrix may result secondarily from the evolution of the G-matrix to conform to the axis of divergence and the shape of the adaptive landscape. Thus, rather than genetic architecture biasing divergence, divergence along adaptive ridges in phenotypic space may shape genetic architecture to orient g_{max} along so-called selective lines of least resistance (Arnold *et al.*, 2008). Indeed, simulation studies have shown that the G-matrix evolves as a balance between the shape and orientation of the adaptive landscape – which may be skewed by correlational selection – and the shape and orientation of the mutation matrix (M-matrix), which describes the phenotypic effects of new mutations that enter into the population (Jones *et al.*, 2003, 2007, 2012). Directional selection and migration between populations can likewise orient the G-matrix along the axis of divergence between populations by introducing alleles with correlated effects on phenotypic traits – albeit weakly and with transient effects (Guillaume and Whitlock, 2007). Finally, recent simulation studies suggest that the M-matrix itself can evolve, especially in the presence of epistatic interactions between genes, to conform to the shape of the adaptive landscape, resulting in triple alignment between the M-matrix, G-matrix, and the axis of divergence among populations (Jones *et al.*, 2007; Hether and Hohenlohe, 2014; Jones *et al.*, 2014).

These alternative explanations are not mutually exclusive and may be reinforcing in natural populations. While this general condition of alignment seems likely under many circumstances, instances of misalignment between the G-matrix and the D-matrix certainly do occur. Furthermore, it seems likely that genetic constraints are underestimated in natural populations. Nonetheless, understanding to what extent the genetic architecture drives patterns of divergence remains an outstanding question in scaling between microevolutionary processes and macroevolutionary patterns.

Does Genetic Architecutre Affect Rates of Diversification?

Until now, we have focused on phenotypic divergence and ignored speciation and diversification. Yet, a vast disparity exists between rates of diversification among clades. Furthermore, radiations can both encompass dramatic diversifications in phenotype, as well as 'cryptic radiations' in which species diversify without phenotypic change. To what extent does the structure of quantitative genetic variation within a species affect these patterns of diversity and phenotypic divergence?

Under some evolutionary processes, the structure and amount of genetic variation can play a key role in driving phenotypic divergence in traits important for reproductive isolation. For example, quantitative genetic models of sexual selection predict that amounts of genetic variation for sexual preference and ornament traits under a variety of circumstances can affect the rate of evolution of reproductive isolation (Lande, 1981; Mead and Arnold, 2004; Gavrilets, 2000; Gavrilets and Hayashi, 2005; Uyeda *et al.*, 2009). Similar arguments can be made for other types of coevolution, so long as a mechanistic link exists between phenotypic divergence and the evolution of reproductive isolation (Felsenstein, 1981; Kiester *et al.*, 1984, but see Yoder and Nuismer, 2010).

Adaptive radiations characterized by large amounts of phenotypic divergence and lineage diversification have long captured the attention of evolutionary biologists. This correspondence between lineage diversification and phenotypic divergence in these clades suggests a potential role for changes in genetic architecture, or of the adaptive landscape, in driving these patterns. Yoder *et al.* (2010) argue that ecological opportunity drives these patterns and can be conceptualized as a weakening of the strength of stabilizing selection, allowing populations to traverse fitness valleys more easily (**Figure 1(e)**). However, such a model is somewhat inconsistent with the seemingly rapid pace of adaptation in many adaptive radiations, as weakened stabilizing selection results in pattern akin to expectations under genetic drift rather than the rapid, niche-based divergence of lineages typically envisaged in such radiations (**Figure 1(a)**). Alternatively, 'ecological release' of populations can be defined as an overall increase in the absolute fitness of populations, resulting in relaxation of demographic constraints while still maintaining stark differences in relative fitness among peaks and strong selection (cf. Wellborn and Langerhans, 2014; **Figure 1(f)**).

Adaptive radiations are sometimes attributed to 'key innovations' that allow colonization of previously unattainable niches. Two types of key innovations are possible: (1) an innovation resulting from novel phenotypic values (**Figure 1(h)**) and (2) a change in the genetic architecture that removes genetic constraints (i.e., a loss of phenotypic integration, **Figure 1(g)**). This latter type of innovation is of primary interest to the subject of this article, as it would indicate that the potential for adaptive radiation may be predicted from genetic architecture of trait variation. A change in the effective dimensionality of trait covariance can affect the overall rate of phenotypic divergence along novel axes of phenotypic space (Nosil and Sandoval, 2008). If these traits are related to mechanisms of speciation and diversification, adaptive radiation may result. This is because higher-dimensionality in trait variation results in more axes along which divergence can occur, and sexual isolation can result if the trait is tied to reproductive isolation (Hohenlohe and Arnold, 2010; Kemp, 2007; Wainwright, 2007; Doebeli and Ispolatov, 2010). For example, Maia *et al.* (2013) showed key innovations in

pigmentation cells resulted in an increase in dimensionality of color phenotypes and are simultaneously correlated with both increased rates of phenotypic evolution and diversification. Nonsexually selected key innovations with de-integrated phenotypes have met with more equivocal effects on diversification (Alfaro *et al.*, 2009; Frédérich *et al.*, 2014). Instead, a common pattern is for the increase in diversification to lag behind the evolution of the key innovation or require a sequence of innovations (Alfaro *et al.*, 2009; Near *et al.*, 2012; Sanderson and Donoghue, 1996; Kemp, 2007). These patterns suggest that diversification rate shifts likely result from a shift into novel regions of the adaptive landscape itself (**Figure 1(g)**), rather than changes in genetic architecture directly influencing diversification rates (**Figure 1(h)**; Wainwright, 2007).

Conclusion

Bridging the divide between micro- and macroevolution requires understanding the degree to which the structure of genetic variation influences macroevolutionary patterns of divergence and diversification among lineages. Quantitative genetics provides a means to generate quantitative and empirically testable predictions that help disentangle the evolutionary processes of drift and selection in explaining divergence. Furthermore, the evolutionary constraints hypothesis posits that among-lineage patterns of divergence are constrained by patterns of genetic variation within lineages. In general, an emerging picture is one in which divergence among lineages generally correlates with within-lineage patterns of trait variation. Naive extrapolation of measured levels of genetic variation, however, appear inconsistent with absolute constraints on divergence. Nevertheless, genetic constraints may still play a role and empirical estimates of evolvability may be affected by unobserved trait correlations limiting divergence in certain directions. Additional empirical research is also necessary on the evolution of genetic architecture itself in a comparative framework to establish the degree to which divergence G-matrix itself evolves among lineages and in response to patterns of selection (Steppan *et al.*, 2002).

While the degree of integration among phenotypes has long been suggested to impact rates of species diversification, relatively few macroevolutionary tests of the effect of phenotypic integration on rates of diversification have been conducted. Increased dimensionality and evolvability for some phenotypic traits may increase diversification rates. However, as with phenotypic diversification, the relationship may be more complex than naive extrapolation would indicate. Rather, the specific means by which patterns and processes can be reconciled across scales and macroevolutionary time require significant further exploration.

In general, connecting 'microevolution' (the variational properties of populations) and 'macroevolution' (the divergence and diversification of lineages) remains a challenging but fertile research avenue. The strong predictive power of quantitative genetic models combined with increasing availability parameter estimates obtained from empirical studies provides a powerful framework for pursuing these important goals.

Ecological Evolutionary Developmental Biology

DW Pfennig, University of North Carolina, Chapel Hill, NC, USA

Glossary

Canalization The situation that arises when a trait is 'fixed' or expressed constitutively regardless of normal changes in the environment.

Cryptic genetic variation Variation that is expressed only under atypical conditions.

Developmental plasticity See 'phenotypic plasticity.'

Differential gene expression The situation that arises when different genes are activated, or expressed, in different cell types or organisms; nearly always accompanies 'phenotypic plasticity.'

Ecomorphs (morphs) Alternative phenotypes induced by the environment that occupy different ecological niches.

Enhancer It is involved in 'differential gene expression'; the region of a gene (i.e., a sequence of DNA) that binds 'transcription factors'; the resulting complex interacts with the gene's 'promoter,' thereby activating the gene and beginning transcription.

Epigenetics Any mechanism of development that generates phenotypic variation without altering the base-pair nucleotide sequence of DNA; phenotypic variation that involves changes in the expression of genes rather than their sequence.

Epigenetic inheritance Heritable phenotypes that are not encoded by the genome.

Genes as followers The hypothesis that the most important role of genetic mutations in evolution may be to contribute not so much to the origin of phenotypic novelties as to the pool of genetic variation that makes 'genetic accommodation' possible.

Genetic accommodation A mechanism of evolution wherein a novel phenotype, generated by either a mutation or environmental change, is refined into an adaptive phenotype through quantitative genetic changes; can result in either increased or decreased environmental sensitivity of an induced phenotype; when environmentally induced phenotypes lose their environmental sensitivity, they undergo 'genetic assimilation.'

Genetic assimilation An extreme form of 'genetic accommodation' that occurs when environmentally induced phenotypes lose their environmental sensitivity over evolutionary time and become 'canalized' or expressed constitutively.

Lamarckianism The hypothesis, attributable to the French naturalist Jean-Baptiste Lamarck (1744–1829), which holds that an organism can pass on characteristics that it acquired during its lifetime to its offspring.

Maternal effects The situation that arises when a female's phenotype influences its offspring's phenotype, independent of the direct effects of the female's coding sequences on its offspring's phenotype.

Phenotypic plasticity The ability of an individual organism to change its phenotype in direct response to stimuli or inputs from the environment (often used synonymously with 'developmental plasticity').

Promoter The region of a gene (i.e., a sequence of DNA) that binds the enzyme RNA polymerase, thereby activating the gene and beginning transcription (see also 'enhancer' and 'transcription factor').

Reaction norm A graphical representation of the sensitivity of a group of organisms of the same genotype to some specific environmental variable.

Transcription factor A protein that binds to a specific DNA sequence, thereby activating the gene and beginning transcription (see also 'promoter' and 'enhancer').

Introduction

Ecological evolutionary developmental biology ('eco-evo-devo') seeks to understand how interactions between an organism's genome and environment shape its development, and how such environmentally responsive development, in turn, impacts ecology and evolution (Sultan, 2007; Gilbert and Epel, 2009). This focus on environmentally contingent development is a departure from how developmental and evolutionary biology have been studied in the past. For example, until relatively recently, developmental biology has focused on a few species ('model organisms') reared in uniform environments. This approach has fostered the view that environmentally contingent development is rare or unimportant. Similarly, evolutionary biology has traditionally regarded environmental responsiveness as simply

 doi:10.1016/B978-0-12-800049-6.00143-8

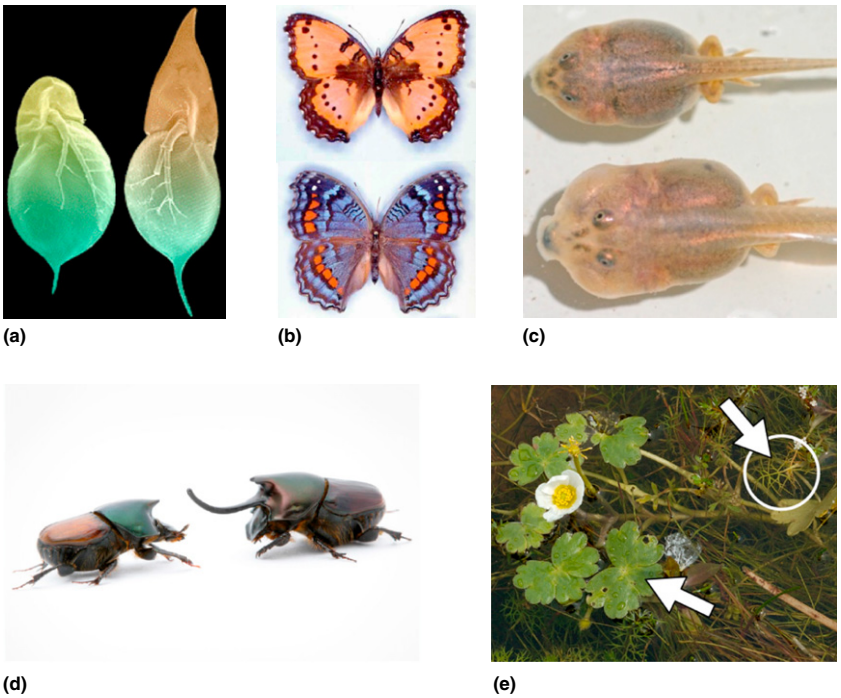

Figure 1 Examples of environmentally contingent development (i.e., 'phenotypic plasticity'). Trends in Ecology and Evolution 25, 459–467.

developmental 'noise' that has no long-term evolutionary consequences (Orr, 1999). Indeed, the architects of the modern synthesis of evolutionary biology explicitly cho se not to incorporate environmentally responsive development into the field's conceptual framework, partly as a reaction against Lamarckianism (reviewed in Pigliucci, 2007).

Yet, it has become increasingly apparent that an organism's environment can profoundly alter its phenotype (**Figure 1**). Moreover, it has even been suggested that such environmentally initiated phenotypic change might often precede, and even facilitate, genetic evolution and therefore plays a key role in generating biodiversity. Additionally, a growing body of evidence has revealed that environmentally induced phenotypic change can be transmitted between generations, which challenges our basic assumptions of how inheritance works (reviewed in Jablonka and Lamb, 2010; see also below).

This article explores these issues in greater detail. As described below ongoing research in eco-evo-devo promises to provide fresh insights into the evolutionary process.

Phenotypic Plasticity

For much of the twentieth century, genes were the dominant paradigm for explaining biodiversity. Yet, scholars have long suspected that genes alone do not determine which traits organisms produce (Bonduriansky, 2012). Indeed, it is now abundantly clear that the environment is a normal and necessary agent in phenotype production (Schlichting and Pigliucci, 1998; Gilbert and Epel, 2009). Nowhere is this point more clearly illustrated than by the widespread occurrence of phenotypic plasticity (Nijhout, 2003; West-Eberhard, 2003).

'Phenotypic plasticity' (often used synonymously with 'developmental plasticity') is the ability of an individual organism to change its phenotype in direct response to stimuli or inputs from the environment (sensu West-Eberhard, 2003). As it turns out, many (perhaps all) organisms can alter their phenotype in response to a diverse array of environmental factors, such as temperature, nutrition, light, pressure, or gravity, and the presence of predators, parasites, or competitors (Gilbert and Epel, 2009). For instance, temperature can influence phenotype production, because nearly all enzyme activity is temperature-dependent (**Figure 1(b)**); food often contains potent chemical signals that induce phenotypic change (**Figure 1(d)**); light can stimulate plants to produce different-shaped leaves and shoots (**Figure 1(e)**); and pressure can cause muscle and bone to grow differently. Moreover, predators can release chemicals that induce defenses in their prey (**Figure 1(a)**) and competitors can cause stress (which releases stress hormones) and alter resource abundance (and thereby an individual's nutritional state), which can trigger an alternative phenotype (**Figure 1(c)**). Regardless of the precise environmental factor, a feature common to all the above is that phenotypic plasticity is nearly always accompanied by changes in gene expression (Gilbert and Epel, 2009; e.g., see **Figure 2**).

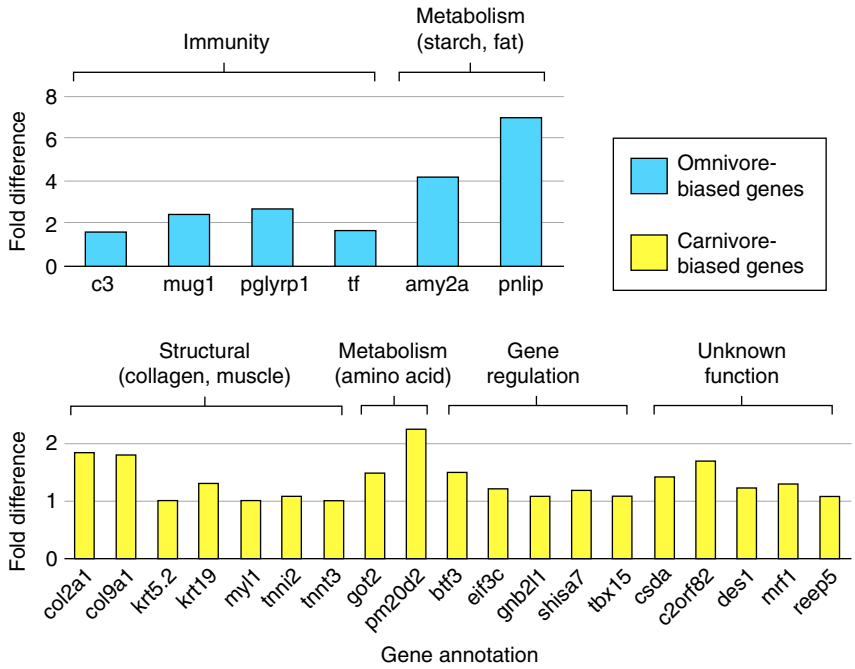

Figure 2 Differential gene expression in alternative, environmentally induced, larval ecomorphs of spadefoot toads (genus *Spea*). Depending on their diet, spadefoot tadpoles develop into either an omnivore morph, which is a dietary generalist, or a distinctive, large-headed carnivore morph, which specializes on shrimp and other tadpoles (see **Figure 1(c)**). Shown are fold differences (a measure of the change in expression level of a particular gene) for each of six genes expressed at significantly higher levels in omnivores than in carnivores and 19 genes expressed at significantly higher levels in carnivores than in omnivores; above each gene is its putative function (where known). Data from Leichty, A.R., Pfennig, D.W., Jones, C.D., Pfennig, K.S., 2012. Relaxed genetic constraint is ancestral to the evolution of phenotypic plasticity. Intergrative and Comparative Biology 52, 16–30.

Considerable effort has gone into identifying the molecular mechanisms of differential gene expression and, thus, of phenotypic plasticity (Gilbert and Epel, 2009). One model (based on studies of how different cells in a multicellular organism that share the same genome can assume different shapes/functions) is that differential gene expression is mediated by the differential binding of proteins called 'transcription factors' to a gene's enhancer region. To understand how this process works, consider that for a gene to be activated (specifically, for RNA polymerase to attach to a gene's promoter and begin transcription), RNA polymerase must be held in place on the promoter site. Transcription factors play a key role in stabilizing RNA polymerase on the gene's promoter. Importantly, different transcription factors bind different enhancers and thereby alter expression of different genes. Moreover, which transcription factors are present in any particular cell can be influenced by signals from outside the cell (e.g., in the organism's external environment). Thus, one proposed mechanism of phenotypic plasticity is that the neuroendocrine system transduces sensory information from the external environment by recruiting different transcription factors, thereby activating different genes (Nijhout, 2003) which, in turn, produce different gene products (e.g., see **Figure 2**) and ultimately, different phenotypes (**Figure 1**).

Other mechanisms can alter phenotype production, however. For instance, gene expression changes can be induced directly, as when bacteria in an animal's gut induce changes in the expression of intestinal genes (Gilbert and Epel, 2009). Future research is needed to identify additional molecular mechanisms of phenotypic plasticity.

Phenotypic Plasticity and Evolution

Although phenotypic plasticity is commonplace, its evolutionary significance remains controversial (Pfennig *et al.*, 2010; Moczek *et al.*, 2011). On the one hand, evolutionary biologists have long held that plasticity has no relevance for the evolutionary process other than to perhaps impede it by dampening the effects of selection (reviewed in Schlichting, 2004). On the other hand, several prominent, early evolutionists, such as Weismann, Goldschmidt, Schmalhausen, and Waddington, maintained that phenotypic plasticity plays a central role in the origins of new traits and phenotypic differences between species (Jablonka and Lamb, 1995).

Indeed, for over a century, researchers have hypothesized that environmentally induced phenotypic change might facilitate genetic evolution and thereby fuel the origins of new, ecologically relevant traits (Baldwin, 1902; Schmalhausen, 1949 [1986]; Waddington, 1953; West-Eberhard, 2003). Although various mechanisms have been proposed (dubbed the 'Baldwin effect,' 'genetic assimilation,' 'stabilizing selection,' and 'genetic accommodation'), all such mechanisms assume that: (1) environmentally induced phenotypes evolve first; and (2) selection favors those phenotypes (whether induced or not) that are the most adaptive (West-Eberhard, 2003).

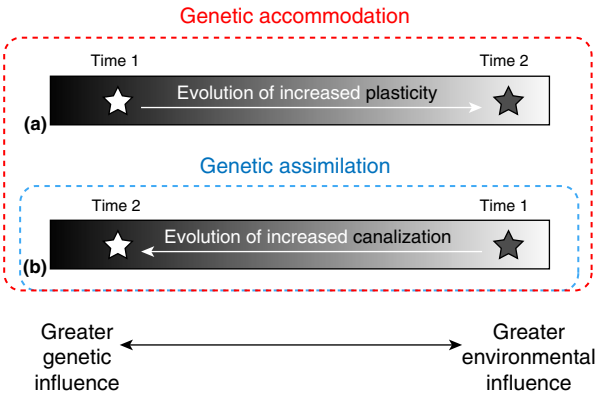

Figure 3 A diagram illustrating the distinction between genetic accommodation and genetic assimilation. Genetic accommodation is any adaptive genetic change in the regulation and form of a phenotype. For example, a trait may evolve either (a) increased or (b) decreased environmental sensitivity (i.e., phenotypic plasticity). The complete loss of phenotypic plasticity (i.e., increased canalization) is an extreme form of genetic accommodation known as genetic assimilation.

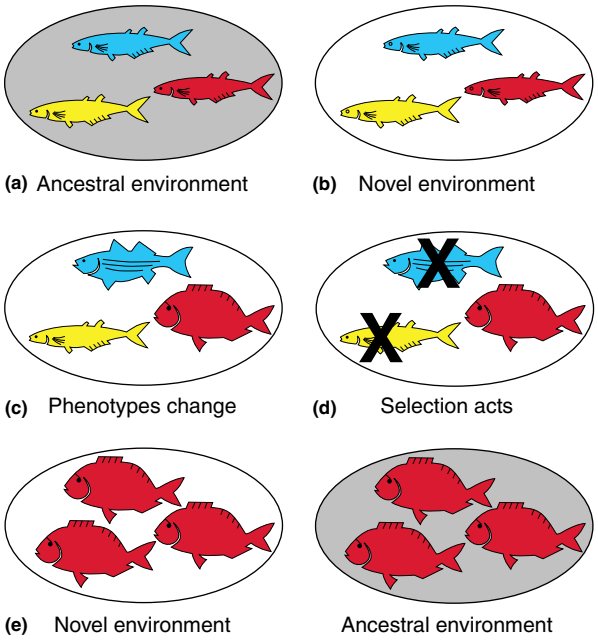

Figure 4 Phenotypic plasticity, along with genetic accommodation/assimilation, may facilitate the evolution of a new, canalized trait through the following steps (here, different fish shapes are alternative ecomorphs; different colors are different genotypes). (a) A genetically variable population (b) experiences a novel environment (indicated here as a change from a shaded to an unshaded background). (c) Consequently, novel phenotypes are induced by the environment, but different genotypes respond differently. (d) Selection disfavors those genotypes that produce maladaptive phenotypes in the new environment (indicated here by an 'X'). (e) Such selection may result in the evolution of a novel, canalized trait (e.g., a novel ecomorph) that is expressed regardless of the environment (i.e., even if the environment changes back to the original, ancestral state).

According to one prominent version of this theory (West-Eberhard, 2003), when selection acts on quantitative genetic variation regulating the expression of an initially environmentally induced trait, it can promote the evolution of either increased or decreased plasticity through an evolutionary process known as 'genetic accommodation' (**Figure 3**). If the affected trait evolves decreased plasticity to the point of becoming constitutively expressed, 'genetic assimilation' occurs (sensu Waddington, 1953; **Figure 3**). The outcome of genetic assimilation is a novel, canalized trait (i.e., a trait that is 'fixed,' or expressed constitutively regardless of normal changes in the environment).

To illustrate this process, imagine a population that experiences a novel environment (**Figure 4**). Individuals in such populations often cope with stress associated with unfamiliar environments by producing new phenotypes through phenotypic plasticity (Badyaev, 2005). If such an induced trait improves fitness, then selection will favor alleles or genotypes that enhance the trait's expression (different genotypes within the same population often vary in the degree to which they respond to any particular environmental stimulus; Gupta and Lewontin, 1982). As these alleles/genotypes accumulate in the population, individuals may express the trait without the original environmental stimulus; i.e., genetic assimilation occurs. In this way, a novel canalized trait emerges from a trait that was originally environmentally induced.

With genetic accommodation/assimilation, the origin of a complex new trait need not require the evolution of new genes. Instead, selection acts on existing genes and converts a plastic trait into a canalized trait via an evolutionary adjustment in the regulation of trait expression (West-Eberhard, 2003). A plausible mechanism whereby such an adjustment could occur is through changes in gene expression (Gilbert and Epel, 2009; Renn and Schumer, 2013; see **Figure 5**). Recall from above that gene expression is typically environmentally sensitive, and that changes in gene expression often (possibly, always) underlie phenotypic plasticity. If selection is persistent and coarse-grained (i.e., individuals encounter only one selective environment), then induced differences in gene expression may evolve to become less environmentally responsive until they become fixed (e.g., via allelic substitutions at regulatory loci; Grishkevich and Yanai, 2013).

Although genetic accommodation can occur whether a novel trait is mutationally or environmentally induced, environmentally triggered novelties likely have greater evolutionary potential than mutationally induced ones for at least two reasons. First, changes in the environment often impact many individuals simultaneously (e.g., consider how exposure to sudden cold temperatures or a new competitor or predator can affect a population). By contrast, a new mutation initially affects only one individual (and its immediate descendants). The widespread impact of environmental change enables a newly induced trait to be tested in diverse genetic backgrounds, thereby increasing the chances that genetic accommodation will occur (see above). Second, an environmentally triggered novelty is automatically associated with a particular environmental situation – the one that induced it. Therefore, such traits are more subject to consistent selection and

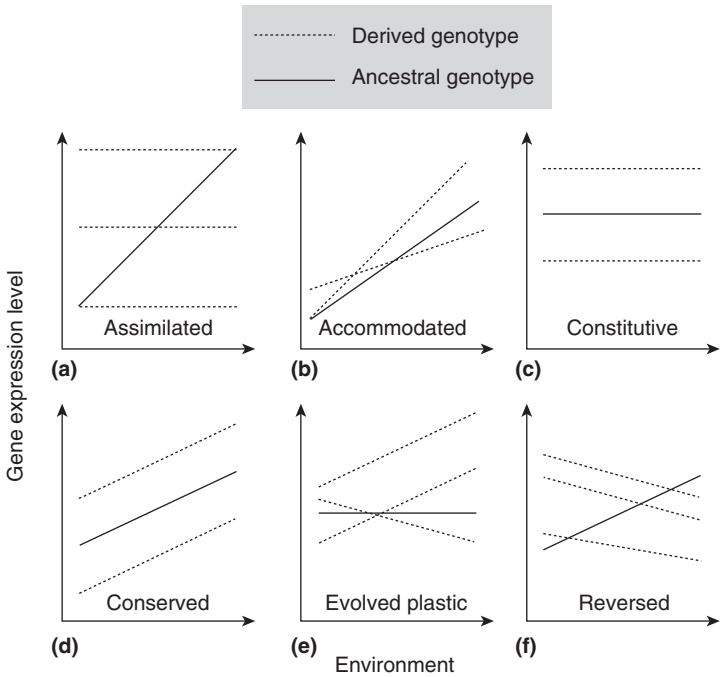

Figure 5 Alternative patterns by which gene expression might evolve. Each panel depicts the 'reaction norms' of ancestral and derived genotypes (a reaction norm is a graphical representation of the sensitivity of a group of organisms of the same genotype to some specific environmental variable). Redrawn, with permission from Renn, S.C.P., Schumer, M.E., 2013. Genetic accommodation and behavioural evolution: Insights from genomic studies. Animal Behaviour 85, 1012–1022.

directional modification than are mutationally induced novelties, for which expression is more likely to be random with respect to the environment.

Phenotypic plasticity also promotes the accumulation of 'cryptic genetic variation' – variation that is expressed only under atypical conditions (Paaby and Rockman, 2014) – that makes genetic accommodation possible. Phenotypic plasticity facilitates the build up of such variation, both because the effects of novel genetic variants are buffered by compensatory plastic responses (Moczek, 2008), and because environment-specific genes experience relaxed selection in the non-inducing environment (Lahti *et al.*, 2009; Leichty *et al.*, 2012). This accumulation of cryptic genetic variation can lead to further phenotypic novelty when it is revealed through a subsequent change in the environment or genome. Such unmasking of standing genetic variation may play an important role in fueling evolutionary changes (Moczek *et al.*, 2011).

Thus, the most important role of genetic mutations in evolution may be to contribute not so much to the origin of phenotypic novelties as to the pool of genetic variation that makes genetic accommodation possible. Or, as West-Eberhard (2003, p. 158) put it, genes may be 'followers, not necessarily leaders, in phenotypic evolution.'

Although laboratory studies have demonstrated that genetic accommodation can occur (Waddington, 1953; Rutherford and Lindquist, 1998; Suzuki and Nijhout, 2006), relatively little is known about whether this process is responsible for ecologically and evolutionarily relevant traits in natural populations (but see Schlichting and Wund, 2014). Generally, if plasticity has preceded – and facilitated – the evolution of a particular novel trait, then there should be evidence that: (1) ancestral species express the trait only conditionally; (2) novel environments uncover cryptic genetic variation; and (3) trait expression has been refined in derived species. A number of examples appear to satisfy these conditions (**Table 1**). Moreover, a recent meta-analysis has uncovered several convincing cases in which genes appear to be 'followers' in the origins of novel traits (Schwander and Leimar, 2011). Additionally, there is evidence that genetic accommodation might even play a role in speciation: there are numerous examples in which a formerly plastic trait has undergone canalization (i.e., lost its plasticity) in a particular lineage, and such shifts are typically accompanied by speciation (Schwander and Leimar, 2011). Yet, additional tests from natural populations are needed to evaluate plasticity's role (if any) in speciation.

Phenotypic Plasticity and Ecology

Phenotypic plasticity also has important implications for ecology, which, in turn, have additional evolutionary consequences. Recall from above that an organism's phenotype is shaped by its ecology. Yet, the reciprocal is also true: an organism's ecological interactions – and thus the selective regimes that it experiences – can be influenced by its developmental responses.

For instance, the individuals of many species respond adaptively to interspecific competition by facultatively modifying their resource-use traits through phenotypic plasticity (Pfennig and Pfennig, 2012). Species that can alter their phenotype in this way may persist in the face of novel

Table 1 Possible examples of genetic accommodation in natural populations of animals. For possible examples in plants, see Schlichting and Wund (2014)

Organism	*Trait(s) undergoing adaptive evolution*	*Reference(s)*
Water fleas (*Daphnia melanica*)	Pigmentation	Scoville and Pfrender (2010)
Stickleback fish (*Gasterosteus aculeatus*)	Benthic and limnetic ecomorphs	Wund *et al.* (2008)
Stickleback fish (*Gasterosteus aculeatus*)	Growth rate	Robinson (2013)
Spadefoot toads	Adult body/leg length and larval duration	Gomez-Mestre and Buchholz (2006)
Spadefoot toads (genus *Spea*)	Carnivore and omnivore ecomorphs	Ledón-Rettig *et al.* (2008); Pfennig and Martin (2010)
Australian tiger snakes (*Notechis scutatus*)	Head size	Aubret and Shine (2009)
House finches (*Carpodacus mexicanus*)	Sex determination and sex-specific resource allocation	Badyaev (2009)

competitive interactions because they can immediately (i.e., within a single generation) switch to a selectively favored phenotype. In the absence of such plasticity, species may be driven locally extinct through competitive exclusion (Pfennig and Pfennig, 2012). Thus, environmentally responsive development can reduce extinction risk, thereby influencing the composition of ecological communities (similar arguments can be made regarding the ability to respond rapidly to any sort of change in an organism's biotic or abiotic environment). Of course, populations that do not go extinct should ultimately be more likely to diversify. This may explain, at least in part, why clades in which conspicuous phenotypic plasticity (e.g., **Figure 1(c)**) has evolved are more species rich than sister clades lacking such plasticity (Pfennig and McGee, 2010).

Epigenetic Inheritance and Evolution

Lastly, research in eco-evo-devo is changing our view of inheritance, and indeed, our very definition of evolution. Because inheritance is a prerequisite for evolution to occur, clarifying how inheritance works has long been a goal of evolutionary biology (Bonduriansky and Day, 2009). Generally, most evolutionary biologists assume that inheritance occurs exclusively through alterations in the base-pair nucleotide sequence of genes; by contrast, phenotypic changes induced directly by the environment are assumed to be incapable of being inherited and to therefore play no role in mediating evolutionary change (Futuyma, 2013). Indeed, evolution is typically defined as change in a population's genes (Futuyma, 2013).

Yet, a growing body of evidence has conclusively shown that various extra- (or epi-)genetic factors that influence phenotype production – and that were initially induced directly by changes in the organism's environment – can be transmitted from one generation to the next (Jablonka and Raz, 2009). Such transmissible 'epigenetic' changes (Gilbert and Epel, 2009) thereby constitute a form of inheritance – distinct from that based on changes in DNA base-pair sequence – known as 'transgenerational epigenetic inheritance' (Jablonka and Lamb, 2010).

Transgenerational epigenetic inheritance is underlain by two main mechanisms. The first involves 'chromatin marking,' which occurs when small chemical groups are added to the DNA strand. For instance, for RNA polymerase to attach to a gene's promoter and begin transcription, the DNA strand must be unwound and untangled from the proteins that surround it (this DNA/protein complex is the 'chromatin'). The addition of a methyl group (CH_3) condenses the chromatin more tightly (Gilbert and Epel, 2009), which can prevent RNA polymerase from finding the promoter, thereby inactivating the affected gene. Importantly, the addition of a methyl group to a DNA strand can be triggered by a change in the organism's environment (Gilbert and Epel, 2009, pp. 43–46). Once a gene has been inactivated in this manner, the gene's inactivated state can be inherited when special enzymes – DNA methyltransferases – recognize a methylated sequence on the parent strand and then methylate the same region on the newly synthesized daughter strand (Gilbert and Epel, 2009).

Thus, the altered state of activation of a gene – as well as any changes to the phenotype – can thereby be transmitted across generations in the absence of any changes in base-pair nucleotide sequence of the DNA. Although the degree to which such epigenetic marks mediate the transmission of ecologically relevant traits across generations is unclear, there are some compelling examples (reviewed in Jablonka and Raz, 2009). Moreover, because chromatin marking mediates inheritance of cellular epigenetic variants (e.g., different cell types within a multicellular organism), the potential for transgenerational epigenetic inheritance is therefore present in all multicellular organisms (Maynard Smith and Szathmáry, 1995).

The second major mechanism of transgenerational epigenetic inheritance involves soma-to-soma transmission of epigenetically based variations (Jablonka and Lamb, 2010). Soma-to-soma transmission encompasses many different processes, all of which entail reconstructing the parental phenotype during somatic development in successive generations without direct involvement of the germline. Three main (non-mutually exclusive) processes mediate such soma-to-soma transmission.

First, phenotypes can be inherited via a 'maternal effect.' Maternal effects arise when a female's phenotype influences its offspring's phenotype, independent of the direct effects of the female's coding sequences on its offspring's phenotype. For instance, in many animals, larger females produce larger young, simply because they produce larger eggs, more milk, and/or have larger wombs. Subsequently, the large daughters of these large females may perpetuate the trend of producing

large offspring (Jablonka and Lamb, 2010). Likewise, females of many species differentially endow their seeds, eggs, or offspring with acquired information or materials (e.g., RNA transcripts, cytoplasm, and hormones) that can influence their offspring's phenotype (Mousseau and Fox, 1998). These effects may endure for many generations, even persisting long after the original environmental stimulus that created the maternal effect disappears (Kirkpatrick and Lande, 1989). Moreover, such maternal effects have been shown to mediate the inheritance of divergent phenotypes in natural populations, often in a manner indistinguishable from a phenotypic shift stemming from a change in DNA base-pair nucleotide sequence (e.g., Badyaev *et al.*, 2002; Pfennig and Martin, 2009).

Second, soma-to-soma transmission of epigenetic variants can occur via transmission of symbionts (smaller organisms that live inside a host organism as parasites or mutualists). Many symbionts alter their host's phenotype, and are transmitted primarily or even exclusively from parent to offspring (Werren *et al.*, 2008). Differential transmission of symbionts may mediate phenotypic divergence between populations and possibly even speciation, especially when different symbionts are incompatible within the same host (Brucker and Bordenstein, 2013).

Third, soma-to-soma transmission of epigenetic variants can occur via learning. For example, in animals, feeding (Papaj and Prokopy, 1989), mating (Crews *et al.*, 2007), and habitat (Slagsvold *et al.*, 2013) preferences can be transmitted from parent to offspring exclusively through learning. The transmission of fitness-enhancing information via learning may play an important role in both ecology and evolution by facilitating speciation and reducing extinction risk (Beltman *et al.*, 2004; Verzijden *et al.*, 2012).

Note, however, that the long-term stability of epigenetically based variations – whether mediated by chromatin marks or soma-to-soma transmission – remains uncertain. Unlike with DNA replication – where accuracy is largely insensitive to the environment – the stability of epigenetic changes depends on an organism's current environment; a change in the environment can modify, and even reverse, epigenetically based variations (Jablonka and Lamb, 2010). Yet, even if most epigenetic variants are found to last only a few generations, epigenetic inheritance mechanisms may still be important if they decrease the chances of extinction and/or increase the likelihood of genetic changes (Pfennig and Servedio, 2013).

Concluding Remarks

Eco-evo-devo is an emerging field that seeks to understand the causes and consequences of a common feature of development – its tendency to be responsive to changes in an individual's environment. Research in this field has at least three important implications for evolutionary biology. First, as described above, an understanding of the interconnectedness between an organism's environment and its developmental responses can illuminate how the environment not only selects among diverse phenotypes, but how it also creates those phenotypes in the first place (essentially, the environment can dictate both the 'survival' as well as 'arrival of the fittest'; Gilbert and Epel, 2009). Second, this phenotypic plasticity might play a critical, and often underappreciated, role in initiating evolutionary innovation and diversification. Finally, such phenotypic change induced by the environment can form the basis of an alternative inheritance system, which might – by itself – mediate evolutionary change. This shift in emphasis on environmentally initiated phenotypic change in evolution should not be seen as a threat to modern evolutionary theory (Orr, 1999); rather, it represents an opportunity to expand the theory (Pigliucci, 2007; Pfennig *et al.*, 2010).

Additional studies are required, however, especially those utilizing new model organisms (Collins *et al.*, 2007). Ideally, these new models would include related groups of species whose phylogenetic relationships are resolved; whose ecology is well known; that experience diverse ecological (and thus, selective) regimes; that display different levels of phenotypic plasticity; and that are amenable to experimental manipulation (e.g., Emlen, 2000; Ledón-Rettig and Pfennig, 2011). Using such new model organisms, greater effort is especially needed to ascertain: (1) the conditions and frequency with which phenotypic plasticity facilitates, rather than impedes, evolution; (2) the degree to which phenotypic plasticity impacts large-scale (i.e., macroevolutionary) change; and (3) the long-term stability and efficacy of epigenetically based variations in mediating evolution. Answers to these and other questions in eco-evo-devo research promise to continue to provide fresh insights into the evolutionary process.

Ecological Fitting and Novel Species Interactions in Nature

M Malcicka, VU University Amsterdam, Amsterdam, The Netherlands
JA Harvey, VU University Amsterdam, Amsterdam, The Netherlands; and Netherlands Institute of Ecology, Wageningen, The Netherlands

Glossary

Adaptive syndrome An organism's long-term adaptation and response to various biotic and abiotic stresses in the environment, such as pathogenic infection and temperature.
Ecophysiological equivalence In evolutionary terms, the sharing of important traits, such as immunity or morphology, in allopatric species that exhibit close phylogenetic affinity. In fitting equivalence is important because it enables one species to exploit novel resources that nevertheless are similar to resources on which they coevolved.
Phenotype-environment matching Phenotypic variation in traits such as body color, morphology, and behavior in a species that provide adaptation to local conditions in the habitat.

Introduction

The theory of coevolution underpins our understanding of interspecific interactions in nature (Ehrlich and Raven, 1964; Rosenzweig, 1973; Abrams, 1986; Marrow and Cannings, 1993; de la Peña *et al.*, 2011). Moreover, it has provided an essential link that connects disparate fields in biology, such as organismal behavior, community ecology, and studies of larger scale ecosystem-related processes such as productivity, stability, and resilience (Levin, 1999). Many classic studies on coevolutionary arms races and adaptive syndromes have been based on interactions between plants and insect herbivores (Ehrlich and Raven, 1964; Benson *et al.*, 1975; Berenbaum and Zangerl, 1992; Pilson, 1996; Janz and Nylin, 1998; Becerra *et al.*, 2009), as well as between herbivorous insects and their natural enemies, such as predators and parasitic wasps (Godfray, 1994). These and other studies have demonstrated that host–parasite interactions are often based on long and intimate periods of coevolution (Carius *et al.*, 2001).

One of the drawbacks of coevolutionary theory, however, is that it leads investigators to assume a long history of tight, reciprocal selection between contemporaneously interacting species. In contrast, it is now well established that many organisms interact quite diffusely in both space and time, and some interspecific relationships have little or no coevolutionary history (hence invocation of the term evolutionary 'hotspots' (Thompson, 2005) to describe this phenomenon). As an example, some herbivores feed on many closely related plant species in nature but are rarely found on any individual plants of a given species at a given time. When this happens, selection can be weak in one respect (at the level of interactions between the herbivore and any individual plant), but highly reliable in other respects (at the species or population levels of the plant or herbivore). This also implies that there are many evolutionary 'colds-spots' in nature, where little selection is being generated, and that it is in the 'hotspots' – where interactions occur with much higher regularity or frequency – that selection for various adaptations and counter-adaptations is strong.

An extreme, though potentially common, type of false coevolutionary relationship is 'ecological fitting' (**Figure 1**), wherein organisms colonize and persist in novel environments, use novel resources, and form novel associations with other species as a result of a suite of traits that they evolved under different circumstances (Janzen, 1985; Agosta, 2006; Brooks *et al.*, 2006; Agosta and Klemens, 2008). Fitting underpins many key ecological processes, including community assembly and structure and is broadly relevant to many fields of biology and environmental sciences, including invasion ecology. Recent opinion articles by Agosta (2006) and Agosta and Klemens (2008) propose three different mechanisms to explain the phenomenon of ecological fitting: (1) exaptation, which

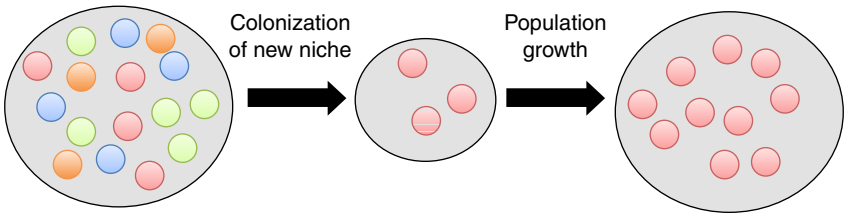

Figure 1 The ecological fitting concept in an invasive species. In this figure, each differently colored circle represents a different species which compete for the same resources; the left circle represents the native habitat in which these species coexist. The red species, through some process (natural or man-aided dispersal) is able to colonize a new habitat elsewhere containing novel resources with which it has not coevolved but nevertheless which it successfully exploits. This fulfills the criteria of 'ecological fitting.' Having escaped from coevolved enemies as well, in time, the population of this species grows, enabling it to become dominant in its new habitat.

 doi:10.1016/B978-0-12-800049-6.00199-2

argues that an existing trait may be co-opted for a new function that enables an organism to survive and reproduce in a new environment. For example, feathers and wings likely used for insulation or display in therapod dinosaurs later enabled the evolution of flight in birds (Agosta and Klemens, 2008); (2) the correlated evolution of traits that preadapt organisms to novel conditions. This involves selection for parallel changes in multiple traits rather than a single one (for instance, physiological and morphological characteristics), which, working in concert, enhance the ability of a species to colonize or exploit novel habitats or resources; and (3) the process of 'phylogenetic conservatism,' whereby the evolutionary history of a species is related to its ability to exploit novel resources that have a close ecophysiological affinity to the resources in the environment where it evolved (Agosta, 2006). Agosta and Klemens (2008) also developed the term 'sloppy fitness space,' which they defined as the range of niches – both realized (actual niches) and fundamental (potential niches), in which a species can have realized fitness (survival to reproduction) (**Figure 2**). A niche is not a static entity but changes over time in response to changes or shifts in local (and global) conditions. Thus, sloppy fitness space may include components of a fundamental niche that are incorporated into the realized niche as conditions become more favorable for an organism. Some of the resources in the fundamental niche may actually be novel but are incorporated into the diet of the organism, representing an example of ecological fitting.

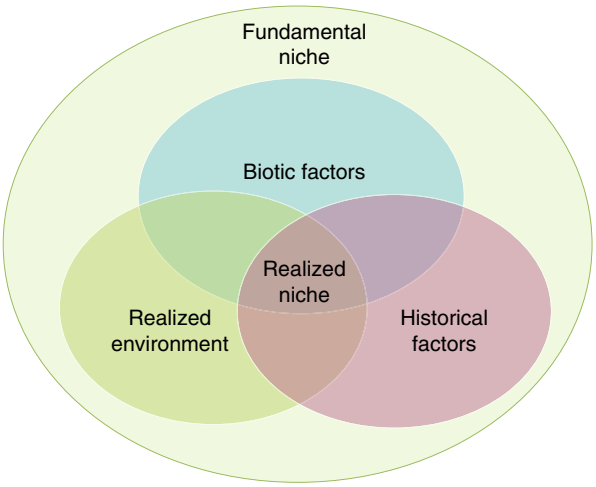

Figure 2 The habitat/niche concept. Factors that facilitate the potential (fundamental) and actual (realized) niches of a species are shown. Niches are not linear but encompass many dimensions (hence the definition of a niche as an 'n-dimensional hypervolume') but for reasons of clarity it is simplified here. The fundamental niche is often large, encompassing a broad range of habitats and resources. On the other hand, the realized niche is reduced due to the effects of biotic factors (predation, pathogenic infection, and competition), historical factors (constraints imposed in the distant and recent past), and realized environment, in which the populations actually exist in the field or/and in which individuals are not present, but could survive and reproduce. Ultimately, these factors in concert generate a realized niche which is the actual boundary of a habitat at different scales occupied by a species.

The Role of Evolution in Ecological and Evolutionary Fitting: Ecophysiological Equivalence and the Expression of Complementary Traits

In a broad sense, evolution is results in adaptation to a range of environmental constraints. In that context, ecological fitting is not 'evolution-free' but 'evolution-light.' A species may possess traits in habitats in which it evolved that may also give it high fitness in novel environments if the two habitats are alike in some way. In other words, provided the new conditions are benign or equivalent to those in which an organism evolved, then 'phenotype-environment' matching can occur. There are many examples of species that thrive in habitats (or on resources) with which they have no coevolutionary history. Evolution has outfitted these species with phenotypes that enable them to exhibit realized fitness in new habitats or on new resources. In a seminal study, Brooks *et al.* (2006) showed that a parasitic flatworm that had coevolved with North American frogs (Ranidae) was able to infect and reproduce in frogs native to Costa Rica if the habitats in which both were found were equivalent (e.g., wetlands) and if the Costa Rican and North American host frogs exhibited close phylogenetic affinity. Similarly, Harvey *et al.* (2012) showed that two species of closely related parasitic wasps from North America and Europe which attack closely related moths in their native ranges were highly successful in developing inside each other's hosts. These studies show that successful fitting is at least partially based on the possession of evolved traits that enable a species to exploit a particular set of novel resources or conditions.

Invasive Species: Highly Visible Examples of Ecological Fitting

Some of the best examples of successful ecological fitting in nature involve invasive organisms that have been introduced into nonnative ecosystems and which have established, spread, and in many cases become highly disruptive pests (Lowe *et al.*, 2000; **Figure 3**). The most visible and ecologically dramatic examples of invasive species involve plants and animals introduced to new regions separated by immense distances of land or water (Mooney and Hobbs, 2000; Lockwood *et al.*, 2013). When an exotic species enters a nonnative ecosystem it encounters abiotic and biotic conditions with which it has not evolved. The majority of successful invasive species are habitat generalists (Marvier *et al.*, 2004) possessing suites of traits that enable them to fit into many novel habitats ('broad-spectrum fitting'). These traits allow exotic organisms to outcompete native species which have to deal with coevolved enemies and competitors. Invaders are often able to escape their coevolved natural enemies, such as pathogens and predators (Keane and Crawley, 2002), enabling them to invest limited metabolic resources toward other functions, such as growth and competitiveness (Blossey and Notzold, 1995). Still other invasive species possess novel traits, such as secondary metabolites in plants, that are toxic to native herbivores that have not coevolved to deal with them (Callaway and Ridenour, 2004; Cappuccino and Arnason, 2006). For these reasons invasion ecology is a field that is strongly suited to the study of false coevolution and ecological fitting.

Alliaria petiolata

Salenopsis invicta

Rhinella marina

Pacifastacus leniusculus

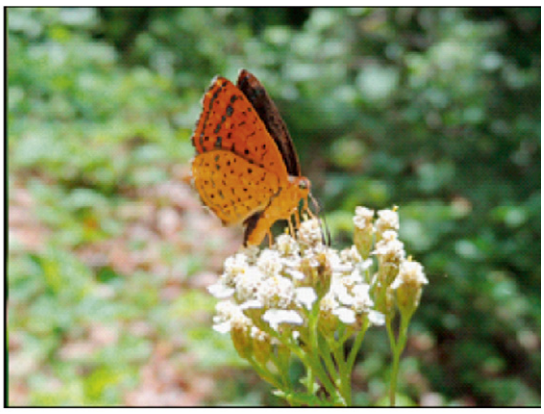
Figure 3 Examples of highly invasive species that are habitat generalists and possess traits that they evolved in their native habitats that have enabled them to establish and spread (broad-spectrum fitting) in nonnative ecosystems. The garlic mustard (*Alliaria petiolata*) is native to Eurasia but has spread across much of eastern North America where it is dispalcing native vegetation; the fire ant (*Solenopsis invicta*) is native to South America, but was introduced into Florida, spread north and has now displaced many native ants from the southeastern United States; the cane toad (*Rhinella marina*) is native to central and South America but has been introduced to several other countries, including Australia, where it is now spreading and decimating local fauna; the signal crayfish (*Pacifasticus leniusculus*) is a North American freshwater crustacean species that was introduced into Europe in the 1960s. It has since spread and dispalced many natives in its new range.

Bis Interimitur, Qui Suis Armis Perit (What Goes Around, Comes Around)

Important insights into the conditions that permit (or do not permit) ecological fitting can be elucidated by comparing the habitat and dietary breaths of organisms (plants or animals). Organism–organism interactions are often assumed to be ecologically specialized, tightly coevolved systems driven by mutual modification (Brooks *et al.*, 2006). However, many interactions are of a far more generalist nature. Generalists can exploit multiple resources or occupy multiple niches, whereas many specialists have evolved much more highly refined traits that enable them to successfully exploit a much narrower range of niches but with more effectiveness than generalists (Loxdale *et al.*, 2011). Generalist organisms may be able to adjust their behavior to exploit novel conditions much more effectively than specialists, and food or other resources can be less limited by resource availability for generalists than for specialists. It follows, then, that dietary and habitat generalists may be more prone to ecological fitting.

Alternatively, although specialists may exploit local resource types or habitats more effectively than generalists, this may lead some specialist species down evolutionary dead-ends. Much coevolutionary research involving specialist consumers and their resources have thus far been based on parasite–host interactions, where speciation in one lineage causes speciation in another lineage (e.g., Hafner and Nadler, 1990). Hafner and Nadler (1988, 1990) describe this process as 'synchronous co-speciation' where adaptive radiation in one species depends on another species. In this scenario, the consumer loses the ability to evolve independently of the resource it is exploiting or the habitat in which it lives. Consequently, the conditions required for survival and reproduction become so incredibly narrow that they do not allow for a switch to other diets or habitats (**Figure 4**). These species are evolutionarily 'frozen' in space and time and therefore are not

Ailuropoda melanoleuca



Calephelis borealis

Phascolarctos cinereus

Rostrhamus sociabilis

Figure 4 Examples of species that have become so specialized that they exhibit exceedingly narrow niches ('super-fitting-dead-end'). The giant panda (*Ailuropoda melanoleuca*), which is not only constrained by one narrow type of sufficient food (25 species of bamboo) but also by abiotic conditions; the Northern metalmark butterfly (*Calephelis borealis*) whose larvae are only able to digest the round-leafed ragwort (*Aster umbellatus*); the koala (*Phascolarctos cinereus*) with a monophagous diet of eucalyptus trees; and the snail kite (*Rostrhamus sociabilis*), a raptor which has evolved a beak that is adapted solely for a diet of aquatic snails.

able to respond to even potentially minor environmental changes and thus adapt to them. Extreme specialist organisms are therefore unlikely to experience ecological fitting.

Unwittingly Fitting, and How Manufactured Interactions are Often Used to Explain Biological Processes

In spite of the clear importance of local interspecific interactions in driving trait evolution, many studies in the laboratory from both an applied and fundamental perspective have been based on facetious interactions involving species that have little or no coevolutionary history. These studies have included a wide range of biota, from plant–herbivore to herbivore–natural enemy interactions. Indeed, the preponderance of plant–herbivore research using the model plant system *Arabidopsis* is an example of researcher-mediated ecological fitting. Some species studied in the lab are not even sympatric, but originate from different biogeographical regions. Such studies are possible because the interacting species are able to exploit novel resources based on phylogenetically conserved traits or convergent evolution. This enables them to form immediate and sometimes highly intimate associations with completely novel species. Some theories in life-history (co)evolution – such as the efficacy of indirect plant defences via the release of herbivore-induced plant volatiles or selection for plant defences – are based on studies involving species that probably do not (or at best only rarely) interact in nature (e.g., Turlings *et al.*, 1990; Züst *et al.*, 2012). This is not necessarily a criticism of such studies – an intimate evolutionary history between two or more species is not an essential prerequisite for addressing important biological questions and exploring mechanisms. However, the results of these studies must be interpreted with caution because the ways in which selection plays out under conditions involving coevolving species may be profoundly different when independently evolving species are fitted together in a laboratory.

Summary

Although it is still largely not recognized, the concept of ecological fitting is broadly relevant to many fields in ecology and evolutionary biology. Novel ecological interactions arise constantly in nature, and when these enable a plant to establish in

a new habitat, or an herbivore to successfully incorporate a new plant into its diet, they become examples of ecological fitting. A necessary prerequisite for ecological fitting between interacting species is a coevolutionary history of interactions involving closely related or convergent species exhibiting physiological equivalence. Importantly, many lab-based biological studies are based on interactions between species that have been selected for convenience rather than their coevolutionary history.

Glossary

Divergent natural selection Selection that acts in contrasting directions in between two populations (e.g., large body size confers high survival in one environment and low survival in another), including the special case in which selection favors opposite phenotypes within a single population (i.e., disruptive selection).
Eco-evolutionary dynamics Interactions between ecology and evolution on contemporary timescales (i.e., generally driven by rapid evolution and rapid ecological change).
Ecological speciation The process by which barriers to gene flow evolve between populations as a result of ecologically based divergent selection between environments.
Epistasis Interactions between alleles found at different loci such that the phenotypic effect of an allele at one gene relies on an allele at one or more other genes.
Linkage disequilibrium Nonrandom statistical associations between alleles at two or more loci.
Mutation-order speciation The evolution of reproductive isolation by the fixation of different advantageous mutations in separate populations experiencing similar selection pressures (i.e., 'uniform selection').
Pleiotropy Multiple phenotypic effects of a single gene.
Reproductive isolation Biological barriers to interbreeding between populations, which can occur before or after mating.
Speciation continuum Quantitative variation in the degree of speciation (i.e., reproductive isolation).

Biologists have long sought to explain the origin and maintenance of biological diversity within and among species. Natural selection is generally recognized as a central mechanism driving evolutionary change within species (Kingsolver *et al.*, 2001; Darwin, 1859; Endler, 1986). Thus, natural selection plays a key role in producing the array of phenotypic and genetic diversity we see in nature. But to what extent is selection, the process driving adaptation within species, also responsible for the formation of new species? In other words, to what extent do phenotypic and species diversity arise via the same process?

Renewed efforts to address these questions have emerged, based on the following general scenario. Populations living in different ecological environments (e.g., desert vs. forest habitats) might undergo divergent and adaptive evolutionary change via divergent natural selection. These same evolutionary changes can also result in the populations evolving, perhaps incidentally, into separate species. For example, adaptation to different environments, via divergent selection, might cause the evolution of genetically based differences between populations in the way that individuals tend to behave, look, or smell. These differences might then in turn cause individuals from different populations to dislike mating with one another, or for hybrids to be unfit if mating occurs. Thus, the populations would cease exchanging genes, thereby diverging into separate species because of the adaptive changes that occurred via divergent selection. This is a simple description of the 'ecological speciation' hypothesis (Juan *et al.*, 2010; Funk, 1998; Schluter, 1996a,b, 1998, 2000, 2001, 2009; Rundle and Nosil, 2005; Nosil *et al.*, 2002; Nosil, 2012).

More specifically, 'ecological speciation' is defined as the process by which barriers to gene flow evolve between populations as a result of ecologically based divergent selection between environments (Nosil, 2012). This will often occur because traits under divergent selection, or those genetically correlated with them, incidentally cause reproductive isolation (Muller, 1942; Mayr, 1963). Under such a scenario, speciation occurs as a 'by-product' of adaptive divergence. In some instances of ecological speciation, divergent selection might operate directly on reproductive isolation itself. This occurs, for example, if the evolution of mating signals and preferences is dependent on the ecological environment such that ecologically differentiated populations diverge in signals and preferences, resulting in premating sexual isolation (Boughman, 2001; Seehausen *et al.*, 2008).

Selection itself is considered ecological when it arises as a consequence of the interaction of individuals with their external environment during resource or mate acquisition, or from the interaction of individuals with other organisms. Selection is divergent when it acts in contrasting directions in the two populations (e.g., large beaks in a bird species confers high fitness in one environment and low fitness in the other). This includes the special case of disruptive selection in which selection favors opposite extremes of the trait distribution within a single population (Rundle and Nosil, 2005). The agents of divergent selection during ecological speciation are thus extrinsic and can include abiotic and biotic factors, such as food resources and habitat, and interspecies interactions, such as parasitism and competition.

Ecological speciation thus has three necessary components (Rundle and Nosil, 2005; **Figure 1**). The first is a source of divergent selection, such as differences between environments (e.g., in aridity, temperature, etc.), interactions between species, or ecologically based sexual selection. Examples of all these sources of selection in ecological speciation now exist. The second component is a form of reproductive isolation,

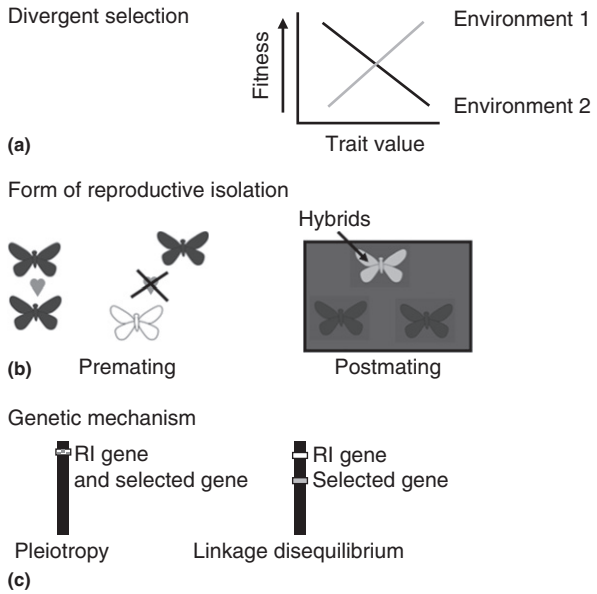

Figure 1 The three components of ecological speciation (c.f., Rundle and Nosil, 2005). (a) A source of divergent selection. The commonly recognized sources are differences between environments, interactions between populations, and sexual selection. (b) A form of reproductive isolation, which might act before or after mating. The example of premating isolation here concerns divergent mating preferences such that there is assortative mating based upon color. The example of postmating isolation concerns environment-dependent selection against hybrids such that the intermediate phenotype of hybrids renders them more vulnerable to visual predation in the environment of each parental species. (c) A genetic mechanism linking selection to reproductive isolation. The genes under selection and conferring reproductive isolation may be one and the same (pleiotropy) or physically different (but statistically associated via linkage disequilibrium). Modified from Nosil, P., 2012. Ecological Speciation, Oxford: Oxford University Press with permission from Oxford University Press.

which can occur before or after mating. Examples of premating isolation are habitat isolation resulting from divergent habitat preferences, immigrant inviability due to selection against migrants between environments, and sexual isolation due to divergent mating preferences. The prime example of postmating isolation is hybrid inviability, which can occur for ecological reasons or due to intrinsic genetic incompatibilities between the genomes of parental species when they are brought together in a hybrid. All of these forms of reproductive isolation can evolve as an incidental by-product of genetic divergence created by divergent adaptation, and each has been implicated in ecological speciation. For example, ecotypes of stickback fish and host-associated beetles have adapted to different environments via divergent selection and exhibit multiple forms of reproductive isolation as a consequence (Egan and Funk, 2009; Matsubayashi and Katakura, 2009; Mckinnon and Rundle, 2002). The third component of ecological speciation is a genetic mechanism to link divergent selection to the genes causing reproductive isolation. Two main such mechanisms are distinguished by whether the genes affected by divergent selection are one and the same as those causing reproductive isolation (e.g., pleiotropy) or the genes under selection being different than those causing reproductive isolation. In the latter case, statistical associations (i.e., linkage disequilibrium) between the different sets of genes can cause selection on genes involved in divergent adaptation to be transmitted to the genes causing reproductive isolation. Additionally, interactions between genes (i.e., epistasis) involved in ecological speciation, be they those under selection or those causing reproductive isolation, can affect observed levels of reproductive isolation (Arnegard *et al.*, 2014).

With this description of the process of ecological speciation in place (see Nosil, 2012 for details), we now turn to outlining: (1) alternatives to ecological speciation, (2) evidence and support for ecological speciation, (3) the genomic basis of ecological speciation, (4) constraints on speciation, and (5) the broader consequences of ecological speciation for communities and ecosystems. We conclude by discussing promising avenues for further research.

Alternatives to Ecological Speciation

Ecological speciation can be distinguished from other models of speciation in which the evolution of reproductive isolation involves key processes other than deterministic and ecologically based divergent selection (Nosil, 2012; Schluter, 2009). These alternatives tend to involve stochastic events, such as random changes in alleles frequencies and differences among populations in the specific mutations that arise. Such alternatives can be classified into two main categories. The first category considers mechanisms of speciation that do not involve selection, such as speciation via genetic drift, perhaps involving population bottlenecks and founder events. The second considers mechanisms that do involve selection, but selection is not divergent between ecological environments. One such alternative to ecological speciation is thus 'mutation-order speciation,' defined as the evolution of reproductive isolation by the fixation of different advantageous mutations in separate populations experiencing similar selection pressures, i.e., 'uniform selection' (Schluter, 2009; **Figure 2**). In essence, different populations find different genetic solutions to the same selective problem (Mani and Clarke, 1990). In turn, the different genetic solutions (i.e., mutations) are incompatible with one another, causing reproductive isolation (Price, 2007; Schluter, 2001, 2009; Nosil and Flaxman, 2011). During mutation-order speciation, the same alleles would be favored in both populations, but divergence occurs anyway because, by chance, the populations do not acquire or fix the same mutations. Divergence therefore involves stochasticity, but the process also involves selection, and thus is distinct from speciation via genetic drift. Selection can be ecologically based under mutation-order speciation, but ecology does not favor divergence as such, and a correlation between ecological divergence and reproductive isolation is not expected. Notably, these models that do not involve divergent selection are explicit alternatives to ecological speciation, but are not mutually exclusive to it (i.e., several different models could be operating simultaneously).

Support for Ecological Speciation

The process of ecological speciation makes some explicit and simple predictions. We outline below five approaches for

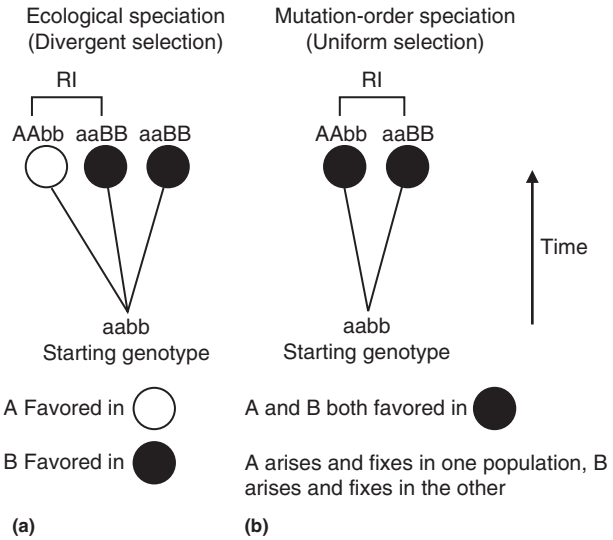

Figure 2 Schematic diagram of (a) Ecological speciation vs. (b) Mutation-order speciation (following Schluter, 2009). Distinct environments are indicated by open vs. filled circles. Genetic drift is ignored and change occurs via selection. Genetic changes are shown at two bi-allelic loci, with the derived alleles A and B being incompatible with one another. 'RI' denotes the types of population crosses that result in reproductive isolation. The essential distinction depicted is that under ecological speciation only populations in different environments evolve reproductive isolation, whereas under mutation-order speciation populations adapted to the same environment evolve reproductive isolation. Modified from Nosil, P., 2012. Ecological Speciation, Oxford: Oxford University Press with permission from Oxford University Press.

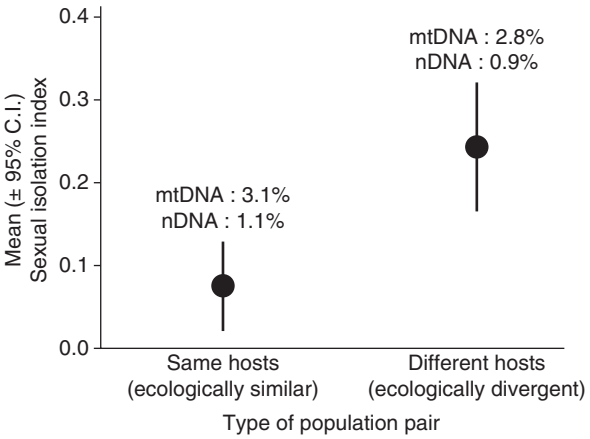

Figure 3 Evidence for ecological speciation in host-plant associated populations of *Timema cristinae* walking-stick insects (individual populations feed on either the host plant *Ceanothus spinosus* or on *Adenostoma fasciculatum*). Pairs of populations feeding on the same host plant species, but in different geographic localities, are ecologically similar. In contrast, pairs of populations feeding on different host plant species are ecologically divergent and subject to host-associated divergent selection. Different-host pairs (n=15 pairs) exhibit significantly greater reproductive isolation due to divergent mating preferences (i.e., sexual isolation) than do same-host pairs (n=13 pairs). This pattern is independent from neutral genetic divergence, a proxy for time since divergence. Mean divergence is shown for the mitochondrial COI gene (mtDNA) and for the nuclear IT-2 gene (nDNA). Modified from Nosil, P., 2012. Ecological Speciation, Oxford: Oxford University Press with permission from Oxford University Press.

testing for ecological speciation, all of which have received some empirical support (Nosil, 2012). The first class of 'comparative' approaches examines multiple taxon pairs and tests for a positive association between levels of reproductive isolation and levels of ecological divergence, independent from time since population divergence (following Funk *et al.*, 2002, 2006; Funk, 1998; **Figures 3** and 4). Such correlations between ecological divergence and reproductive isolation have been detected across disparate plant, vertebrate, and invertebrate taxa (Funk *et al.*, 2006). Second, when analysis of multiple taxon pairs in a comparative framework is not possible, 'trait-based' approaches can test if the same traits involved in divergent adaptation also affect reproductive isolation ('magic traits', c.f., Gavrilets, 2004; Servedio *et al.*, 2011). For example, butterfly wing patterns can be under ecological selection for mimicry but also contribute to premating isolation (Jiggins *et al.*, 2001; Merrill *et al.*, 2012). Likewise, body size can contribute to adaptive divergence and to premating isolation, as observed in fish (Langerhans *et al.*, 2007; Mckinnon *et al.*, 2004).

Sometimes it will not be possible to know *a priori* which traits are subject to divergent selection. In this case, one may use a third class of 'fitness-based' approaches to test if reproductive isolation is a direct consequence of ecologically based selection against immigrants and hybrids. These approaches involve measuring fitness in different habitats, rather than selection on specific phenotypic traits. Fitness-based methods predict a reduction in the fitness of individuals placed into

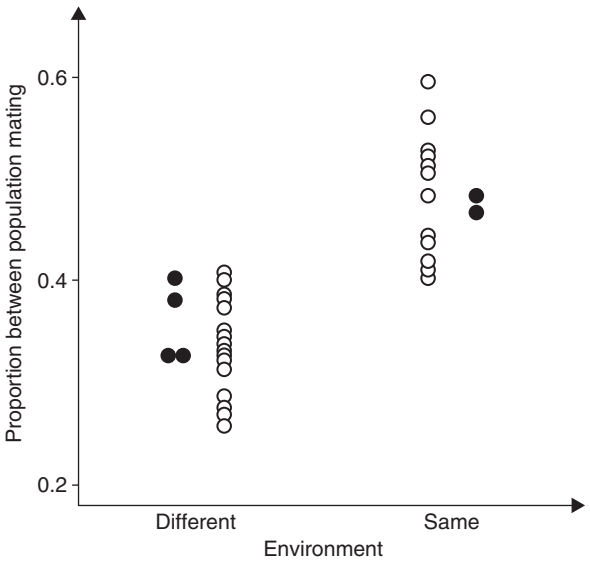

Figure 4 Evidence for ecological speciation from experimental evolution studies in the lab. Each dot represents a replicate experimental line. Shown is the proportion of matings occurring between independently evolved lines of *Drosophila* as a function of the dissimilarity of their environments. Mating between populations is less common when populations have been adapted to different environments. Open circles are from Dodd (1989) and closed circles from Kilias *et al.* (1980).

a novel environment relative to resident individuals. When experimental data cannot be collected, 'gene-flow based' approaches can test whether gene flow at molecular markers is reduced as adaptive divergence increases. Finally, a fifth 'phylogenetic shift' approach can ask whether branching (i.e., speciation) events in a phylogenetic tree coincide with ecological shifts.

Although evidence for ecological speciation is abundant and stems from each of the aforementioned approaches, almost all of it is correlative and indirect, or from lab studies. Manipulative field experiments testing whether adaptive divergence reduces gene flow in nature are lacking and represent a 'final frontier' in tests of ecological speciation.

Genomic Basis of Ecological Speciation

Although there are clear examples of ecological speciation, we are only beginning to understand the genomic basis of the process. For example, we know little about the number, distribution, and effect sizes of genes driving ecological speciation. Moreover, the nature of genomic divergence during ecological speciation is unclear because empirical evidence is mixed. Although there are examples of incipient speciation involving divergence in only a few genomic regions (Heliconius Genome, 2012; Nadeau *et al.*, 2012; Poelstra *et al.*, 2014), there is accumulating empirical evidence that ecological speciation can involve divergence in many regions of the genome, even at its earliest phases (Michel *et al.*, 2010; Soria-Carrasco *et al.*, 2014; Jones *et al.*, 2012; Ellegren *et al.*, 2012; Lawniczak *et al.*, 2010). However, theoretical models often predict that when fewer loci control a trait, speciation with gene flow is easier, because each locus experiences a stronger per-locus selection coefficient (Gavrilets, 2004; Yeaman and Whitlock, 2011).

How can widespread genomic divergence be reconciled with the aforementioned theoretical predictions? These findings can be readily reconciled by considering the important distinction between: (1) the number of loci affecting a given, individual trait versus (2) the total number of loci across the entire genome experiencing divergent selection (i.e., summed across all traits subject to selection). In the former case, fewer loci affecting the trait can aid divergence of the specific trait. However, if more loci overall experience selection and can overcome gene flow (perhaps aided by synergistic effects across loci on reducing gene flow), this increases genetic divergence and the chances of extrinsic or intrinsic genetic incompatibilities which cause reproductive isolation (Flaxman *et al.*, 2013, 2014). Thus, ecological speciation with gene flow might be easiest when selection acts on many traits influenced by few loci each, and hardest when selection acts on a single trait influenced by many loci. What do empirical data say concerning the numbers of loci involved in ecological speciation?

One approach taken by empirical studies of the genetic basis of ecological speciation is to determine the genetic architecture of traits that play a role in adaptation to divergent ecological environments. By definition, these are the same loci that are involved in ecological speciation. Studies taking this approach have shown that the genetic architectures of such traits fall along a continuum ranging from traits controlled by a few genes each with large phenotypic effects (Bradshaw and Schemske, 2003; Hoekstra *et al.*, 2006; Jiggins and Mcmillan, 1997; Peichel *et al.*, 2001; Rosenblum *et al.*, 2010; Van't Hof *et al.*, 2011) to those controlled by many genes that each have modest effects on phenotypic variation (Arnegard *et al.*, 2014; Ellison *et al.*, 2011; Gompert *et al.*, 2013; Atwell *et al.*, 2010; Brachi *et al.*, 2010). Thus, there are examples of ecological speciation driven by strong divergent selection acting on 'simple' traits controlled by few loci with large phenotypic effects, such as wing coloration traits in butterflies (Heliconius Genome, 2012), as well as by selection acting on complex suites of traits controlled by many loci with small phenotypic effect, such as foraging traits involved in niche adaptation of stickleback fish (Arnegard *et al.*, 2014). But to what extent do these different genetic architectures influence the likelihood of ecological speciation? How common are each? It is too early to answer these questions because data are currently available only on a case-by-case basis. A major goal in ecological speciation research is thus to determine the relative roles that either strong selection acting on a few loci versus 'multifarious' selection acting on many loci play in generating reproductive isolation, and the conditions under which each is expected to drive speciation. Another major question is how strongly physical linkage of loci involved in ecological speciation promotes the process (Feder *et al.*, 2012). It might be the case that simple genetic architectures comprised of a few loci are required for ecological speciation with high gene flow, but not otherwise.

A second approach to understanding the genomic basis of ecological speciation relies on what has been termed 'reverse ecology' (Li *et al.*, 2008). Specifically, genome-wide surveys of molecular variation (so-called 'genome scans') that do not rely on *a priori* candidate traits or loci can identify outlier loci with elevated levels of differentiation relative to the rest of the genome. Such outlier loci can be identified in the absence of knowledge concerning the traits under selection, and are candidates for regions harboring genes under divergent selection. Frequently, genome scans identify hundreds or even thousands of outlier loci spread across the genome (Hohenlohe *et al.*, 2010; Parchman *et al.*, 2013; Soria-Carrasco *et al.*, 2014; Lawniczak *et al.*, 2010). At face value, this pattern is consistent with ecological speciation being the result of selection affecting many loci. However, the situation is much more complex than this. Many processes other than divergent selection, such as demographic history, mutation, recombination, and drift, can also generate outlier loci (Bierne *et al.*, 2011; Ellegren *et al.*, 2012; Roesti *et al.*, 2014; Feder *et al.*, 2012). In particular, background selection in regions of low recombination can create outlier loci in genomic regions not involved in divergent adaptation (Noor and Bennett, 2009; Cruickshank and Hahn, 2014). Therefore, it is important to move beyond genome scans alone to disentangle the contribution of divergent selection versus other processes in generating observed patterns of differentiation (Feder *et al.*, 2012).

One possibility in this regard is to use experiments that can quantify selection's effect on genomic variation, for example, by exposing experimental populations to selection in different environments and then obtaining genome sequence data from them. The main premise is that selection on phenotypic traits

is transmitted to causal genetic variants affecting the traits (direct selection) as well as to additional genetic loci correlated via linkage disequilibrium with these functional variants (indirect selection). Thus, the genome-wide response to selection (i.e., total selection = direct selection + indirect selection) can be measured experimentally (Gompert *et al.*, 2014). Indirect targets of selection may be spread across the genome, and while these loci may not functionally control adaptive phenotypes, their evolutionary response to selection is real, and they may still contribute to the evolution of reproductive isolation. Recent studies adopting such experimental approaches have shown that: (1) divergent natural selection can have a widespread effect on the genome that involves multiple genomic regions, and/or (2) outlier loci in genome scans of natural populations harbor loci affected by divergent selection in experiments (Gompert *et al.*, 2014; Anderson *et al.*, 2014; Pespeni *et al.*, 2013; Soria-Carrasco *et al.*, 2014). For example, experimental populations of stick insects transplanted between two host-plant species showed evidence for host-plant associated selection, and this selection affected regions of the genome that differ between natural populations on different hosts (Soria-Carrasco *et al.*, 2014). However, these studies quantified total selection and thus did not isolate the effects of direct selection from indirect selection. Isolating the specific loci that are under direct selection and driving the process of ecological speciation will be more difficult, and likely require combining ecological, mapping, experimental, genomic, and functional data (Barrett and Hoekstra, 2011). In addition to experiments, the geographic setting of populations may help infer the role of divergent selection versus other factors in promoting genetic differentiation. For example, gene flow is less likely to affect differentiation between sets of geographically isolated populations (where gene flow is reduced by geographic barriers for all populations), reduced recombination aids adaptive divergence more strongly for populations that are exchanging genes, and high gene flow can negate the effects of genetic drift (Ortiz-Barrientos *et al.*, 2002; Nosil, 2012).

Constraints on Ecological Speciation

Once ecological speciation is initiated, there is often quantitative variation in how far it proceeds. Thus, divergence among populations tends to span a continuum ranging from weakly reproductively isolated populations, to moderately divergent ecotypes, to distinct species (i.e., this variation is referred to as the 'speciation continuum') (Nosil *et al.*, 2009). In this context, many examples exist in populations for which reproductive isolation remains incomplete (Alcaide *et al.*, 2014; Peccoud *et al.*, 2009; Renaut *et al.*, 2013; Soria-Carrasco *et al.*, 2014). These examples beg the question, what are the processes that impose limits on ecological speciation?

One obvious factor is time: 'incomplete' speciation might simply require more time to complete the speciation process. However, other factors may constrain speciation. Gene flow between populations has arguably received the most attention in terms of imposing constraints on speciation because of its homogenizing effects on population divergence (Slatkin, 1973, 1985). The nature of selection can also influence the likelihood of ecological speciation. For example, temporal variation in selection can constrain ecological speciation by counteracting divergent selection that results from spatial heterogeneity in the environment. In addition, selection can vary among traits. If universally favored phenotypes evolve, they can facilitate gene flow and maintain connectivity among populations. Finally, genetic correlations among traits can impose constraints on speciation if the quantitative genetic variation underlying adaptive traits is not coincident with the direction of divergent selection (Agrawal and Stinchcombe, 2009). One example of such constraints on speciation due to gene flow, variable selection, and genetic architecture concerns a melanistic phenotype of the stick insect *Timema cristinae* (Comeault *et al.*, 2015). This phenotype is cryptic on the stems of both host plant species used by *T. cristinae*, has a high dispersal rate, and exhibits a universal mating advantage. These factors increase gene flow between populations adapted to different host plants, counteracting divergent between populations. Gene flow is also affected by genetic architecture, because, for example, the locus affecting melanism is physically linked to a locus under divergent selection, counteracting divergence at this locus.

Consequences of Ecological Speciation

Much recent research in evolutionary ecology focuses on how different genotypes can differentially influence community structure, and ecosystem function (Whitham *et al.*, 2006). Because adaptive divergence affects genetic diversity, this begs the question whether and how ecological speciation itself can influence ecology. Research in the field of eco-evolutionary dynamics investigates how rapid evolutionary change can influence the ecology of populations, communities, and ecosystems (Pelletier *et al.*, 2009; Schoener, 2011), and often uses systems that exemplify adaptive divergence between populations. Such systems allow well-controlled 'common gardening' experiments, whereby two or more ecologically divergent populations (i.e., ecotypes) are transplanted to a common environment, and the effects of different ecotypes on ecological properties are evaluated (Matthews *et al.*, 2011). Demonstrations of the ecological consequences of adaptive divergence and/or ecological speciation for populations, communities, and ecosystems exist using fish (Harmon *et al.*, 2009; Post and Palkovacs, 2009; Bassar *et al.*, 2010), insects (Farkas *et al.*, 2013), and plants (Agrawal *et al.*, 2012; Johnson *et al.*, 2009). For example, adaptive divergence of stickleback ecotypes that are undergoing ecological speciation influences the composition of invertebrate prey in a community, which further affects nutrient flux at the ecosystem level (Harmon *et al.*, 2009). More recently, studies of stick-insect ecotypes have shown how quantitative variation in the degree of adaptive divergence affects community-level dynamics by mediating the attraction of bird predators that eat stick insects, but also other cohabiting arthropod species (Farkas *et al.*, 2013).

Studies like those described above make a strong case that rapid evolutionary dynamics during ecological speciation can be a powerful driver of contemporary ecological processes. An extension of one-way effects of evolution on ecology is the

idea of eco-evolutionary feedbacks (Schoener, 2011), whereby modified ecology subsequently influences the trajectory of evolutionary change (Yoshida *et al.*, 2003; Farkas and Montejo-Kovacevich, 2014). Though understudied, eco-evolutionary feedbacks could influence the fate of ecological speciation, whereby the ecological effects of adaptive divergence in turn constrain or further promote subsequent divergence. Further work on eco-evolutionary feedbacks is highly warranted.

Conclusions

Much progress has been made in understanding ecological speciation. Numerous examples of the process now exist and the occurrence of ecological speciation is now fairly well accepted. However, the relative importance for ecological speciation of different sources of divergent selection, forms of reproductive isolation, and genetic architectures of traits under selection remains unclear. Major questions also remain concerning the importance of ecological speciation relative to its alternatives, and the genomic basis and ecological consequences of ecological speciation. Furthermore, the point in the speciation continuum achieved during ecological speciation is poorly understood, and represents a major avenue for further research. Like in most rapidly growing fields, evidence for ecological speciation tends to be indirect, relying on observational and comparative studies. In some study systems, at least some stages of the process might be recreated experimentally in replicate field or lab populations, with experimental results then compared to patterns in natural populations providing some of the strongest evidence and insight possible. The study of ecological speciation is yet to enter a truly experimental phase, where manipulations are commonly employed to isolate causal associations between the factors driving and constraining the process. Thus, much will likely be learned in the future, particularly as genomic methodologies continue to be integrated with classical ecological approaches.

Effective Population Size

WJ Ewens, The University of Pennsylvania, Philadelphia, PA, USA

Glossary

Eigenvalue The eigenvalues of a matrix describe some of the important essential features of that matrix.

Markov chain A Markov chain is a process occurring in time (or in space) such that the state of some process (in the examples in this article the genetic constitution of some population) at any time point (here at the time of an offspring generation) depends in some prescribed random way on the state at the previous time point (here the time of the parental generation).

Matrix A matrix is a rectangular array of numbers that can be manipulated in several well-defined mathematical operations.

Introduction

The effective population size concept is one of the most misunderstood in population genetics theory. Most of the misunderstandings arise in areas largely outside population genetics, for example, in non-genetic evolutionary studies. It is therefore important to describe what the meaning and derivation of the concept are.

In the early days of population genetics theory many simplifying assumptions were made in deriving results. This was especially true of the stochastic theory, in which random changes in gene frequency due to random sampling in small populations were considered (random genetic drift). The theory is difficult enough without taking into account the existence of two sexes, the geographical dispersal of a population, changing population sizes over generations, and so on. The earliest analyses upon which population genetics theory was largely built, in particular those of Fisher (1930) and Wright (1931), were of necessity over-simplified, in which, for example, individuals were assumed to be monoecious (in effect one sex only allowed), random mating is assumed, and the population size is assumed to remain the same from one generation to the next, and so on. Even with such simplifications the stochastic theory rapidly becomes formidable.

The Early Theory

In order to get some idea of the evolutionary properties of a biological population under the Mendelian hereditary scheme, Fisher (1930) and Wright (1931) implicitly used a simple Markov chain model in assessing the frequency changes of a given allele A_1 at some gene locus with two alleles A_1 and A_2 (It was Wright who introduced the concept of an effective population size.). A diploid population of unchanging size N is assumed (so that in any generation there are $2N$ genes at this locus, some of allelic type A_1 and some of allelic type A_2). The genes in any offspring generation are assumed to be derived by random sampling, with replacement, from the genes of the parental generation. This implies that if there are i A_1 genes in the parental generation, the probability p_{ij} that there will be j A_1 genes in the parental generation is given by the binomial formula

$$p_{ij} = \binom{2N}{j}\left(\frac{i}{2N}\right)^{j}\left(\frac{2N-i}{2N}\right)^{2N-j} \qquad [1]$$

This will be recognized as defining the transition matrix of a Markov chain. This Markov chain has two absorbing states, one where there are no A_1 genes and one where there are $2N$ A_1 genes, and eventually one of these two states is entered, implying loss of genetic variation.

We call the model defined by [1] the 'simple' Wright–Fisher model. It fundamentally involves binomial-type form of random sampling in obtaining the genes in the offspring generation from those in the parental generation. In this sense it follows a simple process of obtaining the genes in one generation from those in the previous generation. It is also simple because there is no concept of two genders, no real acknowledgment of the diploid nature of the population, no concept of geographical dispersion of the population, and so on. Further, the size of the population is assumed to be the same from one generation to the next. Models generalizing [1] will be discussed below.

If the model [1] is so unrealistic, why even consider it? There are two answers to this question. First, this model was proposed at the very beginning of the re-writing of the Darwinian paradigm in Mendelian terms. It was always understood that this simple model would be followed by more realistic models. Second, evolution by natural selection requires genetic variation in the population. In the deterministic theory parallel to the model [1], gene frequencies do not change from one generation to another, so that any genetic variation in the population is preserved under Mendelian inheritance. This is an extremely important observation. It was realized, however, that in a population of finite size, and in particular of small size, random changes in gene frequencies will eventually cause one (of two alleles) to be lost. The model [1] was introduced to assess how long, on average, this loss would take. This matter is addressed again below.

Several exact results are known for the Markov chain process defined in [1]. Three of these are the following:

(i) The largest non-unit eigenvalue λ of the matrix $\{p_{ij}\}$ (the entries of which are given by [1]), which largely

 doi:10.1016/B978-0-12-800049-6.00025-1

determines the rate at which genetic variation is lost, is $1 - 1/(2N)$. This means that

$$N = 1/\left[2(1-\lambda)^{-1}\right] \quad [2]$$

(ii) The probably α that two genes in an offspring generation are descended from the same gene in the parental generation is $1/(2N)$. This means that

$$N = (2\alpha)^{-1} \quad [3]$$

(iii) If the fraction of A_1 in some parental generation is x, then given this value, the variance of the (random) fraction y of A_1 in the offspring generation is $x(1-x)/2N$. This means that

$$N = x(1-x)/[2\text{Variance of y}] \quad [4]$$

Quite apart from these results, there is a very large literature giving more conclusions concerning a population evolving as prescribed by [1]. Many of the formulas deriving from these conclusions contain the population size N in them (as do the three listed above). One such formula is the following. It was stated above that under the model [1], eventually either the allele A_1 or the allele A_2 will become lost from the population. If the initial frequency of the allele A_1 is p, then to a very close approximation the (random) number of generations until this happens has a distribution with mean

$$-4N\{p\log p + (1-p)\log(1-p)\} \quad [5]$$

generations.

Models allowing complicating features such as the existence of two genders are very hard to analyze, and the entire purpose of introducing the concept of an effective population size is to use these various formulas but replacing N, wherever it appears in them, by an effective population size. For example, if in some more complex and realistic model allowing, for example two genders, the effective population size (of one type or another – which type will be discussed later) is N_e, common practice is to claim that the (random) number of generations until eventually either the allele A_1 or the allele A_2 will become lost from the population has a distribution with mean

$$-4N_e\{p\log p + (1-p)\log(1-p)\} \quad [6]$$

generations.

The theory justifying this step is not at all well developed, and the procedure just described, while perhaps reasonable, is not well supported theoretically.

For purely historical reasons, the Wright–Fisher model [1] above has assumed a 'gold standard' status. The concept of effective population size as it is discussed in the literature relates entirely to the gold-standard Wright–Fisher model. This fact is seldom noted or appreciated in the literature in which the effective population size is discussed.

The fact that the Wright–Fisher model is used as a gold standard is unfortunate, since a much more realistic model, due to Cannings (1974), would serve as a better gold standard. The Wright–Fisher model is a special case of the Cannings model, and the latter generalizes the Wright–Fisher model in an important way. In the Wright–Fisher model, the number of descendant genes from any parent gene has a binomial distribution with index $2N$ and parameter $1/2N$. Thus the mean number of offspring genes has mean 1 and variance $1 - 1/2N$. In the Cannings model, the number of descendant genes from any parent gene has mean 1 and arbitrary variance σ^2. The numbers of offspring genes from the various parental genes are assumed to be identically, but not independently, distributed (Independence is not possible since it is required that the total number of offspring genes is $2N$.). The full Cannings model is more general than is described here, but the above is sufficient for our purposes. Examples of this model will be given below.

Both the Wright–Fisher model and the Cannings model share one characteristic. This is that there is a concept of a parental and an offspring generation. Such models are called 'non-overlapping generation' models. Other models do not make this assumption. The most important of these is the Moran (1958) model. Here individuals die one by one, at random times, and at each death the dying individual is replaced by a newborn, deriving from a randomly chosen parent, thus maintaining the population size at a constant level. Effective population sizes in such 'birth-and-death' models differ from those in non-overlapping generations models, as discussed further below.

Definitions of the Effective Population Size

How is the effective population size defined? A second point, which is also seldom noted or appreciated in the literature in which the effective population size is discussed, is that there are various definitions of the effective population size. Suppose then that one considers a complicated evolutionary model involving, for example, the existence of two sexes or a geographically structured population. One might then construct a complicated Markov chain model generalizing [1], taking these complications into account. Suppose that in this model the largest non-unit eigenvalue of associated Markov chain matrix generalizing [1] is λ^*. One could then use [2] to define an eigenvalue effective population size $N_e^{(e)}$ as

$$N_e^{(e)} = 1/\left[2\left(1-\lambda^*\right)^{-1}\right] \quad [7]$$

Similarly, if in this more complicated model the probability that two genes in an offspring generation are descended from the same gene in the parental generation is α, one could use [3] to define an inbreeding effective population size $N_e^{(i)}$ by the formula

$$N_e^{(i)} = (2\alpha)^{-1} \quad [8]$$

Finally, one can define a variance effective population size $N_e^{(v)}$ through the variance of the (random) fraction (w) of A_1 in the offspring generation in model more complicated than the simple Wright–Fisher model [1]. Here we use [4] to define a variance effective population size $N_e^{(v)}$ by the formula

$$N_e^{(v)} = x(1-x)/[2\text{ variance of } w] \quad [9]$$

Further definitions of an effective population size are possible. Thus Sjödin *et al.* (2005) introduce the important

concept of an evolutionary effective population size. This is discussed further below.

Just as the central role playing by the Wright–Fisher model in defining the effective population size is not widely appreciated, so also is the fact that there are several definitions of effective population size not widely appreciated. One almost invariably sees the expression 'effective population size' without any qualifying adjective, or which concept of effective population size is most relevant to the situation at hand. These matters are also discussed further below.

Calculations of the Effective Population Size

We consider first the cases of two sexes. Suppose that in any generation there are N_1 diploid males and N_2 diploid females, with $N_1 + N_2 = N$. There are two possible alleles at some specific gene locus, A_1 and A_2, so that each individual is either A_1A_1, A_1A_2, or A_2A_2. We assume that the genetic makeup of any individual in the offspring generation, male or female, is found by randomly sampling one gene from the pool of $2N_1$ genes among the males in the parental generation and one gene from the pool of $2N_2$ genes among the females in the parental generation. All sampling is with replacement. Now there is a Markov chain of the vector (X_1, X_2), where X_1 is the number of A_1 genes among the males of any generation and X_2 is the number of A_1 genes among the females of any generation. This Markov chain is very complex. It can however be shown that the largest non-unit eigenvalue of its transition matrix is very close to $1 - (N_1 + N_2)(8N_1N_2)^{-1}$. Applying eqn [7] we find that to a very close approximation,

$$N_e^{(e)} = 4N_1N_2(N_1 + N_2)^{-1} \qquad [10]$$

Considering the possible sources of two genes taken at random in the offspring generation, it is found that the inbreeding effective population size is also very close to $4N_1N_2(N_1 + N_2)^{-1}$. On the other hand it is impossible even to define a variance effective population size, since there is no single Markovian random variable with a variance that can be used in eqn [9]. An advanced theory, using the concept of quasi-Markovian variables, allows a definition of a variance effective population size, which is found also to be close to $4N_1N_2(N_1 + N_2)^{-1}$.

The expression in [10] bears some discussion. Suppose that $N_1 = 1$ and N_2 is very large, so that there is only one male in the population and a large number of females. The effective population size is then very close to 4. Using this value in [6], it becomes clear that we can expect one or other of A_1 and A_2 to be quite quickly lost from the population. It is clear why this happens. Half the genes in any generation are derived from a single male parent, and the random genetic makeup of this one male ensures a rapid loss of one or other allele from the population.

Similar calculations can be made for a simple Wright–Fisher-type 'gender-less' geographically dispersed population. Here it is found that with even a small amount of migration from one geographical area to another, the eigenvalue effective population size is close to the actual population size. Calculations can also be made for a simple Wright–Fisher-type population whose size assumes cyclically the k values N_1, N_2, N_3, …, N_k, N_1, N_2, … One perhaps thinks in this cycle of an insect population having large summer and small winter sizes. Here the eigenvalue effective population size is close to the harmonic mean of the various sizes taken during any one cycle. This is usually much closer to the smallest size in the cycle than to the largest.

We turn now to the 'simple' Cannings model. By 'simple' we mean that the assumptions made in the simple Wright–Fisher model (on genders, no geography, unchanging population size, etc.) continue to hold. It can be shown for this model that

$$N_e^{(e)} = N_e^{(i)} = N_e^{(v)} = (N - 1/2)/\sigma^2 \qquad [11]$$

where (as above) σ^2 is variance in the number of 'offspring' genes from any parental gene.

It is worthwhile investigating some of the consequences of eqn [11]. Suppose for example that in a diploid population exactly k of the $2N$ parental generation genes are chosen to have 'offspring' genes, and that each offspring generation gene is chosen randomly, without replacement, from these k chosen parental genes. Any given parental gene has either no offspring genes (probability $1 - (k/2N)$) or some random number m of offspring genes, where m has a binomial distribution with index $2N$ and parameter $1/k$. It can be shown that in this case $\sigma^2 = (2N - 1)/k$. Inserting this value in [11] we find that all three effective population sizes are $k/2$. If for example only one individual is chosen to reproduce ($k = 2$) the effective population size becomes 1, as expected. Equation [6] then shows that we can expect that one allele is very soon lost from the population. For any small value of k the same conclusion is reached.

These calculations bear on the importance of the so-called neutral theory. In brief, this theory claims that many gene substitutions in the past did not occur because of selection but because of purely random changes in gene frequencies among selectively neutral genes. Calculations such as those above shows that random substitutions are more likely to arise in populations having a small effective population size than in those having a large effective population size.

More generally, for the Cannings model, eqn [6] should be replaced by

$$-(4N - 2)\{p \log p + (1 - p) \log (1 - p)\}/\sigma^2 \qquad [12]$$

The Cannings model can be generalized to the case where the diploid nature of the population is more explicitly taken into account (Apart from this we make all the simplifying assumptions described above.). Consider then a diploid population of N individuals, and define the diploid inbreeding effective population size $N_e^{(i,dip)}$ as the reciprocal of the probability that two genes taken at random from the offspring generation are both descended from the same diploid parental individual. It can be shown that

$$N_e^{(i,dip)} = (4N - 2)/(\sigma^2_{dip} + 2) \qquad [13]$$

where σ^2_{dip} is the variance of the number of offspring genes from any parent generation diploid individual.

In many cases the effective population size is less than the actual census size. Equation [13] provides an interesting

counter-example. Suppose that each diploid individual is allowed to pass on exactly two genes to the next generation. Then $\sigma^2_{\text{dip}}=0$ and $N_e^{(\text{i,dip})}=2N-1$, almost exactly twice the actual population size. In the simple Wright–Fisher model $\sigma^2_{\text{dip}}=2(N-1)/N$ and $N_e^{(\text{i,dip})}=N$, as expected. If two individuals are chosen to be the parents of all individuals in the offspring generation, with each of the chosen parents contributing exactly one gene to each offspring individual, then $\sigma^2_{\text{dip}}=2N-4$, and $N_e^{(\text{i,dip})}=(2N-1)/(N-1)$, or almost exactly 2, as expected.

The Time Factor

In order to discuss which version of effective population size is appropriate in any given circumstance the time factor has to be taken into account. Both the eigenvalue effective size and the variance effective size (when it can be calculated) look to the future, since they both relate to properties of an offspring generation given the parental generation. By contrast the inbreeding effective population size looks to the past. These facts should be taken into account when considering which version of effective population size is appropriate. When the population size remains constant from one generation to another, all three versions (again, when the variance effective size can be calculated) are either very similar or even identical. Interest in the effective population size concept arises nowadays often because of the need to infer past population properties from current genetic data. When the population size has fluctuated rapidly in the past, a concept of effective population size has been provided by Sjödin *et al.* (2005). These authors point out, however, that when (as with the human population) the population size has steadily increased for many generations, no useful definition of the effective population size has yet been found. It is therefore important to treat with skepticism statements such as 'Fifty thousand years ago the effective population size of the human population was about 25 000'. Such a statement probably means that it is assessed that at that time the breeding size of the human population was about 25 000, and has nothing to do with the concept of an effective population size as discussed above.

Comments about θ

One of the most important quantities in population genetics theory is the parameter θ. Very often it is simply stated that $\theta=4N_eu$ (here u is a mutation rate). There are at least three difficulties with such a statement. First, it is usually not stated which version of effective population size is implied by N_e. Second, as with the human population size in reference to its past history, there might not be any useful concept of an effective population size. Finally, even when these two problems do not arise, the formula $\theta=4N_eu$ implicitly assumes that the population evolved according to the (unrealistic) simple Wright–Fisher model. Other more realistic models, such as the Cannings model, have different formulas for the effective population size (in the Cannings model, the formula for θ is $\theta=4N_eu/\sigma^2$, where (as defined above) σ^2 is the variance of the number of descendant genes from any parent gene). The Moran model has a different formula again for θ, very close to $2N_eu$.

All the above remarks are intended to promote a much more critical use of the effective population size concept than appears all too often in the literature.

Endogenous Retroviruses and Coevolution

TP Mourikis*, **A Aswad***, **and A Katzourakis,** University of Oxford, Oxford, UK

Glossary

Endogenous viral element (EVE) A virally derived sequence in a host genome that originates from a germ line integration of a viral genome (or part thereof).
Enhancer A region of DNA that can bind proteins in order to increase the transcription of a gene. Enhancers and promoters are regulatory elements.
Evolutionary arms race An evolutionary conflict between two coevolving sides that adapt and counter adapt to each other.
Homologous recombination The exchange of nucleotide regions between similar genetic sequences.
Monophyletic lineage A group of species in a phylogeny that includes their common ancestor and all descendants.
Nonallelic homologous recombination Homologous recombination that occurs between stretches of DNA that are very similar, but are not alleles.
Nonsense mutation A mutation that results in a frameshift or the introduction of a premature stop codon.
Phylogeny A graphical representation of evolutionary relationships.
Fixation (population genetics) The point at which the population frequency of a genetic variant reaches 100%.
Promoter A region of DNA, which initiates the transcription of a gene.
Recombination hotspots Regions of a genome that are particularly prone to recombination.
Restriction factor A general term for host-encoded gene products of the innate immune system that partially or fully inhibit intracellular viral replication.
Retrotransposon Mobile genetic elements found in eukaryotic genomes that can amplify themselves via an RNA intermediate.
Retrovirus Viruses in the family 'Retroviridae' that possess RNA genomes that are reverse-transcribed into DNA.
Tumorigenic The capacity or potential to form tumors.
Virion The viral particle.
Xenotransplantation The transplantation of cells/tissue/organs from one species to another.

Introduction

Viruses are obligate intracellular parasites that replicate by hijacking their host's molecular machinery. Although the viral life cycle ordinarily takes place in somatic cells, germ line infections can sometimes occur and potentially lead to the inheritance of the virus. Such vertically transmitted viruses are called endogenous viral elements (EVEs; Katzourakis and Gifford, 2010) and they can occasionally reach fixation and persist in the host for millions of years. EVEs contain information about ancient infections that would otherwise not be observable, and for this reason they have been described – metaphorically – as a genomic 'fossil record.' The vast majority of EVEs originate from retroviruses because the life cycles of the latter involve obligate genome integration (**Figure 1**). This subset of EVEs arising from retroviruses is usually referred to separately as endogenous retroviruses (ERVs). The increasing availability of sequenced host genomes has revealed the vastness of the viral fossil record, and led to the emergence of paleovirology – a field dedicated to the study of EVEs. While non-retroviral EVEs have also recently been described, ERVs have contributed to studies of the evolutionary history of retroviruses for decades, and have facilitated investigations into the complex evolutionary relationship between retroviruses and their hosts (Feschotte and Gilbert, 2012; Weiss and Stoye, 2013).

The evolution of retroviruses and their hosts has been shaped by a series of adaptations and counter-adaptations. Adaptations of the host are driven by the selective pressure to restrict viral infections, which in turn inflict pressure on viruses to counter-adapt in order to evade host defenses (Daugherty and Malik, 2012). Such adaptive changes will recur in both coevolving partners, predominantly manifesting at the molecular interface between host immunity and viral countermeasures. The resulting evolutionary 'arms race' can also be observed at various timeframes: from host–virus interactions shortly after the first infection of a host cell, to adaptations in host immunity at deep evolutionary timescales. The detrimental effect of viral integration into the host can be assessed at short timescales, such as the course of a single infection or at the host population level over a few years or decades. One can also examine the host–virus relationship over evolutionary timescales using ERVs, or investigate the lasting effects of the arms race on antiviral genes (Duggal and Emerman, 2012a).

This article considers examples from the literature representing a cross section of studies on host–virus relationships as they relate to paleovirology. After a brief description of ERV classification, we discuss the process of ERV formation and the events thought to occur shortly after viral endogenisation. We then review a variety of different effects that ERVs can have on host biology, before considering how they can be useful tools in the study of both viral evolution and the evolution of host immunity. Finally, we examine how ERV research has begun to tackle broader questions about the evolutionary consequences of the virus–host arms race that will eventually lead to a better understanding of ERVs, viruses, and their respective pathogenicity.

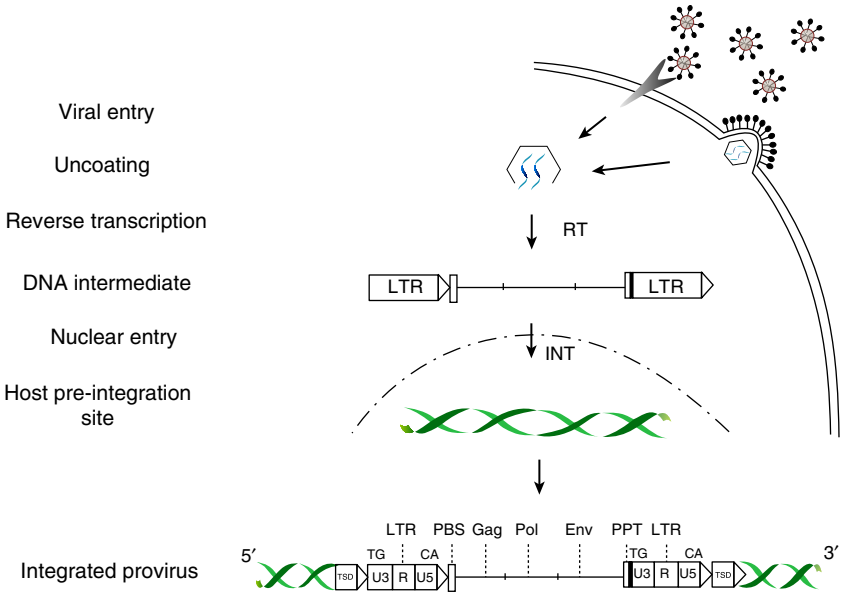

Figure 1 The process of integration. The diagram depicts a stylized cell infected by retroviruses. The virion achieves cell entry by directly fusing to the cell membrane or via receptor-mediated endocytosis. Once inside the cell, the RNA genome is released from the capsid and is converted to double stranded DNA by reverse transcriptase. This DNA intermediate then enters the nucleus where insertion into the host genome is catalyzed by integrase. This process results in the formation of characteristic 'target site duplications' either side of the provirus that are usually 4–6 nucleotides in length.

Classification and Identification of Endogenous Retroviruses

Historically, the classification of ERVs has been complicated by their relationship to both retrotransposons and exogenous retroviruses, both of which have established and distinct classification schemes. Efforts toward a unified system for ERV classification have encountered obstacles when studies that use one naming scheme are compared to studies that use another (Bannert and Kurth, 2006; Blomberg *et al.*, 2009). Early systems attempted to classify ERVs based on their primer-binding site (PBS). However, numerous ERVs use the same PBS, and as more novel families were characterized, it soon became clear that this scheme could not serve as a unified classification system. Contemporary classification of ERVs is based on reverse transcriptase phylogenies that include endogenous sequences and their exogenous relatives, but maintain widely accepted names based on older schemes. Current exogenous retrovirus taxonomy follows conventions set by the International Committee on Taxonomy of Viruses (ICTV). The family *Retroviridae* is subdivided into two subfamilies, the *Orthoretrovirinae* and *Spumaretrovirinae* with the genera *Alpharetrovirus*, *Betaretrovirus*, *Gammaretrovirus*, *Deltaretrovirus*, *Epsilonretrovirus*, and *Lentivirus* being members of *Orthoretrovirinae* and the genus *Spumavirus* of *Spumavirinae*. ERVs are classified based on relatedness to exogenous retroviruses; Gammaretroviruses are designated as Class I, while Class II and III ERVs are related to betaretroviruses and spuma-like retroviruses, respectively. Although this phylogenetically informed approach has proved capable of classifying highly degraded ERVs that are distantly related to exogenous retroviruses, the three classes have few distinguishing features (such as genomic, morphological, or functional), which limits the utility of the classification system. Recent discoveries place certain ERVs firmly within exogenous genera such as lentiviruses, while certain class I ERVs are in fact more closely related to the epsilonretroviruses than the gammaretroviruses (Katzourakis and Tristem, 2005). Furthermore, retroviruses undergo complex patterns of recombination, posing further limitations on efforts to classify them based on a single gene.

From Exogenous to Endogenous: How an Endogenous Retrovirus Is Formed?

Germ line Integration and Fixation

ERVs typically comprise 5–10% of vertebrate genomes (Lander *et al.*, 2001; Waterston *et al.*, 2002), and the history of these elements can be understood by considering the evolutionary forces at play, beginning with germ line invasion of the host by an exogenous circulating retrovirus. After heritable integration, an ERV will be subjected to genetic drift and its frequency in the population may change by chance due to random sampling. ERVs with a fitness cost will be negatively selected out of the population, and a small proportion of neutral (or nearly neutral) ERVs may eventually reach fixation. In rare instances where an ERV offers a fitness advantage, its population frequency will increase rapidly.

Intragenomic Proliferation

ERVs will proliferate in the host genome if a viable infectious particle can be produced, resulting in the reinfection of germ line cells. This will continue until they are either inactivated by nonsense mutations, or are removed as a result of recombination between their long terminal repeats (LTRs) (**Figure 2**; Stoye, 2001). ERVs that are incapable of producing virions (e.g., because of the inactivation of one of their genes)

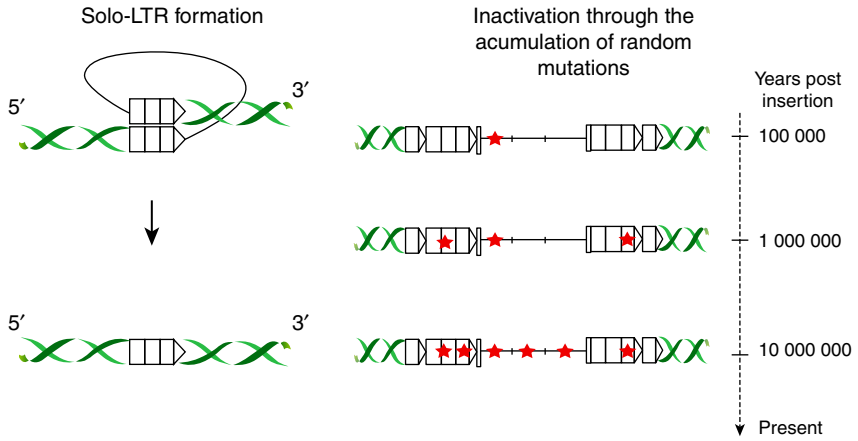

Figure 2 ERV inactivation. The two diagrams shown represent the main mechanisms of ERV deletion or inactivation. Because the long terminal repeats that flank retroviral genomes are identical at the time of integration, accidental recombinational deletion of the ERV can occur resulting in 'solo-LTR' formation. Alternatively, the accumulation of inactivating nonsense mutations over time will render an ERV incapable of producing viral particles or achieving retrotransposition.

can nonetheless proliferate by retrotransposition. Intracellular retrotransposition can occur in *cis* or *trans* where either an intact ERV or other viruses provide the enzymatic activity, respectively (Belshaw *et al.*, 2004). ERV proliferation will lead to the emergence of phylogenetically distinct groups called families that are defined as monophyletic lineages derived from distinct germ line invasions (Tristem, 2000). Once inactivated however, ERVs become subject to the host evolutionary rate that is much slower than that of the exogenous virus. Whereas the inactivation of a single ERV usually occurs within a few thousand years, the fossilization of an ERV family can presumably take several millions of years, and have substantially different evolutionary dynamics.

One way to determine the proliferation mechanism that dominated the early history of an ERV family is by interpreting the patterns of selection that can be detected in their sequences. For example, evidence of post-integration purifying selection in the *env* gene would suggest that the ERV family multiplied by reinfection, since the envelope is a necessary component of mature virions. For human ERV (HERV) families with less than 200 copies, almost all were found to have proliferated by reinfection (Belshaw *et al.*, 2005). However, loss of the *env* gene shifts the mode of ERV amplification from reinfection to retrotransposition, leading to far greater proliferation (Magiorkinis *et al.*, 2012). This is possibly because of the fitness costs to the host associated with reinfection or the expression of *env*, which in turn also determines the survival of the ERV (Magiorkinis *et al.*, 2012).

The Influence of Endogenous Retroviruses on Hosts

The Effect of Endogenous Retroviruses on Genome Architecture

ERV integrations affect the host in a number of ways that can be selectively neutral, detrimental or in rare cases advantageous to the host. We can assess the post-integration effects on genome architecture by considering the potential selective pressure they impose on their hosts based on the site of integration. For example, ERV insertions in genes or other functional regions are rapidly purged from the host population since they usually interrupt essential functions (Nellåker *et al.*, 2012). Integration is likely to be selectively neutral if it occurs in a noncoding region, assuming also that it does not interfere with transcription and can no longer produce infectious particles. However, multiple apparently harmless integrations can have non-neutral downstream consequences by providing recombination hotspots that can significantly alter genome architecture. This is because nonallelic homologous recombination (NAHR) between members of the same ERV family can result in genomic rearrangements such as duplication, deletion, translocation, or inversion (Feschotte and Gilbert, 2012).

In humans, the HERV-K family in particular has undergone extensive recombination since integration (at least 16% of full-length copies) (Hughes and Coffin, 2001). Moreover, some HERV-related genomic rearrangements have been associated with pathogenesis. For example, recent studies of the human genome have shown that structural variation may result from NAHR between HERV elements rich in recombination hotspot motifs (Campbell *et al.*, 2014). For instance, HERV-mediated NAHR has been reported to lead to the deletion of the *eyes absent 1* (EYA1) locus, which can cause branchio-oto-renal syndrome (Sanchez-Valle *et al.*, 2010). Another example is the deletion of the azoospermia factor gene (AZFA or AZF1). The consequent male infertility is the result of a nonreciprocal recombination event of two HERV-I loci on the Y chromosome (Kamp *et al.*, 2000; Sun *et al.*, 2000).

The Effect of Endogenous Retroviruses on Gene Expression

In addition to gene disruption, ERVs can also affect the genome's integrity by influencing their transcriptional regulation. Retroviral insertions near a host gene can modify its regulation by offering alternative promoters or enhancers during transcription. This is because retroviral LTRs contain a promoter for RNA polymerase II along with enhancers and transcription factor binding sites. In humans, for example,

salivary amylase expression was found to be associated with an ERV integration in a tissue-specific manner (Ting *et al.*, 1992). The domestication of an LTR has also been found to promote the expression of neuronal apoptosis inhibitory protein (Romanish *et al.*, 2007). If inserted into introns, ERVs may promote changes in gene transcription by introducing alternative termination sites or novel splice donor and acceptor sites. Such an example is the *slc15a2* locus in mice, where an ERV integration was shown to substantially decrease its transcription as a result of truncated transcripts (Li *et al.*, 2012).

Endogenous Retroviruses, Recombination and the Emergence of New Viral Types

The impact of ERVs extends beyond the direct effect of their integration on host genomes. Indirect consequences include the interaction of ERVs with exogenous viruses or other ERVs that can give rise to novel recombinant viral types. ERVs can be a source of emerging infection if recombination with exogenous viruses leads to the acquisition of novel pathogenicity (Sheets *et al.*, 1993). This can happen through the replacement of the *env* gene with one of different viral origin, and since *env* plays a key role in determining viral tropism, it can facilitate cross-species transmission of the virus. A typical example of *env* acquisition that has led to a new viral type is the feline leukemia virus type B (FeLV-B), which emerged after the endogenised FeLV sequences acquired an *env* gene by the exogenous circulating FeLV-A viruses (Overbaugh *et al.*, 1988; Stewart *et al.*, 1986).

Even more complex patterns of recombination that result from a series of sequence exchanges between viruses have also been described. The RD-114 virus is a product of recombination between the *gag-pol* region of the *Felis catus* endogenous retrovirus (gammaretrovirus) and the *env* locus of baboon endogenous retrovirus (BaeV; gammaretrovirus; van der Kuyl *et al.*, 1999). BaEV is in turn a chimeric virus formed by the *gag-pol* region of *Papio cynocephalus* endogenous retrovirus (PcEV; gammaretrovirus) and the *env* of a beta-like retrovirus. Furthermore, PcEV is the product of a recombination event between the *gag-pol* region of a betaretrovirus and the *env* region of a gammaretrovirus (van der Kuyl *et al.*, 1999). RD-114 is therefore the result of recombination between four distinct retroviruses from two different families. Members of the deltaretrovirus genus perhaps represent an entire clade of recombinant viruses in that their *env* gene appears to have been derived from gammaretroviruses (Manel *et al.*, 2005). Even though they are phylogenetically distant, gamma- and delta- *env* genes exhibit identical modular organization and they seem to utilize the same receptors in order to achieve cell entry (Manel *et al.*, 2005).

Recombination between two ERVs may also repair inactivating mutations and give rise to viral sequences with novel pathogenic characteristics, which in turn can lead to new disease phenotypes. Porcine endogenous retroviruses have been shown to spontaneously recombine, resulting in ERVs that are capable of infecting human cell lines, which has serious implications for pig-to-human xenotransplantation (Bartosch *et al.*, 2004). Furthermore, *in vivo* models have linked the emergence of recombinant viruses with potential pathologies, such as that of retrovirus-induced cancers (Young *et al.*, 2012). For example, it has been shown that infectious Murine Leukemia Viruses (MLVs) are produced by recombination between replication-incompetent ecotropic and non-ecotropic endogenous MLVs in antibody-deficient mice (Young *et al.*, 2012).

Occasional Beneficial Effects of ERVs on Hosts

ERVs can have a detrimental effect on their hosts by directly altering either genome architecture or gene expression, or indirectly by contributing to the emergence of new viral types through recombination. However, the flow of viral genomes into that of their hosts can also generate genetic novelty. Rather than being detrimental, ERV-mediated changes to expression can have a positive influence on the host. For example, the antiviral restriction factor APOBEC3G was found to be upregulated by an LTR insertion (Sanville *et al.*, 2010). As well as the beneficial co-option of LTRs, viral genes can also be co-opted by the host, and while this is extremely rare, such examples have been described in the literature. Domesticated ERV genes can perform important physiological functions – *syncytin*s being the most notable example. *Syncytins* are *env*-derived genes that contribute to the development of the placenta. Specifically, they facilitate the cell–cell fusion of the syncytial cell layer in the syncytiotrophoblast. Evidence shows that *syncytins* were the result of at least eight independent domestication events in at least six mammalian orders (Mi *et al.*, 2000; Lavialle *et al.*, 2013; Cornelis *et al.*, 2014).

As well as syncytins, a number of ERV genes have been captured as part of the evolutionary arms races and repurposed to fulfill an antiviral role. A number of these ERV-derived immunity (EDI) genes have been recognized and function by a range of mechanisms (Aswad and Katzourakis, 2012). Among them is the Friend-virus-susceptibility-1 (*Fv1*) restriction factor, which has been identified in mice and originates from the *gag* region of an endogenous retrovirus (Best *et al.*, 1996). *Fv1* restricts retroviral infections in the early stages of viral entry by interfering with the viral capsid (Best *et al.*, 1996). As well as *Fv1*, other EDIs that prevent viral infections originate from the *env* gene. For example, *FV4* is a defective *env* in mice which when expressed results in the occupation of cell-entry receptors, thereby preventing the binding of incoming viruses (Taylor *et al.*, 2001).

The impact of ERVs on their host can be studied based on the nature of the interaction, i.e., the direct effects of integration or the indirect consequences such as their influence on emerging infection. The outcomes of integration can also be categorized based on their selective effect, and both of these consequences of integration can be examined across the different evolutionary timescales at which they occur. For example, the consequences of a retroviral insertion into a host gene will take effect almost instantly, whereas the co-option of a viral gene is likely to take time before the selective pressure from a viral threat drives the emergence of a novel function. The timescale at which intragenomic proliferation occurs is more continuous, and is likely to be ongoing for millions of years, which in turn will influence the more discrete processes that occur at short and long timescales.

Endogenous Retroviruses as Tools in the Study of Host–Virus Coevolution

ERVs can also be used to study the evolutionary history of host–virus arms races by identifying their influence on both viruses and host immunity. Arms races are a distinct form of natural selection in that the selective pressure on viruses and hosts is highly recurrent (Daugherty and Malik, 2012). Moreover, because viruses evolve more rapidly than their hosts, they have an opportunity to quickly evade antiviral defenses in the cell. Stretched over evolutionary timescales, the evidence of this rapid adaptation will erode from the exogenous viral sequences. However, evidence of past evolutionary arms races can be detected in ERV sequences, as can the selective pressure past viruses may have imposed on restriction factors such as APOBEC, TRIM, SAMHD1, and Tetherin. In primates, APOBEC3G-derived mutations have been found in members of the HERV-K (HML2) family, indicating that the hypermutation-induced restriction of retroviruses by APOBEC3G had evolved long ago (Armitage *et al.*, 2008). This is consistent with the evidence of positive selection on APOBEC3G genes that has persisted for millions of years (Sawyer *et al.*, 2004).

Different host lineages will have been subjected to infection by different viruses at different times, and we can consider the variable effect this could have had on their respective restriction factors by examining the signatures of selection in their sequences. TRIM5α inhibits retroviral entry by recognizing the capsid protein and interfering with uncoating (Stremlau *et al.*, 2006). Selection analysis of *TRIM5* and other *TRIMs* such as *TRIM22* across multiple primate lineages revealed that positive selection has mainly acted on either *TRIM5* or *TRIM22* in a given lineage, but normally not on both (Sawyer *et al.*, 2007). A possible explanation for the mutually exclusive selection on *TRIM5* and *TRIM22* could be that they target different viral strains. This changing selection pressure can also result in the complete loss of a restriction factor. For instance, in carnivores, there were at least two independent *TRIM5* inactivation events in canines (gene disruption; Sawyer *et al.*, 2007) and felines (gene truncation; McEwan *et al.*, 2009), which is evidence for an unknown past viral threat that had been eradicated without replacement. These findings are consistent with the observation that dogs have an uncharacteristically low ERV copy number (Martínez Barrio *et al.*, 2011). Together, these studies suggest that the host repertoire of antiviral defense genes has a high turnover and is shaped by the specific viral threat(s) at a given time.

The inferences one can make about past viruses using only the information imprinted on host genes is indirect evidence of ancient host–virus arms races. Indeed, such approaches have been dubbed 'indirect paleovirology' (Patel *et al.*, 2011; Aswad and Katzourakis, 2012) and allow one to easily and cheaply investigate ancient virus–host arms races retrospectively. These ancient molecular battles can also be studied by creating chimeric viruses that are capable of infection and contain ERV sequences *in vitro*. For example, the capacity of APOBEC3-A, -B, -F, and -G to induce hypermutations in HERV-K have been demonstrated in cell cultures infected with artificially reconstructed viruses (Lee *et al.*, 2008). Similarly, functional envelopes of endogenous chimpanzee retroviruses 1 and 2 (CERV) were reconstructed to investigate the host range of this now extinct retrovirus, revealing the specific entry receptor it uses as CTR1 (Soll *et al.*, 2010). Interestingly, while no copies of CERV have been found in the human lineage, the resurrected CERV was nonetheless capable of infecting human cells, which raises questions about the barrier to endogenisation in humans. A different study that investigates the absence of CERV in humans determined that CERV was insensitive to TRIM5 inhibition, ruling out another explanation for its absence (Perez-Caballero *et al.*, 2008). *Tetherin* is another antiviral factor that was initially characterized as an inhibitor of HIV1, where it prevents release of newly formed virions by 'tethering' them to the cell surface (Neil *et al.*, 2008). It has been shown that *tetherin* has a broad viral activity, with the ability to restrict many enveloped viruses, including HERV-K (Neil, 2013). Interestingly, however, the most recently active family of HERVs (HERVK-HML2) were shown to inhibit *tetherin* activity *in vitro* (Lemaître *et al.*, 2014). Furthermore, this anti-*tetherin* activity was also found against the *tetherins* of other primates that also possess HERVK-HML2, suggesting that the property was advantageous to its proliferation in the lineage (Lemaître *et al.*, 2014).

Endogenous Retroviruses in the Study of Viruses and Virus–Host Interaction at Evolutionary Timescales

The study of ERVs goes beyond that of their causes and consequences; they can be used to understand the evolutionary history of viruses. ERVs are direct evidence of past infections that allow us to reach further back into the evolutionary history of viruses than is possible with contemporary data alone, thereby enabling us to characterize host–virus interactions at evolutionary timescales. Not only can this change an estimate of the age of a viral group, but it can also reveal previously unrecognized hosts. For example, foamy viruses are a group of complex retroviruses that infect a range of mammal hosts, and the identification of an endogenous foamy virus in the two-toed sloth (*Choloepus hoffmanni)* expanded their host range to include Xenarthrans. When combined with both biogeographic data and phylogenetic evidence of coevolution, this finding suggested that the close association between foamy viruses and their hosts had been maintained for over 100 million years (Katzourakis *et al.*, 2009). Foamy virus ERVs that confirm this timeframe were later identified in a number of other species, including the aye-aye (*Daubentonia madagascariensis*) and Cape golden mole (*Chrysochloris asiatica*) (Han and Worobey, 2012a; Katzourakis *et al.*, 2014).

Another clear example of what ERVs can reveal about deep virus evolution was demonstrated for lentiviruses, which include HIV and were thought to be only thousands of years old based on molecular clock dating, or at most a few million years old if inferring from co-speciation with their hosts (Holmes, 2003). However, the identification of an endogenous lentivirus (RELIK) in the genome of rabbits allowed us to confidently estimate a minimum age of $\sim$7 million years based on LTR-dating (Katzourakis *et al.*, 2007). This date was pushed back even further at least 12 million years with the discovery of orthologs in the European hare and weasel family (Keckesova *et al.*, 2009; Han and Worobey, 2012b). These studies were not only surprising in terms of how old we

thought lentiviruses were, but also revealed a much broader host range (at least in the past), which could have implications for the identification of reservoir species. Furthermore, analysis of RELIK revealed a much simpler genome that lacked contemporary features such as the HIV *vif* accessory gene (Katzourakis *et al.*, 2007) that defend the virus against host restriction factors (Larue *et al.*, 2010).

Investigating the lasting effect of antiviral factors on ERVs and demonstrating their efficacy *in vitro* has allowed us to understand the long-term dynamics of virus–host arms races, while studies of ancient foamy viruses and lentiviruses using ERVs have revealed their date of origin and other aspects of evolution. Furthermore, in addition to identifying previously unknown hosts, we can use ERVs to study the changes in host ranges in such large timescale studies of virus–host coevolution. In the case of foamy viruses, for example, discordance between the topology of host and viral phylogenies indicates at least two interspecies transfers in their evolutionary history (Katzourakis *et al.*, 2014). In gammaretroviruses, a major spillover has been revealed by the phylogenetic reconstruction of MLV-related viruses in vertebrates, indicating that certain mammalian viral strains emerged from a bird-to-mammal cross-species transmission (Martin *et al.*, 1999). Furthermore, phylogenetic analysis of endogenous betaretroviruses in bats indicates that interspecies transfer is particularly prevalent, and it has been suggested that this transmissibility could be the result of adapting to evade host defenses that also act as interspecies barriers (Hayward *et al.*, 2013).

Whether we investigate their pathological consequences, or use them to reveal ancient evolutionary history, ERVs enhance our understanding of viral biology and virus–host interaction that can in turn be applied to clinical intervention and epidemiological strategies. In addition to understanding their direct consequences on host genomes and effects on host immunity, we are beginning to build a broader picture of the extent to which ERVs have influenced host evolution. For example, the recent finding that the genomes of larger mammals harbor fewer ERVs raises questions about the mechanisms employed to control their endogenisation and proliferation (Katzourakis *et al.*, 2014). This observation has been linked to Peto's paradox, which is the observation that larger mammals do not exhibit higher rates of cancer despite a greater risk due to their size. It could be that the same mechanisms that control cancer emergence in larger hosts are also responsible for controlling ERVs, which themselves impose a tumorigenic risk (Katzourakis *et al.*, 2014). Answers to such fundamental questions are now being sought through the study of ERVs, which also continue to inform us about the evolutionary processes of viruses and their interaction with host immunity. In parallel to the continued effort to understand the influence of ERVs on host genomes, pathogenesis and broad evolutionary patterns, the study of non-retroviral endogenous viruses are rapidly opening new avenues of enquiry (Katzourakis, 2013; Feschotte and Gilbert, 2012; Aswad and Katzourakis, 2012). As more non-retroviral EVEs are described, we will be able to both investigate insights that emerged out of the study of retroviruses, as well as ask new questions that are unique to each non-retroviral group.

Glossary

Antiherbivory Deterrence of consumption of plant by herbivores.
Ascomycota Phylum of fungi.
Ascospore Sexually produced spore of the Ascomycota.
Balansia Genus of fungal endophytes in warm-season grasses.
Biotrophic Feeding on living organisms.
Clavicipitaceae Family of Ascomycota.
Conidia An asexual reproductive spore produced by fungi.
Epichloë Genus of fungal endophytes in cool-season grasses.
Ergot alkaloids Toxic chemicals produced by fungi in the family Clavicipitaceae.
Fungivore Animal or insect that eats fungi.
Herbivore Animal or insect that eats plants.
Heterothallic Having multiple mating types.
Homopteran Insect in order Homoptera.
Intercellular Growing in spaces between cells.
Intracellular Entering into the cell itself.
L-form Intracellular form of a bacterium that loses cell walls.
Muller's ratchet Accumulation of deleterious mutations in asexual populations of organisms.
Mycorrhizae Fungi that grow on roots and assist plants to absorb soil nutrients.
Necrotrophic Feeding on dead organisms.
Perithecia Flask-shaped structure containing ascospores of fungus in Ascomycota.
Sclerotium Seed-like resistant structure produced by a fungus.
Spermatia Fungal reproductive cells comparable to sperms of animals.
Stromata Fungal structures on which reproductive structures or cells may form.

Introduction

In this article we examine the evolution of endophytic microbes of plants and some of the factors affecting evolution of endophytism. Endophytes are typically metabolically active microbes (usually bacteria, fungi, or algae) that enter into healthy tissues of plants without causing symptoms of disease (Stone *et al.*, 2000; Schulz and Boyle, 2006; Compant *et al.*, 2008; Cheplick and Faeth, 2009; Reinhold-Hurek and Hurek, 2011) (see **Figures 1** and **2**). The presence of endophytes in plant tissues cannot usually be detected without application of microscopic, culturing, or molecular methods of detection (White, 1987; Hardoim *et al.*, 2015). Mycorrhizae are often systemic root endophytes of plants, but in this article we will predominantly focus on the kinds of endophytes that may become systemic in aerial plant parts, including stems, leaves, flowers, and seeds (Rodriguez *et al.*, 2009).

Endophytic microbes have been shown to enhance the fitness, competitiveness, and sometimes growth of host plants (Clay, 1988; James *et al.*, 2002; Rudgers and Clay, 2008; Puente and Bashan, 2009; Janir *et al.*, 2010; Paungfoo-Lonhienne *et al.*, 2010; Beltran-Garcia *et al.*, 2014). In some cases endophytes have been shown to produce secondary metabolites that deter pathogens or herbivores of plants (White, 1987; Clarke *et al.*, 2006; Ongena and Jacques, 2008; Ambrose and Belanger, 2012; Gond *et al.*, 2014). Some endophytic microbes have been found to enhance tolerance of plants to abiotic stresses (Malinowski and Belesky, 2000; Redman *et al.*, 2002; Waller *et al.*, 2005; Kuldau and Bacon, 2008). The beneficial effects of endophytes on plants have increased interest in use of endophytic microbes to enhance agricultural production of crop plants.

In this article we will discuss features of some common types of endophytes and how these microbes evolved and adapted to plant hosts. Two important groups of endophytic

Figure 1 Endophytes in plant tissues. Endophytic hyphae (arrows) emerging from roots of *Phragmites australis* (100 ×).

Figure 2 Endophytes in plant tissues. Endophytic bacterial L-forms (arrows) located within root hair cells of a candle cactus (*Subpilocereus repandus*) (1000 ×).

microbes include the class I and class II endophytic microbes (Rodriguez *et al.*, 2009). Class I endophytes are typically systemic in leaves, stems, and seeds, are obligately endophytic, and are often seed transmitted, entering into the embryo within seeds of host plants (Schardl *et al.*, 2004; Selosse and Schardl, 2007; Tadych *et al.*, 2014). The class II endophytes become systemic in plants but they are not obligately endophytic, and often they bear very close relationship to soil microbes or pathogens (Compant *et al.*, 2010; Johnston-Monje and Raizada, 2011). Class II endophytes do not show evidence of coevolution with any particular host and may move horizontally between hosts of diverse plant families. Class II endophytes may be seed transmitted but typically they are vectored on the surfaces of seeds rather than within embryos.

Class I Endophytes

The typical evolutionary path of class I endophytes can be illustrated by examination of the development of endophytism in the fungal family Clavicipitaceae (Ascomycota). In this family the ancestral state is insect pathogenic fungi like *Cordyceps* (Spatafora *et al.*, 2007). These species infect insects and use their mummified bodies to obtain the nutrients to produce reproductive structures (perithecia and ascospores). They generally do not obtain nutrients from plants. Some of these insect necrotrophs have adapted to obtain nutrients from scale insects that are themselves biotrophic parasites of plants (White *et al.*, 2003). Scale insects attach to plant tissues and use their stylets to penetrate the plant epidermis and tap into the nutrients in plant vascular tissues. Scale insect pathogens in the fungal genera *Hypocrella*, *Dussiella*, *Torrubiella*, *Hyperdermium*, and *Ascopolyporus* obtain nutrients from plants by consuming the scale insects and then using the nutrient flow from the plants to produce their own reproductive structures (Sullivan *et al.*, 2000; Bischoff *et al.*, 2004; Bischoff and White, 2004; Bischoff *et al.*, 2005). These fungal species are necrotrophic on insects and biotrophic on plants; however, they depend on the insect to create the stylet wound through which they obtain plant nutrients. The production of ergot alkaloids is notably high in these species that obtain nutrients from plants through parasitizing insects, whereas these alkaloids are generally not detectable in forms that feed exclusively on insect tissues (Bacon *et al.*, 1977; Torres *et al.*, 2008). It has been suggested that the abundant nutrients available in plant tissues enabled the fungi to invest in defensive secondary metabolites like ergot alkaloids; in addition, exposure on surfaces of plants make fungi vulnerable to predation, increasing the need for defensive compounds (Torres *et al.*, 2008).

In the family Clavicipitaceae, endophytism developed in species that adapted to live exclusively on nutrients available in plants. Among these species are those classified in the non-endophytic genus *Claviceps*. These species developed the ability to infect ovaries as a way to obtain plant nutrients (Bischoff *et al.*, 2004). *Claviceps* ascospores infect an ovary of a grass, suppress ovary development, and then produce a sclerotium using the nutrients that would have gone into the developing ovary. The resistant sclerotium later germinates to form a stalked stroma bearing perithecia and ascospores that may be ejected into the air to infect additional grass ovaries. *Claviceps* is restricted to ovule tissues, essentially replacing seeds.

Species of genera *Epichloë* and *Balansia* made the final step to endophytism by evolving meristem-infection mechanisms (White *et al.*, 1995; Tadych *et al.*, 2012, 2014). In *Epichloë*, the fungus produces conidia or ascospores that germinate on host tissues to form a mycelium that at first grows epiphytically onto the nutrient-rich grass shoot meristems, and then proliferates intercellularly within tissues of developing stems and leaves (Tadych *et al.*, 2012). As the plant meristem grows, the endophytic hyphae remain in the plant tissues as they differentiate and mature (White and Cole, 1986). Endophytes of genus *Balansia* adapted to warm-season (Panicoid) grasses, while species of genus *Epichloë* are endophytes of cool-season (Pooid) grasses (Bischoff *et al.*, 2004).

The *Epichloë* Life Cycle and Its Evolutionary Reduction

To understand factors affecting evolution of endophytism it is illustrative to examine the development and life history of *Epichloë*. *Epichloë*, classified as an endophyte because that is its predominant mode of living, forms two types of reproductive structures on grasses. The sexual reproductive structures form on fungal stromata that develop on plant inflorescence primordia (White and Bultman, 1987). A stromal mycelium forms as the inflorescence primordium expands, producing a stroma that embeds and permeates a living but modified inflorescence (White *et al.*, 1991; White and Bultman, 1987). Inflorescence

development is arrested and cuticular barrier layers do not form, permitting free flow of water from plant inflorescence to the mycelial stromal layers on its surface (White *et al.*, 1997). On the surface of the stromal mycelium a layer of spermatia are formed. *Epichloë* is heterothallic with two mating types; spermatia of one mating type must be transferred to a stroma of the opposite mating type to initiate sexual crossing and perithecial development on the stroma surface (White and Bultman, 1987). Symbiotic flies vector spermatia between stromata of the opposite mating type to initiate fertilization and perithecial formation (Bultman *et al.*, 1997).

Epichloë also forms asexual conidia on mycelium on surfaces of leaf blades (White *et al.*, 1996; Moy *et al.*, 2000). The epiphytic conidia of this stage are water dispersed and will not release from the conidiophores unless water is present (Tadych *et al.*, 2007). The conidia may flow off leaves to tillers or seedlings that grow in the vicinity of grass plants (Tadych *et al.*, 2012; Wiewióra *et al.*, 2015). A third means of reproduction of *Epichloë* endophytes is clonal, in which endophytic mycelium from maternal plants colonize developing ovaries and then embryos in seeds (White and Cole, 1986; Selosse and Schardl, 2007). This clonal mode of reproduction has been referred to as vertical dissemination; infection of neighboring plants is considered horizontal dispersal (White, 1988; Wiewióra *et al.*, 2015).

Water restriction is probably the main selective force that may cause reductions in the life cycles of *Epichloë* endophytes. This is due to the vulnerability of *Epichloë* reproductive stages to water restriction. Stromata lose water rapidly and in its absence stromata are selected against (White *et al.*, 1993; White and Camp, 1995). Grasses in very dry or rain-restricted areas will often contain *Epichloë* endophytes that grow very slowly in culture and are incapable of forming conidia, suggesting loss of capacity to reproduce by stromata or conidia. These totally sterile endophytes reproduce exclusively clonally through dissemination in seeds of the maternal plant (White and Cole, 1986; White and Morgan-Jones, 1987). Totally sterile endophytic strains represent the ultimate in reduction of the *Epichloë* endophyte life cycles because these strains cannot form stromata for sexual reproduction or disseminate horizontally via conidia.

Hybridization and Diversification

One important mechanism for diversification of endophytes such as *Epichloë* is through hybridization. Christopher Schardl and collaborators over several years have shown that many endophytes, especially those that do not show capacity to produce perithecia and ascospores, contain evidence of genome hybridization between distinct endophytes (Schardl *et al.*, 1994; Clay and Schardl, 2002; Moon *et al.*, 2002, 2004; Selosse and Schardl, 2007). Hybridization was proposed to be a way that asexual endophytes may increase their gene diversity and overall survival capacity, perhaps counteracting the accumulation of mutations resulting from loss of sexual reproduction and 'Muller's ratchet' (Selosse and Schardl, 2007).

Examples of Diversification into Different Plant Groups

Pseudocercosporella Trichachnicola

An endophytic fungus, *Pseudocercosporella trichachnicola*, was found to be widespread in the warm-season grass species *Trichachne insularis* (White *et al.*, 1990). *Pseudocercosporella* intercellularly colonizes leaves, culms, and seeds of its host through use of endophytic mycelium that appears to grow in meristematic tissues of leaves and tillers. The near relatives of *Pseudocercosporella* are plant pathogens. It thus seems reasonable that the ancestors of the *Pseudocercosporella* endophyte were pathogens. The *Pseudocercosporella* endophyte is comparable to the *Epichloë* endophytes in its life cycle, and also in that it likely coevolved with and is widespread in its host plant. As far as is known, this endophyte is also predominantly vertically transmitted in seeds in a way comparable to the highly reduced forms of *Epichloë* endophytes.

Morning Glory Symbionts

Some species of morning glories (Convolvulaceae) have been shown to contain systemic fungi in the genus *Periglandula* (Clavicipitaceae) in leaves, stems, and seeds (Steiner *et al.*, 2011). These epibionts have been found to produce high levels of ergot and other toxic alkaloids that are believed to be antiherbivory compounds. These fungi like class I endophytes, appear to be closely coevolved and obligate associates of their host plants. Before discovery of the morning glory symbionts it was generally believed that morning glories were the source of the toxic ergot alkaloids contained within their tissues. However, it is now clear that fungal symbionts are the source of the alkaloids that toxify morning glories.

Class II Endophytes

Class II endophytes are facultatively associated with hosts and there is little evidence that they coevolved with any particular host (Compant *et al.*, 2008; Rodriguez *et al.*, 2009). Examples of class II endophytes are those that are recruited from soils or from adjacent plants to systemically colonize hosts (Campisano *et al.*, 2014). The bacterial endophyte *Bacillus amyloliquefaciens*, widespread in soils and in plants (Gond *et al.*, 2014), is a good example of this type of endophyte. In recent studies we have encountered *B. amyloliquefaciens* as a systemic endophyte of vanilla orchids (White *et al.*, 2014a), grasses, and English Ivy; in these species the bacterium colonizes external and internal tissues of roots, stems, leaves, and seeds (Soares *et al.*, 2015). The bacterial endophyte can be spread both vertically on surfaces of seeds and horizontally by water splash to uninfected adjacent plants of diverse species. Unlike the class I endophytes, a strain of the bacterium from one host may be readily inoculated into a host of another plant species. One peculiar feature of many bacterial endophytes is that they may become wall-less 'L-forms' within shoot or root cells (**Figure 2**; White *et al.*, 2014b). In this endosymbiotic form the bacteria are thought to be able to evade host cell-defenses. The bacteria appear to masquerade as intracellular organelles, thus giving a clue as to how organelles may have evolved.

Fungal endophytes belonging to diverse genera (e.g., *Fusarium*, *Alternaria*, etc.) also belong to this class of endophyte. Evidence from studies of many plants suggests that plants may host communities of endophytes (Zambell and White, 2014). In a study of green brier (*Smilax* spp.) it was

found that stems were colonized by three dominant species of endophytes that tended to partition themselves in distinct zones within stems (Zambell and White, 2014). Some class II endophytes may also become pathogenic under certain circumstances. An example here may be seen in the *Diplodia mutila* endophyte of the tropical palm tree *Iriartea deltoidea* (Alvarez-Loayza *et al.*, 2011). *Diplodia mutila* occurs as a pathogen and perhaps endophyte in a wide array of plants. This endophyte is transmitted as a mycelial and conidial crust on surfaces of the palm seed. Seedlings bear the endophyte within leaves and stems. When these seedlings grow in the shaded understory of the forest, the fungus is mutualistic and protects seedlings from insect herbivory; however, when seedlings grow in full sunlight, the fungus reverts to a pathogenic necrotrophic phase and induces necrosis in leaves and stems of plants, often resulting in mortality of seedlings.

Parasitism–Mutualism Continuum

Diplodia mutila is a good example of the parasitism–mutualism continuum concept of Schulz and Boyle (2005) who postulated that beneficial effects (mutualism) of endophytic microbes are dependent on a specific set of conditions, while in some other conditions, the same organism may be a deleterious parasite of the host (Saikkonen *et al.*, 1998; Schulz *et al.*, 1999). Whether the endophyte persists as a widespread symbiont of the host may depend on its relative survival value to the host in its environment. Plants grown under ideal conditions may be expected to lose endophytic microbes; this has been observed in the case of plants grown in greenhouse culture (personal observation).

Host Role in Regulation of Endophytic Microbes

Fossil evidence has revealed that the earliest land plants were colonized by endophytic microbes (Taylor *et al.*, 2015), and modern plants are colonized by communities of microbes that enter into their tissues (Arnold *et al.*, 2003; Unterseher *et al.*, 2013; Zambell and White, 2014; White *et al.*, 2014b). The fact that some of the endophytic microbes also have the capacity to be pathogens makes it imperative that plants have mechanisms to control pathogenic behaviors of endophytes. It seems likely that many of the secondary metabolites produced by plants that have been thought to function in defense are actually produced to regulate endophytic microbes in plants (Ku *et al.*, 2013; Torres *et al.*, 2011; Mandal *et al.*, 2010; Tadych *et al.*, 2015). Such compounds may include those that suppress pathogenicity traits of microbes (Tadych *et al.*, 2015) such as rapid unchecked growth and production of reactive oxygen that would induce host defensive reactions. Tadych *et al.* (2015) demonstrated in cranberry fruits that the secondary metabolites quinic and benzoic acids reduced mycelial growth and suppressed reactive oxygen secretion of several fungi that colonize developing fruits. Investigators have shown that caffeic acid from mulberry leaves suppresses pathogenicity of the bacterial pathogen *Streptococcus faecalis*, a common microbe of the silkworm intestinal community (Koike *et al.*, 1979). When silkworms are removed from mulberry leaves and fed on an artificial diet, the *Streptococcus* pathogen inflicts disease and kills its silkworm host. These few examples are evidence that plants produce an array of compounds that evolved to regulate endophytic microbes. The full diversity of those compounds and their modes of action to regulate endophytic microbes remain to be discovered.

Two major types of systemic endophytes, classes I and II, differ from one another in the degree to which they have coevolved with hosts. Class I endophytes are closely coevolved with hosts and obligately endophytic, while class II endophytes are not closely coevolved with hosts and generally facultatively endophytic. Among the class I endophytes evolution of defensive secondary metabolites and availability of moisture are factors that played roles in evolutionary development and loss of sexual reproduction of the endophytes. Among the class II endophytes environmental factors, host suppression of pathogencity, and capacity of the endophytes to avoid elicitation of defensive responses of hosts may be important factors in evolution of endophytism.

Endosymbiotic Theory

S Garg, V Zimorski, and WF Martin, Heinrich-Heine-Universität Düsseldorf, Düsseldorf, Germany

Glossary

Aerobic organisms Aerobic organisms live in oxic environments. Obligate aerobes are strictly dependent on oxygen and need it to grow. Aerobes usually use oxygen as the terminal electron acceptor in energy metabolism.

Alveolates The alveolates are a group of unicellular eukaryotes, including dinoflagellates, apicomplexans, and ciliates.

Amoebozoa The Amoebozoa are one eukaryotic supergroup containing ameboid microorganisms.

Anaerobic organisms Anaerobic organisms do not require oxygen for growth. For obligate anaerobes oxygen is harmful, because various enzymes of anaerobes are readily inactivated by oxygen.

Apicomplexa Apicomplexa are a large group of obligate parasitic, unicellular eukaryotes belonging to the supergroup Chromalveolata.

Archaeplastida The Archaeplastida are one eukaryotic supergroup containing glaucophyta, rhodophyta, and chlorophyta (with land plants).

Autotrophy Autotrophic organisms are able to produce organic compounds (food/energy-source) from inorganic ones using light or chemical reactions.

Chlorarachniophytes Chlorarachniophytes are ameboid eukaryotes belonging to the rhizaria. They possess secondary (green) plastids with four membranes and a nucleomorph.

Chlorophytes The lineage of Archaeplastida having green primary plastids.

Endosymbiosis One cell living in stable symbiosis within another.

Facultative anaerobic organisms Facultative anaerobes are able to grow with or without oxygen.

Fermentation Enzymatic conversion of organic compounds (sugars) into acids, gases, or alcohol.

Functional redundancy (through endosymbiosis) The retention of divergent but homologous gene copies donated both by host and endosymbiont at organelle origin for the same functions (e.g., ribosomal proteins of chloroplasts, mitochondria, and the cytosol).

Glaucophytes A group of unicellular algae with plastids that still possess a rudimentary peptidoglycan wall and that together with the rhodophytes and the chlorophytes comprise the eukaryotic supergroup Archaeplastida.

Heterocyst Differentiated cells of some cyanobacteria that are specialized for nitrogen fixation.

Heterotrophy Heterotrophic organisms use reduced organic substances as their source of carbon.

Hydrogenosome Hydrogenosomes are anaerobic mitochondria that have a double membrane and synthesize ATP via hydrogen-producing fermentations. They lack cytochromes, a membrane-associated electron transport chain, and (except in rare cases) a genome. Hydrogenosomes arose several times independently in evolution and can be found in trichomonads, anaerobic ciliates, and some fungi.

Methanogen Methanogens are archaea that produce methane as a metabolic byproduct of core energy metabolism.

Mitosome Mitosomes are organelles of mitochondrial origin that do not produce ATP. They have retained components of FeS cluster assembly or sulfate activation.

Nucleomorph Found only in some groups of eukaryotic algae whose plastids stem from secondary endosymbiosis, the nucleomorph is the highly reduced nucleus of the eukaryotic endosymbiont, it is located inside the periplastidal compartment. The nucleomorph is lost in most algae with secondary plastids but still can be found in chlorarachniophytes and cryptophytes.

Opisthokonts Another name for the group consisting of animals and fungi.

Periplastidal compartment The periplastidal compartment can be found in plastids of secondary origin within the chlorarachniophytes and cryptophytes. It corresponds to the cytosol of the eukaryotic endosymbiont.

Phagocytosis Phagocytosis is the engulfment of cells or particles by living cells.

Primary plastids Designates plastids that stem from a symbiotic association of a cyanobacterium with a eukaryotic host.

Proteobacteria Proteobacteria are a major group of bacteria. They are Gram-negative.

Pseudogene Pseudogenes are DNA segments resulting from multiple mutations, which look like genes, but are dysfunctional.

Rhodophytes Red algae, a group of Archaeplastida.

Ribosome Ribosomes are cellular particles composed of proteins and rRNA, where proteins are synthesized. They can be found in the cytosol, in mitochondria, and in plastids. In algae with a nucleomorph, a fourth set of ribosomes occurs in the periplastidal compartment.

SAR An eukaryotic group of organisms including stramenopiles (heterokonts), alveolates, and rhizaria.

SCH An eukaryotic group including stramenopiles, cryptophytes, and hacrobia.

Secondary plastids Designates plastids that stem from secondary endosymbioses in which the product of the primary endosymbiosis (a green- or a red-algae) came to reside into a heterotrophic, eukaryotic host.

Symbiosis Living together. When symbiosis involves benefit for both partners, it is mutualism.

Syntrophy 'Eating together,' designates a kind of metabolic association in which one cell is dependent upon a metabolic endproduct of another. The metabolic endproduct is often molecular hydrogen.

Introduction

Endosymbiotic theory designates a class of hypotheses that view various organelles in eukaryotic cells as descendants of endosymbionts: cells that came to live inside another cell (a host). In its oldest and most familiar versions, endosymbiotic theory posits that mitochondria and plastids were once free-living cells: mitochondria (the powerhouses of eukaryotic cells) stemming from free-living proteobacteria and plastids (the chlorophyll-containing solar panels of plant cells) stemming from cyanobacteria. The Russian botanist Constantin Mereschkowsky is generally credited with the first formulation of endosymbiotic theory. He described plastids as reduced cyanobacteria that entered into a symbiosis with a heterotrophic host, which itself originated via a symbiosis between a heterotrophic host cell and a smaller endosymbiont that, in his view, gave rise to the nucleus (Mereschkowsky, 1905). Mereschkowsky's reasoning was remarkably modern with regard to the origin of plastids. He did not consider that mitochondria might also be of endosymbiotic origin (Mereschkowsky, 1910). That idea probably traces back to the French biologist Paul Portier (1918), who developed ideas about the relationship between bacteria and mitochondria. But Portier proposed that mitochondria could be cultured outside their host cells, and this precipitated considerable criticisms from peers (Archibald, 2014). The American biologist Ivan Wallin developed endosymbiotic theory further for mitochondria (Wallin, 1927). He was convinced that mitochondria are descendants of endosymbiotic bacteria, but he did not expound upon the ancestry of the host that acquired them (Wallin, 1927). Like Portier, he thought that the cultivation of mitochondria outside their host should be possible. Though initially quite popular in the early 1900s, endosymbiotic theories endured scathing criticism in a leading college textbook of the day (Wilson, 1928), whereupon they fell into disrepute for decades.

Endosymbiotic theory was revived in 1967 when Lynn Sagan (later named Margulis) argued that chloroplasts and mitochondria had descended from separate endosymbionts. Sagan envisaged as a host for the origin of mitochondria a heterotrophic anaerobic prokaryote, in whose cytoplasm an aerobic prokaryotic microbe had taken up residence. The resulting heterotrophic protozoan later engulfed a cyanobacterium, resulting in the origin of plastids (Sagan, 1967). However, germane to all of Margulis's versions of endosymbiotic theory, from 1967 onward, is the notion that the eukaryotic flagellum arose from a symbiotic spirochete (Margulis, 1970; Margulis *et al.*, 2006) – a view that never received reproducible experimental support and that remained outside the mainstream of developments surrounding endosymbiotic theory. Since Margulis's revival of the idea, more than 30 different versions of endosymbiotic theory, with varying degrees of detail, and with different areas of focus, have been put forward (reviewed in Martin *et al.*, 2015). Some versions introduce new ways to imagine the origin of mitochondria and chloroplasts, other versions suggest endosymbiotic origins for other cell compartments like peroxisomes or the nucleus, or aim to account for the origin of various eukaryotic traits. In the main, however, endosymbiotic theory is about the origin of chloroplasts and mitochondria.

Mitochondria

Early models for the origin of mitochondria have a primitive mitochondrion-lacking (amitochondriate) microbe as the hosts of an aerobic bacterium (De Duve, 1969). Following the discovery of archaebacteria (archaea), an archaeon was often viewed as the host that acquired the mitochondrion (Van Valen and Maiorana, 1980; Doolittle, 1980). The model of Vellai and Vida (1999) operates with a prokaryotic host, as does the sulfur cycling theory of Searcy (1992). López-García and Moreira (2006) proposed a three-partner endosymbiosis between a fermenting, heterotrophic, hydrogen-producing ancestral myxobacterium (delta-proteobacterium) that serves as the host, a strictly anaerobic, methanogenic archaeon that becomes the nucleus, and an alpha-proteobacterium that was then surrounded by the syntrophic couple and became the mitochondrial ancestor. The model presented by Martijn and Ettema (2013), like that put forward by Yutin *et al.* (2009), suggests a phagocytosing archaeal host, which engulfed an alpha-proteobacterium.

Most models for the origin of mitochondria posit that the mitochondrial endosymbiont was an aerobic bacterium, if they take a stance on its physiology at all. But various anaerobic forms of mitochondria like hydrogenosomes also occur among eukaryotes (Müller *et al.*, 2012) and these also need to be accounted for under endosymbiotic theory. One variant of endosymbiotic theory, called the hydrogen hypothesis, accounts for these anaerobic mitochondria. It posits a symbiotic association of an anaerobic, strictly hydrogen-dependent and autotrophic archaebacterium as the host with a facultatively anaerobic, heterotrophic bacterium as the endosymbiont, with specialization and differential loss leading to aerobic and anaerobic forms of mitochondria (Martin and Müller, 1998). Today, some models for the origin of mitochondria entail the assumption that the host that acquired the mitochondrial symbiont was already a eukaryote, others operate on the premise that the host was a prokaryote and that the origin of eukaryote cell complexity came later (reviewed in Martin *et al.*, 2015). Present data tend to favor the view that the host was a prokaryote, specifically an archaeon in most current views (Lane and Martin, 2010; Williams *et al.*, 2013; Bolte *et al.*, 2015; Raymann *et al.*, 2015; Spang *et al.*, 2015). The endosymbiotic origin of mitochondria in an archaeal host is illustrated in **Figure 1**.

Plastids

All models for the origin of chloroplasts propose that the host was already a eukaryote. The nature of the symbiotic association between host and plastid symbiont varies across models. Today, plastids are involved in photosynthesis, carbon fixation, amino acid biosynthesis, lipid and cofactor biosynthesis as well as nitrogen metabolism. This gives rise to several hypotheses about the physiological context for the establishment of the plastids. In Mereschkowsky's version of endosymbiotic theory, the production of carbohydrates for the host was the key contribution by the cyanobacterial endosymbiont right from the start (Mereschkowsky, 1905). Another reason for the establishment of the symbiosis could

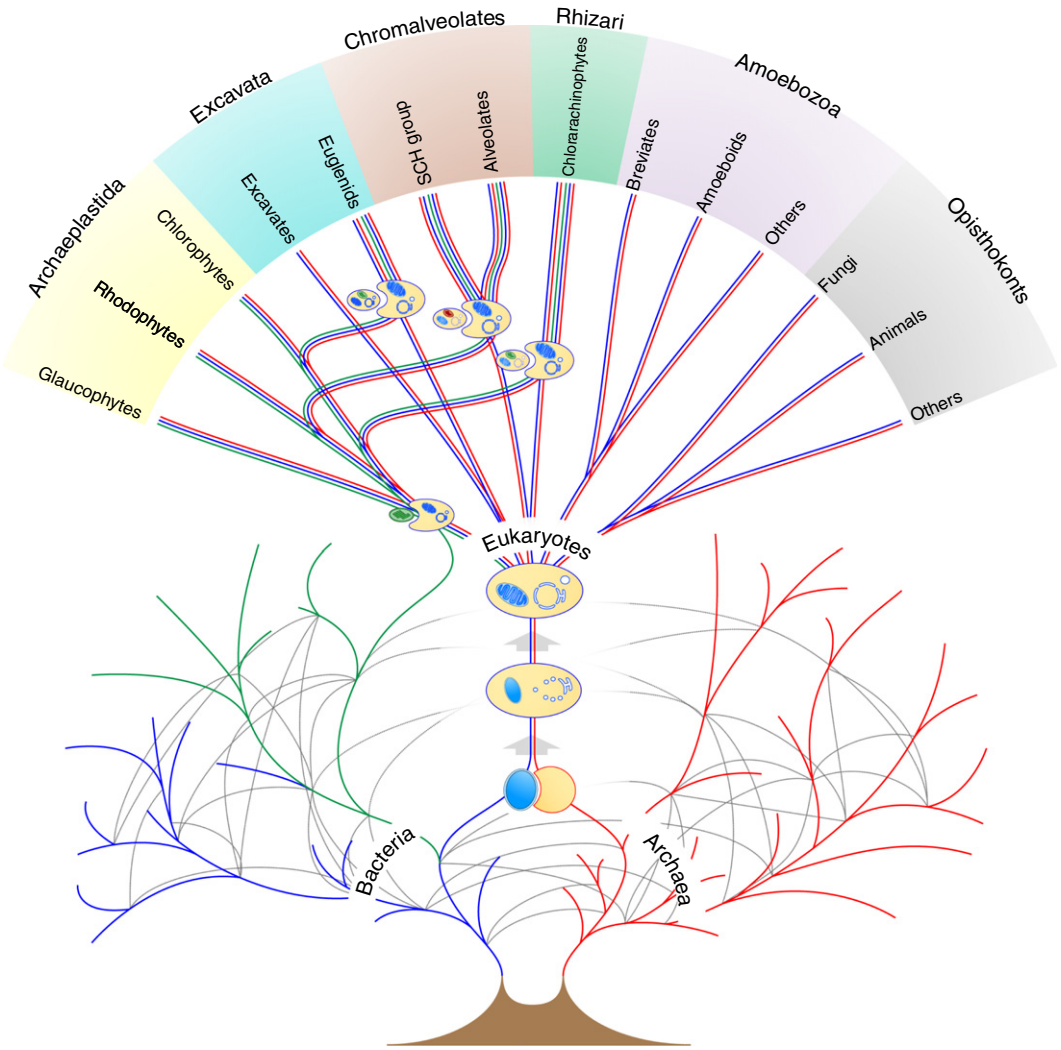

Figure 1 A schematic representation of the origin of the three domains of life and their relationships: The bacteria are shown in blue while the archaea are shown in red. Each colored line serves to show the number of genomes involved in shaping that lineage while also indicating phylogenetic relationships between the various groups. Life arose from alkaline hydrothermal vents as the two bacterial kingdoms the bacteria and the archaea. Prokaryotic evolution is rampant with Lateral Gene Transfers (LGT) – shown in dotted gray lines between the various groups – that shape the various prokaryotic lineages. A symbiotic association of an archaea and bacteria gave rise to eukaryotes where genome evolution is dominated by endosymbiotic events rather than LGT. The taxonomic groups shown correspond to those recognized by Adl *et al.* (2005). The term SCH-group is introduced here to designate Stramenopiles, Cryptomoads, and Haptophytes, whose plastids appear to share a single common origin (Zimorski *et al.*, 2014; Gould *et al.*, 2015).

have been the low concentration of oxygen in the air at the time of endosymbiosis, such that the oxygen produced by the symbiont subversed the host's mitochondrial respiration (Martin and Müller, 1998). However, if we look at modern symbioses involving cyanobacteria, they mostly involve cyanobacterial nitrogen fixation (Kneip *et al.*, 2007; Ran *et al.*, 2010). Today's plastids do not fix nitrogen. Possibly they have lost this attribute (and the associated genes) as a consequence of the evolution of the nitrogen cycle (there is more nitrate in the environment today because of environmental O_2). This aspect of endosymbiotic theory for plastid origin (nitrogen fixation) is not directly supported by data, but is congruent with recent analyses that today's filamentous, heterocyst-forming and nitrogen fixating cyanobacteria (sections IV and V) are most similar, from the genomic perspective, to the plastid ancestor (Deusch *et al.*, 2008; Dagan *et al.*, 2013).

In recent literature, a proposal for the origin of plastids involving chlamydia continues to surface. It posits that a chlamydial endosymbiont was involved as a kind of metabolic helper in the origin of plastids (Ball *et al.*, 2013), a kind of preplastidial infection that the cyanobacterial symbiosis somehow cured. That suggestion, though published in prominent journals, is problematic, because the observations upon which it is founded (phylogenetic trees) are subject to simpler alternative interpretations that do not require the participation of any symbionts other than a cyanobacterium at the origin of plastids (Deschamps, 2014; Zimorski *et al.*, 2014;

Domman *et al.*, 2015). Moreover, the chlamydia story has the problem that if one infers the existence of a symbiont from a few gene trees (which is how the chlamydia symbiosis narrative operates), then for every unexpected branch that we observe in phylogenetic trees we would have to infer a new endosymbiont, and that kind of reasoning in endosymbiotic theory simply does not work (Ku *et al.*, 2015).

A member of the rhizaria, the ameba *Paulinella chromatophora*, harbors within its cytoplasm cyanobacteria of the genus *Synechococcus* (Marin *et al.*, 2005; Yoon *et al.*, 2006). These endosymbiotic cyanobacteria have been known for over 100 years and are called chromatophores (Mereschkowsky, 1905; Melkonian and Mollenhauer, 2005). Their genome is reduced compared to their closest free-living relatives, but is larger than typical plastid genomes (Nowack *et al.*, 2008). Some authors refer to this classical cyanobacterial endosymbiont as a 'photosynthetic organelle' (Marin *et al.*, 2005, Nowack and Grossman, 2012).

The timing in Earth history of mitochondrial and plastid origin cannot be pinpointed, but plausible ranges are often cited that stem from fossil evidence. The oldest eukaryotic microfossils are about 1.8 billion years old (Knoll, 2014). Because mitochondria arose only once in eukaryote evolution (Lane and Martin, 2010), this age can also be seen as a minimum age for mitochondria. The origin of plastids has been estimated at about 1.5 billion years ago (Parfrey *et al.*, 2011), the minimum age for plastids is 1.2 billion years ago because a fossil red alga called *Bangiomorpha* (Butterfield, 2000) is found in rocks of that age. The origin of plastids is sketched in **Figure 1**.

Secondary Endosymbiosis

Mitochondria and chloroplasts can take on a diversity of form and function across different eukaryotic groups. But they have one attribute in common: chloroplasts and mitochondria are always surrounded by two membranes. This is a telling character that betrays their endosymbiotic origin. The two membranes surrounding chloroplasts and mitochondria correspond, in terms of homologies, to the plasma membrane and lipopolysaccharide layer of the Gram-negative bacteria from which the organelles arose (Lister *et al.*, 2005; Schleiff and Becker, 2011). Yet there are photosynthetic eukaryotes whose plastids are surrounded by three or even four membranes (Gould *et al.*, 2008; Stoebe and Maier, 2002; Van Dooren *et al.*, 2001), such organelles are often called 'complex plastids.' The plastids of euglenids and dinoflagellates are surrounded by three membranes. The plastids of the chlorarachniophytes, the cryptophytes, the diatoms, the brown algae, and relatives are surrounded by four membranes.

How did these algae obtain their plastids? Under endosymbiotic theory, these additional membranes are explained as a result of secondary symbiosis. That is, the plastids of these algal groups stem from secondary endosymbiosis: symbioses between a eukaryotic host and a eukaryotic alga. In contrast to the single endosymbiotic origin of primary plastids from cyanobacteria, these secondary symbioses have occurred at least three times independently in evolution: once in the euglenid lineage, once in the chlorarachniophyte lineage, and (at least) once in the 'chromalveolate' lineage (for a discussion of what chromalveolates are, see Zimorski *et al.* (2014) and Gould *et al.* (2015)). The euglenid and chlorarachniophyte lineages acquired their plastids from green algae, the chromalveolate lineages acquired their plastids from a red alga (or red algae).

The uncertainty about the number of secondary endosymbiotic events in the red algae has to do with the conflicting data from molecular phylogenies (gene trees). The gene trees that would address the question of how many secondary endosymbiosis took place among the chromalveolates conflict with one another, giving rise to many suggestions for independent origins of the red secondary plastids. Considerations relating to protein import into red secondary plastids argue for a single secondary endosymbiotic event at the origin of this group (Zimorski *et al.*, 2014; Gould *et al.*, 2015). The additional two membranes surrounding red secondary plastids are most easily interpreted as the inner and outer leaves of the endoplasmic reticulum (ER) of the host that acquired the red algal endosymbiont (Zimorski *et al.*, 2014; Gould *et al.*, 2015). The workings of secondary endosymbiosis in algal evolution are shown in **Figure 1**.

The number and nature of secondary hosts involving the origin of red secondary plastids remain unclear – some red secondary plastids are been suggested to be of tertiary or even quaternary endosymbiotic origin (Stiller *et al.*, 2014). Lineages with secondary red plastids include the nucleomorph-bearing cryptophytes, the haptophytes, the diatoms (stramenopiles), some dinoflagellates, the chromerids, and the perkensids and some apicomplexans (McFadden, 2014), which secondary lost their photosynthetic ability – all lineages of the SCH-group and alveolates. Within these lineages the dinoflagellates are the only organisms with three-membrane bound plastids. Considerations relating to protein import suggest that it was the second outermost membrane (corresponding to the host's distal ER leaf) that was lost in the dinoflagellates (Zimorski *et al.*, 2014; Gould *et al.*, 2015), all other secondary plastids derived from red algae are surrounded by four membranes. In the context of membrane homologies in endosymbiotic theory, there have been several suggestions that the nucleus was once an endosymbiont (reviewed in Martin, 2005). However, such theories often state that the nucleus is surrounded by two membranes (or a double membrane), which is incorrect: the nucleus is surrounded by one folded membrane that is contiguous with the ER (Martin, 1999).

The Rationale Behind Mitochondrial Ubiquity

Because plastids arose more recently in evolution than mitochondria, we know a bit more about the host of plastids than we do about the host of mitochondria. It is a particularly curious aspect of endosymbiotic theory that ideas about the bacterial ancestry of mitochondria developed historically long before concepts about the host for the origin of mitochondria appeared. Ideas about the nature of the mitochondrial host came as a necessary afterthought in the wake of the more pressing debate about whether endosymbiosis for organelle origins was a good idea or not. In the early 1970s and well into the 1990s it was customary to view the mitochondrial host as a mitochondrion-lacking eukaryote – a cell that had mastered the evolutionary transition from being a prokaryote to one that had

a nucleus, a cell cycle, and all the other myriad attributes that separate eukaryotes from prokaryotes (for a long list of such attributes see Cavalier-Smith, 2002). In that view, summarized succinctly by Doolittle (1998), the mitochondrial host became eukaryotic more or less by point mutation, and eukaryotes that were then known to lack mitochondria were most simply seen as descendants of that host.

It turned out, however, that all of the eukaryotes that then appeared to lack mitochondria actually had mitochondria after all, albeit sometimes in highly reduced forms (Tovar *et al.*, 1999, 2003; Williams *et al.*, 2002). That placed the origin of mitochondria at the very base of eukaryote evolution (Embley and Martin, 2006). All the while it should have been evident that the host for the origin of mitochondria was related to archaea (or was an archaeon outright), because the eukaryotic cytosol harbors archaeal ribosomes (Esser *et al.*, 2004). Improvements in phylogenetic methods have gradually brought forth a picture in which the host for the origin of mitochondria branched within the archaea (Cox *et al.*, 2008; Williams *et al.*, 2013; Spang *et al.*, 2015), not as a sister to the archaea, as the older rRNA tree of life implied (Pace, 2006). That suggests that the mitochondrion was acquired by an archaeon (a prokaryote), as some of the endosymbiotic models had suggested. As a consequence, the origin of eukaryotic-specific traits might have come in the wake of mitochondrial symbiosis.

In line with that view, the nucleus could have arisen in the wake of mitochondrial endosymbiosis, the proliferation of (rapidly self spliced) group II introns and their transformation into (slowly spliced) spliceosomal introns may have caused the need for a nuclear membrane to separate splicing from translation (Martin and Koonin, 2006). Also in agreement with the view that eukaryote complexity emerged in the wake of the mitochondrial endosymbiosis is the comparatively recent recognition that the many evolutionary inventions that separate eukaryotes from prokaryotes did not come for free, they came at an energetic price. The configuration of bioenergetic membranes that mitochondria conferred upon the ancestor of the eukaryotic lineage allowed it to do the evolutionary inventing required to forge the eukaryotic lineage (Lane and Martin, 2010). Such bioenergetic considerations would readily explain why mitochondria are ubiquitous among eukaryotes (they were required for eukaryote origin) and why no prokaryote on its own ever made the leap to eukaryote-like complexity: without a mitochondrial endosymbiont, it lacked the energy per gene to do so (Lane and Martin, 2010; Lane, 2014). Thus, the ubiquity of mitochondria among eukaryotes, including among anaerobic eukaryotes (Müller *et al.*, 2012), is perhaps best seen as evidence that endosymbiosis really was important, not just in terms of making eukaryotes more efficient at what they do, but bringing them into existence in the first place.

Endosymbiotic Gene Transfer

One of the important aspects of endosymbiosis is that it can, and does, lead to gene transfer from organelles to the nucleus (Martin *et al.*, 1998; Martin and Herrmann, 1998; Timmis *et al.*, 2004). Ninety years ago, even Wallin sensed that somehow the process of endosymbiosis should be connected to a transfer of genetic material from the organelle to the host. He wrote: "It appears logical, however, that under certain circumstances, [...] bacterial organisms may develop an absolute symbiosis with a higher organism and in some way or another impress a new character on the factors of heredity. The simplest and most readily conceivable mechanism by which the alteration takes place would be the addition of new genes to the chromosomes from the bacterial symbiont" (Wallin, 1925; p. 144). That is a fairly modern formulation of a process that is now called endosymbiotic gene transfer (Martin *et al.*, 1993). About 15–18% of the genes in a higher plant's nuclear genome come from the cyanobacterial antecedent of plastids (Martin *et al.*, 2002; Deusch *et al.*, 2008), and in eukaryotes that lack plastids, such as yeast, the vast majority of genes having prokaryotic homologues come from bacteria, not archaea (Esser *et al.*, 2004; Cotton and McInerney, 2010; Thiergart *et al.*, 2012). The simplest interpretation is that these bacterial genes in nonphotosynthetic eukaryotic lineages come from the mitochondrial ancestor (Pisani *et al.*, 2007; McInerney *et al.*, 2014).

The process of endosymbiotic gene transfer entails the integration of bulk chunks of organellar chromosomes, or in some cases even a whole organelle genome spanning more than 100 kb (Huang *et al.*, 2005). The evidence that this has happened can be seen at the computer by comparing organelle genomes to nuclear genomes (Hazkani-Covo and Covo, 2008) and in laboratory experiments where organelles are transformed with constructs that only become active in the nucleus (Huang *et al.*, 2003, 2004). The mechanism of DNA insertion entails nonhomologous end joining and most eukaryotic genomes are replete with such recent organelle insertions (Hazkani-Covo and Covo, 2008). One might wonder how organelle DNA gets to the nucleus in the first place so that it can recombine. The most likely mechanism is simply stress induced organelle lysis, and there is some evidence for this in plants (Lane, 2011; Wang *et al.*, 2012). Importantly, organelle lysis means that there has to be more than one organelle copy in the cell, one to lyse and one for progeny, and this is the crux of the 'limited window' hypothesis (Barbrook *et al.*, 2006).

There is another important aspect to gene transfer to the nucleus. Both at the origin of mitochondria and at the origin of plastids, host, and symbiont possessed a large number of genes for homologous functions. Such genes would include ribosome biogenesis, amino acid biosynthesis, nucleotide biosynthesis, core carbon and energy metabolism, cofactor biosynthesis, and the like. Chloroplasts and mitochondria have both retained their own ribosomes, for example, and divergent members of homologous gene families for ribosomal proteins as one example, but other examples have been well studied, including core carbohydrate metabolism. This phenomenon is called 'functional redundancy through endosymbiosis' (Martin and Schnarrenberger, 1997). It generates highly divergent copies of genes homologous to prokaryotes even though they reside on eukaryotic chromosomes.

Protein Import

The origin of organellar protein import machineries played an important role in the evolution of mitochondria (Dolezal *et al.*, 2006) and plastids (Schleiff and Becker, 2011), because

it allowed the genetic integration of host and endosymbiont while allowing the endosymbiont to maintain its biochemical identity. In the early phases of organelle evolution, before the invention of the protein import apparatus that allowed plastids and mitochondria to import proteins from the cytosol, the transferred genes either became pseudogenes or became expressed as cytosolic proteins. In this way, endosymbionts can easily transfer whole pathways from the organelle to the cytosol. The transfer of whole pathways from the cytosol to an organelle is also possible, but the mechanisms are different (Martin, 2010).

With the advent of organelle protein import, however, transferred genes had the opportunity to obtain the necessary expression and targeting signals to be targeted back to the organelle from which the nuclear gene was acquired. This process has resulted in an expansion of the eukaryotic nuclear gene repertoire and in reductive genome evolution in the organelle. While it has long been known that the genes retained most tenaciously by plastids and mitochondria encode for proteins involved in the electron transport chain of the bioenergetic organelle or for the ribosome required for their synthesis (Allen, 2003, 2015), only recently was it recognized that even within the ribosome, the same core of proteins has been retained independently by plastids and mitochondria, probably owing to constraints imposed by the process of ribosome assembly (Maier *et al.*, 2013).

Conclusion

Endosymbiotic theory explains why some organelles of eukaryotic cells are so similar to prokaryotic cells. It is a fairly powerful theory in that it can explain a number of disparate observations within a single unifying framework. Mutation theory, population genetics and selection can explain many aspects of evolutionary divergence among cells, but they cannot explain how mitochondria, chloroplasts, and complex plastids arose; for those major events in evolutionary cell biology, endosymbiotic theory is the only explanatory tool available. It works quite well, but it works best when used sparingly and in close conjunction with neighboring disciplines like microbial physiology and genetics.

EDITOR IN CHIEF

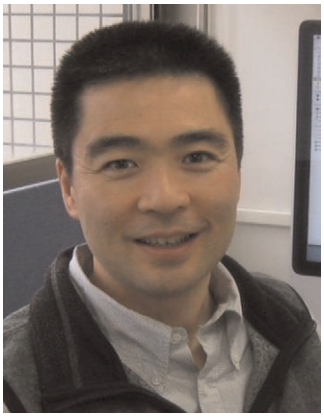
Richard M. Kliman, PhD, is Professor of Biological Sciences at Cedar Crest College in Allentown, Pennsylvania. He received his BA from Colby College in biology and music. His graduate work at Wesleyan University focused on quantitative genetics of circadian rhythms and photoperiodism in the Djungarian hamster, *Phodopus sungorus*. As a postdoctoral fellow at Rutgers University and Harvard University, he studied molecular evolution and population genetics. Prior to Cedar Crest College, he taught at Radford University in Virginia and Kean University in New Jersey. He has also served as a program director in the Division of Environmental Biology at the US National Science Foundation (NSF).

Kliman's research interests center on questions in molecular evolution, including the evolution of codon usage bias in a variety of organisms; speciation and natural history; and ecology and conservation. Much of this work has relied on population genetics/genomics and bioinformatics approaches. He has also collaborated with Cedar Crest colleague John Cigliano on an Earthwatch-supported "before-after-control-impact" study on the effects of a new marine reserve in Belize on queen conch populations. His research in evolutionary and ecological genetics has been supported by the US National Institutes of Health and by Conservation International.

Kliman has served on the editorial boards of *Genetica* and *The Journal of Molecular Evolution*. He has been deeply involved in evolution education, helping to coordinate "Undergraduate Diversity at SSE/SSB," an NSF-supported program to bring a diverse group of undergraduates to the annual Evolution research conference. He was a lead editor of population/quantitative genetics and evolutionary genetics for *Nature Education/Scitable* at its inception. He is a member of the Education and Outreach Committee of the Society for the Study of Evolution, and editor of the society's peer-reviewed educational resource, the *EvoEd Digital Library*.

SECTION EDITORS



Hiroshi Akashi is a Professor of Evolutionary Genetics at the National Institute of Genetics, Japan. He worked with Marty Kreitman for his PhD in Ecology & Evolutionary Biology from the University of Chicago (1996) and with John Gillespie as a postdoctoral fellow at UC Davis. He has been a faculty member at the University of Kansas (1998–2000), Penn State University (2000–2008), and NIG (2009–present). Akashi's research focuses on inferring causes of genome evolution, especially weak selection, from within and between species sequence variation. His studies of codon usage employed population genetic methods to detect natural selection acting at its limit of efficacy and identified a phenotypic basis of natural selection (translational accuracy) from sequence comparisons in *Drosophila*. Extensions of this work revealed constraints related to biosynthesis that act globally on compositional properties of microbial proteins. The interplay of weak evolutionary forces appears to shift frequently among closely-related species and current interests include tests of adaptive changes in protein/DNA composition.

Tim Coulson's primary interest is in creating better links between the fields of ecology and evolution. He does this by developing theory, parameterising models for field and laboratory systems, making predictions from these models, and, where possible, testing these predictions with experiments. He works on a range of systems, from bulb mites within the laboratory, to guppies living in streams in Trinidad, to wolves in Yellowstone. His motivation to do this comes from observations that ecological and evolutionary change can be observed occurring on similar time scales, yet ecological theory typically ignores evolutionary processes and vice versa.

Tim was awarded his PhD in plant ecology from Imperial College, London, in 1994. He moved on to research genotype-by-environment interactions as Natural Environment Research Council (NERC)-funded post-doc at the Institute of Zoology in London. He remained at the Institute on a fellowship where he developed models to investigate the economic and life history consequences of a range of population management strategies. In 2000 he moved to the University of Cambridge, where he briefly lecturered in the Zoology department. In 2004 he moved back to Imperial College London as a senior lecturer where he started developing models that allow the simultaneous investigation of the dynamics of life history, populations, and quantitative characters. In 2007 he became Professor of Population Biology at Imperial College London. He left Imperial in 2013 to take up his current position as Professor of Zoology at the University of Oxford. He is also a Professorial fellow of Jesus College, Oxford.

Andrew Forbes

Rosemary Gillespie is a Professor at the University of California, Berkeley, where she also holds the Schlinger Chair in Systematics. She is Past President of the *International Biogeography Society* and Trustee and Fellow of the *California Academy of Sciences*, and serves as Associate Editor for *Molecular Ecology*. Gillespie was born and educated in Scotland, receiving her BSc in Zoology from Edinburgh University in 1980. She came to the US to conduct graduate work on the behavioral ecology of spiders at the University of Tennessee. After her PhD she spent several months at the University of South in Tennessee, and then started work at the University of Hawaii in 1987, initially as a postdoc, and then in 1992 as Assistant Professor in Zoology and Researcher in the Hawaiian Evolutionary Biology Program. It was during her first year in Hawaii that she discovered an adaptive radiation of *Tetragnatha* spiders. She left Hawaii in 1999 to join the faculty at the University of California in Berkeley, where she continues her research focus on the islands of the Pacific, Hawaii in particular, using islands of known age and isolation to assess the combined temporal and spatial dimension of biogeography and determine patterns of diversification, adaptive radiation, and associated community assembly.

David Guttman received his PhD from Stony Brook University in 1994 working with Daniel Dykhuizen on questions related to the role and importance of recombination in structuring genetic diversity in bacterial populations. He followed this with a postdoc in molecular evolution with Brian and Deborah Charlesworth at the University of Chicago, and a second postdoc at the University of Chicago with Jean Greenberg to gain experience in the fields of molecular plant pathology and plant-microbe interactions. He started his faculty position at the University of Toronto in 2000, and is currently a Professor in the Department of Cell & Systems Biology (CSB). He is also the Associate Chair for Research in CSB, founder and Director of the University of Toronto Centre for the Analysis of Genome Evolution & Function, and Canada Research Chair in Comparative Genomics. He has served as the Chair of the American Society for Microbiology, Division R (Evolutionary and Genomic Microbiology), and was the *PLoS Pathogens* Section Editor for Bacterial Evolution & Genomics.

Dr. Guttman runs a highly diverse research program generally focused on bacterial evolutionary genomics, with three major foci: (1) the evolution of host specificity and virulence in plant pathogenic bacteria; (2) microbial comparative genomics; and (3) studies of the human and plant-associated microbiome. He is best known for elucidating and linking evolutionary and mechanistic processes that determine the course and fate of bacterial infections, and characterizing the impact of genetic variation on the balance between disease and immunity.

Norman A. Johnson, the section editor for Applied Evolution, is an evolutionary geneticist and author. He received his PhD from the University of Rochester in 1992 and did postdoctoral research at the University of Chicago. His research interests have generally focused on aspects of speciation, specifically those related to the genetics and evolution of hybrid incompatibility: sterility, inviability, or other reduction of fitness in hybrids between species. Dr. Johnson, an adjunct professor in the Biology Department at the University of Massachusetts at Amherst, has taught classes there, as well as at Hampshire College, the University of Texas at Arlington, and the University of Chicago.

Dr. Johnson also has a long-standing commitment toward improving the communication of science in general and evolutionary biology in particular to other scientists, educators, and the public at large. He is the author of *Darwinian Detectives: Revealing the Natural History of Genes and Genomes* (Oxford University Press: 2007), a book geared to general audiences that shows how biologists use DNA sequence data to make inferences about evolutionary processes. He also was the lead organizer for a working group on communicating human evolution at the National Evolutionary Synthesis Center (NESCent).

Laura Kubatko received a PhD in Biostatistics from The Ohio State University (OSU) in 1999. After seven years on the faculty at the University of New Mexico, she returned to OSU in the Fall of 2006, and is now Professor of Statistics and of Evolution, Ecology, and Organismal Biology at OSU. Laura served as an Associate Director of the Mathematical Biosciences Institute at OSU from 2013–2015. At OSU, she is a Faculty Affiliate of the Initiative in Population Research, and a Faculty Affiliate in Translational Data Analytics (TDA@OSU). She holds appointments as an Affiliate Faculty Member at the Battelle Center for Mathematical Medicine at Nationwide Children's Hospital in Columbus and as an Adjunct Research Scientist at Lovelace Respiratory Research Institute in Albuquerque, NM. Laura's research interests are in statistical genetics, with a focus on the development of statistical methods for inferring phylogenies from molecular data. Her recent work in this area concentrates on bridging the gap between traditional phylogenetic techniques and methodology used in population genetics analyses, primarily through the application of coalescent theory to species-level phylogenetic inference. She develops and distributes several software packages for phylogenetic inference, and has been an active member of the *Society of Systematic Biologists*. She has served as an Associate Editor for the journal *Systematic Biology* since 2007.

Amy Litt has been studying plant evolution and diversity since her PhD on floral structure and evolution in the neotropical plant family Vochysiaceae, known for its beautiful but unusual flowers many of which have only one petal and one stamen. While completing her PhD in plant systematics and morphology in the joint City University of New York/New York Botanical Garden Plant Sciences program under Scott Mori and Dennis Stevenson, she became interested in the molecular basis of plant diversity. She did her post-doc in the developmental genetics lab of Vivian Irish at Yale University on the evolution of a family of transcription factors involved in flower development, and she continues to study the functional evolution of this gene family currently. After one year on the faculty of University of Alabama, she moved back to The New York Botanical Garden as Director of Plant Genomics, where she developed her research program studying the evolution of plant form along two paths: studying evolutionary changes in genes to see how those changes affected flower and fruit form; and identifying the genes that underlie differences in form among closely related species. Dr. Litt also served as a program director in Plant, Fungal, and Microbial Development and Evolutionary Development at the National Science Foundation. She recently moved to the University of California at Riverside, where she continues to study the genetic basis of plant diversity.

Maria E. Orive is a professor of evolutionary genetics in the Department of Ecology and Evolutionary Biology at the University of Kansas. Her research in theoretical population genetics aims to develop mathematical models that provide a conceptual framework for exploring important questions in evolutionary biology and analytical tools for demographic and genetic data. Her work has considered levels of selection and mutation in organisms that reproduce both sexually and asexually, the relationship of population structure and life-history attributes to gene flow and genetic diversity, and models of within- and between-host pathogen and symbiont population dynamics. Orive received her BS from Stanford University and her PhD from the University of California at Berkeley. After spending two years as a postdoctoral researcher in genetics at the University of Georgia, she was an NSF-NATO Postdoctoral Fellow at the University of Edinburgh. Her research has been funded by multiple grants from NSF and NIH. In 2007–2008, she was the Carl and Lily Pforzheimer Foundation Fellow at the Radcliffe Institute for Advanced Study (Harvard University), and has served as the University Faculty Ombudsman for the University of Kansas since 2007.

Daniel Ortiz-Barrientos is an Associate Professor in evolutionary genetics in the School of Biological Sciences at The University of Queensland, Brisbane, Australia. During his scientific career he has investigated the ecological and genetic basis of speciation both in plants and animals. His current research program explores the early stages of speciation, the molecular basis of parallel speciation, and the interplay between recombination and natural selection during the origin of new species. His research funds come from The Australian Research Council. He is married to Antonia Posada, and is the father of three energetic and beautiful kids.

Claudia Russo was born in Leeds, England, but has lived in Rio de Janeiro, Brazil since she was two years old.

Claudia has an academic major in Ecology from Universidade Federal do Rio de Janeiro completed in 1989, and finished her Master's thesis in 1991 on population genetics of two actiniid species of sea anemones with different reproductive strategies, under the supervision of Associate Professor Antonio Mateo Sole-Cava. Her PhD dissertation was on the diversification of drosophilids and on the use of a known phylogenetic tree to estimate the reliability of tree building methods. The dissertation was completed in 1995 under the supervision of the Evan Pugh Professor Masatoshi Nei who recently received the prestigious Thomas Hunt Morgan Medal. Her graduate degrees were obtained as a student at the Genetics Program from the Universidade Federal do Rio de Janeiro and as a visiting scholar at the Pennsylvania State University (1992–1995).

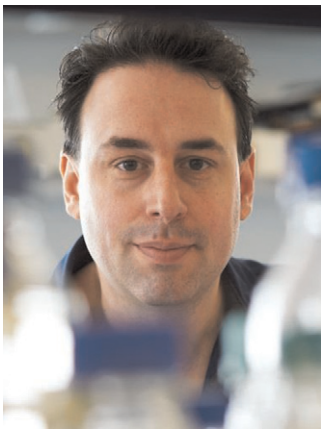
Claudia is currently the Head of the Genetics Department at the Federal University of Rio de Janeiro, having been a member since 1997. Claudia has supervised 13 Master's dissertations, eight PhD theses and seven post-docs, of which eight are now Assistant Professors at universities in Brazil and abroad. She has published 42 academic papers that have been cited over 1,200 times. Her *h-index* is 14. Since 2012, Claudia has been a member of the editorial board, and an associate editor of the *Molecular Biology and Evolution* journal. Since 2012 she has been a council member for the Pan American Association of Computational Interdisciplinary Sciences and since 2009 for the Brazilian Association for the Advancement of Science.

Claudia's general academic interests are on key aspects of animal phylogenetics, including their diversification patterns in time and space. She has worked with various metazoans groups but more prominently on marine sponges, sea anemones, arthropods, passerine birds, and mammals. Claudia has also published on the use of known phylogenetic trees to estimate the efficiency of phylogenetic methods in recovering and rooting those trees. More recently, she has developed some interesting *hands-on* educational tools for evolutionary biology practices in the classroom.

Karen E. Sears is an evolutionary developmental biologist whose primary research goal is to determine how developmental variation within a species produces congenital malformations in humans, and among species generates new evolutionary forms in mammals. Dr. Sears earned her PhD from the University of Chicago, did postdoctoral research at in the Howard Hughes Medical Institute (HHMI) lab of Dr. Lee Niswander, and joined the faculty of the University of Illinois at Urbana-Champaign. At Illinois she holds positions as an Associate Professor in the Department of Animal Biology, a Faculty Member in the Institute of Genomic Biology, and an Affiliate of the Program in Ecology, Evolution and Conservation Biology and the Department of Cell and Developmental Biology. She is also the President of the Pan American Society for Evolutionary Developmental Biology. She has authored or co-authored over 35 publications including first-authored publications in *Nature*, *Proceedings of the National Academy of Sciences*, and *Evolution*. She has served as a principal investigator on multiple, nationally-funded research projects, and presented invited seminars at more than 30 institutions and symposia. She is routinely ranked among the top 10% of Illinois professors for her teaching, and was a featured scientist in the PBS/HHMI documentary "*Your Inner Fish*."

Vassiliki "Betty" Smocovitis is Professor of the History of Science in the Department of Biology and in the Department of History at the University of Florida. Her areas of expertise include the history of evolutionary biology, genetics and systematics and the history of botany. She is best known for her contributions to understanding the historical event known as the "evolutionary synthesis" and in gaining greater understanding of the origins of the discipline of evolutionary biology. She has published extensively on both the intellectual and social aspects of the history of evolutionary biology including a history of the Society for the Study of Evolution, a history of the Darwin Centennial of 1959, and the integration of botany, genetics, and anthropology into the evolutionary synthesis. She was the contributor to the *Oxford Bibliographies* entry on Charles Darwin at over 25,000 words and the entry on the modern synthesis. She is the author of *Unifying Biology: The Evolutionary Synthesis and Evolutionary Biology* (Princeton: Princeton University Press, 1996).

Nina Wedell is a professor of evolutionary biology with research interests focused on the evolutionary ecology of sex. She has worked extensively on various aspects of sexual selection and sexual conflict, in particular on the role of selfish genetic elements in reproductive biology. Nina is the Academic lead for the Behaviour research group at the University of Exeter.



Jason Wolf is Professor of Evolutionary Genetics in the Department of Biology & Biochemistry and The Milner Centre for Evolution at the University of Bath. His research is unified with a special focus given to understanding the influence that frequently ignored or under-appreciated sources of genetic variation have on the genotype-phenotype relationship and how this, in turn, influences evolutionary processes. He integrates theoretical, computational and empirical quantitative and population genetic techniques to achieve this goal. He is particularly interested in understanding the evolutionary consequences of various types of interactions, including gene interactions (epistasis), parent-offspring interactions and social interactions. He received a PhD from the University of Kentucky, after which he was a postdoctoral researcher at Indiana University and a US National Science Foundation Postdoctoral Fellow at Washington University School of Medicine. Prior to moving to the University of Bath he held positions at the University of Tennessee and the University of Manchester. He won the Dobzhansky Prize from the Society for the Study of Evolution, a Young Investigator's Prize from the American Society of Naturalists and the Scientific Medal from the Zoological Society of London.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Alphabetical Contents List

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

All articles within the encyclopedia have an extensive list of cross-references which appear at the end of each article, for example:

Adaptive Mutation Controversy

> *See also*: Directional Selection and Adaptation. Microbial Experimental Evolution. Mutation, Population Genetic Models of. Natural Selection, Introduction to. Recombination in Bacterial Populations

3. Subject Classification List

A subject classification list has been developed by the editors to group articles under broad topics. This index is useful for making broad connections between articles and locating the relevant article for a topic that is covered in more than one article.

4. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

5. Contributors

A full list of contributors appears in the front mater of each volume.

PREFACE

The *Encyclopedia of Evolutionary Biology* was developed to provide an authoritative overview of the current state of evolutionary biology. It was an ambitious goal, especially given that the field did not pause for the two and a half years needed to complete the project. The encyclopedia's 15 section editors collaborated to ensure that content gaps were kept to a minimum, and their efforts show. When the project was completed, we had compiled 256 entries, covering a broad range of topics selected by the editors to ensure a comprehensive resource. It was a privilege to read every one of these entries, and I was truly humbled by the collective efforts of hundreds of authors to communicate the excitement and sophistication of a field of study that touches on every conceivable topic in biology today.

There are many ways to envision an encyclopedia of evolution, and we had to choose an approach that would lead to a cohesive resource. Readers will note that, in the more organismal-focused entries (edited by David Guttman, Amy Litt, and Claudia Russo), there is an emphasis on *diversification* of life. We did not set out to provide an overview of the diversity of life, as such a goal would be untenable; rather, we focused on the evolutionary processes and key events responsible for diversity. Numerous entries deal with speciation, life history evolution, evolutionary biogeography, and coevolution. These entries (edited by Daniel Ortiz-Barrientos, Tim Coulson, Rosemary Gillespie, and Andrew Forbes) bring to light how the evolution and diversification of life is intimately entwined with ecology. Of course, there is extensive coverage of population genetics, quantitative genetics, evolutionary developmental biology, the evolution of sex and mating systems, molecular/genome evolution, and phylogenetic analysis (edited by Maria Orive, Jason Wolf, Karen Sears, Nina Wedell, Hiroshi Akashi, and Laura Kubatko), all fundamental to our understanding of evolutionary processes. And as thematic bookends, several entries (edited by Betty Smocovitis and Norman Johnson) cover the history of evolutionary biology and applications of evolutionary biology.

Readers of the encyclopedia will find that entries are generally pitched at a somewhat advanced level, although with great effort by authors to make entries as accessible as possible to a broad audience. Encyclopedias, like living organisms, are compromises. If all entries could be readily understood in their entirety by first-year university students, this encyclopedia would be of limited value to experts. At the other extreme, if entries were extremely technical – and our authors were undoubtedly capable of producing such entries – the encyclopedia might be inaccessible to students. While there is, by necessity, variation among entries in this regard, we settled on a general target: the majority of an entry should be accessible to a motivated, advanced undergraduate. Readers are, of course, directed to additional resources, with authors providing bibliographies and lists of further reading.

As with any undertaking of this scale, there are many individuals who should be recognized for their roles in the development of this encyclopedia. Special thanks go to Norman Johnson for early discussions that helped us develop the general structure of the encyclopedia. The dedicated and distinguished team of section editors deserves the credit for drafting the table of contents, recruiting authors, and working extensively with authors to ensure the highest quality product. It should go without saying that the high quality of this encyclopedia ultimately reflects the efforts of the editors and authors. Finally, the project management and development teams at Academic Press were always ready to assist, and while it is not possible to name everyone who contributed to the effort, I am particularly indebted to Simon Holt, Will Bowden-Green, Paula Davies, and Justin Taylor.

Richard Kliman
Editor in Chief

FOREWORD

What is life, how did it originate, and what accounts for its great diversity? These are fundamental scientific questions that have and will always be the source of endless fascination and wonderment. Charles Darwin and Alfred Russel Wallace provided an answer to the latter question through the grand idea of evolution and the process of natural selection. Darwin also speculated on the where question of the origin of life by hypothesizing it originated long ago in a warm lagoon. Most importantly, however, Darwin shattered the notion that the natural world is static and replaced it with a biology that is dynamic and continually changing. Species are not fixed, typological entities. Rather, they are related by common descent in a great tree of life. Analogous to tracing one's ancestors back in time in a pedigree, one can climb down the tree along its branches and boughs that connect species in a hierarchy of phylogenic relationships until reaching the base of its trunk and the common ancestor of us all. One can also climb up the tree and quickly realize that evolution produces a seemingly endless array of new forms (and sometimes extinction). Thus, as the tree of life grows, populations are continuously evolving and diverging from one another, creating novel varieties and races (showing slight differences) that eventually evolve into new species (separated by distinct gaps). And natural selection – the differential survival of individuals in populations possessing heritable traits favorable for their survival and reproduction – is the primary materialistic process causing evolutionary change and the origin of new species.

The *Encyclopedia of Evolutionary Biology* chronicles our current state of understanding of the dynamics of evolution and its product, Darwin's great tree of life. A diversity of seminal topics are covered including overviews of the history of the field, the origin of life, the history of life (including the phylogentic methods used to reconstruct life's history), the myriad ways and means (including mechanisms other than natural selection) that evolution is affected, and the important roles that conflict versus cooperation, and mergers and acquisitions, occurring within across varying levels of biological organization, play in the narrative of life. In so doing, the *Encyclopedia* highlights the grandeur in Darwin's view of life. We are not separate, but rather a twig along a branch of life, a twig that has evolved the ability to comprehend the existence of and our connectedness to the tree, and climb around its branches to see what has been and think about what may come. It is a wonder of life that it can look at and understand the meaning of itself.

But Darwin's grand view has even larger ramifications, going beyond providing a materialist basis for organismal change and putting us in our place. The reality of evolution also answers the question of what life is. If pressed to define life, most of us would reply with a list of the things that living organisms do. For example, living organisms metabolize, grow, develop, move, behave, mutate (are variable), and reproduce with inheritance. One can investigate these different characteristics of life separately and discern the mechanistic basis for the different processes that constitute life – the "how" of life. And such studies represent the basis for many fields of the life sciences. However, these are only the components of life and, in isolation, produce a static view of the natural world. Rather, the seminal insight is that populations of living beings possessing these characteristics have the emergent property that they evolve. Darwin's "*On the Origin of Species*" therefore not only describes how populations evolve, and as a logical extension how new species form, but also conveys the essence of what life itself is – evolution. Thus, as Theodosius Dobzhansky famously stated "nothing makes sense except in the light of evolution." The Encyclopedia wonderfully brings this view of life to light, providing the reader with the breadth of knowledge and overview of the current state of the field of evolution needed to appreciate and participate in the next major ongoing synthesis in our understanding of life, the so-called "Omics Revolution."

The study of evolution is in an accelerated phase of discovery brought about by major technical advances in our ability to DNA sequence whole genomes (genomics), and to generate profiles of mRNA transcription (transcriptomics), protein levels and enzymatic activity (proteomics), and metabolic products (metabolomics) at varying stages in the life cycle and development of organisms. This "Omics Revolution" may not change foundational evolutionary principals, per se. Our understanding of evolution has been heightened by a series of such advances in the past, including the "Modern Synthesis" when Mendelian genetics was wedded to Darwinian thinking and the "Molecular Revolution" in which genetic technology increasingly allowed allele frequencies in natural populations to be analyzed. The Omics Revolution is an extension of these pervious advances, but one in which the workings of whole organismal systems and the composition of entire communities can be gleaned at once.

Perhaps, the most important discoveries in Omics will come from linking an understanding of the process occurring at the cellular and microevolutionary level with large scale patterns and trends at the macroevolutionary scale. Previously, processes occurring within and interactions occurring among cells could be studied in at least some detail. Omics is providing an opportunity to fully understand how all of these processes interact simultaneously to result in the development and functioning of integrated, multicellular systems of life. At the other end of the spectrum, fossils attest to the evolution of new life forms through time and the creation of great and observable morphological diversity. Genomic sequencing is providing a powerful means to help accurately place these fossils within the framework of a fully resolved molecular phylogenic tree to better understand the history of life, including major trends, themes, and variation in the tempo and mode of evolutionary change. But it is the middle of the micro and macro at the branching points in the tree of life that Omics may prove most insightful. Now it is possible to not only DNA sequence large numbers of individuals within populations, but to equate these genetic differences within and between populations to morphological, physiological, and behavioral phenotypes, and discern the developmental

and physiological mechanisms by which these genetic changes produce organismal variation, diversity, and reproductive isolation – the stuff of evolution and speciation itself. Thus, we will be able to not only understand the everyday processes responsible for how the tree of life grows, but be able to translate this into a mechanistic appreciation of how these processes result in new branches on the tree forming and others dying out, giving shape to the history of being on our planet.

The field of evolution is currently inundated with a mass of Omics data and the bottleneck is the development of bioinformatic analytical tools to edit, analyze, and interpret the results. However, it is clear that many new insights are on the horizon, and even if they do not affect the root principles of evolution, soon a deep connection of the how and why of life will emerge to help forge a truly integrative evolutionary biology: The *Encyclopedia of Evolutionary Biology* is an excellent guide to prepare readers to assimilate these new findings, keeping bioinformatics grounded in the bio and providing a valuable source for seeing the tree through the forest to understanding the grand synthesis of life that is flowering.

Epigenetic Inheritance

HG Spencer, University of Otago, Dunedin, New Zealand

Glossary

CpG sites A cytosine base followed by a guanine base in a DNA sequence. The p is for the phosphate linking the C and G.

DMR Part of a DNA molecule that is methylated differently (usually) according to its parental origin. DMRs are critical in effecting the differential expression of paternally and maternally derived gene copies that characterizes genomic imprinting. Also known as differentially methylated domains (DMDs); some DMRs function as imprinting control region (ICRs).

DNA methylation The addition of a methyl (CH_3) group to a cytosine base in place of a hydrogen atom. This biochemical change usually occurs at CpG sites; when methylation modifies clusters of CpG sites, known as CpG islands, which are often associated with gene promoters, the expression of the gene can be significantly reduced or even silenced. Special enzymes are required for *de novo* methylation and separate enzymes are responsible for its maintenance.

Genomic imprinting The differential expression of genes according to their parental origin. In the archetypal cases, which are confined to mammals and angiosperms, only one copy (say, the maternal copy) is expressed in certain tissues for some period of development.

Histones Proteins that help in packing DNA into chromatin. Their modification changes the shape of the chromatin and hence access other molecules have to the DNA. Thus, histone modifications affect the expression of the genes coded in that section of DNA.

Metabolic disease (or syndrome) Several linked conditions – high blood pressure, elevated blood-sugar levels, excess body fat, especially around the waist, and abnormal cholesterol levels – that increase the risk of heart disease, stroke, and diabetes, often later in life.

Epigenetic Modification

Epigenetic inheritance constitutes the processes by which epigenetic modifications of the genome are passed on during cell divisions, either within an individual (usually via mitosis), which we call 'persistence,' or between generations (usually via meiosis), a property we view as 'inheritance.' (Some molecular biologists use 'inheritance' for both phenomena, but they differ in fundamental ways, and so here we use different words to describe them.) Epigenetic modifications can alter the way in which genes are expressed, but they do so without altering the DNA sequence; instead a variety of mechanisms, such as methylation of CpG sites (a cytosine base followed by a guanine, which are linked by a phosphate), non-coding RNAs (such as micro-RNAs) or modifications of histones that result in chromatin remodeling, change the way in which the gene is transcribed and hence how it is expressed (Box 3 in Heard and Martienssen (2014) outlines a number of mechanisms). Critically, these marks are reversible, and hence epigenetic modification allows gene expression to switch easily between different states.

Epigenetic modifications arise from a variety of stimuli, from the cell's immediate surroundings to the individual's external environment. For example, mouse pups inheriting an *agouti* viable yellow allele (A^{vy}) from their father have darker fur when their mothers are fed a diet rich in methyl donors, such as folate and vitamin B_{12}. These offspring are exposed *in utero* to these methyl donors, which promote the methylation of their normally dominant A^{vy} allele and reduce its expression (Cropley *et al.*, 2006; Waterland *et al.*, 2007).

Genomic imprinting, whereby gene expression at a small number of mammalian and angiosperm loci (and perhaps those in other taxa, but the evidence remains equivocal) depends on the sex of the parent that passed on the gene, is also often mediated by cytosine methylation. For instance, the mouse *H19* gene is expressed only from the maternally inherited copy; a region upstream of the paternally inherited copy known as the differentially methylated domain (DMD), differentially methylated region (DMR), or imprinting control region (ICR) is heavily methylated, suppressing the expression of this copy of *H19* (Gabory *et al.*, 2010).

Another epigenetic phenomenon, paramutation, is an interaction between homologous alleles at a single locus in which one allele (described as 'paramutagenic') induces a heritable change in the expression of the other (which is said to have 'paramutated'). Importantly, in the following generation, the paramutated allele usually becomes paramutagenic itself. Paramutation was originally described in maize, but more recently has been found to occur in nematodes, *Drosophila* and mammals (Erhard and Hollick, 2011; de Vanssay *et al.*, 2012; Adams and Meehan, 2013). Small interfering RNA has been suggested as one possible molecular mechanism of this phenomenon (Erhard and Hollick, 2011), but methylation may also be important in mammals (Adams and Meehan, 2013).

Finally, some epigenetic changes are a secondary consequence of a genetic change elsewhere in the genome: insertion of a transposable element in the genome of *Cucumis* (melon) has led to heritable methylation and altered expression of a nearby sex-determination gene, *CmWIP1* (Martin *et al.*, 2009). Examples such as this last one blur the distinction between genetic and epigenetic inheritance (see Becker and Weigel, 2012).

Inheritance

Although many epigenetic modifications within a cell are likely to be short-lived, some are described as heritable. Confusingly, in addition to the normal use of the term to mean that offspring of a given individual also possesses the epigenetic modification in question, in this context, heritable has also been used to mean that daughter cells within the same organism have the same modification as the parental cell. Nevertheless, these two phenomena differ in many important respects and should be differentiated. Hence, in order to make this distinction clear and to avoid any confusion, we will refer to these two meanings as (transgenerational) inheritance and (within-generational) persistence, respectively.

Persistence is essential if the epigenetic mark is to have some lasting effect in a growing organism. Accurate transmission of an epigenetic modification during development of an organ in an individual means that gene expression will be modified in the same way throughout that organ. Such fidelity is critical if the stimulus inducing the epigenetic change is transient or if it can be perceived by the organism only during a short developmental window. In mammals, the persistence of methylation marks during mitosis is governed by a family of enzymes known as DNA methyltransferases (DNMTs). Dnmt1, for example, maintains methylation state during DNA replication, methylating an unmethylated DNA strand when the other strand is already methylated.

The potential for the stable somatic persistence of epigenetic marks has fundamental biological implications. It is one mechanism by which gene expression can be differentiated among different cell types in an organism but remain co-ordinated within a particular tissue. In addition, epigenetic modification is likely to be a proximal mechanism for the phenomenon of phenotypic plasticity, in which organisms with the same genetic constitution respond in different (and usually appropriate) ways to different environments. Herman *et al.* (2014) explore the evolutionary expectations we might have for the degree of stability of epigenetic modifications. For example, the sites of modification must be able to respond to appropriate cues (especially early in development) but simultaneously ignore spurious cues; moreover, epigenetic states should be resistant to degradation over time if the gene expression they are modifying is important.

Transgenerational epigenetic inheritance also has profound biological consequences (Richards *et al.*, 2012). If epigenetic modifications can be transmitted across generations, then far more than genes are being passed on from one generation to the next (Laland *et al.*, 2014). The extent to which epigenetic marks are transgenerationally transmitted has been seen as controversial (see Haig, 2007; Waterland *et al.*, 2007; Wray *et al.*, 2014), but a large and growing number of unequivocal cases can now be found in the scientific literature (see below). Foremost among these straightforward cases is genomic imprinting in mammals, where differential marking (usually, but not always, methylation) during gametogenesis results in different expression levels of the maternally and paternally derived gene copies in the offspring. Imprinted genes often occur in clusters within which expression is co-ordinated (Morison *et al.*, 2005) and so one set of marks can affect the expression of several genes. The marks at ICRs are critically different from other methylation marks, however. Soon after fertilization, first in the male pronucleus and later over the first few cell cycles in the female pronucleus, most methylation marks across the whole genome are erased (Sanz *et al.*, 2010). Imprinted genes, however, are resistant to this zygotic demethylation and maintain their parentally induced marks until they are reset, according to the sex of the developing embryo, in the primordial germ cells (which go on to produce the next generation).

In addition to imprinting many maternal (and, indeed, paternal) effects are mediated by epigenetic modifications. For example, unfertilized mammalian eggs contain maternal messenger RNAs that subsequently interact with the zygote's genome (Daxinger and Whitelaw, 2012). Maternal behaviors can also be transmitted across generations: differences among mouse dams in how they groom their pups are inherited non-genomically and affect how the pups respond to stress (Francis *et al.*, 1999). Interestingly, these behavioral differences appear to be the result of methylation differences induced by their own mother's grooming; thus the grooming behavior is re-created every generation (Weaver *et al.*, 2004). Such parental regulation of offspring methylation states provides a mechanism for stable non-genomic inheritance over many generations.

Controversies about the importance of transgenerational epigenetic inheritance fall into two categories. First, differentiating between direct and inherited effects can be difficult, in practice. For example, in many mammalian species, the cells that, when eventually fertilized, will grow into pregnant female's grand-offspring are present in the proto-ovarial tissues of the fetus growing within her uterus. Thus exposure of a pregnant female to an environmental stress may also expose the next two generations as well, and these direct effects will mimic genuine transgenerational inheritance (Heard and

Martienssen, 2014). These superficially similar outcomes are significantly different from an evolutionary viewpoint, however: the former can be viewed as one aspect of the standard way in which genes and environment interact to produce the phenotype; the latter requires an expanded view of inheritance (Grossniklaus *et al.*, 2013).

Second, an apparent lack of mechanism for accurate transmission of non-genomic information has led some to argue that the phenomenon is not of major significance (see Campos *et al.*, 2014 for a review of these arguments). The genome-wide demethylation that occurs during mammalian embryogenesis, for example, seems to rule out the archetypal epigenetic mark, methylation, as being of widespread importance (i.e., beyond the exception of genomic imprinting) in mammals (Daxinger and Whitelaw, 2012). Nevertheless, there is an increasing number of well-documented cases of transgenerational epigenetic inheritance (Jablonka and Raz, 2009), from plants (Scoville *et al.*, 2011; Herman and Sultan, 2011; Holeski *et al.*, 2012) to mammals (Lim and Brunet, 2013), *Drosophila* (Seong *et al.*, 2011), and nematodes (Rankin, 2015), and there is general agreement that it is likely to be common as well as critical to our understanding of inheritance and development (Grossniklaus *et al.*, 2013).

Evolutionary Implications

If epigenetic modifications underlie many plastic responses (as seems likely), then persistence of these non-genetic marks (within an organism) is fundamental to how development works. Plasticity plays a crucial role in evolution, because it endows a developing organism with the ability to respond in an appropriate way to various environmental conditions. In addition, numerous properties of the inheritance of epigenetic marks underlying plastic responses, such as whether the signal should attenuate over time, may be the target of selection (Herman *et al.*, 2014).

Of even greater interest to evolutionary biologists, and the reason for much of the controversy on the topic, are the evolutionary consequences of transgenerational epigenetic inheritance. Such inheritance is often described as 'Lamarckian' (Jablonka and Lamb, 2005; Haig, 2007), because it appears to provide a mechanism for 'the inheritance of acquired characters.' Nevertheless, modern observations of transgenerational epigenetic inheritance differ fundamentally from old-school Lamarckian inheritance; in the latter, environmental influences somehow become permanently encoded in the genome and are thenceforth transmitted as in standard genetics (Bonduriansky, 2012).

Certainly, even the uncontentious and well-understood case of genomic imprinting has potential effects at the population level and hence for evolution. Expression of an imprinted gene is effectively haploid in those tissues in which just one copy is transcribed and hence the unexpressed allele is at least partially hidden from selection in that individual. This masking may affect the outcome of natural selection. For example, the frequency of individuals affected by a deleterious allele at an imprinted locus is likely to be approximately twice that of those affected by a similarly harmful recessive mutation at a non-imprinting gene (Spencer and Williams, 1995). Attempts to improve agricultural outcomes through artificial selection on a quantitative trait affected by imprinting are also altered: the standard breeder's equation (which predicts the change in a population's mean in response to selection) is no longer accurate, often overestimating the response (Santure and Spencer, 2011).

The population-level effects of transgenerational inheritance of environmentally induced epigenetic marks have been dubbed 'population epigenetics' by analogy with the purely genetic models of population genetics. Very simple population-epigenetic models of the action of natural selection behave very differently from population-genetic models of selection (e.g., Geoghegan and Spencer, 2012). Most basically, the induction of fresh epigenetic marks each generation means that epigenetic variation is never depleted; in many population-genetic models, by contrast, selection quickly eliminates genetic variation. A critical parameter in such models, somewhat analogous to the mutation rate in population genetics, is the probability with which an environmental cue induces an epigenetic change. In models of paramutation, a similar role is played by the 'paramutation rate,' the chance that the paramutable allele will be paramutated by the partnering paramutagenic allele in a heterozygous individual (Geoghegan and Spencer, 2013).

More general attempts to include non-genetic inheritance (including epigenetic inheritance, but also various other parental cues, such as hormonal signals) into evolutionary theory confirm that epigenetic inheritance is of fundamental importance, especially when it interacts with standard genetic inheritance. In a review of theoretical studies of evolution in changing environments, Bonduriansky *et al.* (2012) found that such forms of inheritance can increase the rate of evolution and even alter its direction. Interestingly, maternal inheritance has similar consequences (Kirkpatrick and Lande, 1989). Moreover, careful empirical investigations are likely to find further natural examples: mathematical analyses imply that non-genetic inheritance should evolve easily in fluctuating environments, depending on the values of critical parameters such as the temporal autocorrelation in environmental state and the accuracy of environmental cues (Leimar and McNamara, 2015). Transgenerational epigenetic inheritance allows the organism to integrate more sources of information (including, obviously, genetic information) in its development, which may give it a selective advantage.

The interaction between genetic and epigenetic inheritance also has the potential to explain previously puzzling observations, such as the 'lek paradox,' the maintenance of female choice in species in which males do not provide their offspring with care or direct benefits. Standard genetic theory had suggested that a population's genetic variation in male quality would rapidly be depleted, which would then lead to the elimination of what is presumably a costly female choice. Mathematical models predict that if males also pass on environmentally induced fitness benefits to their offspring, then costly female choice will remain (Bonduriansky and Day, 2012). This finding is an instance of how such interactions may resolve Lewontin's (1974) 'paradox of variation,' in which theoretical models fail to predict the ubiquity of phenotypic variation in natural populations of many organisms (Sultan, 2015).

Future Questions

The potential for major evolutionary implications of the various sorts of epigenetic effects has generated intense research interest, albeit tempered with a cautious skepticism, largely about mechanism (Grossniklaus *et al.*, 2013). Indeed, some authorities remain unconvinced. For example, writing about adaptive epigenetic inheritance, Heard and Martienssen (2014) say 'concrete evidence from model systems is still lacking.' Ideally, we would have unequivocal cases of transgenerational epigenetic inheritance, preferably in a laboratory species, with clear proximate molecular mechanisms, in which different environmental cues induce measurable phenotypic responses.

Assuming such examples can be discovered, we would then use them to answer some fundamental questions: What is it about these environmentally induced epigenetic changes that allow them to resist the normal molecular erasure processes such as demethlyation? How many generations do the marks persist? Do they fade over several generations or do they have the potential to last indefinitely (or until the next environmental cue)? If they fade gradually, does their effect fade in parallel or is there some threshold above which their phenotypic effect remains and below which it is absent? What is the effect of repeated environmental induction? Does such repetition reinforce the mark(s)? Can transgenerationally inherited epigenetic changes be reversed? If so how? Nadeau (2009) and Holeski *et al.* (2012) have extensive lists of questions like these.

Such questions are not simply matters of academic curiosity. Epigenetic changes have numerous health implications. For example, environmental insults are well known to induce epigenetic changes that increase susceptibility to disease (especially cancer). If such changes are heritable, then offspring, perhaps for several generations, will also have increased susceptibility, even if the original environmental insult is absent (Nilsson and Skinner, 2015). Gluckman and Hanson (2006) have argued that a mismatch between our modern high-energy diets and our evolutionary past has led to the current high rates of metabolic disease. Moreover, they contend that dietary insults can also induce heritable epigenetic changes that predispose our children to these same diseases. Hence, understanding the epigenetic basis of such disease may lead to a solution to the problem.

Epigenetics and Genome Evolution

S Yi, Georgia Institute of Technology, Atlanta, GA, USA

Glossary

DNase hypersensitivity assay DNase is a nuclease that cleaves DNA at phosphodiester linkages. When genomic DNA is subject to DNase, regions that are not tightly bound by nucleosomes are cleaved out. These regions include active enhancers and promoters, as well as nucleosome reposition regions. On the other hand, regions tightly bound by nucleosomes are protected from DNA cleavage.

H3K4me3 Tri-methylation of the lysine 4 residue of the histone 3.

H3K9me3 Tri-methylation of the lysine 9 residue of the histone 3.

Polyploidy When cells and organisms contain more than two sets of paired chromosomes (diploid: $2n$). Polyploidy is especially common in plants. For example, cotton is tetraploid ($4n$) and sugarcane is octaploid ($8n$).

PR/SET domain PR stands for positive regulatory domain, and SET is a domain initially characterized in the *Drosophila* protein (Su)var3–9, *Enhancer-of-zeste* (hence called 'SET'). SET domain consists of 130 to 140 amino acids that are evolutionarily well conserved. The SET domain of some proteins encodes histone methyltransferase activity, especially in case of the PRDM9. The PR domain is 20–30% similar to the SET domain and found in many histone lysine methyltransferases.

SNP It stands for single nucleotide polymorphism. DNA sequence variation where two or more nucleotides are found at the same position in different individuals.

Introduction

The term 'epigenetics' was initially coined to describe how genetic background influences the progress of development (Waddington, 1942; Haig, 2004). However, since its original introduction, the term epigenetics has been used in multiple different biological contexts (e.g., Burggren and Crews, 2014; Holliday, 2006; Jablonka and Lamb, 1998). It is fair to say that epigenetics means different aspects of biology to different individuals. It is thus useful to explicitly define epigenetics for the scope of this article. Here we will take a mechanistic, reductionistic approach and define epigenetics from the biochemical perspective (**Figure 1**). We focus on chemical modifications of genomic DNA template and histone cores of nucleosomes which affect how genomic DNA is packaged in each cell. The packaging of genomic DNA is essential for cells: all of the many cells in complex organisms need to package their genomic DNA in an extremely sophisticated way for accurate transmissions across cell generations. At the same time, local DNA regions that are required for the phenotype of the specific cells should be readily accessible to cellular machineries. As such, epigenetic modifications are critical for cellular processes, in particular gene expression.

The first epigenetic modification we will discuss is DNA methylation (**Figure 1**), especially the addition of the methyl ($-CH_3$) group to the 5th carbon of the cytosine base. This is the most common mode of DNA modification observed in animal and plant genomes (methylation of the adenine base also exists in bacteria, but will not be discussed in this article). In animal genomes, DNA methylation typically occurs at Cs followed by Gs, or 'CpGs,' although low level of non-CpG methylation are also observed. In plants, DNA methylation in CpG, CpHpH, and CpHpG (H refers to A, C, or T) all occur in substantial frequencies (Lister *et al.*, 2008). Recently, another type of modification that is biochemically related to DNA methylation is gaining attention: the hydroxymethylation of the 5th carbon of the cytosines. Hydroxymethylation occurs by the family of 'ten-eleven-translocation' (TET) oxygenases from methylated cytosine templates (Branco *et al.*, 2012; Williams *et al.*, 2011). Hydroxymethylation is also observed in non-mammalian animal genomes (e.g., Bracht *et al.*, 2012; Cingolani *et al.*, 2013). However, the functional role of hydroxymethylation on regulation and evolution are currently not as well understood as that of DNA methylation.

The second major component of epigenetic mechanisms we will discuss is modifications of specific amino acids in histone cores of the nucleosomes (**Figure 1**). Nucleosomes are the fundamental building blocks of chromatin, consisting of eight histone proteins (histone octamers). These histone proteins contain N- and C-terminal 'tails' that often bear specific chemical modifications, or 'marks.' The distinctive chemical modifications of histone tails, including methylation, acetylation, ubiquitination, and phosphorylation, are now appreciated as key regulatory signals in cellular environment (Bernstein *et al.*, 2007; Strahl and Allis, 2000). DNA methylation and histone modifications are deeply implicated with development and diseases, and also with regulatory mechanisms such as gene expression, imprinting, and recombination (e.g., Bernstein *et al.*, 2007; Strahl and Allis, 2000; Bird, 2007).

Epigenetics and Evolution: Compatible Concepts?

Epigenetic mechanisms are intensely studied in many fields of biology, most prominently in development, disease (especially cancer), and regulation. On the other hand, historically, epigenetics has received much less attention from evolutionary biologists. Intuitively, regulation of epigenetic programming should be under strong selection for its integrity, given the critical significance of epigenetics on development and regulation. A potential genetic change that can cause epigenetic

 doi:10.1016/B978-0-12-800049-6.00183-9

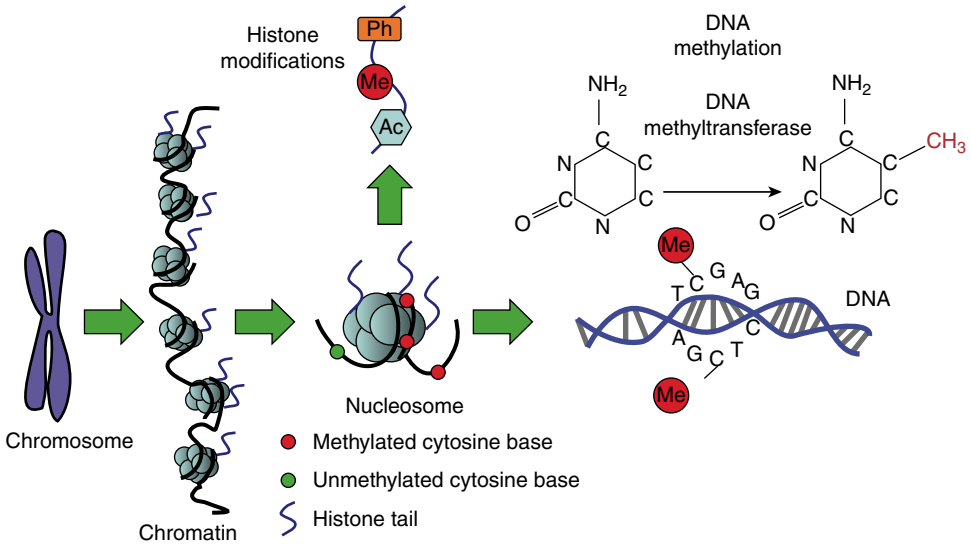

Figure 1 Epigenetic modifications including histone tail modifications and DNA methylation. The basic structure of chromosomes consists of genomic DNA wrapped around histone octamer nucleosomes. Histone proteins have N- and C-terminal 'tails' which are often marked by specific chemical modifications. Genomic DNA is also often modified by the addition of methyl group (CH_3) by dedicated enzymes called 'DNA methyltransferases.' In most animal genomes DNA methylation preferentially targets C followed by G, or 'CpGs.' Modified from Relton, C.L., Davey Smith, G., 2010. Epigenetic epidemiology of common complex disease: Prospects for prediction, prevention, and treatment. PLoS Medicine 7 (10), e1000356.

shifts should be subject to natural selection as long as the epigenetic shifts generate evolutionarily visible phenotypes. One candidate for such a phenotype is gene expression, which is often tightly regulated by epigenetic mechanisms.

However, a prevailing perspective on epigenetics has kept evolutionary biologists at bay. Until recently, it was widely viewed that epigenetic patterns are highly variable within an organism, and even between the same cell types depending upon specific biological conditions, because they are largely determined by environmental signals rather than the genetic code. However, emerging data suggest an imperative revision of this view. Like many other fields of biology, epigenetics is experiencing a transformative explosion of data, thanks to advances of next-generation sequencing technology. These new data begin to reveal that, in the human genome, only minor fractions of positions exhibit epigenetic variation across cell types for DNA methylation (Ziller *et al.*, 2013; Zeng *et al.*, 2014). Consequently, the extent of cellular epigenetic reprogramming is much more substantial than previously envisioned. Moreover, targeted and genome-wide studies continue to present evidence that epigenetic variations have genetic bases, at least within some genomic contexts (e.g., Heyn *et al.*, 2013; Lienert *et al.*, 2011; Eichten *et al.*, 2013).

On the practical side, the lack of comparative data on epigenetic variation between species was also a limiting factor for evolutionary biologists. However, data on genome-wide epigenetic modifications from diverse group of taxa are accumulating, in some cases from matched cell types (e.g., Molaro *et al.*, 2011; Shulha *et al.*, 2012). Large-scale population data on epigenetic variability are also becoming available (e.g., Schmitz *et al.*, 2013). These data, together with the increased understanding of the extent of epigenetic variation across cell types and developmental stages (Lister *et al.*, 2013; Ziller *et al.*, 2013), provide a ripe opportunity for evolutionary biologists to explore the evolutionary dynamics and significance of epigenetic modifications.

It should be noted that epigenetic modifications at some genomic regions appear as truly variable across cell types (Ziller *et al.*, 2013), and potentially determined by environmental signals (Schmitz *et al.*, 2013; Stroud *et al.*, 2013). It is possible that epigenetic patterns of some genomic sites are under strong genetic control while those of other positions are more labile and susceptible to environmental effects. Comparative studies of epigenetic variation have the potential to illuminate such yet unknown aspect of genome organization and regulation.

Classical Role of DNA Methylation on Mutation and Sequence Composition

One important evolutionary consequence of epigenetics is the impact of DNA methylation on genomic mutations. It has been long known that methylated cytosines are highly subject to rapid spontaneous deamination, which turns methylated cytosines to thymines (e.g., Coulondre *et al.*, 1978). Consequently, DNA methylation increases rates of C to T (or G to A) transition mutations.

The effect of this process is best understood in animal genomes, and recognized as an important evolutionary force affecting mutation rates, mutation spectra, and genome sequence composition. For example, in primate genomes, transitions due to DNA methylation are over an order of magnitude more prevalent than those that arise due to other mechanisms such as DNA replication errors (Elango *et al.*, 2008). In fact, transitions at CpG sites account for a quarter of all point mutations that separate the genomes of humans

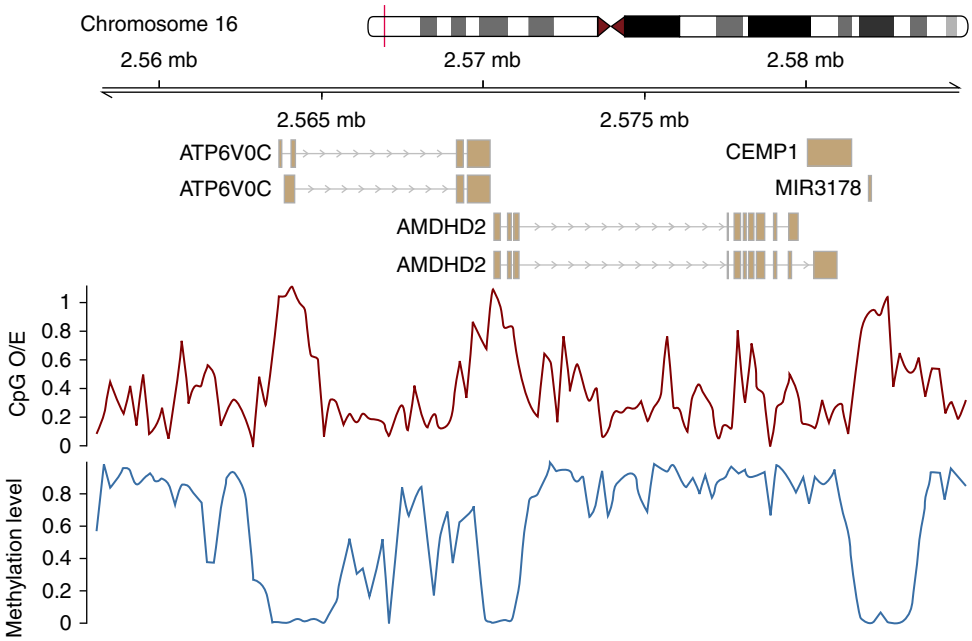

Figure 2 Depletion of CpG dinucleotides is negatively correlated with the actual DNA methylation levels. CpG O/E, which is a metric calculated as the observed CpG counts divided by the expected CpG counts (Bird and Taggart, 1980; Yi and Goodisman, 2009) reflects the level of CpG depletion. Here a 200 kb region of the human chromosome 16 is depicted: CpG O/E are generally low with some peaks, particularly near transcription start sites and exons. Correspondingly, DNA methylation level is generally high with conspicuous dips. Lowly methylated regions tend to overlap with high CpG O/E regions and near transcription start sites and genes. Note that ATP6V0C and AMDHD2 are encoded on the sense strand, while CEMP1 and MIR3178 are encoded on the complementary strand. DNA methylation data are from the brain of a 25-year-old male. Reproduced from Lister, R., Mukamel, E.A., Nery, J.R., *et al.*, 2013. Global epigenomic reconfiguration during mammalian brain development. Science 341 (6146), 1237905.

and chimpanzees (The Chimpanzee Genome Sequencing and Analysis Consortium, 2005). Mutations that originate due to DNA methylation are also less prone to the generation time effect (Hwang and Green, 2004; Kim *et al.*, 2006).

Due to the increase of CpG to TpG (or CpA) transition, DNA methylation effectively reduces the CpG content of affected regions, when compared to the expected values calculated from the observed frequencies of G and C nucleotides (Yi and Goodisman, 2009). In fact, almost four decades ago, based upon the observed CpG contents of small genomic fragments, it was proposed that mammalian genomes are heavily methylated, and invertebrate genomes are sparsely methylated (Bird and Taggart, 1980). These predictions largely hold true. For example, in the human genome, CpG dinucleotides exist at only approximately 1/5th of the expected frequency (**Figure 2**). Some genomic regions, however, maintain high CpG contents, and are often devoid of DNA methylation (**Figure 2**). Such regions tend to occur near genes, especially near the transcription start sites (**Figure 2**). Regions particularly enriched in CpGs and exhibiting reduced DNA methylation are referred to as 'CpG islands' (Illingworth and Bird, 2009). DNA methylation of CpG-rich regulatory regions near genes (such as promoters) is often associated with silencing of gene expression (e.g., Jones, 2012).

The degree of CpG depletion is widely used to infer historical DNA methylation events in diverse animal (e.g., Elango *et al.*, 2009; Sarda *et al.*, 2012) and plant genomes (Takuno and Gaut, 2011). A particularly useful feature of the CpG contents analysis is that it can detect regional differences in DNA methylation, even in genomes where DNA methylation is rare and highly localized. For example, genomes of many hymenopteran insects are sparsely methylated, and most of their DNA methylation is targeted to a subset of transcription units (often referred to as 'gene bodies' (e.g., Lyko *et al.*, 2010; Zemach *et al.*, 2010; Gavery and Roberts, 2013)). Unlike DNA methylation of regulatory regions, DNA methylation of gene bodies are often associated with increased gene expression and reduced gene expression variability (Zemach *et al.*, 2010; Huh *et al.*, 2013). Interestingly, the overall CpG contents of these hymenopteran insect genomes are often highly increased beyond the expected value (e.g., Honey Bee Genome Project, 2006; Werren *et al.*, 2010) for reasons that are not clearly resolved yet (however, a recent study suggests recombination-associated processes, see Wallberg *et al.*, 2015). Nevertheless, CpG content analyses can clearly separate methylated and unmethylated gene bodies (**Figure 3**).

Potential Mutational Effects of Histone Tail Modifications and Chromatin Structures

Studies have also begun to examine the effects of histone tail modifications on sequence composition and mutation rates. In the case of cancer cells, there is strong evidence that specific modifications of histone tails affect mutation rates and spectra (Schuster-Böckler and Lehner, 2012). In particular, the H3K9me3 modification, which is associated with heterochromatin and repression, accounts for a large number of

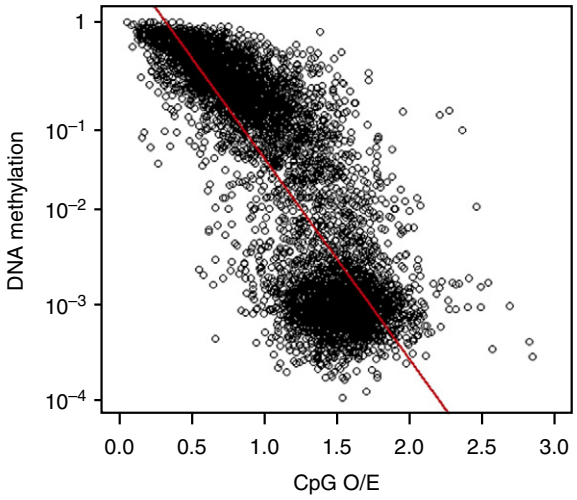

Figure 3 The relationship between CpG depletion (on the *x*-axis) and the experimentally measured methylation levels (*y*-axis) in the honey bee genes. Highly methylated genes and sparsely methylated genes are found in two distinctive clusters, and CpG O/E is very well correlated with the actual DNA methylation levels. The red line is the linear regression between the two variables. Data from Sarda, S., Zeng, J., Hunt, B.G., Yi, S.V., 2012. The evolution of invertebrate gene body methylation. Molecular Biology and Evolution 29, 1907–1916.

mutations in several cancer cell lines. The relationship between H3K9me3 modification and mutations was statistically independent of other sequence-associated features that are known to affect mutation rates (Schuster-Böckler and Lehner, 2012). Whether this finding extends to evolutionary timescale and germline mutations is currently unknown.

It is worth noting that there is also some evidence that large-scale chromatin structures affect evolutionary rates. Prendergast *et al.* (2007) demonstrated that regions characterized by more 'closed' chromatin structures in the human genome tend to harbor more nucleotide substitutions. This trend was consistent across various genomic regions (intergenic regions, ancestral repeats, and coding sequences) and across different phylogenetic distances (human SNPs, human–chimpanzee, and human–mouse pair comparisons), indicating that mutation rates themselves may be affected by chromatin structures. A caveat of this study was the fact that the chromatin structures were derived from lymphoblastoid cell lines, rather than germ cells. There is also a somewhat opposing observation that genomic regions that are particularly 'open' in pluripotent cells, measured by DNase hypersensitivity assays, are known to accumulate more mutations (Thurman *et al.*, 2012). Future studies are necessary to determine how large-scale chromatin structures and histone modifications influence evolutionary rates and genome sequence composition.

Emerging Studies of Epigenetics on Molecular Evolution

Recent advances in genome-wide epigenetic profiling have allowed researchers to examine aspects of molecular evolution other than mutation rates that are potentially affected by epigenetic modifications. We first discuss two areas of research that are particularly promising.

Recombination Hotspots and Epigenetic Variation

A fantastic example of the interplay between evolution and epigenetics is the evolution of recombination hotspots. Recombination hotspots are genomic regions (typically in ~kb ranges) that experience intensely high levels of recombination compared to the genomic background (Jeffreys *et al.*, 2001). Recombination hotspots are numerous in mammalian genomes (Myers *et al.*, 2005), yet extremely transient over evolutionary timescales. For example, few recombination hotspots are shared between human and chimpanzee genomes (Auton *et al.*, 2012). Why, and how do such critical genomic hallmarks evolve so fast?

A major piece of this puzzle came to light when it was discovered that a gene called PRDM9 is an important regulator of recombination hotspots in the human and mouse genomes (Baudat *et al.*, 2010; Berg *et al.*, 2010; Myers *et al.*, 2010; Parvanov *et al.*, 2010). The molecular structure of PRDM9 indicates that it is capable of interacting with genomic DNA as well as performing histone tail modification: it contains both a zinc-finger domain that binds genomic DNA, and a PR/SET domain capable of histone tri-methylation (Hayashi *et al.*, 2005). Interestingly, the DNA-binding zinc-finger domain evolves extremely rapidly in mammalian genomes, often accompanied by sequence signatures of positive selection (Oliver *et al.*, 2009; Buard *et al.*, 2014; Schwartz *et al.*, 2014). The rapid evolution of the DNA-binding domain of PRDM9 can explain why the locations of recombination hotspots change rapidly between species, as the locations of the majority of human and mouse recombination hotspots are controlled by PRDM9 itself (Ségurel *et al.*, 2011). However, the nature of the evolutionary force underlying the rapid evolution of zinc-finger domains themselves is not fully resolved: it may be directly due to its effect on recombination, or due to some other functions of PRDM9 (Ségurel *et al.*, 2011).

The evidence so far supports that PRDM9 performs 'epigenetic' functions. In addition to its ability to generate H3K4me3 marks (Hayashi *et al.*, 2005), modifying the DNA-binding zinc-finger domain of PRDM9 redistributes recombination hotspots as well as of H3K4me3 marks (Grey *et al.*, 2011). However, apart from its function as an epigenetic modifier, precisely how PRDM9 determines recombination hotspots is not known. For example, in the human genome, there are many tens of thousands of sequence motifs that PRDM9 can potentially bind, yet only a subset of them function as recombination hotspots (Ségurel *et al.*, 2011). Likewise, there are many other proteins capable of generating H3K4me3 marks, without influencing recombination events. In addition, even though H3K4me3 marks are typically associated with active gene promoters, mammalian recombination hotspots generally avoid genic regions and targeted to non-genic, repetitive regions (McVean, 2010). It is possible that additional chromatin marks may be necessary for the determination of recombination hotspot locations (Zeng and Yi, 2014).

Furthermore, PRDM9 is directly linked to hybrid sterility in mouse. In fact, it remains as the only known 'speciation gene' in mammals up to date (Mihola *et al.*, 2009). This role is most likely to be mediated by the epigenetic functions of the PRDM9. For instance, a modification of the PR/SET domain itself causes sterility (Hayashi *et al.*, 2005). It is notable that there exists a large body of evidence connecting epigenetic incompatibilities and molecular mechanisms of speciation in a variety of taxa (e.g., Brown and O'Neill, 2010). The study of PRDM9, with its distinctive roles on recombination and speciation, promises to be a unique system to elucidate the details of a crosstalk between epigenetics and evolution.

Evolutionary Trade-Off between TE Methylation and Gene Expression

Another research area where the functional effects of epigenetic modification can be put into specific evolutionary contexts is the effect of transposable element (TE) methylation on expression of nearby genes in plant genomes (Hollister and Gaut, 2009; Diez *et al.*, 2014). Plant genomes are moderately methylated compared to the heavily methylated mammalian genomes and sparsely methylated hymenopteran genomes. DNA methylations in plants are often targeted to transposable elements and gene bodies. Transposable elements are autonomous selfish genetic elements that can propagate by inserting themselves to different positions of the genome. Host genomes have utilized epigenetic modifications such as DNA methylation to suppress the mobilization of TEs. Consequently, DNA methylation of TEs should be 'beneficial' to the host genome. However, DNA methylation of some TEs can 'spread' or 'leak' to nearby regions (Ahmed *et al.*, 2011; Eichten *et al.*, 2012). One consequence of such a leaky TE methylation is that expression of nearby genes can be directly affected (Ahmed *et al.*, 2011; Lippman *et al.*, 2004; Martin *et al.*, 2009; Eichten *et al.*, 2012). Specifically, methylation of TEs can silence the expression of neighboring genes, which can be deleterious for host plants.

Formalizing these potential evolutionary conflicts, Hollister and Gaut (2009) proposed the 'evolutionary trade-off' model. They posited that genomic distribution of TEs could be affected by the balance of the beneficial effect of TE silencing and the deleterious effects of TE methylation on the expression of nearby genes. One prediction of this model is that heavily methylated, older TEs should be preferentially removed from genic regions via natural selection (Hollister and Gaut, 2009). This prediction has been met for several species examined so far (Diez *et al.*, 2014). In addition, methylated TEs that occur in genic regions exhibit stronger signals of natural selection than non-methylated TEs or non-genic TEs, rendering additional support to the evolutionary trade-off model (Hollister and Gaut, 2009).

It is further proposed that the evolutionary trade-off model could explain non-random patterns of gene expression in plant hybrids or polyploids. Transcriptional reprogramming in hybrids or polyploids is largely driven by epigenetic changes (Rapp and Wendel, 2005). Freeling *et al.* (2012) proposed that expression of specific alleles in hybrids or allopolypoids could be influenced by the differences in the TE distribution of the parental genomes. According to the evolutionary trade-off model, if one parental allele of a gene harbors strongly methylated TE nearby, its expression in the hybrid/polyploidy would be reduced (Freeling *et al.*, 2012). Changes in the epigenetic profiles of the hybrids/polyploids can further cause preferential loss of alleles of specific parental origin (Freeling *et al.*, 2012). Even though more studies are necessary to comprehensively evaluate these hypotheses, it is clear that the evolutionary trade-off model presents an attractive evolutionary framework to examine how natural selection on gene expression mediated by epigenetic patterns affect genome evolution and hybridization events (Diez *et al.*, 2014).

Concluding Remarks

Even though the term epigenetics is used by different groups of researchers with different foci, on the mechanistic level epigenetic modifications can be classified into only a few major molecular processes. Here we discussed two of the best-understood processes: DNA methylation and histone tail modification. Apart from the important role of DNA methylation on mutational processes, how epigenetic mechanisms themselves evolve, and how epigenetics shapes evolution, remain largely unresolved. Auspiciously, functional epigenetics research is gaining dramatic momentum at the moment, fueled by the technical advances of next-generation sequencing methods. As our understanding on the molecular processes of epigenetics improves, so will our knowledge of the relationship between epigenetics and evolution. It is an opportune time for evolutionary epigenetics: several solid examples where key evolutionary processes are associated with epigenetic modifications exist (as discussed above). Population-level and comparative epigenetic data have begun to appear and likely to rapidly accumulate. Disentangling genetic versus environmental effects on the establishment and maintenance of epigenetic modifications may become feasible soon. Consequently, we will be able to illuminate genetic and evolutionary bases of epigenetic programming, which may reveal new aspects of genome evolution.

Evo-Devo: Regulatory and Protein-Coding Evolution in Plant Diversification

JC Preston, The University of Vermont, Burlington, VT, USA

Glossary

Alternative splicing The inclusion or exclusion of exons from messenger RNA (mRNA) resulting in a single gene that codes for multiple proteins.
Chromatin Complex of eukaryotic DNA, protein, and RNA that packages chromosomal DNA around histones for increased cellular control.
Darwinian evolution Charles Darwin's theory that all organisms are derived from a common ancestor whose descendants diversified through natural selection of small, inherited variations.
Epialleles Genes that are identical at the sequence level but differ in their extent of methylation.
Heterochrony Change in the timing or rate of developmental processes, such as gene expression, growth rate, and differentiation, which commonly lead to changes in character size and shape.
Heterometry Changes in the size or amount of a developmental process.
Heterotopy Changes in the position of a developmental process, such as reiteration of gene expression at different locations to form serial homologs (e.g., leaves or flowers).
Homeologs Duplicate genes in an allopolyploid plant genome derived from the maternal and paternal parent.
Macroevolution Evolution that occurs above the level of species through similar (see microevolution) or distinct (e.g., mass extinction and species selection) mechanisms as microevolution.
Macromutation (saltation) A mutation that causes a profound change in an organism, originally conceived by Richard Goldschmidt to explain the divide between microevolution and macroevolution.
Microevolution Change in allele frequencies over time within a population.
Modules Quasi-independent parts of an organism that are tightly regulated, but develop somewhat independently of each other.
Neo-functionalization The evolution of a novel function for one paralog derived from a gene duplication event.
Noncoding RNA Functional RNA that is not translated into a protein.
Orthologs Related genes in different species that evolved from a common ancestral gene through speciation.
Paralogs Related genes derived from duplication events within a genome.
Pleiotropy The influence of a gene on two or more phenotypic traits.
Sub-functionalization The partitioning of ancestral function between descendent duplicate genes.
Toolkit genes Small subset of highly functionally conserved genes whose products control the body plan, and can affect morphological evolution depending on when and where they are deployed.

An Historical Perspective on Plant Evo-Devo

The evolution of development (evo-devo) is a field of biology that attempts to uncover the biophysical, ontogenetic, and molecular genetic changes that have resulted in the Earth's vast array of organismal diversity. Plant evo-devo can be traced back to the pioneering work of comparative morphologists of the eighteenth century, whose observations of similarities between body plans/organs of distinct species during early development provided key evidence for Darwin's theory of evolution, i.e., descent with modification (Friedman and Diggle, 2011). However, it was not until the 1970s that the modern age of evo-devo was really born, fueled primarily by the synthesis of developmental genetics, molecular phylogenetics, and both micro- and macro-evolutionary theory (Gould, 1977).

Among the major discoveries that followed the birth of modern evo-devo, a few were to have profound effects on our understanding of plant evolution. These include the fact that plants share a conserved (deeply homologous) genetic toolkit that is subject to the laws of natural selection and genetic drift (Coen and Meyerowitz, 1991), and that changes in where and when a gene is expressed have major consequences for plant development and its evolution (Hoekstra and Coyne, 2007; Carroll, 2008; Lemmons *et al.*, 2014). The following sections discuss the role of genetic and epigenetic (heritable non-genetic) variation in the evolution of plant form and function, and summarize our understanding of how genome structure/behavior can both constrain and promote developmental evolution.

Gene Expression, Development, and Phenotypic Evolution

In the 1950s Watson, Crick, and colleagues elucidated the structure of DNA, a type of nucleic acid found in all cells that encodes the heritable information required for protein synthesis (Franklin and Gosling, 1953; Watson and Crick, 1953a, b). These findings finally provided the mechanistic basis for faithful cellular replication. However, they also begged the question as to how, if all cells of multicellular organisms have the same DNA, tissues can differentiate to form distinct structures. The answer to this question turned out to lie partially with the environmental control of gene expression, which can be regulated at both the transcriptional and

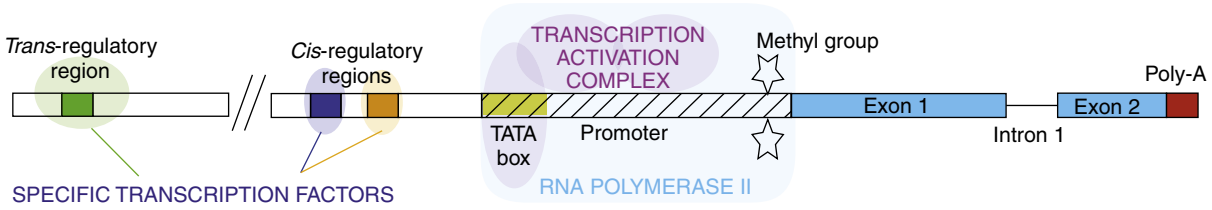

Figure 1 Simplified representation of a eukaryotic gene showing the role of epigenetic DNA methylation (stars), and both generic (purple) and specific transcription factors in the binding of RNA polymerase II to initiate transcription. The TATA box (yellow) is a common regulatory element that facilitates binding of the transcription activation complex within the promoter.

posttranscriptional level. In this context 'environmental' can refer to anything from cell position and lineage effects to the stresses applied by neighboring tissues or abiotic forces (Rodríguez-Mega *et al.*, 2015). In the last several decades, evo-devo studies have found increasing evidence that changes in the position (heterotopy), amount (heterometry), and timing (heterochrony) of gene expression have influenced the evolution of plant development. Nevertheless, it is only recently that the diversity of proximate mechanisms underlying shifts in gene expression has started to be uncovered.

Transcriptional Control and the Evolution of Gene Expression

The transcription of eukaryotic messenger RNA (mRNA) from DNA is a complex process involving numerous interacting proteins (transcription factors) that guide RNA polymerase II to the 5′ promoter regions of protein-coding genes (**Figure 1**). Although general transcription factors are essential for the transcription of all coding genes, so-called specific transcription factors bind to DNA motifs within (*cis*-regulatory elements) or distant to (*trans*-regulatory elements) the promoter of just a few coding genes, acting to either promote or repress their transcription (Phillips, 2008). A good example of specific transcription factors in plants are MADS-box proteins that bind to specific regulatory motifs often associated with downstream genes involved in flowering and flower development (Theissen *et al.*, 2000).

Evolutionary shifts in the binding efficiency and spatiotemporal expression of specific transcription factors can lead to different expression profiles of their downstream targets (Badis *et al.*, 2009). A compelling example of a heterometric change comes from an examination of binding preferences for the transcriptional regulator LEAFY (LFY) across land plants. Specifically, amino acid differences in LFY proteins across the plant kingdom have been demonstrated to affect DNA-binding specificities (Sayou *et al.*, 2014), which combined with quantitative changes in protein expression are hypothesized to explain clade-specific roles for these proteins in cell division and flower development (Tanahashi *et al.*, 2005).

In addition to evolution of upstream transcription factors, modifications to the number, position, and sequence of *cis*- and *trans*-regulatory elements of specific genes can have major impacts on gene expression, and thus the developmental functions of translated proteins. In the Brassicaceae (cabbage family) species *Capsella grandiflora*, insertions and/or single nucleotide polymorphisms in the promoter region of *REDUCED COMPLEXITY* (*RCO*) have resulted in a major heterometric reduction in gene expression, causing a concomitant reduction in leaf dissection compared to its close relative *Capsella rubella* (Sicard *et al.*, 2014). A similar alteration (this time caused by insertion of a retrotransposon) in *cis*-regulatory sequences of the maize (*Zea mays* spp. *mays*) gene *TEOSINTE BRANCHED 1* (*TB1*) resulted in a shift from the highly branched pre-domesticated body plan of the maize progenitor te1osinte (*Zea mays* spp. *parviglumis*) to the unbranched domesticated body plan of maize (Doebley *et al.*, 1997; Studer *et al.*, 2011). Multiple studies have thus demonstrated that changes to both transcription factor proteins and the regulatory sequences they bind to are important components shaping the evolution of plant form and function.

Posttranscriptional Control and the Evolution of Gene Expression

It is becoming increasingly clear that posttranscriptional processes, including mRNA degradation by noncoding small interfering RNAs (siRNAs) and long noncoding RNAs (lncRNAs), and differential splicing of mRNA introns, have major impacts on patterns of gene expression, and thus might be important for the evolution of plant form. In maize, mutations that cause overexpression of the microRNA miR156 result in plants with features reminiscent of their progenitor teosinte, including increased root formation and vegetative branching (Chuck *et al.*, 2007). Thus, since miR156 targets several known transcription factor mRNAs for degradation, it is hypothesized that maize domestication, and perhaps phenotypic evolution of other grasses, occurred partly through the evolution of miR156 function (Chuck *et al.*, 2007). A more recent example of posttranscriptional mechanisms affecting the evolution of plant form is in the elaboration of novel splice forms of the *Solanum* (e.g., potato, tomato, and eggplant) gene *BRANCHED1a* (*BRC1a*) (Nicolas *et al.*, 2015). The ancestral unspliced form of *BRC1a* functions as a nuclear transcription factor to repress stem branching, whereas the alternative splice form in *Solanum* becomes localized to the cytoplasm and has no transcriptional activity. The ratio of splice forms is dependent upon both internal and external environmental conditions, including hormone levels and light quality. Thus, the evolution of alternative splicing in this gene allows flexibility in *Solanum* branching, possibly as an adaptation to occasional shading.

Epigenetic Regulation of Gene Expression

Narrow sense epigenetics refers to stable heritable changes in gene expression that occur in the absence of DNA sequence

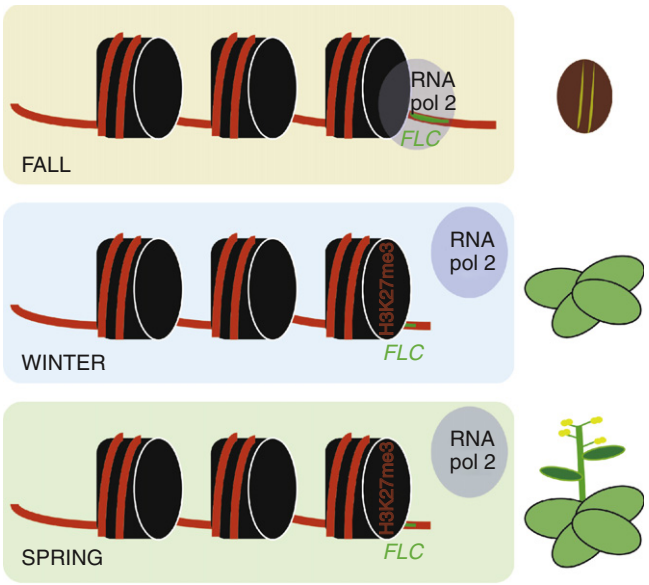

Figure 2 Temperature regulation of the *Arabidopsis* flowering repressor gene *FLOWERING LOCUS C* (*FLC*) through DNA methylation. In 'winter' ecotypes of *Arabidopsis*, seeds are planted in the fall, during which time warm temperatures promote transcription of *FLC* by reducing DNA methylation, thus allowing RNA polymerase II to bind to the promoter. During winter, cold vernalizing temperatures promote the transcription of long noncoding RNAs (lncRNAs) that guide histone 3 lysine 27 trimethylation (H3K27me3) to *FLC*, repressing *FLC* transcription. The epigenetic silencing of *FLC* is maintained through mitotic divisions even when temperatures increase in the spring, triggering flowering and the production of flowers (yellow) and seeds.

variation (Iwasaki and Paszkowski, 2014). The most common mechanisms underlying epigenetic inheritance are DNA methylation, histone modifications, and the synthesis of noncoding RNAs (Rodríguez-Mega *et al.*, 2015), all of which can affect the structure of chromatin, and consequently the ability of RNA polymerase to bind to promoters for transcriptional activation (**Figure 2**). Environmental stresses, such as cold temperatures and pathogen attack, are known to have major impacts on gene expression by triggering the transcription of siRNAs and lncRNAs that mediate DNA methylation (Matzke and Mosher, 2014). Furthermore, epigenetic changes can be stably inherited through several generations, and 'epialleles' generated through the process of natural selection (Richards, 2008).

Several plant species growing in seasonally cold regions of the world are able to use winter chilling (vernalization) as a cue to ready them for rapid spring flowering. Although the cold-sensing mechanism is not well understood, cold-mediated epigenetic modifications to flowering time loci have been implicated in evolution of vernalization responsiveness in the distantly related model species *Arabidopsis* and cereal grass barley (*Hordeum vulgare*) (Heo and Sung, 2011; Oliver *et al.*, 2009). In *Arabidopsis*, the flowering repressor gene *FLOWERING LOCUS C* (*FLC*) is transcriptionally active in individuals grown at warm fall temperatures, but during cold winters the evolutionally conserved polycomb complex PRC2 is recruited to the *FLC* locus, causing increased H3K4me3 DNA methylation (Bastow *et al.*, 2004) (**Figure 2**). Localization of PRC2 to *FLC* can partially be explained by the cold-mediated transcription of the lncRNA *ColdAIR*, which physically interacts with PRC2 and is located within the first intron of *FLC* (Heo and Sung, 2011). Following vernalization, *FLC* methylation (and hence repression) is stably maintained through mitotic divisions, only to be 'reset' during meiosis (Iwasaki and Paszkowski, 2014). This is one of many examples of a derived epigenetic mechanism that has allowed plants to adapt to harsh environmental conditions that might otherwise be too detrimental for growth and development.

Protein-Coding Changes and Developmental Evolution

Eukaryotic genes usually have multiple *cis*- and *trans*-regulatory elements, allowing their protein products to be deployed in a number of developmental contexts. This multi-usage of proteins is termed genetic pleiotropy and is an important factor in explaining why protein-coding regions of genes might be strongly conserved over long evolutionary timescales (Carroll, 2008). However, despite long-standing debates over the prevalence of regulatory versus protein-coding changes in the evolution of plant development (e.g., Doebley and Lukens, 1998), there are multiple examples where amino acid transitions have led to phenotypic evolution. Two important mechanisms that can lead to escape from genetic pleiotropy, and hence make protein-coding changes less deleterious to the developing organism, are modularity and gene duplication.

Modularity Can Promote Both *Cis*-Regulatory and Protein-Coding Evolution

An important feature of toolkit genes is their high level of modularity (Carroll, 2008). In other words, many regulatory genes such as transcription factors are composed of independent

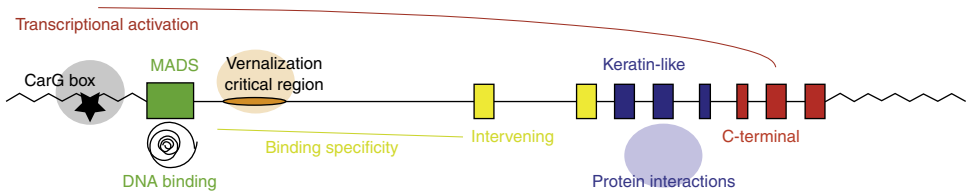

Figure 3 Typical modular structure of the diploid wheat (*Triticum monococcum*) MIKC MADS-box transcription factor *VERNALIZATION 1* (*VRN1*) that might facilitate evolution through discrete *cis*-regulatory and protein-coding changes. The coding region can be separated into four distinct functional domains separated by introns (thin lines): MADS (green) involved in DNA-binding, Intervening (yellow) affecting DNA-binding specificity, Keratin-like (blue) allowing protein–protein interactions, and C-terminal (red) often involved in transcriptional activation and/or forming multi-protein complexes. Important *cis*-regulatory regions, such as the MADS-box binding CarG box and the vernalization critical region, are found upstream of the promoter and within the large first intron. Deletions in these regulatory sequences are implicated in the loss of vernalization responsiveness in some cereal grasses.

units or regions, each of which has a discrete effect on protein function and/or development. An exemplar for modular genes in plants is the MIKC subfamily of MADS-box transcription factors that have evolved novel functions through changes to different protein-coding modules (**Figure 3**). MIKC MADS-box genes are composed of four functional domains: the MADS-box domain involved in DNA-binding, the Intervening domain that influences the specificity of DNA-binding dimers, the Keratin-like domain involved in protein–protein interactions, and the C-terminal domain that is often involved in transcriptional activation and forming multimeric protein complexes (Gramzow and Theissen, 2010). In the genus *Medicago* (e.g., alfalfa) an amino acid change in the C-terminal domain of the MADS-box gene *SHATTERPROOF* (*SHP*) was recently shown to affect protein–protein binding specificities, and is correlated with an important change in fruit morphology that led to the evolution of a novel seed dispersal strategy (Fourquin *et al.*, 2013). Thus, although the biochemical function (i.e., a nuclear-localized transcription factor) has not evolved within *Medicago*, its developmental function has.

In addition to modularity within the coding region of developmental genes, a large number of regulatory elements upstream of the promoter, and within introns and the 5′- or 3′-untranslated regions of genes, can cause modularity in gene expression. Indeed, following up on the previous example, MADS-box genes have a huge number of *cis*-regulatory binding sites that can be bound by their protein products (i.e., autoregulated) or other transcription factors, miRNAs and siRNAs involved in epigenetic modifications (Gramzow and Theissen, 2010). In the vernalization-regulated MADS-box gene *VERNALIZATION 1* (*VRN1*) of cereal grasses, multiple regulatory elements have been found within the promoter and first intron that have different effects on developmental gene function (Yan *et al.*, 2003; Hemming *et al.*, 2009; Alonso-Peral *et al.*, 2011; Zhang *et al.*, 2012) (**Figure 3**). Discrete changes in the regulation of *VRN1* can have important fitness consequences through the control of flowering time, depending on the duration, intensity, and predictability of winter within different geographic regions.

Gene Duplications Can Reduce Genetic Pleiotropy and Foster Phenotypic Novelty

Gene duplication events in plants are a common occurrence. Single genes can be replicated through the action of transposable elements, slippage during DNA replication, or unequal crossing during meiosis, whereas whole genomes can be duplicated via accidents in meiosis (autopolyploidization) or hybridization between distinct taxa (allopolyploidization). The most common fate for duplicate genes is the functional conservation of one paralog and non-functionalization of the other (Rensing, 2014) (**Figure 4(a)**). Non-functionalization can occur extremely rapidly through epigenetic silencing of paralogs or homeologs (genes duplicated through allopolyploidy), possibly as an adaptation to combat gene dosage effects, or gradually over evolutionary time due to relaxed selection (Woodhouse *et al.*, 2014). Less often, both functional paralogs can be maintained in the genome, either through the process of sub-functionalization (where the descendent genes partition the functions of their parent) (**Figure 4(b)**), or neo-functionalization (where one gene evolves a new function) (Ohno, 1970) (**Figure 4(c)**).

Sub- and neo-functionalization of duplicate genes can occur through mutations in either protein coding or *cis*-regulatory regions of genes (**Figure 4**). Although sub-functionalization does not promote phenotypic change *per se*, it can substantially reduce genetic pleiotropy by constraining the impact of mutations to only a subset of developmental functions carried out by the parental (pre-duplication) gene. In this case, mutations in the coding regions of sub-functionalized genes can lead to evolutionary 'tinkering' of phenotypes (Carroll *et al.*, 2001) rather than 'hopeful monsters' caused by so-called macromutations (Goldschmidt, 1940). For example, in snapdragon (*Antirrhinum majus*) a single amino acid change in combination with the rewiring of interacting protein expression has been sufficient to convert the MADS-box gene *FARINELLI* (*FAR*) from a regulator of stamen and carpel develop (as is seen in its paralog *PLENA* (*PLE*)) to a regulator of stamen development alone (Airoldi *et al.*, 2010).

There are numerous examples of neo-functionalized duplicate genes that have driven major developmental innovations in plants, including shoot apical meristems and flowers (Rensing, 2014). In the fewer instances where the underlying mutation for neo-functionalization has been determined, some are due to regulatory changes, some to protein-coding changes, and others both. For example, a single amino acid substitution in the duplicated domestication gene *TEOSINTE GLUME ARCHITECTURE 1* (*TGA1*) was responsible for converting the solidly encased kernels of teosinte to naked kernels

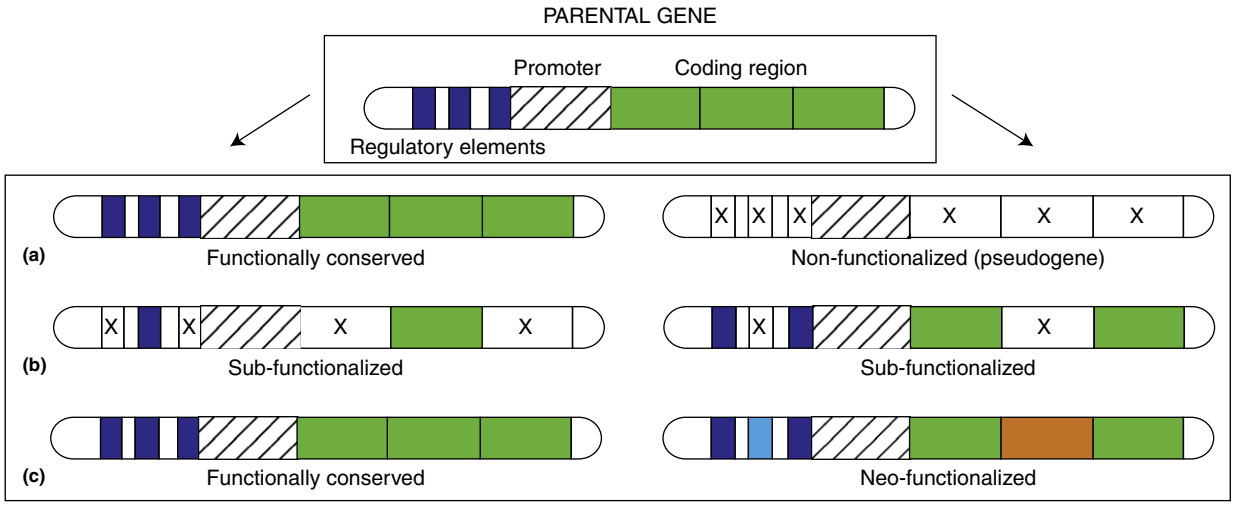

Figure 4 Potential fates of duplicated genes. (a) One paralog becomes a non-functional pseudogene by acquiring deleterious mutations while the other retains the ancestral functions. (b) Both genes acquire deleterious mutations in different *cis*-regulatory and protein-coding modules, thus partitioning the ancestral gene function through sub-functionalization. (c) One paralog acquires a novel advantageous mutation (orange) that can lead to evolutionary innovation in plant form, whereas the other paralog retains the ancestral functions.

in maize (Wang *et al.*, 2005, 2015). Thus, protein-coding changes can affect discrete phenotypes in plants, and are perhaps more important to the evolution of development than was once thought.

Conclusions and Future Directions in Plant Evo-Devo

Several decades of work have demonstrated the importance of both changes in *cis*-regulatory elements and their interacting regulatory proteins to the evolution of organismal development (Carroll, 2008). However, there are also several examples of mutations within nonregulatory proteins (e.g., enzymes and structural proteins) – such as changes in substrate specificity of pigment pathway enzymes that cause shifts in flower color (Smith *et al.*, 2012) – that have been important for morphological evolution. Together these data thus suggest a lack of inherent constraint on what types of developmental genes or genic regions are subject to natural selection or genetic drift. Rather, the modularity of genes, and their relative position within one or more developmental gene regulatory networks (GRN), might be more important determinants driving diversification.

Since the advent of affordable comparative/functional genomic and complex system modeling platforms, our ability to predict regions within GRNs that have affected plant developmental evolution has steadily increased. Like regulatory genes, GRNs are modular, consisting of highly interconnected units (modules) that are more loosely connected to other units (Rodríguez-Mega *et al.*, 2015). Transcription factors that regulate the expression of many to few genes in GRNs are referred to as hub and peripheral proteins, respectively, and it is proposed that peripheral GRNs and peripheral proteins are more likely to evolve than integral GRNs and hubs due to the smaller impact of genetic pleiotropy. Supporting this hypothesis, differential expression of the peripheral *BLADE-ON-PETIOLE* (*BOP*) GRN module across tomatoes correlates well with leaf complexity (Ichihashi *et al.*, 2014). Although many more studies are needed to test the effects of gene position on the evolvability of GRN elements, large-scale network studies, combined with functional analyses in both model and non-model species (e.g., Bortesi and Fischer, 2015), are paving the way for a comprehensive understanding of the commonalities and differences underlying evolution of distinct plant traits.

Evolution and Agriculture I. The Evolution of Domestication

RG Allaby, University of Warwick, Coventry, UK

Glossary

Commensal An organism engaged in commensalism. Commensal organisms in the human environment include house sparrows, mice, and some agricultural weeds such as darnel.

Commensalism An interaction between species in which one species benefits, but the other is unaffected.

Domestication The adaptation of an organism to a host (usually human) organism environment that occurs in response to a mutualistic relationship in which the host assumes a high degree of control over the life cycle of the organism in the interests of procuring a resource such as food or service.

Domestication syndrome A group of traits that is typically associated with the adaptations of domestication. In the case of plants these include a reduced ability to disperse seeds, loss of dormancy, changes in architecture, and seasonality of flowering. In animals traits include increased docility, changes to reproduction pattern and output, altered coat color, floppy ears, neotony, a reduction in size, and other changes in body proportions.

The incorporation of plants and animals into human ecologies and their subsequent domestication was one of the most significant evolutionary transitions in the history of the human species. The associated division of labor and intensification of settlement patterns precipitated the social evolution of complex societies replacing the previous hunter-gatherer existence that accounts for 95% of human history (McDougall *et al.*, 2005). Since Darwin first used domestication as an illustration of how natural selection might work (Darwin, 1859, 1868), it has increasingly become recognized as a complex suite of evolutionary trajectories that display parallelisms and convergences (Larson *et al.*, 2014).

Spatiotemporal Rise of Domestication

Hominin lineages have interacted with plants and animals by disturbing the environment and providing new niches since the Pliocene epoch (Allaby *et al.*, 2015), but it was not until the late Pleistocene and early to mid-Holocene epochs that a profusion of domestications occurred around the world over a relatively short period of time. Currently, there are up to 20 regional centers of domestication recognized around the world in which the process is thought to have occurred independently (**Figure 1**). Domestications broadly cluster into two time periods, a late Pleistocene/early Holocene group and a mid-Holocene group (Larson *et al.*, 2014). The older group is mostly comprised of the southwest Asian domesticates that originated in and around the Fertile Crescent region over a time period of 12 000–8000 years ago. These include wheat, barley, cattle, sheep, and pigs that make up the bulk of western agriculture today. Very few crops were domesticated in this time period outside of this region, exceptions being species of squash in Meso-America and South America and the pig in East Asia. There is evidence of pre-domestication exploitation of numerous wild species at this time that later became domesticated in South Asia, East Asia, New Guinea, Africa, and southern areas of the Americas. The mid-Holocene group of domesticates includes a large range of plants and animals from diverse areas around the world over a time period of around 8000–3000 years ago. Only a handful of species were domesticated after this period, including the duck, turkey, and guinea fowl. A notable exception to the general temporal trend is that of the dog, which represents the earliest known instance of domestication and predates these clusters by as much as 20 000 years (Larson *et al.*, 2012; Skoglund *et al.*, 2015).

The Domestication Syndrome

A diverse range of plants and animals have become domesticated and while few generalizations can accurately be applied universally, domestication can broadly be described as a selection process for the adaptation to the human agroecological niche. A number of traits recur frequently between organisms in this adaptation that have collectively become known as domestication syndrome traits (Hammer, 1984; Harlan, 1992). In plants, these traits include reductions in seed dispersal without human intervention, physical and chemical defenses, side-shoots and seed dormancy, combined with increased seed size and more synchronous germination and maturation. In animals, these traits include an increased docility, changes to reproduction pattern and output, altered coat color, floppy ears, neotony, a reduction in size, and other changes in body proportions. Any one species may only contain a selection of such traits, and the primacy of traits may differ between species.

In the case of plants the genetic mechanisms underpinning domestication syndrome traits are well understood in many cases (Fuller and Allaby, 2009; Olsen and Wendel, 2013). Given the similarities between the various plant groups around the world in their respective syndrome traits, it has been postulated that parallel mutations in equivalent genes between species could be responsible (Paterson *et al.*, 1995). However, while there is considerable convergence at the phenotypic level, at the genetic level the general rule has been that each plant species lineage has been found to have different specific mechanisms underlying traits such as loss of

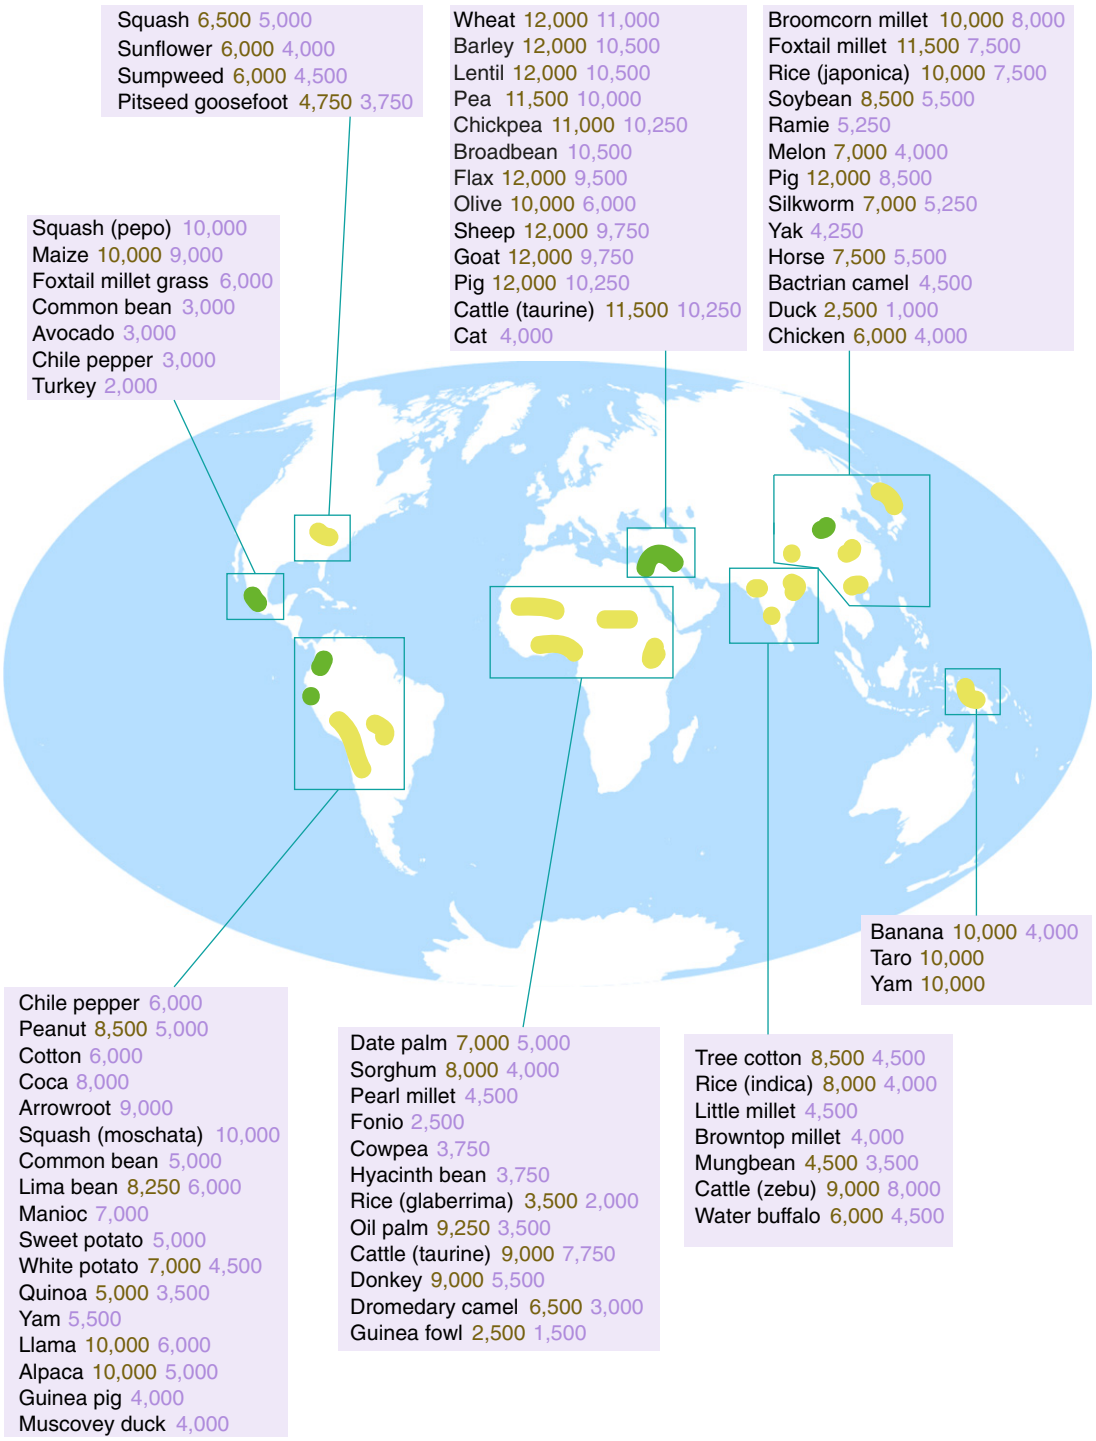

Figure 1 Regions of domestication around the world. Areas of early domestication are shown in green, areas of later domestication are shown in yellow. Dates for species listed for regions indicate first known exploitation or pre-domestication management before domestication (brown), and first known indications of domesticated forms (purple). Reproduced from Larson, G., Piperno, D., Allaby, R.G., *et al.*, 2014. Current perspectives and the future of domestication studies. Proceedings of the National Academy of Sciences of the United States of America 111, 6139–6146.

shattering (Li and Gill, 2006), although there have been exceptions to this (Lin *et al.*, 2012). The complexity of the underlying genetic control of traits varies from very simple with one or two genes being involved in the case of seed shattering, dormancy, and architecture (Abbo *et al.*, 2014; Vollbrecht *et al.*, 2005), to highly polygenic control for traits such as seed size (Gupta *et al.*, 2006). In the case of plants the overwhelming majority of domestication syndrome loci have been identified to be regulatory in nature (Purugganan and Fuller, 2009; Meyer and Purugganan, 2013), consequently it

can be inferred that most mutations have been epistatic in their effect. Far less is known about the genetic control of domestication syndrome traits in animals (Larson and Fuller, 2014). A clear parallelism is the modification of coat color in the same gene (MCR1) in many different species. However, it seems to be the case that the animal domestication syndrome is more typically controlled by many genes of small effect with very few instances of single genes underlying traits (Larson and Fuller, 2014; Carneiro *et al.*, 2014). It has been speculated that most of the domestication syndrome traits in animals could be accounted for by a reduction in the production and spread of cranial neural crest cells resulting in reduced facial features, floppy ears, coat patterning, and tameness, although this remains unproven (Wilkins *et al.*, 2014). Attempts to identify the number of loci involved in the domestication process by identifying genomic regions of low genetic diversity in the domesticated species relative to the wild progenitor species generally suggest a similar story in plants and animals with around 30–100 regions typically involved (Axelsson *et al.*, 2013; Carneiro *et al.*, 2014; Chapman *et al.*, 2008; Peleg *et al.*, 2011; Wright *et al.*, 2005).

Domestication Evolution Trajectories: Pace, Mode and Mechanism

Debate on this topic includes the role of unconscious versus conscious-based selection (Abbo *et al.*, 2014), whether domestication was concentrated in time to events (single or multiple) or whether more protracted and complex processes underlie (Allaby *et al.*, 2008; Brown *et al.*, 2009), and the motivations of hunter-gatherer societies of the Mesolithic to take up agriculture (Larson *et al.*, 2014). It is likely that no one specific explanation of mechanism and process can be universally applied to all domesticated species; however, there is general agreement that the factors of a changing climate, human demography, and changing social systems through time were involved (Larson *et al.*, 2014; Belfer-Cohen and Goring-Morris, 2011). Traditionally, the rise of domestication has been associated with small groups of innovators from localized areas, who rapidly acquired domesticated forms through changing practices in the early Holocene. It is also well established that it is possible to domesticate wild progenitors of domesticated plants (Hillman and Davies, 1990) and animals (Trut *et al.*, 2009) rapidly, but the archeological record indicates a more complex mix of processes. It has become apparent that at least in the case of cereals such as wheat and rice the process was slow with selection strengths akin to that found with natural selection (Purugganan and Fuller, 2011). Similarly, in the case of dogs, the rise of the domesticated phenotype occurred tens of thousands of years after wolves entered into a mutualistic partnership with humans (Skoglund *et al.*, 2015). In the case of cereals archeological evidence also suggests a long period of pre-domestication cultivation into the Pleistocene prior to domestication (Weiss *et al.*, 2006; Willcox and Stordeur, 2012). Reviews of the archeological evidence of the Near East also challenge the notion domestication rising from a single group in a single area, but rather from diffuse activity over a wide area in space and time (Fuller *et al.*, 2011; Willcox, 2005). Recognition of the slow nature of the process for some plants and animals challenges the notion of rapid domestication events, and therefore the mechanistic processes underlying. Most scholars are agreed that domestication was for the most part an unconscious process in contrast to Darwin's original vision of domestication being a case of conscious skilled selective breeding that illustrated mechanistically how natural selection could operate (Darwin, 1859). In many cases a conscious-based process leads to a problem of teleology in that the architects of domestication would be required to be insightful about the consequences of their selective pressures without any precedent. It is also questionable whether in the case of processes involving large stands of plants the proto-farmers would be able to observe the phenotypes of the rare mutations associated with domestication. Of course there are contrasting examples in which domestication was likely both conscious and rapid. Where there were not large stands of organisms, it is more reasonable to suppose that proto-farmers could have observed useful characteristics and breed those on (Sauer, 1965). An example of such a crop is squash in which bitterness appears to have been rapidly selected out in the domestication process (Dillehay *et al.*, 2007).

Mechanisms to explain the domestication process need to provide unconscious pathways in many cases, conscious pathways in others, and the often-slow pace of change. Integral to these considerations are the consequences and drivers of human agency. The shift from a hunter-gatherer to an agrarian-based diet is associated with a diminution of body size (Frayer, 1980), adaptation to a starch diet (Perry *et al.*, 2007), and rising disease load (Wolfe *et al.*, 2007). The reasons why hunter-gatherer societies would take on an agrarian lifestyle were complex and not likely to have been due to an obvious and immediate gain in nutritional benefit. Indeed, evidence shows that European hunter-gatherer and farming societies coexisted with exchange and interbred for thousands of years while maintaining their cultural differences (Haak *et al.*, 2015; Lazaridis *et al.*, 2014; Smith *et al.*, 2015). Models to explain the possible mechanisms of the evolution of domestication have correspondingly become pluralistic with an increased emphasis on natural adaptive processes in the earlier stages, followed by more conventional artificial selection in later stages.

Animal domestication has been categorized into three principal pathways (Zeder, 2012). The three pathways are termed commensal, prey, and directed, respectively, which occurred progressively overtime and provide a framework in which mechanisms of unconscious selection can be invoked (Larson and Fuller, 2014). In the first pathway, the principal agents are the animals themselves, which are attracted to aspects of the human environment such as food waste and adapt to it without any human intervention. To adapt to such an environment such animals would be required to reduce aggression and develop a level of tameness. Such animals are termed synanthropes, and the evolutionary pathway would lead to habituation, commensalism and then to a reciprocal interaction between humans and the animals, which would eventually lead to selective breeding controlled by humans. Companion animals such as cats and dogs are believed to be examples, and represent the earliest known interactions between humans and animals that led to domestication. Pigs and chickens are also considered to have become domesticated

this way. Many animals only proceeded a small way along this pathway and remain commensal today, examples including pigeons, house sparrows, and various rodents such as rats and mice. Notably, hunter-gatherer communities were responsible for the domestication of some commensals such as the dog. Unlike the commensal pathway, the prey pathway is instigated by human action. In this case the initial intention is not to domesticate either but to increase hunting efficiency, which may have had unintended consequences (Larson and Fuller, 2014). Human activities include overkilling males of a species and leaving females to produce more offspring so increasing selection for fecundity, an adaptation currently seen in animals in zoo captivity (Gilligan *et al.*, 1997). Generally, overhunting progressed to herd management, with consequences of increased docility possibly as the most aggressive males were killed off preferentially, and increased fecundity. The archeological record indicates that overhunting occurred prior to the domestication of cows (Marom and Bar-Oz, 2013). The last pathway differs from the previous two in that it is driven by human intentionality and consciousness, occurring sometime after the initial episodes of domestication. In this pathway humans are aware that animals can become domesticated and target them. Examples include horses, donkeys, camels, and rabbits, many instances occurred in the last few hundred years.

Similar natural adaptive explanations occur for the early stages of plant domestication. Like animals, plants can be considered as commensal or domesticated in the human environment. The human agency mechanism transitioned from gathering wild stands of plants to actively cultivating plants closer to settlements. It is likely that seeds dropped by gatherers would have resulted in plants growing in and around settlements, and a selective advantage would be conferred to plants that prospered with the qualities of that environment. Plants would be favored that thrived in a disturbed environment and that could take advantage of the richer nutrient supply from waste. Early cultivation of these plants manifest in the archeological record as a preponderance of wild species within human settlements (Weiss *et al.*, 2006; Willcox, 2005). These early gathering and cultivating practices acted on a community of plants rather than single species in isolation that included weeds as well as plants used for food. Both weeds and proto-crops adapted to the human environment through the manifestation of domestication syndrome traits. The different syndrome traits arose at different times, possibly in response to changing cultural practices (Fuller, 2007; Fuller *et al.*, 2010). The earliest indications of the transition to domesticated forms in the case of cereals was increased seed size, followed later by a rise in the loss of shattering (Fuller, 2007). It is thought that these adaptations were responses to cultivation and harvesting pressure respectively, wherein larger seeds survive burial more easily and convey an advantage in seedling competition, and failure to disperse increases the probability of successfully becoming part of the harvested stock which then goes on to seed the next generation (Fuller, 2007). Even gathering of seeds in the wild is likely to lead to increased frequency of loss of seed dispersal in wild stands through the reduced efficiency of gatherers to retrieve non-shattering seeds as they shake or strip the seeds off plants. Such selection pressures could theoretically have stretched far into the Pleistocene many millennia before the onset of domestication. Loss of shattering is also observed in weeds such as rye brome, darnel, and corncockle (Howard *et al.*, 2011; Senda *et al.*, 2006; Spahillari *et al.*, 1999) which have also adapted to the human environment but remain as commensals. Some commensals from this plant community subsequently transitioned to food crops, classic examples being oats and rye which were weeds for some considerable time before later becoming food crops (Küster, 2000). The coevolution between the humans and the environment they construct and plant communities is further apparent in the observation that different early Neolithic societies were specifically adapted to different ecologies (Banks *et al.*, 2013).

In both the cases of plants and animals there are numerous examples of evolutionary dead-ends, domestication trajectories that ceased. For instance, despite being on the prey trajectory of animal domestication, neither gazelles nor zebras became domesticated (Diamond, 2002; Zeder, 2006). Species of pea, lentil, rye and bean are among a catalog of plants that appear to have reached early stages of the domestication trajectory but were abandoned (Fuller *et al.*, 2011). These may represent instances where the organisms failed to adapt to the human environment sufficiently, or simply that human settlements moved into new environments leaving these natural communities behind. The suitability of an organism for domestication to certain extent is determined by its adaptability, which in turn is determined by the underlying genetic diversity and genomic structure of the species. It has been noted that genes contributing to domestication syndrome traits are often colocated in the genome despite their physiological level of irrelevance to each other in the normal functioning of the organism (Gepts, 2004). This may be a contributing factor to the ease in which an organism can become domesticated because desirable traits are less likely to be broken up by gene flow between wild and cultivated populations. Debate also concerns the nature of the genetic variation upon which the selection process acted. New mutations may have occurred within the population of organisms within the human environment that gave rise to domestication-associated adaptations, or alternatively, selection in the human environment may have acted on standing variation in the wild (Weber *et al.*, 2007). Often the traits that distinguish wild and domesticated forms are diametrically opposed in their selective advantages in each environment giving a tension between the two types of selection pressure. Under these circumstances one might expect it to be more likely that a mutation associated with such a domestication syndrome trait would be very rare in the wild or derived *de novo* in the cultivated environment. However, if the trait in question is essentially neutral in the wild environment but advantageous in the human environment, then such standing variation in the wild may be expected to occur at much higher frequencies. This latter type of adaptation is unlikely to leave a signature of selection in the genome, caused by a large genomic region of low genetic diversity, even if the selection associated with it is very strong indeed (Innan and Kim, 2004; Teshima *et al.*, 2007). Many of the known genetic mechanisms that underlay syndrome traits involve loss of function mutations, such as in the case of loss of seed dispersal or coat color in animals (Fuller and Allaby, 2009; Larson and Fuller, 2014), and as such would be expected to be recessive. The length of time required to select for

the same selection strength recessive traits varies greatly with mating system. Species that have propensity to self-cross (selfing), will rapidly produce individuals homozygous for a recessive trait and therefore manifest the trait phenotype. Selfing, mostly associated with plants rather than animals, is often an adaptation to colonizing new and disturbed environments (Baker, 1955; Massol and Cheptou, 2011), and so reflects well the plant communities that adapted to the human environment that included cereals. In the case of these communities it is possible that the genetic variation required for the adaptation spontaneously formed within those communities in the human environment. Conversely, outcrossing species would take a timescale longer than that of the rise domestication to select recessive traits because of the relatively high frequency of heterozygote individuals. It is probable then that outcrossing species by necessity must adapt on the basis of standing genetic variation if the traits involved are recessive. This applies to all domesticated animals, and it is notable that examples of high-standing genetic variation for domestication syndrome associated loci have come from outcrossing plants such as maize (Weber *et al.*, 2007; Nesbitt and Tanksley, 2002), but is not restricted to outcrossers (Jones *et al.*, 2008).

Post Domestication Evolution

An emerging consensus among scholars is that domestication should be considered an evolutionary trajectory rather than a discrete event in time (Larson *et al.*, 2014). A corollary is that the sequence of adaptations to the human environment is ongoing, and at which point one could consider a plant or animal domesticated is a point of legitimate debate and varies between species. A convenient milestone for plants is the loss of seed dispersal trait, or the loss of dormancy has also been suggested as a similar threshold (Abbo *et al.*, 2014). Less discrete parameters occur for animals, but general traits such as size reduction can be applied (Larson *et al.*, 2014).

Further adaptation in domesticated plants and animals include 'improvement' traits, such as the increased row number in barley associated with increased protein content (Komatsuda *et al.*, 2007), the development of fragrant forms of rice (Kovach *et al.*, 2009), or the development of a rich array of breeds in dogs (vonHoldt *et al.*, 2009). Such improvements are still ongoing today, arguably into the age of genetically modified (GM) crops. A second category of adaptation in plants and animals is in response to the dynamic nature of the human environment. Agriculture spread from the 20 or so regions of the world into new environments and latitudes. For plants this required the adaptation to changing environmental cues and stresses. The longer day lengths of higher latitudes can cause earlier flowering, which can result in stunted plants with under-resourced propagules. Plants that require a cold winter period before initiating flowering, the vernalization requirement, found winters increasingly difficult to survive at higher latitudes (Fuller and Allaby, 2009). Typically, plants have responded to these pressures by losing sensitivity to environmental cues, such as photoperiod insensitivity in rice, barley, and wheat and loss of the vernalization requirement allowing crops to be planted after the harsh winter period (Fuller and Allaby, 2009). Although there are many losses of function mutations for these traits, often one is sufficient to achieve the phenotype.

The pace of the spread of agriculture from domestication centers was likely limited by the capability of the broader human ecology to adapt to new environments. A hiatus in agricultural spread for several hundred years in the southern Balkans is thought to have been due not only to the lag associated with latitudinal adaptation, but also adaptation to the changing community assemblage emphasizing the interdependence of domesticated and commensal plants on each other (Colledge *et al.*, 2005; Coward *et al.*, 2008). Despite this adaptation, it is likely that spread was still too rapid for the package to adapt, and the general trend in the archeological record is one of repeated collapse throughout Europe as agriculture arrived and then disappeared, often for long periods of time up to the millennium scale (Stephens and Fuller, 2012; Shennan *et al.*, 2013). This time required for adaptation may be a contributing factor to explain why Mesolithic hunter-gatherers retained their lifestyle for a long period of time after becoming aware of the existence of the agrarian way of life (Smith *et al.*, 2015).

Evolution and Agriculture II. Evolutionary Applications to Breeding

NA Johnson, University of Massachusetts-Amherst, Amherst, MA, USA

Glossary

Additive genetic variance The genetic variance that is due to the average additive effects of alleles.
Association mapping It is also called linkage disequilibrium mapping. It is the mapping of traits to loci using historical linkage disequilibrium in the population.
Breeders' equation $R=h^2S$ relates the response to selection (R) in a single generation to the narrow sense heritability of a trait (h^2) and the selection differential (S).
GWAS Genome-wide association mapping. See association mapping.
Heritability The ratio of genetic variance in the population to its phenotypic variance. The 'narrow sense' heritability is the additive genetic variance divided by the phenotypic variance.
Indirect genetic effect Effect from the genetic composition of socially interacting conspecifics on the focal individual.
Linkage disequilibrium The correlation of allele frequencies at different sites.
Quantitative trait locus (QTL) mapping The use of markers to map continuous traits to regions of chromosomes.

Introduction

Although humans have been domesticating animals and plants for many thousands of years, widespread use of selective breeding to consciously alter traits is a much more recent phenomenon, dating back to the last few centuries (Smith, 1998). This selective breeding has led to tremendous variation in many animals, including notably dogs, but the largest contribution of selective breeding has been in agriculture.

Professional breeding programs for crops and livestock improvement remains a cornerstone of agricultural research. Despite worldwide population increases and a substantially decreased percentage of people in developed countries involved in farming, food supply in developed countries substantial improved in quality and quantity over the last half century and breeding programs are largely responsible for these improvements (e.g., Havenstein, 2006). For instance, growth rates and sizes of chicken markedly increased between 1957 and 2001, and at least 85% of that improvement was owing to genetic factors, with the remainder being dietary (e.g., Havenstein *et al.*, 2003).

The agricultural industries cannot rest on these accomplishments. In its '2015 Revision of World Population Prospects' (1), the United Nations estimated the 2015 world population at 7.3 billion and predicted that number will increase to 9.7 billion by 2050 and 11.2 billion by 2100. Feeding these additional billions will require further agricultural improvement.

Historical Overview

Darwin and Wallace in the Nineteenth Century

The relationship between breeders and evolutionary biologists is characterized by a long history of rich reciprocal exchanges of information, ideas, and approaches. Moreover, many luminaries have made substantial contributions to both fields (Hill, 2014; Hill and Kirkpatrick, 2010).

This mutualistic relationship between evolutionary biologists and breeders starts with Charles Darwin. A breeder of pigeons and other animals and plants himself, Darwin had extensive correspondence with various breeder communities, and used insights from them in his development of evolutionary theory (Browne, 2002; Secord, 1981). Notably, Darwin made the analogy between what breeders did in selecting some variants while discarding others – a process that would be called 'artificial selection' – to what occurs in nature, what Darwin called 'natural selection' (Darwin, 1859). Darwin (1868) also produced a two-volume series on variation under domestication. Darwin used this book to continue to present evidence for evolution, but also went in new directions. Among other things, Darwin (1868) discussed differences between wild and domesticated animals, attempted to trace back the lineage of dogs to the progenitor, and suggested a 'provisional hypothesis' of 'pangenesis' to discuss how offspring inherited traits from their parents.

Although the late Victorian scientific community quickly embraced Darwin's ideas about common ancestry, they were more reluctant about his main explanation for evolutionary change – natural selection. Indeed, natural selection remained controversial for several decades after his death (Provine, 1971). Evolution via natural selection requires heredity – that offspring resemble their parents. While Darwin had evidence for heredity, his mechanism of pangenesis was sharply criticized (Mayr, 1982). Moreover, he lacked a quantitative theory of heredity (Provine, 1971).

Development of such a quantitative theory of heredity begun with Darwin's cousin, Francis Galton, who was obsessed with measurement and had passion for understanding how heredity works (Crow, 1993). Among Galton's major contributions was the development and application of the related concepts, correlation and regression (Stigler, 1989). Galton noticed a phenomenon called 'regression to the mean' (also called 'regression to mediocrity') wherein offspring of parents with extreme values of a trait tended to be less extreme than their parents (Lynch and Walsh, 1998, p. 8; Provine, 1971). For example, the offspring of extremely short parents

tend to be shorter than average, but not as short as their parents. This concept was an important early step in the foundation of what is now known as quantitative genetics, and would lead to advances in breeding.

Why does the regression to the mean occur? Traits of individuals have both heritable and non-heritable (mainly environmental) components, and by definition, only the heritable component is transmitted to the offspring. Extremely short individuals are likely to be short because they have 'short' heritable factors and 'short' non-heritable factors. Their offspring, however, have 'short' heritable factors but not the 'short' non-heritable factors; and thus, the offspring should be taller than their parents, but shorter than the average of the original population. The early quantitative geneticists at the turn of the twentieth century realized that the extent of the regression to the mean could explain how much a population could respond to selection (Lynch and Walsh, 1998). This understanding would lead to the development of formal treatments of heritability, the 'breeders' equation' (see below), of great importance for both evolutionary quantitative genetics and breeding.

Fisher and Wright in the Twentieth Century

The interexchange between evolutionary biologists and professional breeders continued through the twentieth century. Between World War I and World War II, a new science called population genetics developed and matured, unifying Mendelian genetics and Darwinian evolution. Two early leaders in population genetics, Sir Ronald Fisher and Sewall Wright, strongly influenced breeding programs (Hill, 2014).

Fisher (1918) showed that patterns of correlation between relatives for continuous characters could be explained by Mendelian genetics. This was an important milestone for both the synthetic theory of evolution and breeding programs. Fisher (1918, 1930) developed a model of evolution that assumed traits were determined by huge numbers of genes, each with small effect. This so-called infinitesimal model became widely used in both evolutionary quantitative genetics and in breeding, in part because of its mathematical tractability. In particular, the use of the infinitesimal model allows one to easily apply normal (Gaussian) distributions and standard methods of multiple regression and linear models in addressing expected evolutionary change (Lynch and Walsh, 1998; Hill, 2014). Not all traits conform to the infinitesimal model, but many do; for example, human height, which is determined by at least several hundreds of genes with tiny effect, comes very close (Lango Allen *et al.*, 2010).

Fisher was particularly interested in responses to short-term selection, which has obvious breeding implications. Notably, he formulated what he called 'the fundamental theorem of natural selection' in which he stated, "the rate of increase in fitness of any species is equal to the genetic variance in fitness" (Fisher, 1930, p. 46; see also Price, 1972, for a derivation). The genetic variance that Fisher referred to is the additive genetic variance (the part due to average additive effects of alleles, see Lynch and Walsh, 1998, p. 69) and not the total genetic variance (Price, 1972). Robertson (1966), in what is known as the secondary theorem of natural selection, extended Fisher's theorem to show that changes in traits equaled their genetic covariance with fitness. Later, George Price (1970, 1972) would extend and generalize this theorem in what is known as the Price equation. Fisher's fundamental theorem and its extensions have been influential in both evolutionary genetics (Price, 1972; Frank, 1995) and breeding (see Heritability and the Breeders' Equation below) because they illustrate and quantify the relationship between additive genetic variation and the response to selection.

Wright, who spent the first decade of his career (1915–25) at the United States Department of Agriculture (USDA), was extraordinarily influential in both developing evolutionary theory and applying it to agricultural programs (Provine, 1986). One of Wright's major contributions from his time at the USDA was in ascertaining patterns and effects of inbreeding in livestock, particularly cattle (e.g., Wright, 1922, 1969). Wright devised coefficients of inbreeding, which could be calculated from pedigrees, and developed patterns of mating that would minimize inbreeding (Wright, 1969). Minimizing inbreeding and its deleterious effects (inbreeding depression) continues to be of great importance both in agriculture (Leroy, 2014) as well as in conservation biology. Moreover, inbreeding depression has been a persistent topic of interest in general evolutionary biology (Charlesworth and Charlesworth, 1987; Hartl and Clark, 2007).

Wright (1931, 1969) also made fundamental contributions to the study of random genetic drift, the sampling that occurs each generation due to the finite size of populations. Genetic drift can pose challenges for breeding for two reasons: (1) it reduces genetic variation and thus reduces how well populations can respond to selection and (2) it can lead to the fixation of slightly deleterious alleles (Wright, 1931, 1969; Hartl and Clark, 2007). Drift is also strongest in small populations, which are typical of breeding populations. In his investigation of drift, Wright realized that its strength depends not just on the current size of the population, but also the population's sex ratio, fluctuations in population size, and the extent of variance in the numbers of offspring. Thus, he devised the metric of the effective population size (N_e), which standardizes the expected effect of genetic drift experienced by actual populations under different circumstances (Wright, 1931, 1969; Hartl and Clark, 2007; Crow, 2010).

Fisher and Wright both developed seminal statistical methodologies that laid the foundation for biometry, influencing both studies of evolution and breeding. Fisher's analysis of variance (ANOVA), a staple of biometry, uses properties of variances to determine statistical significance of differences between the means of various samples (Sokal and Rohlf, 1995). Wright (1921, 1968, Chapters 13 and 14) developed path analysis, an extension of multiple regression, that attempts to tease apart causation from correlation by measuring the influence of different factors on others in a system.

Heritability and the Breeders' Equation

Galton attempted to parcel out the influences of heredity (nature) and environment (nurture). Building on Galton's foundation, Fisher (1918) and Wright (1920) independently

(and through different methodology) formalized the concept of heritability as a quantitative measure of the proportion of phenotypic variation that is due to genetic factors (Lynch and Walsh, 1998; Visscher *et al.*, 2008).

There are several different types of heritability, but the one of greatest importance to breeders is 'narrow sense' heritability. This quantity is defined as the additive genetic variance divided by the total (phenotypic) variance and is usually represented as h^2 (Lynch and Walsh, 1998, pp. 170–175). Narrow sense heritability can be estimated from parent–offspring regressions, and is often used in making predictions about short-term responses to selection (Lynch and Walsh, 1998). Although nonadditive effects of genes are important in evolutionary genetics (Wright, 1968; Wade and Goodnight, 1998; Lynch and Walsh, 1998), only additive effects are directly transmitted from parent to offspring (Visscher *et al*, 2008). Because it is based on the additive genetic variance, narrow sense heredity is also directly related to Fisher's fundamental theorem.

Heredity is a concept fraught with misconceptions (Visscher *et al.*, 2008). A high heredity does not equate to genetic determinism because environmental changes could alter the phenotype. Moreover, heredities can and do change over time. In fact, a heredity value is specific to a given population with its distribution of genotypes, phenotypes, and environments (Lynch and Walsh, 1998; Visscher *et al.*, 2008).

That caveat aside, narrow sense heredities are informative in making short-term predictions about responses to selection. Jay Lush (1937), who was inspired by Wright and especially Fisher, expressed a quantitative expectation for the response to selection in each generation based on the narrow sense heritability of the trait and the strength of selection (Hill, 2014). Lush's expression, which is now known as the breeders' equation, remains an important concept in both breeding programs and evolutionary quantitative genetics (Lynch and Walsh, 1998).

A simple formulation of the breeders' equation is $R=h^2S$, where R is the response to selection in a single generation and S is the difference between the mean of the selected individuals and the mean of the population. For instance, suppose that a population of tomatoes has a mean weight of 150 g and the selected individuals have a mean weight of 180 g. If the heritability is 0.3, then the response should be $0.3*(180-150)$ or 9 g, and the next generation should have a mean weight of 159 g.

Another formulation of the breeders' equation is $R=\sigma_A^2 i$, where σ_A^2 is the additive genetic variance and i is the selection intensity (the selection differential divided by the phenotypic variance) (Roff, 2006). This formulation emphasizes the importance of additive genetic variance to the selection response.

Traits do not evolve in a vacuum, but instead are often associated and evolve with other traits. Using the phrase 'correlation of parts,' Darwin (1859) had noted that selection on one trait could influence the evolution of other traits. This correlated response is now known to be due to pleiotropy (genes having multiple effects) and/or genetic loci for different traits being genetically linked (Roff, 2006).

Both breeders (Hazel, 1943) and evolutionary quantitative geneticists (Lande and Arnold, 1983) have developed methods to deal with correlated responses to selection. In the multivariate breeders' equation, $\Delta z=\mathbf{G}B$, the expected responses to selection (Δz) is a vector and B represents the vector of selection intensities. **G**, which is sometimes called the G matrix, is the additive genetic variance–covariance matrix (Lande and Arnold, 1983; Roff, 2006). See **Box 1** for more detail about the multivariate breeders' equation.

Some traits change with age and condition. Both breeders (e.g., Kirkpatrick and Heckman, 1989) and evolutionary quantitative geneticists (e.g., Schaeffer and Dekkers, 1994) have developed methods to incorporate such traits in the breeders' equation.

Box 1 The multivariate breeders' equation

Consider the case where average weight of pigs (trait 1) and their protein content (trait 2) are negatively correlated, with a covariance of -0.5 units. The additive genetic variance of traits 1 and 2 are 0.8 and 0.2 respectively and the selection intensity is 0.2 for trait 1 and 0.1 for trait 2.

If there were no covariance between the traits, the response to selection for weight would be 0.16 and the response for protein content would be 0.02.

Expanding the breeders' equation $\Delta z=\mathbf{G}B$

$$\begin{bmatrix}\Delta Z_1\end{bmatrix} = \begin{bmatrix}\mathrm{Var}_1 & \mathrm{Cov}_{1,2}\end{bmatrix}\begin{bmatrix}\mathrm{B}_1\end{bmatrix}$$
$$\begin{bmatrix}\Delta Z_2\end{bmatrix} \quad \begin{bmatrix}\mathrm{Cov}_{1,2} & \mathrm{Var}_2\end{bmatrix}\begin{bmatrix}\mathrm{B}_2\end{bmatrix}$$

Substituting the values gives

$$\begin{bmatrix}\Delta Z_1\end{bmatrix} = \begin{bmatrix}0.8 & -0.5\end{bmatrix}\begin{bmatrix}0.2\end{bmatrix}$$
$$\begin{bmatrix}\Delta Z_2\end{bmatrix} \quad \begin{bmatrix}-0.5 & 0.8\end{bmatrix}\begin{bmatrix}0.1\end{bmatrix}$$

With matrix algebra, we find that $\Delta Z_1=0.11$ and $\Delta Z_2=-0.08$. With the negative covariance, the response to selection for weight is reduced and the response to selection for protein content is actually in the opposite direction of the selection. The extent to which these covariance structures constrain evolution and how G matrices themselves evolve in natural populations is still debated among evolutionary geneticists (Roff, 2006).

Breeding Value

Breeders aim to alter the genetic composition of populations over the course of generations to obtain desired phenotypes. In making decisions about which individuals to choose, breeders attempt to estimate the effects of the individual's genes on the trait of interest. Recall from Fisher's fundamental theorem and the breeders' equation above, that short-term selection responses are due to primarily to the additive effects of genes. The sum of the additive effects the individual's genetic loci define its 'breeding value' (Lynch and Walsh, 1998, p. 72). It is this quantity that breeders attempt to estimate.

Breeding values are seldom readily apparent, but instead need to be estimated, generally based on phenotypic information from the individual as well as that of its relatives. Charles Henderson, who as a graduate student at Iowa State was influenced by Lush and Hazel, pioneered estimation of breeding values. Henderson's (1950, 1975) best linear

unbiased prediction (BLUP) remains an important tool in breeding value estimation (Lynch and Walsh, Chapter 26).

Marker-Assisted Selection

The standard approach to estimating breeding value has been to use phenotypic and pedigree information (Henderson, 1950; Lynch and Walsh, 1998). Marker-assisted selection incorporates predictive phenotypic information from particular genotypes when making decisions about which individuals to select (Hayes and Goddard, 2010).

QTL Mapping

The goal of quantitative trait locus (QTL) mapping is to map loci that contribute to the value of a trait to small regions of chromosomes. Despite the name 'locus' in the name, QTL analysis generally maps traits to regions of chromosomes that often contain many (possibly hundreds of) genes. Although the idea of mapping quantitative traits to regions of chromosomes had been around since the early days of Mendelian genetics, widespread implementation of what is now called QTL mapping did not begin until the mid-1980s when molecular marker and computer algorithm technology had sufficiently matured (Lander and Botstein, 1989; Lynch and Walsh, 1998).

QTL analysis usually begins with crosses between parental lines that differ substantially in value for the trait. Although QTL analysis can be done with F_2 and/or backcross offspring, contemporary QTL analysis usually involves the creation of lines of numerous individuals each with similar genotypes at a particular region of the chromosome. Commonly used types of lines are recombinant inbred lines (RILs) and nearly isogenic lines (NILs). Molecular markers are generally used in the creation of these lines to identify genotypes (Lynch and Walsh, 1998, Chapter 14; Rothschild *et al.*, 2007). Next, individuals from these lines are evaluated for the trait(s) of interest. Given data on the traits from various lines, computational tools evaluate the value of the contributions of different chromosomal regions to each of the traits and their statistical significance (Lynch and Walsh, 1998). See **Figure 1** for an example of QTL results.

Given knowledge of which QTLs affect traits of interest, breeders can genotype individuals and use this genotypic information in assessing breeding value. The extent to which the added QTL information improves breeding value estimation depends on the quality of the analysis and the proportion of phenotypic variation that is explained by the QTL (Hayes and Goddard, 2010).

QTL analyses are limited in several respects. First, traditional QTL analyses require crossing between extreme lines and work best with the generation of inbred lines such as RILs and NILs. Such preparation is especially challenging for livestock. QTL analysis is also prone to bias from several sources (Lynch and Walsh, 1998). One such bias is that QTL analyses frequently substantially overestimate the magnitudes of effect sizes, especially when sample sizes are modest (Beavis, 1994). This so-called 'Beavis effect' is a statistical artifact that is a source of concern for both breeders and evolutionary biologists attempting to understand the genetic basis of their traits of interests (e.g., Slate, 2013). Another concern is that for most traits, QTL analyses capture only a fraction of the phenotypic variance (Hayes and Goddard, 2010).

Association Mapping and Genome-Wide Association Mapping

Evolutionary geneticists, medical geneticists, and breeders also use a related strategy to genetically map traits. This mapping analysis, which is known as association mapping, does not require crosses between extremes and the generation of inbred lines, but instead relies on past recombination events that have occurred in the population.

Association mapping looks for associations between alleles at molecular markers and the traits of interest. If the markers are from across most or all of the genome, the study is known as genome-wide association mapping or GWAS. These markers may not have any causative bearing on the trait, but they are associated with trait. This association arises because the markers are correlated with the actual causative genetic variants. This genetic correlation, which is known as linkage disequilbrium (LD), makes markers useful to evolutionary geneticists and breeders. (For this reason, association mapping is sometimes called LD mapping.) Given knowledge about the allele an individual has at a marker locus in LD with the causative genetic variant, one can infer which allele at the causative locus the individual has. Thus, these markers can inform estimation of breeding values (Hayes and Goddard, 2010).

Development and application of GWAS requires understanding LD patterns, which in turn requires population genetic theory (Hartl and Clark, 2007). For instance, the effective population size (Ne) plays a major role in shaping LD patterns. Because allele frequency changes via genetic drift generate LD, the extent of LD is inversely related to Ne (Sved, 1971; Hartl and Clark, 2007). The application to association mapping has brought LD from obscure theory to one of the fundamental concepts of population genetics (Slatkin, 2008).

Genome Selection

Like traditional QTL analyses, GWAS poses statistical challenges. Often in GWAS, the total variance explained by statistically significant markers is modest. This limits the application of GWAS for estimating breeding values (Hayes and Goddard, 2010). One way around this limitation is to use all of the markers from GWAS, and not just the statistically significant ones, in calculation of breeding values. This approach is known as genome selection (Meuwissen *et al.*, 2001; Hayes and Goddard, 2010).

Genome selection will be particularly useful for certain traits: (1) those that are expressed only after breeding decisions have been made, including traits whose measurement require destruction of the individual, (2) those that are expressed only in a single sex (e.g., milk yield), and (3) those that are difficult to measure (Hayes and Goddard, 2010). Because it uses information directly from genotypes instead of patterns of relatedness, genome selection should minimize the effects of

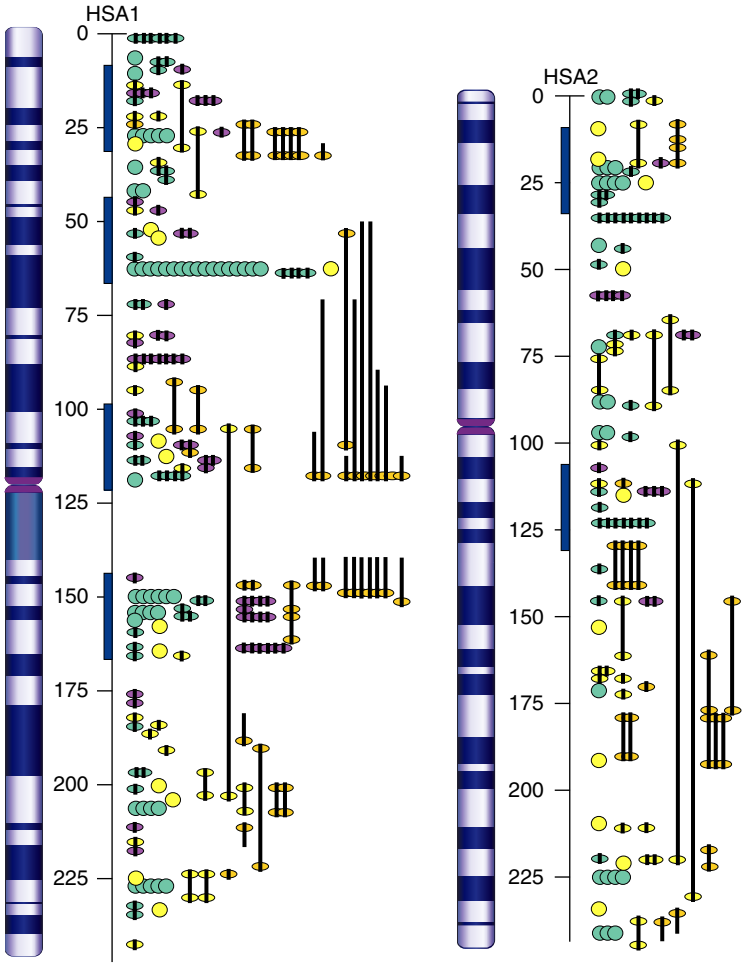

Figure 1 The results of QTL analysis. For each column, on the left are positions mapped on the various chromosomes with affected traits on the right. Note only two chromosomes are shown here. Reproduced from Rothschild M.F., Hu, Z.I., Jiang, Z., 2007. Advances in QTL mapping in pigs. International Journal of Biological Sciences 3, 192–197.

inbreeding and associated inbreeding depression in comparison to methods that employ pedigrees to estimate breeding values (Daetwyler *et al.*, 2007).

Hayes *et al.* (2009) present a promising use of genome selection to ameliorate the negative effects of human-induced climate on agricultural crops and livestock. One particular concern is how milk yield of cows in hot, arid regions, like much of Australia, will be affected by further increases in temperature. Hayes *et al.* (2009) noted that genetic variation exists in cattle with respect to sensitivity to heat. They then used GWAS to demonstrate how genome selection can be used to select for more heat-tolerant cattle. This analysis revealed several SNPs that are associated with lower slopes between milk yield and the temperature–humidity index, and thus indicative of greater tolerance. Breeding programs now can use this additional information.

Long-Term Selection

The breeders' equation and its extensions were formulated to make short-term predictions about responses to selection, both artificial and natural. These tools were not designed for predicting or explaining long-term selection responses (Barton and Turelli, 1989; Lynch and Walsh, 1998; Roff, 2006).

Although evolutionary biologists are generally more interested in long-term selection than are breeders, there are exceptions. Long-term artificial selection is important to on-going breeding programs, and thinking about how to implement them. For instance, how intense should selection be? Robertson (1960) noted a potential trade-off between short-term and long-term selection. More intense selection will generally lead to a faster short-term response, but this will come at a cost: intense selection reduces the effective population size of the breeding population and that limits the potential long-term response. Evolutionary theory shows that extent to which selection will reduce Ne will be inverse proportion to the recombination rate (Hill and Robertson, 1966, 1968; Hartl and Clark, 2007).

One well-known long-term experiment is the Illinois long-term selection experiment (Dudley, 2007). Started by C.G. Hopkins in 1896, it has been selecting on maize traits for well over a century, with a single generation per year. Selection has been imposed for both increases and decreases in both oil and

protein content. The lines selected for decreased oil (low oil) and decreased protein (low protein) stopped responding to selection after about 75 generations, but the lines selected for increased oil (high oil) and increased protein (high protein) continue to respond. The selection response has been dramatic. At the start, the lines contained about 5% oil. The high-oil lines now have around 20%, and the low lines have around 1%.

Why can responses in the Illinois long-term selection experiment continue? Genetic variation should have been exhausted a long time ago. Yet, additive genetic variation in the high-oil and high-protein lines is still abundant (Dudley, 2007). Likely multiple factors explained the continued response. These include the founding population being conducive to long-term selection because it had ample variation with many loci at low allele frequency contributing to the traits. Additional factors likely include the input new mutations and the conversion of genetic variance caused by gene interactions (epistasis) into additive genetic variance (Dudley, 2007; see also Goodnight, 2004). This conversion of genetic variation due to epistasis into additive genetic variance is an on-going subject of evolutionary genetics (Wade and Goodnight, 1998; Visscher *et al.*, 2008).

Social Interactions and Indirect Genetic Effects

Organisms interact with conspecifics and these interactions can substantially traits. These social interactions are part of the individual's environment, and both affect the evolution of individuals and can be shaped by evolution (Bleakley *et al.*, 2010). In social evolution, an individual is not only influenced by its own genes, but also by genes of conspecifics. Such influences are known as indirect genetic effects. Recent evolutionary theory has incorporated indirect genetic effects into the breeders' equation (reviewed in Bleakley *et al.*, 2010). Many agricultural researchers have found social interactions giving considerable contribution to traits of interest, including growth rate in pigs and survival time of laying hens (reviewed in Wade *et al.*, 2010). Interestingly, body weight in cannibalistic quail has a large variance due to indirect genetic effects and there is a negative correlation between direct and indirect genetic effects, complicating selection experiments (Wade *et al.*, 2010).

Selecting on the performance of groups of individuals (instead of individual performance) is a way to incorporate social evolution into breeding designs without direct estimation of indirect genetic effects. In a seminal evolutionary genetic study, Wade (1977) showed that selection on groups of flour beetles for productivity led to responses that could not have been predicted by responses from individual-level selection.

Muir (1996) used an approach similar to Wade's studies of flour beetles to select on groups of chickens. Here, hens from each sire family were caged together and the cage performance (egg production) was used to select or reject the group as a unit. Over the course of this experiment, group egg production increased dramatically, while mortality declined. The responses in multi-hen cages were faster than those in single-hen cages, illustrating the power of such group-level selection. Other examples of agricultural applications of group selection can be found in Wade *et al.* (2010).

Genomics and Effects of Domestication

Evolutionary genomic studies can reveal the genes that have been under selection during domestication as well as the overall genomic effects that occurred due to domestication. Flint-Garcia (2013) found that domestication of maize from teosinte led to a modest decrease in overall genetic variation, but a severe loss of genetic variation in the loci that were presumably selected during domestication.

Similarly, a recent study of sunflowers found that cultivated varieties have accumulated more missense mutations and putatively deleterious mutations compared with wild varieties (Renaut and Rieseberg, 2015). Determination of which mutations are likely to be deleterious is based on bioinformatic criteria commonly used in molecular evolution. Interestingly, the presumptively deleterious mutations were clustered in regions of low recombination (Renaut and Rieseberg, 2015), consistent with evolutionary theory (Hill and Robertson, 1968; Hartl and Clark, 2007). In maize (Flint-Garcia, 2013), sunflowers, and likely other crop species, the progenitor species could be useful as a source of genetic variation to be used for further breeding studies.

Concluding Remarks

The mutualistic relationship between breeders and evolutionary geneticists that began in the mid-nineteenth century is likely to persist over the coming decades. Both are engaged in comparative genomic and population genomic studies, and the development of the associated tools and resources. Improving association mapping studies continues to be a pressing need across many scientific communities. Long-term predictions of responses to selection and how the **G** matrix evolves will continue to interest both breeders and evolutionary geneticists.

Despite the mutualistic relationship, the aims of breeders and evolutionary geneticists are not perfectly aligned. As Hill and Kirkpatrick (2010, p. 2) note: "The breeder is looking forward and wants to know how to make rapid and continuing changes in desired directions, whereas the evolutionary biologist is primarily looking back and wants to understand what forces caused the changes that have occurred and shape the current population".

Evolutionary Biology, History of

VB Smocovitis, University of Florida, Gainesville, FL, USA

Introduction

Evolutionary biology is widely considered to be the scientific discipline devoted to understanding the origin and maintenance of biological diversity; it is the area of inquiry directly concerned with evolutionary processes leading to the origin of new species, and with descent from shared ancestors. Because of its central location in the disciplines of knowledge, the belief is commonly held that evolutionary biology serves a unifying function, integrating the diverse disciplines of knowledge, although the extent to which it unites, or reduces the social sciences and even humanities to the biological and physical sciences has drawn more than its share of controversy (see Wilson, 1998, for one instance of how these unifying properties are thought to inform the humanities; see Mayr, 1982, 2001, for more on evolution and its unifying properties).

Although the study of evolution is most commonly associated with names such as Charles Darwin (1809–1882) and Alfred Russel Wallace (1823–1913) in the nineteenth century, it reached the status of scientific, unifying discipline embodying rigorous methods including experimentation and quantification, only in the first few decades of the twentieth century, and accompanied the establishment of the modern or 'synthetic' theory of evolution during the period of 'evolutionary synthesis' (Smocovitis, 1996; and see Mayr and Provine, 1980, for more on the 'evolutionary synthesis').

Etymological research into the origins of the term 'evolutionary biology' confirms its recent origin. The first recorded use of the term, more precisely the identifying label, 'evolutionary biologist' appears to have been in 1881, in a passage from English naturalist Grant Allen's *Vignettes from Nature*, in a passage reading: "and it is these self-same odd, overgrown outer flowers which make the guilder rose so interesting a plant in the eyes of the evolutionary biologist" (Allen, 1881, p. 93). The term was first used in 1912 in the title of the book *Outlines of Evolutionary Biology* by English zoologist Arthur Dendy and then again in 1938 by English embryologist Gavin de Beer in his *Essays on Aspects of Evolutionary Biology Presented to E. S. Goodrich* (de Beer, 1938). Thus, though the term was used in obscure contexts as early as the late nineteenth century, and had some limited use in the first couple of decades of the twentieth century it began to gain currency and used in its present disciplinary formulation during the interval of time between 1930–1950. It was used especially heavily by English zoologist, Julian Huxley (1887–1975), whose 1942 book titled *Evolution: The Modern Synthesis*, announcing the synthesis between Mendelian genetics and Darwinian selection gave name to this critical period in the history of evolutionary thought (Huxley, 1942).

The Origins of Evolutionary Thought

Evolutionary thought itself had a much earlier origin and grew out of a concern with the problem of change, especially organic change, beginning in antiquity and associated with thinkers like Heraclitus (*c*. 540–*c*. 480 B.C.E.), who believed that change was a fundamental property of the universe, and Empedocles (*c*. 490–430 B.C.E.), who formulated a crude but dynamic theory for the origin of life that suggested organic change. Concern with organic change fell into disfavor with the philosophical worldview of Aristotle (384–322 B.C.E.), his many translators, commentators, and supporters, who believed in a static universe and that the world had been created by a designer (the so-called Demiurge of Plato's *Timaeus* or the biblical Creator) that then remained essentially unchanged. The diversity of life on earth was frequently seen in terms of idealized types, or species that were arranged hierarchically in the 'ladder' of creation, or what came to be called the *scala naturae*. During the early modern period, this metaphor began to give way to the 'great chain of being,' which referred to a progression of living forms, or species, linked chain-like in an orderly fashion. Extinction, or the sudden disappearance of a species was therefore unthinkable as it meant a break in the chain of life. Belief in the fixity of species and in idealized types seen in strict relation to each other dominated thinking about living organisms and was most clearly demonstrated in the modern classification scheme associated with Carolus Linnaeus (1707–1778) (Mayr, 1982; Bowler, 2009).

The belief in species change or 'transmutationism,' as it came to be called, began to emerge in the period of the Enlightenment after the growing recognition that the earth was much older than previously believed and that fossils, long thought to be curiosities or 'sports of the creator,' were in fact of organic origin. The shift toward a progressive view of the world in both social and scientific terms also helped fuel the belief in transmutationism as did the many geological theories that began to entertain uniformitarian instead of catastrophist views (Bowler, 2009).

Uniformitarianism and transmutationism were associated most closely with the French naturalist George-Louis Leclerc, Comte de Buffon (1707–88) whose forty-four volume treatise in natural history known as *L'histoire Naturelle* (or *Natural History*) suggested a theory of species change (Roger, 1997). Although Buffon was a respected naturalist, he did little to convince the community of his insights, in part because of his own writing style which often appeared confused, but also because he provided no real convincing evidence in support of his theory of species change. He was also undercut by the philosophical teachings of his successor Georges Cuvier (1769–1832), who was a staunch catastrophist and anti-uniformitarian and who thought successive revolutions had given rise to the pattern and diversity of life on earth. Ironically, he was the first to recognize the phenomenon of extinction, or the view that biological species had disappeared from the biological record, while all the while upholding the fixity of species.

The first viable theory of transmutation was associated with another French zoologist, Jean-Baptiste de Lamarck

 doi:10.1016/B978-0-12-800049-6.00001-9

(1744–1829). He was a contemporary of Cuvier's and faced notable opposition from him. Trained in botany, Lamarck was given the task of organizing the invertebrate collection at the Musée National d'Histoire Naturelle in Paris. It was while organizing the material, that his attention was drawn to particular trends in the group that appeared to be progressive in nature. He was especially intrigued by the phenomenon of adaptation, or the manner and process by which organisms adapted to their environment in both physiological and morphological terms. He became especially interested in how well-adapted organs originated and for this reason is most closely associated with the example of the adaptive modification in the neck of the giraffe, which became elongated in response to stretching during feeding on the leaves of trees on the African savannah. According to Lamarck, the use or disuse of such organs could lead to the origin of novel, but well-adapted traits, the cumulative effect of which could eventually lead to new species. Lamarck never really provided a cogent mechanism by which this transformation happened, though he drew on contemporary theories of physiology to explain the physical transformation of the organ (Burkhardt, 1977). Lamarckian transmutationism, which became known as 'Lamarckism' or the inheritance of acquired traits, was subsequently shown to be wrong because such changes lacked heritability, though it resurfaced periodically despite the celebrated experiments of the German biologist August Weismann (1834–1914) who famously cut off the tails of hundreds of mice hoping to generate tailless mice.

Transmutationism became increasingly acceptable in the early decades of the nineteenth century and could be seen in the thinking of the French anatomist Étienne Geoffroy Sainte Hilaire (1772–1844) whose interest was in the science of birth defects and their sudden origin, as well as Erasmus Darwin (1731–1802), Charles Darwin's grandfather, who suggested that life had originated from 'one living filament' in the *Zoonomia* (1794–96). Remarkably, a number of individuals began to search for mechanisms of species change that closely resembled natural selection well in advance of Charles Darwin. As early as 1813, for example, William Wells suggested that new human races originated when groups moved into new environments requiring adaptation to conditions of life and in 1831 Patrick Matthew came even closer to formulating a view of natural selection in an obscure treatise *On Naval Timber and Arboriculture*; Matthew suggested that catastrophic extinctions of species took place leaving behind hardy survivors that would in turn diversify, giving rise to better adapted species. But by far the outstanding example of the importance of transmutationism in the first half of the nineteenth century, was a book published in 1844, at first anonymously, by Robert Chambers and titled *Vestiges of the Natural History of Creation.* Marketed widely, the book became an instant sensation to very wide Victorian audiences who entertained a provocative, and at times scandalous theory for the origins of the solar system and the origins of humanity, which postulated evolution from the apes (Secord, 2000). Though it was widely discussed, it also drew heavy criticism from the scientific community. The criticism was so devastating that this was one reason that Charles Darwin, who by then had formulated his own theory of species change, was dissuaded in delaying publication of his own theory for some 15 years (Browne, 1995).

Charles Darwin and Descent with Modification by Means of Natural Selection

Charles Darwin was, of course, the leading transmutationist of the nineteenth century. He sought a general explanation for his observations of the natural world following his celebrated 5 year voyage aboard the H.M.S. Beagle. Between 1837 and1838, regarded as the crucial years in the formulation of his theory that followed his return to England, Darwin read Thomas Malthus's (1766–1834) *Essay on the Principle of Population*. This essay provided Darwin with the backdrop for his theory by suggesting that competition for natural resources was a fact of life and that populations remained stable as a result of a complex set of processes involving checks and balances. In such a competitive world, those organisms with favorable heritable variations would survive and reproduce themselves. With enough time, such a process would lead to divergence, with new species arising from ancestral forms. The novelty of Darwin's theory thus lay in his appropriation of the competitive struggle for existence from Malthus, but also in his emphasis on heritable variation that conferred an advantage, and that would ultimately be transmitted to the progeny (Browne, 1995).

Darwin's own theory, which he called 'descent with modification' by means of the primary, though not sole means of natural selection therefore drew heavily from his many predecessors, and did not emerge in a sudden 'aha' moment while making observations in the Galapagos during his celebrated voyage on the H.M.S. Beagle. Recent scholarship on Darwin and the history of evolutionary thought has given us a more nuanced and complex portrait of how his theorizing emerged in the context of engaging the work of not only his predecessors but also his contemporaries like the geologist and uniformitarian Charles Lyell (1797–1875) and naturalists like Robert Edmond Grant (1793–1874), along with scores of other naturalists like German-Brazilianist Fritz Müller (1821–97) who worked on a staggering diversity of living forms and geographic contexts (West, 2003). On a more domestic front, Darwin also followed popular breeding practices, especially tracking the pigeon fancy craze in Victorian England; this was to provide him with immediate familiar examples of artificial selection in demonstration of his own natural selection (Secord, 1981). He also embarked on a careful study of the systematics of barnacles at this time. This was likely meant to buttress his own theory but also earn him his credentials as someone who had committed to a close taxonomic study of a group of organisms.

The 20 years roughly between the formulation of his theory and its final publication was thus well spent on sharpening his thinking, earning his credentials, and garnering support as well as evidence to buttress what he knew would be a controversial theory. He also spent a great deal of time anticipating criticism and forming arguments in defense of his theory, well in advance of receiving it. Indeed, had he not been approached in benign and casual manner by Alfred Russel Wallace (1823–1913) a younger naturalist, who had independently formulated his own theory of species change resembling Darwin's, he probably would not have published *On the Origin of Species* in 1859, which was merely intended to be an 'abstract' of what he was ambitiously planning to be a larger work.

After consultation with a group of distinguished Victorian naturalists that included Darwin supporters, such as Charles Lyell, and Kew Garden botanist, Joseph Hooker (1817–1911), the two jointly published an early formulation of their theory in 1858. With good reason, some scholars now refer to the 'Darwin–Wallace' theory of evolution, which is inclusive of Wallace's many contributions especially on the topic of island biogeography, which is now informing contemporary understanding of conservation biology (Quammen, 1996; Fichman, 2004). Evolution itself, as a term for the general theory of descent with modification was not used by either individual initially, but gained currency only shortly after the publication of Darwin's book in 1859. Its currency is owed to the use of the term by Darwin's contemporaries like social evolutionist Herbert Spencer (1820–1903) as well as Darwin's most famous advocate and celebrated 'bulldog,' Thomas Henry Huxley (1825–95). A little known fact is that only at the very end of his long treatise did the word 'evolve' appear; until then the term evolution, which meant 'unrolling or unfolding' was mostly associated with embryology (Bowler, 1975, 2009).

Because of his keen insights, abundant examples, and his literary and rhetorical flourish, Darwin is now regarded as the giant of evolutionary theory and his name is nearly synonymous with it. But clearly he was not alone in this and drew heavily from the community of scientists engaged with similar concerns. Nor was his theory entirely complete; he spent the remainder of his life collecting more evidence in support of it or in highlighting special concerns revising and rewriting his *On the Origin of Species* into some six editions. Most of Darwin's original books after 1859 were actually botanical in nature, some heavily experimental, and some meant to bolster his theory (Browne, 2002). His studies on orchids, for example, not only capitalized on the availability of the plants in an era obsessed with them, but was also meant to study the adaptive functions of the many 'contrivances' in a group known for its stunning morphological diversity. His attempt to apply his theory to humans and to human social evolution led to the publication of his *Descent of Man* in 1871, which was also a prolonged discussion of sexual selection, a kind of amendment to natural selection. Here it should be noted, that he held a fundamental difference of opinion with Wallace (Gayon, 1998).

Most importantly Darwin embarked on an examination of the study of variation and its origins, publishing *The Variation of Animals and Plants under Domestication in 1868*, which included his celebrated 'provisional hypothesis of pangenesis,' a theory of heredity, that while appropriate to his thinking, turned out to be wrong. Darwin did not actually have a viable theory of heredity, one that required a particulate instead of a blending theory, and that remained one of the fundamental weaknesses of his theory. Remarkably, he also did not have adequate direct support for natural selection. His examples in *On the Origin of Species*, for example, were either 'imaginary' illustrations or were indirect in nature such as the evidence from biogeography. Thus, though Darwin, along with others – convinced the world that species change and organic evolution had taken place in a mechanistic and orderly fashion, he lacked deep knowledge of heredity as well as good examples of the actual means by which that took place. Darwin in fact included several other means by which species change could take place, including the inheritance of acquired characters, or Lamarckism. By the end of the century, even advocates of Darwin's theory offered a number of amendments, interpretations, and alternative theories. Indeed so many people extended, appropriated, or reinterpreted Darwin's own views, especially as they applied to humans and to human social evolution, sometimes inventing entire areas of science, or more correctly pseudosciences such as eugenics (a theory of human 'improvement') or social Darwinism that many scholars have drawn the distinction between Darwin, Darwinism, and Darwinisticism (Peckham, 1959).

The Eclipse of Darwin and the Modern Synthesis of Evolution

The interval of time after Darwin's death, and around the turn of the century is thus regarded as a historical moment characterized by widespread discussion of Darwinism, that was often confused, and at times even anti-Darwinian in outlook (Bowler, 1983). A number of theories were proposed including a return to a belief in the inheritance of acquired characters, or neo-Lamarckism, or directed evolution, which upheld the view that evolution was guided by an internal driving force; and even creative evolution, a kind of mystical evolutionary theory put forth by French philosopher Henri Bergson (1859–1941). Indeed, some have even claimed that some of these theories were non-Darwinian or at times even anti-Darwinian (Bowler, 1988). This was so much the case that Julian Huxley (1887–1975), the grandson of Thomas Henry Huxley, designated this interval of time as the 'eclipse of Darwin' in 1942 (Huxley, 1942; Bowler, 1983). This was certainly true of the mutation theory (also called mutationstheorie) a popular theory associated with the Dutch botanist Hugo De Vries (1848–1935) who argued for rapid or saltationist species change due to the phenomenon of mutation pressure. This formulation thus gave Darwinian natural selection merely an eliminative instead of a creative role, and contrasted with Darwinian views of evolution taking place slowly and gradually on small, individual differences. It is one of the ironies of the history of science that de Vries was one of the three codiscoverers of Mendel's theory of heredity in 1900, along with Eric Tschermak (1871–1962) and Carl Correns (1864–1933), so that Mendelism, which actually supplied the particulate theory of inheritance needed by Darwin, was instead seen to bolster a rival mutation theory. Mutation theory also had the additional strength of being experimental in methodology and therefore more rigorous; Darwinism, was increasingly seen as descriptive and came to be associated with statistical data collection and analysis. It was associated with the school of Biometricians, who, for methodological, intellectual, and even personal reasons began to clash with the proponents of Mendelism. Thus ensued one of the most celebrated and counter-productive episodes in the history of evolution, which witnessed a number of feuds and misunderstandings, over the means and mode of evolution (Provine, 1971). The truth was that variation, and its origin, was incompletely understood, hence the hypothesizing over 'mutation pressure' as a way of generating biological novelty.

Only after a series of developments, that included the death of many of these argumentative individuals, and the

development of new mathematical techniques and methods, such as the 'Hardy–Weinberg Equilibrium Principle,' which determined the conditions under which there would effectively be no evolutionary change, did a proper synthesis between Mendelian genetics and Darwinian selection theory began to take place. The application of mathematical and indeed statistical methods, which viewed natural selection, genetic drift, and even mutation as interacting variables within varied population structures, eventually set the stage for what would become the new or modern synthesis of evolution and lead to a kind of restoration of a modified or synthetic view of Darwin's original theory of 1859. The work of three mathematical population geneticists in particular, R. A. Fisher (1890–1962), Sewall Wright (1899–1988) and J. B. S. Haldane (1892–1964) working in tandem with field practitioners and experimentalists such as E. B. Ford (1901–88) and Theodosius Dobzhansky (1900–74), thus laid the foundations for the synthetic theory of evolution (Provine, 1971). Though there were notable differences of opinion about the relative importance of these variables within varied population structures, all agreed that the alternatives proposed at the turn of the century were diminished if not eliminated outright; indeed they became alternative, once natural selection was established as the primary mechanism of evolution.

Although historians of science have tended to favor the contributions of one or more of these individuals, most agree that Theodosius Dobzhansky, a Russian émigré, played an especially critical role in establishing the new field of evolutionary genetics (Adams, 1968, 1980). Trained in systematics in Russia in what was a kind of ecumenical and population-oriented approach to understanding variation in natural populations, Dobzhansky moved to study classical genetics in the laboratory of Thomas Hunt Morgan (1866–1945) in the United States (Provine, 1981). He then took this latest laboratory understanding of transmission or classical genetics to the field through his studies of the genetical structure of field populations of varied related species of *Drosophila*. Engaging in a close collaboration with the theoretical understanding of evolution by the mathematical population geneticist Sewall Wright, Dobzhansky brought evolutionary theory to the field and to natural populations, gaining new insights into population structure and in the genetic basis of evolutionary processes such as speciation (Provine, 1986). Dobzhansky's (1937) book, the culmination of his efforts to understand speciation in natural populations and titled *Genetics and the Origin of Species*, was thus intended to redress the absence of the genetic basis for evolutionary change in Darwin's (1859) book. It was widely read, and highly influential, shaping an entire generation of younger workers entering what was an emerging field that drew on both genetics and systematics and emphasized the populational aspects of species change. This was so much the case, that it also functioned as the first textbook of evolutionary biology bringing new practitioners to the field.

The Convergence of Biological Disciplines and the Emergence of Evolutionary Biology

Dobzhansky's book also functioned as a kind of catalyst for the publication of other synthetic books that built on, amended, or extended the views set forth in *Genetics and the Origin of Species* and that served to bring a number of related disciplines to consensus (Mayr and Provine, 1980). These books included Ernst Mayr's (1904–2004) 1942 book *Systematics and the Origin of Species*, that brought systematics into the synthesis and set forth the modern biological species concept; George Gaylord Simpson's (1902–84) 1944 *Tempo and Mode in Evolution* that brought the paleontological record, a serious problem for Darwin, in line with the modern synthesis of evolution; and G. Ledyard Stebbins's (1906–2000) 1950 *Variation and Evolution in Plants*, that offered a synthesis of knowledge that had accumulated in plant genetics, systematics, and evolution and that resolved fundamental problems of variation in the plant world. Finally, Julian Huxley's (1942) book, *Evolution: The Modern Synthesis* appeared, signaling the emergence of a new and modern view of Darwinian evolution. Indeed, more than any other, this book heralded the new synthesis of evolution between Mendelian genetics and Darwinian selection theory and it did so in a way that supported a progressive but also mechanistic view of evolution that was palatable in terms of its sociopolitical outlook. The book reached wide audiences and gave the name 'modern synthesis' to the new understanding of evolution that incorporated Mendelian genetics and Darwinism in a populational way of thinking.

The growing consensus on evolution by means of natural selection along with the integration of a number of disciplines grounded in evolutionary genetics and looking to each other for new insights and methods, was also accompanied by new organizational activities that provided opportunities for intellectual exchange. Starting as early as the mid-1930s, groups of workers came together informally at first, to discuss some of the new trends in evolution (Smocovitis, 1994). In the United States (increasingly the locus for evolutionary activities), in the San Francisco Bay area, a group of primarily systematists looking to new understanding from genetics and ecology organized themselves into an informal scientific society they called the 'Biosystematists.' Echoing the call from Julian Huxley for a 'new systematics' that integrated these new approaches, the group included people like Theodosius Dobzhansky who was a frequent visitor to the Bay area. In 1939, many of these systematists were active participants at a meeting of the American Association for the Advancement of Science, where they organized a formal society for the new systematics called Society for the Study of Speciation. In 1943, a group on the east coast comprised mostly of paleontologists formed the Committee on Common Problems of Genetics and Paleontology, later changing their name to the Committee on Common Problems of Genetics, Paleontology, and Systematics. During the war years, when meetings were difficult, members shared their conversations with each other and interesting new insights in the form of mimeographed bulletins that they circulated with each other. The very last bulletin included a special notice from G. G. Simpson, newly returned from service in the war, that 'a field common to the disciplines of genetics, paleontology, and systematics' had recently come into existence that was 'beginning to be defined.' (Simpson, 1944). In 1946, shortly after the war, members from these varied groups came together in St. Louis, Missouri in agreement to found a formal scientific organization devoted

to the study of evolution known as evolutionary biology. After much deliberation they chose the name of Society for the Study of Evolution, which sponsored the new journal titled *Evolution*. It was the first international journal devoted to the subject (Smocovitis, 1994, 1996).

Shortly thereafter in 1947, on the occasion of Princeton University's Bicentennial, an international assemblage of evolutionists from a staggering diversity of backgrounds convened at a meeting devoted to the new synthetic science, and began to explicitly reidentify themselves as evolutionary biologists. The proceedings of the meeting, edited by Glenn L. Jepsen, G. G. Simpson, and Ernst Mayr titled *Genetics, Paleontology and Evolution* published in 1949 made reference to this new 'synthetic field' which represented a fusion of a number of independent disciplines. Writing one of the better known essays in the collection, geneticist Hermann J. Muller (1890–1967) stated that there had been a "convergence of evolutionary disciplines." He noted that there had been convergence of evolutionary types, such as between paleontologists and geneticists to form a 'synthetic' type of evolutionist (Muller, 1949:421). Most importantly, he noted what had made this possible was a 'common ground of theory' that served to unite formerly disparate areas. The fundamental points of agreement included that: (1) natural selection was the primary mechanism of evolutionary change; (2) it operated at the level of small individual differences, making evolution a slow, gradual process; (3) the same processes that operated at lower levels also accounted for higher order phenomena; in other words there was a continuum between microevolution and macroevolution. Muller then echoed Julian Huxley's insights in his 1942 book noting that a more unified science of evolution had emerged and that it served as the unifying principle of the whole of the biology – hence the choice of name evolutionary biology, for the new discipline that came to be commonly used around this time (Smocovitis, 1996).

The Watershed: The Darwin Centennial and After

By 1959, most of the critical developments leading to a scientific discipline of research called evolutionary biology had therefore taken place. This was just in time for the 100th anniversary of Darwin's *On the Origin of Species* that also corresponded with the 150th birthyear of Charles Darwin. At this time, members of the new synthetic science of evolutionary biology came together all over the world in contemplation, reflection, and celebration over Darwin's theory. Until then, little actually existed in the way of historical scholarship on Darwin and his theory, but after the Darwin Centennial, a number of biographies of Darwin began to appear and a rich body of literature began to accumulate (Smocovitis, 1999).

So too, a number of other developments happened to bring in additional disciplines to resolve long standing concerns. Human evolution, for example, had been barely mentioned by Darwin in his 1859 book, and was not properly included even in the evolutionary synthesis of the preceding decades. This, despite the fact that individuals like R. A. Fisher were attempting extensions of the synthetic theory to areas like eugenics. In the 1940s, it fell to Dobzhansky to help integrate biological anthropology into the synthetic theory (Dobzhansky, 1941). Again, it was his emphasis on populations and his background drawn from Russian population genetics that facilitated this. He drew on the notion of 'gene pool,' (a concept derived from his Russian mentors) as a replacement for 'race' or 'racial type.' In doing this, Dobzhansky deftly eliminated the criticism made by cultural anthropologists like Franz Boaz, and his influential school of anthropology, that evolutionary theory attached to humans necessarily essentialized and racialized humanity (Smocovitis, 2011).

By 1959, an additional set of new of disciplines – and individual practitioners – were drawn to evolutionary study. After the articulation of the structure of DNA in 1953 and after the celebrated experiments of Stanley Miller (1930–2007) and Harold Urey (1893–1981) established the biochemical basis for the origins and evolution of early life in the same year, even more scientists entered the study of evolution. This was evident at the many events organized in honor of the Darwin centennial, at places like Cold Spring Harbor, but especially at the University of Chicago that hosted the largest celebration of all. Organized by anthropologist Sol Tax, the five-day event was designed to bring all the scientific disciplines together in a spirit of unity made possible by the synthesis of evolution, but to also allow the process of unification between disciplines to continue especially between areas like anthropology as well as to open discussion of topics like the evolution of mind, culture, and even the evolution of the physical world (Smocovitis, 1999).

From the large number of attendees, to the international attention garnered by the Darwin Centennial at the University of Chicago, indications were that it was a great success, and for the most part consensus appeared to dominate discussions. Some participants, however, viewed this as an unhealthy sign of a growing orthodoxy. Years later a similar point was made by paleobiologist Stephen J. Gould (1941–2002) who saw the 1959 consensus around natural selection as the 'hardening' of the synthesis around a selectionist core (Gould, 1980, 1983). But while consensus and unity appeared to exist, some disciplines such as embryology, or developmental biology appeared to be left out of the synthetic theory (Waddington, 1953; Amundson, 2005); and even paleontology appeared to be incompletely integrated (Olson, 1960). Criticisms aside, the Darwin centennial celebration does reveal the extent to which evolutionary biologists, indeed evolutionary scientists, had endorsed evolution by means of natural selection, who began to also recognize that evolution served as a unifying or organizing principle of the whole of the biological sciences, and indeed within a unified theory of knowledge. Taken as a whole, the year 1959 and the opportunity to reflect on Darwin and his science represented a kind of watershed demarcating the struggle to establish Darwin's theory of evolution by means of natural selection with the emergence of the new science of evolutionary biology. That new science was growing rapidly, especially in the wake of the Darwin centennial year. By the end of the 1950s, membership in the Society for the Study of Evolution began to spike, despite the increasing resistance, especially in the United States of America from creationists who were galvanized into action as a result of the lavish attention given to Darwin and evolution (Smocovitis, 1994, 1999).

Evolutionary Biology in the Post-Sputnik Area and Challenges to the Synthetic Theory

The biological sciences as a whole began to boom in the Cold War era. Funding for research began to increase significantly especially in the United States of America, which dominated the world stage at this time. New directions in biological research especially from the discovery of the structure of DNA in 1953, as well as new techniques made available in sciences like biochemistry and genetics were at first only slowly integrated by evolutionary biology. Indeed, in some circles, the emphasis on molecular biology and its philosophy of reductionism caused initial tumult for many evolutionary biologists who felt that the autonomy of biology was challenged as it stood to be engulfed by the physical sciences (Mayr, 1982; Wilson, 1996). For some, a series of 'molecular wars,' broke out between the younger molecular biologists and biochemists and the older, established evolutionary biologists, as the two disciplines appeared to collide. The friction between the two areas – and the protection of the lesser funded evolutionary biology – was resolved by a process of fission separating or cleaving the two halves of biology, one molecular and the other organismic (Smocovitis, 1996). As a result, beginning in the late 1960s, entire departments of organismic biology began to spring up, many focusing on 'ecology and evolutionary biology,' or 'ecology, evolution, and behavior,' offering doctoral degrees in the area, and enrolling even more practitioners to evolutionary biology.

Whatever the initial tension between the two disciplines, newer methods and critical insights made their way into evolutionary biology leading to a new area of research traveling under the new banner of molecular evolution. It began to dominate the study of evolution, posing a series of challenges to the synthetic theory of evolution, and culminating with the views of Japanese geneticist Motoo Kimura (1924–94) and others who argued that the vast majority of variation seen at the molecular level was due to random genetic drift and mutation and not to natural selection, which acted merely in a negative or eliminative role. They began to cast doubt on the primacy of natural selection as the driver of evolutionary change. In 1983, for example, in a book titled *The Neutral Theory of Molecular Evolution*, Kimura went so far as to claim that the synthetic theory was but an 'orthodox view' that had held back understanding of evolution at the molecular level. Debates between Kimura and his supporters called 'neutralists,' and those who favored a more conventional positive or creative role for natural selection ensued, and continue to the present with little hope in the way of resolution.

Organismic biologists came through the period of the 'molecular wars' intact, rallying around Dobzhansky's oft-heard assertion that 'nothing in biology makes sense, except in the light of evolution' (Smocovitis, 1996). The centrality of evolution and its organizing, unifying properties made its way into textbooks of evolution that reached both secondary school and university level students, bolstering the discipline of evolutionary biology and its inclusion into the biological sciences curriculum; this was increasingly the case all over the world. It was also a powerful argument against creationist attacks on science, which began to dominate discussions over the teaching of evolution especially in the 1970s and 1980s (Dobzhansky, 1973). As a result of the inclusion of evolution, often as an undergirding theme, in widely used textbooks like the Biological Sciences and Curriculum Study (the 'BSCS') a new generation of students received their primary biological training with a view that evolutionary biology was a foundational science in the biological sciences (Smocovitis, 1996).

Challenges to the synthetic theory continued, however, especially in the 1970s and began to peak in the 1980s. Drawing a great deal of attention was a reform of Darwinian evolution promoted by paleobiologists endorsing 'punctuated equilibrium,' a theory of species change that read the fossil record in terms of punctuated events and that involved a revision of the rates of evolution as being slow and gradual. Examining the fossil record, proponents of this theory saw instead long periods of stasis, punctuated by periods of rapid phenotypic evolution. Publishing two papers on the topic first in 1972 and then in 1977, Stephen Jay Gould and Niles Eldredge called for a reform of the synthetic theory and precipitated a round of heated debates, many of which unfolded in a public settings (Eldredge and Gould, 1972; Gould and Eldredge, 1977). In 1980, Gould added more heat to the fire of controversy by suggesting the possibility of evolutionary change taking place in terms of radical reorganization at the genic level which implied that different kinds of evolutionary mechanisms operated below and above the species level (Gould, 1980). As a result, Gould and a number of proponents began to call for a decoupling of micro- from macroevolution (Smocovitis, 1996; Sepkoski and Ruse, 2009). Along with a critique of 'the adaptationist program' launched with population geneticist Richard C. Lewontin (1929), which challenged the 'hyper-selectionist' rhetoric and its overly uncritical applications to biology, Gould was instrumental in challenging some of the fundamental tenets of the synthetic theory (Gould and Lewontin, 1979). Along with a group of other 'young Turks' with paleontological backgrounds, he was also part of an effort to create another discipline or subdiscipline related to evolutionary biology, namely paleobiology (Smocovitis, 1996; Sepkoski and Ruse, 2009).

Adding even more fuel to fires that raged around evolutionary biology in the 1970s and 1980s, were debates over group selection, sociobiology and 'selfish genes' (Wilson, 1975; Dawkins, 1976), a return to Lamarckism under the guise of 'somatic selection' (Steele, 1981), and a reform of the principles of systematics launched by Willi Hennig's systematic manifesto and its application (see Hull, 1988, for many of the controversies over 'schools of classification').

By the next decade, furthermore, long standing concerns pertaining to development, which had not been part of the formulation of the synthetic theory began to take center stage as discussions over 'deep homology,' the recognition that distantly related organisms may share a kind of toolkit of developmental genes, gained acceptance. It was with good reason that beginning in the 1990s one commonly began to speak of an exciting area of research that integrated perspectives on evolution with genetics and with development, known as 'evo-devo,' and as the century drew to a close the possibility of integrating ecology began to be entertained as the term 'eco-evo-devo' began to gain traction (Futuyma, 2013; Gilbert, 2013).

Despite the heated discussions that remained about the importance of 'evo-devo,' or what molecular evolution meant for the synthetic theory, and despite a number of challenges from outside of science such as the 'intelligent design,' or ID advocates, the century drew to a close with a much broader view of evolutionary biology. Indeed by the middle decades of the 1990s, evolutionary biology was already being wedded to medicine, and especially epidemiology as interest in emerging pathogens grew and as the principles of evolutionary biology were increasingly applied to more practical ends not only in medicine, but also in agriculture, computer sciences, and even robotics. For good reason, evolutionary biologists now sometimes speak in terms of theoretical and applied evolutionary biology, indicating that the scientific discipline continues to prosper as it reaches out to new areas of research.

Evolutionary Computation

L Altenberg, The Konrad Lorenz Institute for Evolution and Cognition Research, Klosterneuburg, Austria

Glossary

A-Life 'artificial life' Computational systems in which replication, natural selection, and ecological interactions are not set by the designer but emerge from the dynamics of the system.

EA 'evolutionary algorithm' An algorithm (sequence of mathematical operations on a data set, a computer program) that incorporate analogs of (1) natural or artificial selection and (2) variation generation.

EC 'evolutionary computation' The name for the entire research and engineering fields centered on evolutionary algorithms.

EP 'evolutionary programming' Evolutionary algorithms where the search space is a set of finite-state automata, originated by Fogel in 1964.

ES 'evolution strategies' A class of evol00utionary algorithms originated by Rechenberg and Schwefel in 1964, where the search space is Euclidean space and the variation operators are Gaussian random perturbations.

GA 'genetic algorithm' An evolutionary algorithm that incorporates recombination as a variation operator, originated by Holland in 1975, emphasizing homologous crossover on bit string encodings of the search space.

GP 'genetic programming' An evolutionary algorithm in which the objects being evolved are executable data structures, originated by Koza in 1990, where programs are represented as parse trees of operator and variable symbols, and the principal variation operator is exchange of subtrees between programs evolved in a population.

Encoding A representation of points in the search space that may change from a native representation to an alternate representation, such as encoding real numbers as a binary sequence.

Fitness In EC, 'fitness' is used as a shorthand for 'value of the objective function,' rather than the population genetics usage where it means the expected number of offspring.

Fitness proportional selection Selection in which the expected number of offspring of a candidate solution is proportional to the value of its (possibly rescaled) objective function.

NFL 'no free lunch' theorems The result from Wolpert and Macready in 1995, that all search algorithms have equal average performance when averaged over all problem sets.

Object function A measure of how good a candidate solution is to producing a desired outcome.

Representation The way that candidate solutions in a search space are mapped to the data structures that represent them in the algorithm.

Search space The collection of all candidate solutions to be searched through by the evolutionary algorithm.

Simulated annealing An evolutionary algorithm with a population of one parent plus one mutant offspring ($1+1$ EA), where the offspring replaces a less fit parent with probability one, and it replaces a more fit parent with probability $e^{-(w_P - w_O)/T}$, where w_P is the parent fitness, w_O is the offspring fitness, and T is a 'temperature' which is successively lowered during a run of the search (the 'annealing').

Introduction

Evolutionary computation is an approach to engineering and optimization in which solutions, instead of being constructed from first principles, are instead *evolved* through processes modeled after the elements of Darwinian evolution. Evolutionary computation is one of the principal methods in what is called 'nature-inspired computing.' Nature-inspired computing, which also includes artificial neural networks, swarm intelligence, and fuzzy logic, has also been called 'soft computing,' or 'computational intelligence' to distinguish it from symbolic artificial intelligence. Technically, evolutionary computation is as an example of heuristic search, i.e., search by trial and error, where in EC the 'trials' are candidate solutions, and the 'error' is the measurement of how far a trial is from a desired outcome. The error is used to select which trials are to be used to generate further trials. The fundamental rule-of-thumb is that the best chance to further reduce the error is to generate new trials by making modifications to the previous trials that had the lowest errors.

The *evolutionary algorithm* is the main object of interest in evolutionary computation. There is a problem to be solved, and the solution is conceived to lie somewhere in a space of possible candidate solutions – the *search space*. The evolutionary algorithm searches for good solutions in the search space using this typical structure:

1. Initialization: Randomly generate a population of samples from the search space.
2. Iteration:
   (a) Evaluation. Compute the value of the objective function for each sample.
   (b) Selection operator. Use the values of objective function computed for the evaluated samples to select the samples to be used in the next step 2(c).
   (c) Variation operators. Apply variation operators to the selected samples to transform them into additional samples from the search space.
3. Termination: If the termination criteria are met, halt the computation; if not, return to step 2(a).

 doi:10.1016/B978-0-12-800049-6.00307-3

The problem to be solved usually determines in an obvious way what the search space is, and what the objective function is. For example, if one is trying to find the maximum value of $f(x,y)=\sin(x^2-2x-4)\ \cos(-3y+y^2+1)$ on the intervals $-1\le x\le 1$ and $0\le y\le 1$, the search space is simply the intervals, and the objective function is $f(x,y)$ itself. To give a more elaborate example, when trying to evolve artificial neural networks that implement a desired map between inputs and outputs, the search space is the set of weights and topology of the network connections. The objective function is a measure of how closely a candidate map matches a desired map, using a measure of closeness such as mean squared error over a test set of inputs.

Exploration of the search space is performed by using previously sampled and evaluated points to generate new points to be evaluated. The points in the search space are concretely represented by some data structure in the algorithm, and variation operators that randomly perturb these data structures generate the new points.

The classical variation operators are mutation and crossover (i.e., recombination), based on Mendelian genetics and thus called 'genetic operators.' Mutation is implemented by altering the state of symbols in a string, such as flipping a bit in a binary string from 0 to 1 or vice versa. Crossover is implemented by recombining parts of one parent with parts of another. Crossover may be analogous to homologous chromosomal recombination when the positions in the data structure are fixed, as in a fixed-length bit string, or in a fixed set of real-valued parameters. But there are other search spaces where it is impossible to make the analogy to linear chromosomes. For example, in the Traveling Salesman problem, the search space consists of all tours of a set of cities. Taking parts of one tour and recombining them with parts of another tour is likely to produce a path that repeats some cities and misses others. Special variation operators are used which ensure that a path is a tour.

Choosing which samples to apply the variation operators to is the task of the selection operator. Here, a population structure needs to be introduced. In what is called the '$1+1$ EA,' the population consists of a single sample of the search space. A new sample is generated by applying a variation operator to that sample, to generate a population of size 2. The values of the objective function for the two samples are evaluated and compared, and the sample with the better objective function is selected to generate the next sample. Simulated annealing is a simple modification of the selection operator where inferior offspring may be selected with a certain probability (see Glossary). Larger populations may be used, in which case they may maintain enough variation so that recombination may be used as a variation operator. Many different selection operators are possible in large populations. Both the Wright–Fisher multinomial sampling model and the Moran sampling model have been used.

The selection operators that carry out the computational analog of selective breeding may in fact be the exact same operators used in agriculture, such as culling, or ranking.

History of Evolutionary Computation

Evolutionary computation developed in three phases: the first phase consisted of numerous independent experiments in evolutionary algorithms in the 1950s and 1960s. Principal researchers during this period were Nils Aall Barricelli in the early 1950s, George E. P. Box and Alex S. Fraser in the late 1950s, and Hans J. Bremermann in the early 1960s.

The second phase began in the late 1960s and early 1970s where, out of these multiple lines of investigation emerged three lineages that persisted and produced academic offspring: Fogel (1964) established *evolutionary programming*, Rechenberg (1964) and Schwefel (1965) established *evolution strategies*, and Holland (1975) established *genetic algorithms*. Deriving from the genetic algorithm lineage, Koza (1990) established the field of *genetic programming*.

The third phase came when these four lineages, which had established their own conferences, merged in the mid-1990s into a unified evolutionary computation community. Out of this convergence the field gained its first journals, *Evolutionary Computation* at MIT Press in 1993, *IEEE Transactions on Evolutionary Computation* in 1997, and *Genetic Programming and Evolvable Machines* at Springer in 2000. Before the advent of these journals, research in evolutionary computation appeared mainly in the proceedings of the International Conference on Genetic Algorithms, the Evolutionary Programming conferences, the Parallel Problem Solving from Nature conferences in Europe, and scattered articles throughout academic journals. Because the journal citation index Web of Science does not currently index many of these sources, a large body of the founding literature in evolutionary computation remains invisible to it.

The founding papers in the field from 1953 to 1997 have been collected by Fogel (1998) into a single volume, *Evolutionary Computation: The Fossil Record*.

The history of evolutionary computation differs markedly from that of the field of *artificial intelligence*. Artificial intelligence had a specific birth as a new field in a proposal for a 1956 Dartmouth conference organized by Dartmouth mathematician John McCarthy, Marvin Minsky at Harvard, Nathaniel Rochester at IBM, and Claude Shannon at Bell Labs McCarthy *et al.* (1955 (2006)). John Holland, it should be noted, was one of the invitees. In the founding of evolutionary computation, the Ivy League played almost no role, and the research took root in diverse state universities and industrial research labs in the United States, and universities in Europe and Australia.

Evolutionary computation has developed largely independently from the established field of theoretical population genetics. Yet interchanges between the evolutionary computation and evolutionary biology communities occurred as early as 1980 in Europe during a workshop on the 'Evolution of Evolutionary Mechanisms' held in Göttingen, West Germany (Wagner, 1981), while in the United States, interactions between the two communities were fostered by the advent of the Santa Fe Institute, in which John Holland from the University of Michigan and evolutionary theoretician Marcus W. Feldman from Stanford University were key participants. Paixão *et al.* (2015) have made a recent effort enhance the flow of theoretical results between fields by creating a modeling framework that encompasses both evolutionary algorithms and computational models of evolution.

Variety in Evolutionary Computation Techniques

Designers of evolutionary algorithms have explored a very large space of techniques in the hope of improving the performance of evolutionary algorithms over the very wide variety of engineering problems to which they have been applied. Explorations include the values of algorithm parameters such as mutation and crossover rates, selection strength, and population size, encodings, spatial population structure, generation overlap, niching, fitness sharing, multi-objective optimization methods, feasibility constraints, etc. The theory of evolutionary dynamics has yet to reach the point where one can convert the information one has about an optimization problem into the choices of which techniques and parameters to use. For specific models however, progress is being made in obtaining rigorous theoretical results (portal papers include Oliveto *et al.*, 2007; Valiant, 2009).

Evolutionary algorithms employ a great palette of special operators which may have no analogy in biology. One area under extensive development is multi-objective evolutionary optimization. Another example that has burgeoned into a research program is the method called *estimation of distribution* algorithms (EDAs) introduced by Mühlenbein and Paass (1996). An early method was to merge all of the genomes in the population into a single gene pool and sample the alleles at each locus to generate a new genotype, so that the entire population serves as the parent (Syswerda, 1993). EDAs derive from an abstract view about what the operators of selection, mutation, and recombination are actually doing: they produce (implicitly) a probability distribution from which the genotypes of offspring are sampled. EDAs produce these probabilities explicitly, as a dynamical system on probability models whose parameters are adjusted by the objective function values of sampled candidate solutions, in the hope of concentrating the probability on the best candidate solutions. EDAs readily incorporate techniques from machine learning to generate the probability models (Lozano *et al.*, 2006; Pelikan, *et al.*, 2015).

A significant development in evolutionary computation came with the advent of genetic programming, because the data structures representing candidate solutions are no longer of fixed length, but can grow in complexity. Genetic programming evolves code structures that are themselves executable. Programs can be represented as parse trees, and pairs of parse trees can be recombined by exchanging their subtrees. Figure 1 shows an illustration of how a mathematical function can be represented as a parse-tree in genetic programming, and how subtree exchange between two copies of a program (in this case, for a Gaussian distribution) produces an offspring that encodes a different function. Many other techniques have been developed for variation operators in genetic programming, for example, by placing the executable structures back one step from the variation operators through 'cellular encoding' (Gruau, 1994) or 'developmental encoding' (Mouret and Tonelli, 2014), in which the executable structures are constructed from the encoding through an ontogenic development process.

Contrasts Between Evolutionary Computation and Organic Evolution

The motivation behind the development of evolutionary algorithms is optimization – finding approximate or exact

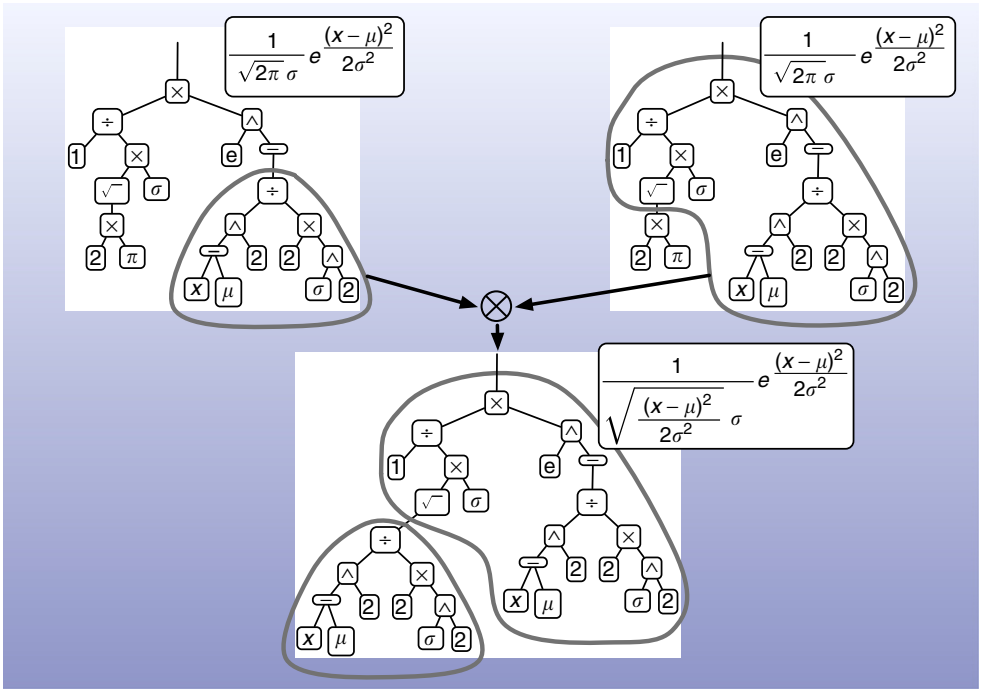

Figure 1 Genetic programming subtree exchange between two parse trees. Two identical parent trees encode the algorithm for the Gaussian normal density. Their recombinant offspring encodes a new mathematical expression.

solutions to diverse problems within the constraints of the computational resources available. The amount of computation required to find an optimum or to achieve a desired level of approximation is therefore a central concern. Such rate of improvement per computation can be considered a measure of *evolvability*. In organismal evolution, everything is conditioned on the survival of the lineage, as pointed out by Palmer and Feldman (2012), and evolvability may conflict with survival if it is tied to increased production of deleterious variation, or leads to the evolution of short-sighted traits that sabotage long-term survival (Nunney, 1989; Altenberg, 2005) or reduces total population size (Frank, 2013). Lineage survival is precluded as an issue in evolutionary optimization because the algorithms are fundamentally search algorithms, and a 'population' is simply the set of previously sampled points from which new samples are to be generated. In other words, population persistence is guaranteed by construction. Evolvability is thus the primary performance goal of evolutionary algorithms.

In terms of sheer computational power, computer-based evolutionary algorithms cannot compare with the number of evolutionary operations taking place in the biosphere (reproduction, mutation, recombination, natural selection). There are an estimated 3×10^{27} cells of the ocean cyanobacterium *Prochlorococcus marinus* alive at any one time (Flombaum *et al.*, 2013) (on the order of the number of atoms in a ton of gold), and with a once-daily cell division, a genome size of 2×10^6 base pairs, and an estimated mutation rate of 5.4×10^{-7} mutations per base pair (Osburne *et al.*, 2011), there are some 3×10^{27} mutations generated daily. That is enough to sample all of the four-mutation neighbors of a parental sequence. The raw information content of organismal genomes, which ranges on the order of 10^5 to 10^{10} bits, is matched by very few instances of the data structures searched with evolutionary algorithms. The current record is set by some special examples in which genetic algorithms have been performed on one-billion-bit strings (Iturriaga and Nesmachnow, 2012).

A run of an evolutionary algorithm typically begins with a population constructed from uniformly sampled random points in the search space. In organic evolution, by contrast, the initial condition was the origin of life itself. At some point life evolved into organisms with DNA-based genomes, but none of the scenarios for the origin of nucleotide-based genomes propose that the initial sequences were uniformly sampled random sequences. So the initial stage in a run of an evolutionary algorithm, where recombination, mutation, and selection are being performed on a population of random sequences, has no parallel in organic evolution, where the processes are always observed in populations that have been evolving for a very long time.

In evolutionary algorithms, there is a clean separation between logical parts of the algorithm: the code for the objective function and the variation and selection operators is entirely separate from the code for the data structures representing the search space, and the entire algorithm is contained in application code separate from the operating system and hardware of the computer. In organic evolution we see the exact opposite: these logical elements are all physically enmeshed – the molecular machinery that produces mutation and recombination and organismal survival and reproduction is all a product of the information in the genome, cytoplasm, and whole organism, interacting with its environment. Some efforts have gone in to blurring the logical separations in evolutionary algorithms, notably the encoding of mutation and recombination rates into the genomes of the individual (see Section Genetic Modifiers, below). The field of *artificial life* distinguishes itself from evolutionary algorithms in that it places a priority on getting reproduction, replication, mutation, recombination, fitness, spatial movement, and ecological interactions to all emerge from the computational system instead of being written by hand in separate parts of the program, emulating the enmeshment of logical levels found in biology (see Section Artificial Life, below).

Contrasts Between Evolutionary Computation and Computational Models of Evolution

When evolutionary algorithms are compared with computational models of evolution, the most obvious difference is that computational models of evolution place a priority on biological realism, while evolutionary algorithms place a priority on computationally efficient optimization. As 'nature inspired' computing, EC has drawn upon many biological and population processes as a source of ideas to try out in algorithmic form, but little priority is given to keeping them biologically realistic.

In the drive toward more biological realism, computational models of evolution have gone beyond the rather limited set of constructs used traditionally in population genetics models, such as additive, multiplicative, low-order epistatic, random, and Gaussian fitness functions. Kauffman and Levin (1987) introduced the more structured, tunably-rugged NK fitness landscapes. Knibbe *et al.* (2007) included insertions, deletions, and duplications in a model with a complex genotype–phenotype map. Computational models of RNA folding (Schuster *et al.*, 1994), protein folding (Lobkovsky *et al.*, 2011), and gene regulatory networks (Wagner, 1994) have provided more biologically grounded fitness landscapes for exploring evolutionary dynamics. More recently, laboratories have been able to obtain fitness estimates for small regions of fitness landscapes, and computational models of evolution on these empirical fitness landscapes have been utilized to explore and even predict evolution (de Visser and Krug, 2014).

The fitness landscapes encountered in evolutionary algorithms are derived from a vast variety of real engineering problems, which may be seen as 'wild' rather than constructed. Evolution on these fitness landscapes ranges beyond the standard population genetics models and the special cases explored thus far in computational models of evolution. They may therefore have value as models to expand the palette of observed evolutionary phenomena.

Parallel Discoveries of Evolutionary Phenomena in Evolutionary Computation

There are several phenomena that were discovered in the field of evolution in parallel with their discovery in the evolutionary biology community. Here, several principal examples will be

given, under the names given to the phenomena in the evolutionary biology literature.

The Problem of Evolvability

The earliest experiences with evolutionary algorithms showed that the combination of Darwinian selection with random variation does not necessarily work to produce adaptation. Friedberg (1958) and Friedberg *et al.* (1959) attempted to evolve computer programs through selection and variation operators, but found that the process frequently stagnated. Conrad (1974a) pointed out that in computer programs, 'slight changes in such a rule (e.g., in the pattern of internal inputs) result in radical changes in the behavior of the system.' In organisms, the physical nature of molecular dynamics makes gradual changes in function possible, and Conrad (1974b) even proposed that gradualism could itself be increased in evolution.

But even where gradualism is abundant, epistasis, multimodality, and deception can stymy evolutionary algorithms from finding global optima or even good approximations. Good performance of evolutionary algorithms was found early on to depend critically on the encoding or representation of the search space, and on parameters of the algorithm such as mutation rate, population size, and selection operators.

A key theoretical breakthrough was the paper, 'No Free Lunch Theorems for Search' by Wolpert and Macready (1995, 1997). They showed that over the space of all problems, all search algorithms have the same average performance. The only way that a search algorithm such as an evolutionary algorithm can have superior performance is if the set of problems is matched to the algorithm, or said in another way, that the algorithm has implicit knowledge about the search space. Concretely, the variation operators have to be able to generate candidate solutions with ever better objective function values as the population evolves. This depends on how the variation operators acting on the representations relate to the objective function (Altenberg, 1995).

Genetic Modifiers

In 1967, Nei (1967) introduced a model for the evolution of recombination in which a modifier locus controls the rate of recombination between two other loci under viability selection. Feldman (1972) gave the first evolutionary stability analysis of the model. Simultaneously, on the evolutionary computation side, Reed *et al.* (1967) included genetic modification for mutation and crossover rates and mutation size in their genetic algorithms. Rechenberg (1973) began to incorporate genetic control of the 'strategy parameters' for his evolutionary algorithms, which included mutational step sizes, and this was termed 'self-adaptation' by Schwefel (1987).

Constructive Neutral Evolution

An early discovery in the field of genetic programming was that the size of evolved programs would keep growing in time, even though there was no explicit selection for larger programs. This was dubbed 'bloat.' One of the explanations proposed by Langdon and Poli (1997) to account for code bloat in genetic programming was that the number of long programs that could implement a given function was much greater than the number of short programs. Offspring produced by exchanging subtrees of parent programs would often have identical fitness to the best parent, and so evolution along neutral networks was possible. Longer programs would evolve as an entropic phenomenon of evolution along neutral networks. As described by Langdon and Poli (1997):

> In general variable length allows many more long representations of a given solution than short ones of the same solution. Thus (in the absence of a parsimony bias) we expect longer representations to occur more often and so representation length to tend to increase. That is fitness based selection leads to bloat.

On the evolutionary biology side, Covello and Gray (1993) proposed that RNA editing may have evolved through a mechanism that Stoltzfus (1999) named 'constructive neutral evolution,' in which needlessly complex mechanisms evolve through a process of neutral evolution simply because there may be a much greater number of complex ways to produce a phenotype than simple ways. Stoltzfus (1999) includes in this list the phenomenon of 'scrambled genes' in ciliates, and the process independently called 'subfunctionalization' by Force *et al.* (1999) in which independently functioning modules within a gene become separated into multiple genes, another essentially entropic process. Echoing the explanation by Langdon and Poli (1997) of bloat, we find the explanation by Stoltzfus (1999) for gene scrambling:

> Given such a buffer against the otherwise adverse effects of micronuclear gene rearrangements, a long-term net increase in scrambling would be expected, simply because there are many more scrambled than unscrambled configurations.

The Evolution of Genetic Robustness

As described above, program bloat is one of the emergent properties discovered in evolving computer programs through genetic programming. Before Langdon and Poli (1997) proposed their entropic mechanism for bloat, an earlier hypotheses was that the code bloat gave programs a 'defense against crossover' (Singleton and Keenan, 1993). They discovered that much of the code in bloated programs could be deleted or exchanged without consequence for the program's behavior. The bloated programs were thus phenotypically robust to the variation operator, and the extra code diverted the crossover operator from hitting sensitive parts of the program. Altenberg (1994) proposed that inherently neutral code would proliferate in the long-term evolution of populations of programs. Nordin and Banzhaf (1995) examined the distribution of fitness effects of subtree exchange (**Figure 2**) and found that, indeed, the proportion subtree exchanges with no effect on program performance (neutral crossovers) increased several-fold during the population evolution.

On the evolutionary biology side, interest in computational models of RNA folding revealed the existence of large mutationally connected networks of RNA sequences that

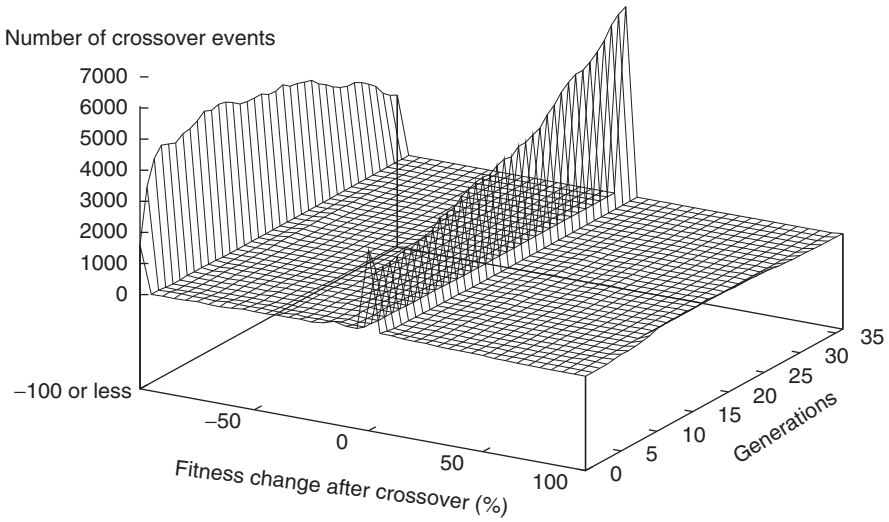

Figure 2 Distribution of fitness effects of recombination during an evolutionary run with genetic programming, Reproduced from Nordin, P., Banzhaf, W., 1995. Complexity compression and evolution. In: Eshelman, L. (Ed.), Genetic Algorithms: Proceedings of the Sixth International Conference. San Francisco, CA: Morgan Kaufmann, pp. 310–317. The proportion of neutral crossovers increases during the run.

folded into the same secondary structure, leading to questions about how evolution would proceed on such neutral networks. In 1999, two papers (Bornberg-Bauer and Chan, 1999; Nimwegen *et al.*, 1999) showed that evolution on neutral networks could move a population to genotypes with greater probability of producing neutral mutants, the same outcome of increased genetic robustness observed in genetic programming by Nordin and Banzhaf (1995).

Artificial Life

The field that has come to be known as 'artificial life' (Langton, 1984, 1986) also focuses on computational systems that exhibit Darwinian evolution. But the motivations behind artificial life and the design of its evolving systems depart significantly from the field of evolutionary computation. In its most ambitious form, the goal of artificial life is to create new 'instances of life' in addition to the actual biological world – i.e., systems that exhibit all the essential features of life – in order to advance our understanding of life by having more than the single 'data point' of terrestrial living systems. The means to this goal is to create artificial systems that exhibit the principal features of life: structures whose activities result in the maintenance and reproduction of the structures (autopoeisis, Varela *et al.*, 1974), ecological interactions, and reproduction with variation that allows Darwinian evolution to occur. Another widespread goal is to design artificial systems that exhibit an unbounded increase in complexity in time.

As stated by a founder of the field, Christopher G. Langton (1986):

> The ultimate goal of the study of artificial life would be to create 'life' in some other medium, ideally a virtual medium where the essence of life has been abstracted from the details of its implementation in any particular hardware. We would like to build models that are so life-like that they cease to be models of life and become examples of life themselves.

The root document of the field is von Neumann (1966) 'Theory of Self-Reproducing Automata.' It spawned numerous efforts to construct cellular automata in which configurations of cell states would self-reproduce through the automaton dynamics. Langton (1984) discovered such a cellular automaton, called the 'Langton loop.' A different approach was the successful construction by Ray (1993) of a virtual machine, Tierra, where a specific configuration of instructions would compute its own replication. By including error prone operators, the self-reproducing configuration could evolve. The evolutionary dynamics of Tierra produced emergent phenomena such as parasitism, where mutants parasitized other programs for their own replication, and a rich structure of ecological interactions. Several other virtual machine systems have been subsequently developed, including Avida (Adami and Brown, 1994) and Amoeba (Pargellis, 1996).

In these systems, sets of instructions in a virtual machine language perform the computation that replicates the set of instructions. Replication is not performed by separate variation or selection operators. Thus, replication emerges from the computational dynamics. Selection – the differential survival and replication of structures in the virtual machine – is also emergent from the computation, when some sets of instruction (the 'digital organisms') outcopy others. Mutation, however, is typically hand-coded into the construction of the virtual machine by making some instructions probabilistic. Also, until recently, the programmer had to design by hand the initial self-replicating configuration of instructions that founds the population. But LaBar *et al.* (2015) searched through 3 billion randomly generated programs in the Avida system and discovered 170 programs that produce self-replication.

Another distinction between evolutionary computation and artificial life is that the latter do not employ objective functions for use by selection operators. There is no 'goal' or outcome to optimize; the digital organisms are not 'candidate solutions' to some exogenously defined problem as is usually the case with evolutionary algorithms. Selection in A-Life systems could be called 'natural' in that differential survival and reproduction of the digital organisms is an emergent outcome of the computations in the virtual machine. The emergent properties of artificial life systems such as Avida have made them useful for exploring the dynamics of evolution, for example the phenomenon of 'survival of the flattest' (Wilke *et al.*, 2001), the evolution of the germline/soma division (Goldsby *et al.*, 2014), and the evolution of complexity (Lenski *et al.*, 2003).

Glossary

Epistasis Epistasis occurs when the alleles at two or more loci combine to produce genotypes whose trait values differ from the values expected if the loci combined in a simple additive manner. The synergism across loci can be such that the multi-locus genotype has a trait value either more or less than expected if the loci had combined additively.

Genetic load The genetic load is the difference between the relative fitness of the most-fit genotype and the average relative fitness in a population, scaled to the average fitness (i.e., divided by the average fitness). It can be described heuristically as the number of offspring that the most-fit genotype must produce to compensate for the deaths distributed among the less-fit genotypes in order to avert a population crash.

Identity by descent Two copies of a gene are identical by descent when they are descended from the same ancestral copy, which occurs with probability 1/2N in a randomly mating diploid population.

Linkage disequilibrium Linkage disequilibrium occurs in a system of two (or more) loci when the frequencies of two-locus (or multi-locus) gametes are not the products of their constituent allele frequencies. Linkage disequilibrium implies that some two-locus (or multi-locus) genotypes are more (less) common than the combinations of their constituent allele frequencies would suggest. It can arise through random drift or selection on two-locus (or multi-locus) systems with epistasis across loci in fitness.

Quasi-linkage equilibrium The frequencies of the four gametes in a model of two-locus evolution with epistatic fitness relationships are said to be in quasi-linkage equilibrium when the variance in fitness contributed by linkage disequilibrium cancels the pairwise epistatic contributions to the variance in fitness. When this happens, the rate of change in mean fitness is proportional to the additive genetic variance in fitness.

Introduction

Evolution is a genetic phenomenon; if it is to be understood, its genetic underpinnings must also be understood. This was obvious to Darwin and his critics (see Reznick, 2010) and for decades after publication of *On the Origin of Species*, the slow accumulation of genetic understanding hindered the acceptance of Darwinian evolution (Provine, 1971).

In this article we trace the path from Darwin and his proposed mechanism of natural selection to the sophisticated evolutionary genetics that validated Darwin's ideas. Our article covers about a century, from the years after publication of *On the Origin of Species* to the publication, in 1970, of Crow and Kimura's *An Introduction to Population Genetic Theory*, which represents the synthetic climax to the first century of evolutionary genetics.

The Origin of Evolutionary Genetics

The Argument over Variation

Darwin argued that the driving force of evolution would be a natural process of selection, acting on variations among individuals within a population and causing some individuals to leave more offspring than others. The notion of a 'natural' selection had been suggested prior to Darwin to explain the persistence of certain populations and the extinction of others through episodes of environmental change (Eiseley, 1958). In these cases, selection was posited to act on traits that were shared by all of the members of a population. Darwin's genius lay in perceiving that selection could act on the *differences* among individuals.

For Darwinian selection to generate evolutionary change, some of the trait variation among individuals must be inherited. Moreover, the mechanism of inheritance must preserve variation in the absence of selection. Blending inheritance, which was the mechanism postulated in Darwin's time, would quickly homogenize heritable variation among individuals. Under blending inheritance, any observable variation among individuals would be environmentally induced and Darwin's postulated mechanism would be unable to produce any lasting change.

The discovery of particulate inheritance did not immediately vindicate Darwin's ideas (Provine, 1971). In fact, it bolstered his critics because the limited genetic variation in one-locus, two-allele systems constrains how much change selection can catalyze. The rapid attainment of limits to selectively driven change in such cases suggested that mutation, and not natural selection, would be the major driving force of evolution. Further, if there were a one-to-one relationship between a gene and a single, discrete phenotypic trait, selection would require enormous periods to alter many of an organism's features because the process would be limited by the rate at which mutations for each feature appeared. In this view, Darwinian selection might explain small, occasional changes in organismal features but could not possibly be a driving force for significant evolution.

 doi:10.1016/B978-0-12-800049-6.00011-1

The Emergence of Evolutionary Genetics

Particulate inheritance of discrete traits has mathematical precision: crosses between individuals with different features produce progeny with a predictable statistical distribution of those features. The earliest studies of inheritance uncovered these predicted distributions in various circumstances: one locus with two alleles, two independently segregating loci each with two alleles, and, eventually, two linked loci (Edwards, 2012).

Once the statistical nature of inheritance was understood, scientists turned their attention to describing the distributions of allele frequencies in large natural populations. It quickly became apparent that with particulate inheritance, variation would not be blended away (the Hardy–Weinberg–Yule equilibrium). Moreover, it became clear that Darwinian selection would act by altering the distribution of allele frequencies over time. Among the earliest of these demonstrations was Castle's (1903) description of how deleterious recessives would be eliminated from a population and Norton's calculations of the number of generations required for selection to change allele frequencies from one set of values to another (presented in Punnett's 1915 book (Provine, 1971)).

There was still controversy. While the mathematics of inheritance was clear for discrete phenotypic traits, attempts to characterize the inheritance of continuous traits, which characterized a species and defined its distinction from other species, had produced no similarly simple mathematical rules. Without such a theory, it was unclear how natural selection could drive changes in such traits.

In a monumental paper in 1918, R. A. Fisher produced that theory (Fisher, 1918). This paper derived precise mathematical predictions for correlations among relatives of specified degrees and demonstrated that those predictions were entirely general, regardless of how many loci were involved, how many alleles segregated at each locus, and what levels of allelic dominance prevailed. Fisher's paper also defined a more sophisticated approach to genetics, a general mathematical representation of a class of problems instead of an arithmetical description of one type of problem. Evolutionary genetics had been born.

The Maturation of Evolutionary Genetics

By the mid-1930s, evolutionary genetics had evolved its current *bauplan*. A student of evolutionary biology today could return to a class in population genetics in the mid-1930s and feel at home; the subject matter, terminology, mathematical machinery, and basic themes had already taken on their modern shapes.

Common Ground: A Theory of Evolutionary Genetics

Science and human nature being what they are, much has been written about the disagreements among the founders of evolutionary genetics. However, it is important to appreciate the broad swaths of theory on which there was general agreement.

Whereas Fisher's (1918) paper can be considered the foundation of quantitative genetics, his 1922 paper, entitled 'On the Dominance Ratio,' became the foundation for evolutionary genetics (Fisher, 1922). In this paper, Fisher took the same approach to describing evolution that he had taken to describing variation in continuous traits: he developed general mathematical representations of entire classes of problems. For example, he developed the general mathematical model for viability selection from which most of population genetic theory would descend.

The genius of this paper was in the sections in which Fisher introduced and developed the idea of evolution as an inherently stochastic process. In Section 2, "Survival of individual genes," of the paper, Fisher calculated the probability of extinction of a new mutant gene, which he showed to be independent of population size and approximately independent of selection. He noted:

> …Only when the number of individuals affected becomes large will the effect of selection predominate over that of random survival, though even then only a very small minority of the population may be affected.

This was the first quantification of the role of chance in evolution and the first application of the theory of stochastic processes in biology (de Vladar and Barton, 2011). In Section 3, "Factors not acted on by selection," Fisher described how the distribution of allele frequencies would change over time due to random factors alone. In Section 4 he extended his calculations to include mutation, providing the first formal statement of mutation-drift dynamics. In Section 5 he mathematically addressed the random loss of alleles due to chance extinction in finite populations, which had been first suggested by Hagedoorn and Hagedoorn (1921). Fisher calculated the rate of loss of genetic variation due to drift as 1/4N, which Wright subsequently showed should have been 1/2N.

In the final, monumental portion of the paper, Fisher studied the combined effects of selection, mutation, drift, and assortative mating. Two novel conclusions emerged. First, Fisher articulated the concept now called 'effective neutrality,' which describes how the relative influence of selection and drift depends on the population size. More specifically, he showed that the smaller the population, the larger must be the selective advantage of an allele for its dynamics to be driven by selection. Second, Fisher showed that the level of genetic variation expected when mutation and selection are in balance is proportional to the ratio of mutation rate to the strength of selection.

Fisher continued to develop novel theory for natural selection and evolution, culminating in 1930 with the publication of *The Genetical Theory of Natural Selection*. This book remains the most important work in evolutionary biology since *On the Origin of Species*. While it summarized much of Fisher's prior work, it also offered three original, important results. First, Fisher demonstrated the relationship between fitness and reproductive value, which is the weighing of an individual's potential future reproduction by its expected future survival. Not only did this idea link evolutionary genetics with demography, it provided the foundation for an eventual evolutionary theory of aging. Second, he identified negative

frequency-dependent selection, in which the fitness of a genotype decreases as its relative fitness increases, as the mechanism that stabilizes the sex ratio at nearly 1:1. Finally, he articulated what has become one of the most durable explanations for the evolution of recombination and sex (the Fisher–Muller model): recombination permits beneficial mutations to come together in the same genome, thereby greatly speeding the rate of adaptive evolution.

Theory for the stochastic components of the evolutionary process was developed in more detail by Sewall Wright. Whereas Fisher came to evolutionary genetics from a background in mathematics, Wright was trained as a geneticist and always considered himself primarily a physiological geneticist (Provine, 1986). He initially developed statistical methods to understand complicated patterns of inheritance and then applied those methods to more general problems. For example, agriculturalists had long been aware of the benefits and drawbacks associated with inbreeding (as was Darwin), and by 1920 there was a body of literature on how the genetic composition of populations evolved under various systems of nonrandom mating. Wright's initial mathematical work was directed toward a general method for studying nonrandom mating, which resulted in his development of the inbreeding coefficient, *f* or F, and the method of path analysis.

Wright's initial foray into evolutionary genetics was his interpretation of the selection experiment on coat color in hooded rates conducted by his mentor, William Castle (Provine, 1986). Wright's analysis revealed the effectiveness of mass selection on genes of small effect, thereby offering an empirical complement to Fisher's development of selection theory.

Wright developed his own approach to evolutionary genetic theory and published his synthetic work in 1931 (Wright, 1931). Beyond the formal mathematical exposition on evolution in finite populations, two fundamental contributions in this paper stood out. First, he showed that the rate of decay of genetic variation in a finite, random mating population will be 1/2N per generation, drawing on a probabilistic argument foreshadowing Malécot's development of identity by descent (see below). Second, he defined the genetic effective population size, *Ne*, a measure of how many individuals actually leave offspring behind, and illustrated its role in the stochastic distribution of allele frequencies.

J. B. S. Haldane rounds out the great triumvirate of the founders of mathematical population genetics. Haldane published a series of papers in the 1920s, collectively titled 'A mathematical theory of natural and artificial selection,' in which he characterized a wide variety of selective scenarios, culminating in 1932 in his own synthetic book, *The Causes of Evolution*. Haldane is most appreciated for two results. In 1927, he showed that in a sufficiently large population, the probability of fixation of a new beneficial mutation is approximately twice its selection coefficient (Haldane, 1927). Later (Haldane, 1937), he showed that the reduction in fitness when mutation and purifying selection are at equilibrium is approximately equal to twice the genome-wide mutation rate and is approximately independent of the strength of selection.

The Russian geneticist Sergei Chetverikov is not as well-known as Fisher, Wright, and Haldane, but he independently reached similar conclusions with respect to many of the important basic results mentioned above, which he published in 1926. This paper was available only in Russian until Theodosius Dobzhansky published some excerpts in English translation in 1959 and the full translation by Malina Barker appeared in 1961 (Chetverikov, 1961). His influence on evolutionary genetics in this period was exerted primarily through his students and others who were inspired by his original papers. Chetverikov was among the first evolutionary biologists to design his empirical work as an explicit attempt to test mathematical theory. His argument that natural populations harbored extensive genetic variation would inspire a tradition of field-based research that, ultimately, infused what Mayr (1988) called "population thinking" into genetics. By "population thinking," Mayr referred to considering a natural population to be a collection of genetically variable individuals. The triumph of "population thinking" would ultimately change the focus of evolutionary genetics from describing how selection altered genetic variation to how so much genetic variation could be maintained.

Contention and Argument: Which Theory Does Nature Follow?

While a general theory of evolutionary genetics was in place by the late 1930s, the major architects of that theory, Fisher and Wright, did not agree on how it applied to nature. Fisher envisioned nature as the laboratory for weak selection (i.e., very small differences in fitness among genotypes) acting in extremely large, panmictic populations (Provine, 1986; Ewens, 2004; Crow, 2010). Under these conditions, selection could sift all combinations of alleles at different loci; those alleles contributing most to the combinations that produced the highest fitness would increase in frequency. Fisher saw mass selection on the average effect of an allele across all possible genetic backgrounds as an efficient means of ensuring that the best possible genotype would predominate.

Wright thought this view unrealistic on two grounds (Wright, 1980; Provine, 1986). First, he expected natural populations to be sufficiently limited in size that all possible allelic combinations would never occur. Second, Wright thought that synergistic effects of gene combinations – dominance between alleles, epistasis between alleles at different loci – were prevalent and would prove more important than the average effects of an allele. For Wright, these two issues demanded a wholly different mechanism for increase in the frequency of alleles that combine to produce the best available genotypes.

Wright's view, which came to be called his shifting balance theory of evolution, was that a species consisted of numerous populations of limited size that were connected by modest levels of migration and genetic interchange (Wright, 1980; Provine, 1986; Ewens, 2004). The random drift within each population would generate a variety of allelic combinations at different loci on which selection could act. The partial isolation among populations would allow different statistical distributions of these combinations to emerge and be sampled by selection in different populations. Once favorable combinations rose to appreciable frequencies in each population, migration between populations, enhanced by higher

population sizes resulting from increased fitness, would spread the best combinations and thereby ensure that the best possible genotype will predominate in the species. For this mechanism to perform as postulated, there must be a precise combination of population sizes and migration rates (Ewens, 2004). How often nature finds that combination is an empirical matter that remains unresolved.

These dramatically different views of nature led to each man's taking different positions on issues like the evolution of dominance and whether inbreeding and genetic drift should be regarded as separate processes (Crow, 2010). Wright and Fisher fought bitterly over the evolution of dominance precisely because they perceived that a defeat on this topic would falsify one or the other's entire conception of evolution (Provine, 1986). While they agreed that dominance was an evolved property and not a fixed attribute of genes (Wright, 1977, p. 571), they proposed very different theories for that evolution. Fisher posited that dominance at one locus evolved via changes in allele frequency at a second locus, whose alleles modified the expression of a mutant allele at the primary locus when the mutant allele at the primary locus was in heterozygous condition. Wright was critical of this hypothesis. He argued that because heterozygotes for mutant alleles will be rare, selection on the modifier locus will be extremely weak. This will render the process ineffective except in very large populations. Moreover, this mechanism would require that the modifier gene have no pleiotropic effects on other characters or epistatic interactions with other genes. It is obvious that Fisher's postulate follows directly from his view of nature and, of course, that Wright would find this theory wholly inadequate. The plausibility of Fisher's theory for altering dominance within balanced polymorphisms, in which heterozygotes are common, was never in question (Charlesworth, 1979) and, indeed, new discoveries about balanced polymorphisms may vindicate Fisher's view in this context (Billiard and Castric, 2011).

Wright argued that dominance evolved via more complicated interactions among genes in a common metabolic pathway (Wright, 1977). His theory assumes strong interactive effects among genes at different loci as enzymatic reactions regulate the concentrations of substrates in a pathway. In particular, his theory, which has been expanded in theories of metabolic control (Kacser and Burns, 1981; Bagheri, 2006), predicted the negative association between the degree of dominance of a mutant allele and the magnitude of selection against the allele seen in studies of mutants in *Drosophila* (Charlesworth, 1979) and yeast (Phadnis and Fry, 2005).

Evolutionary Genetics Permeates the Study of the Evolutionary Process

The Dominance of Evolutionary Genetics

By the mid-1930s, the study of evolution was becoming a genetic discipline. At one level, many field naturalists devoted themselves to studying the distribution and dynamics of visually conspicuous genetic variation. The school of 'ecological genetics' associated with E. B. Ford (1975) is one example. Ford's field studies had been shaped by his interactions with Fisher. Together, they applied evolutionary genetic theory to data on the spatial distribution and temporal dynamics of Mendelian pattern variations in moths with an eye toward demonstrating that natural selection was the predominant influence on the distribution and dynamics of gene frequencies. Ford's and Fisher's students extended this approach to studying polymorphisms in snails, butterflies, and even plumage patterns in birds.

On the other side of the Atlantic, Dobzhansky and his collaborators, including, for a period, Wright, were engaged in the same kind of work. Dobzhansky had been trained in Russia in the tradition championed by Chetverikov and brought that sensibility to the United States, where he began studying the genetics of *Drosophila*. He was struck by what he saw as Wright's more realistic view of nature and focused his work on understanding how natural selection and genetic drift combined to drive the distribution and dynamics of genetic variation. Dobzhansky and his colleagues studied a variety of genetically controlled traits, primarily in *Drosophila pseudoobscura* but also in other organisms (including the desert plant *Linanthus parryae*), combining observational data from natural populations and laboratory experiments with theory and models.

Beyond the explicit study of genetics, practitioners studying other aspects of biological evolution drew inspiration from ideas in evolutionary genetics or interpreted their data in the language and concepts of evolutionary genetics. An example of the former is Simpson's (1944) depiction of the adaptive landscape in paleontology, which he borrowed from Wright's graphical depictions of genetic fitness surfaces within his shifting balance theory (described in Provine, 1986). An example of the latter is Huxley's (1942, Chapter 5) extensive discussion of clinal variation in continuous characters.

Every phase of the evolutionary process was being described and studied in genetic terms, from microevolution to systematics. However, the emergence of evolutionary genetics as a discipline in itself was pivotal for advances in two subjects that were crucial, but poorly understood, components of Darwin's theory of evolution: the origin and maintenance of genetic variation and the genetic changes that drive the formation of new species.

The Randomness of Mutation

The fundamental principle of Darwinism is that selection acts on preexisting random variation among individuals, i.e., selection itself does not influence the creation of new variation. By the time the unification of Darwinian selection with Mendelian genetics was complete – the 'Modern Synthesis' (Smocovitis, 1996) – almost all biologists working with higher organisms accepted that mutation was random. That was not true of biologists working with microbes, many of whom continued to entertain the possibility that the external environment acted to create its own favored variants, i.e., 'directed' mutations. That idea was put to the test first by Luria and Delbruck (1943) and later by Lederberg and Lederberg (1952) and others in studies of mutations in *Escherichia coli* that promoted resistance to bacteriophage or antibiotics. Those experiments showed that mutations promoting

resistance were already present in the bacterial populations prior to the exposure to those agents of selection. These were crucial vindications of Darwin's basic precept.

The more provocative challenge to the Darwinian paradigm has been the recent discovery that there are conventional mechanisms through which apparently directed mutations can occur, at least in principle. These include transcriptional mutations (Whitehead *et al.*, 2008) in which a transcribed variant RNA sequence may be integrated into the genome by a process of reverse transcription. This process offers the possibility of bringing epigenetic processes into the mainstream of evolutionary thought.

Genetics and the Formation of New Species

Evolutionary genetics transformed the study of speciation. In the decades since Darwin, a major issue in the study of speciation was whether differences in traits between pairs of closely related species had been molded by natural selection's favoring different features in different species (Provine, 1986). Because many of the characters used to reliably distinguish species seemed of no ecological value, many biologists argued that speciation occurred solely as a consequence of two populations being isolated from each other long enough for them to lose the ability to interbreed, with little to no role for natural selection.

This view of speciation was a direct challenge to Darwin's view that reproductive isolation was itself a product of divergent natural selection in different populations. Darwin had argued that there would be a continuum between incipient and complete isolation; where a pair of populations would be found on that continuum would depend on the magnitude of the divergent selection pressures driving them apart and the time over which those pressures will have been operating. Darwin's view began to get its empirical support when Lancefield (1929, described in Provine, 1986) showed that reproductive isolation between stocks of *D. pseudoobscura* was indeed a continuum of effects based on the distribution of genes affecting hybrid sterility. This work inspired Theodosius Dobzhansky to initiate his far-reaching studies of the genetics of hybrid sterility (Dobzhansky, 1951). Dobzhansky's work, in turn, set an entire research agenda for others who followed him in examining the genetics of hybrid fitness and the genetic nature of species differences.

Four patterns emerged from these efforts. First, as Lancefield's work had suggested, there were gradations of reproductive isolation between pairs of stocks, populations, or closely related species. Second, the reduction in hybrid fitness was, quite often, more pronounced in one gender than the other, usually the gender with heterogametic gender determination, a result predicted by Haldane (1922). Third, in many cases, there were asymmetries in hybrid fitness in which crosses between populations in one direction (i.e., from which population the female was drawn) produced normal progeny whereas crosses in the other direction produced dramatically reduced hybrid fitness. Subsequent research has shown that this is caused by incompatibilities between genes inherited from only one parent, for example, mitochondrial genes, and genes inherited from both parents (Turelli and Moyle, 2007). Fourth, reduced hybrid fitness could often be shown to be caused by the effects of mixing two distinct sets of epistatically acting allelic combinations (which are now called Bateson–Dobzhansky–Müller incompatibilities; Coyne and Orr, 2004).

Studies on the genetics of speciation led to other discoveries. The role of chromosomal changes in the speciation process, including chromosomal mutations and the formation of polyploid species, became a major focus in the study of plants and some animals (Stebbins, 1950; White, 1954). The formation of new species via hybridization and introgression was beginning to be recognized (Anderson, 1949). The variety of genetic patterns of species differences inspired new ideas about how speciation could occur and how isolating mechanisms could be classified (Mayr, 1963).

By the early 1960s, the study of speciation had been transformed almost beyond recognition from what it had been 40 years previously. The transformation was so complete that, in 1970, Mayr would write:

> The essence of speciation, we now realize, is the production of two well-integrated gene complexes from a single parental one. All early attempts to explain the genetics of speciation missed this essential point, since they were concerned entirely with the problem of the origin of the difference. To be sure, the differences between species are due to mutation and selection, but demonstrating that does not explain how species split. Mayr (1970, p. 296)

The Next Generation of Evolutionary Genetics

The Expansion of Theory

The second wave of evolutionary genetic theory expanded into three broad topics. The first of these was a reconsideration of the stochastic population genetic theory initiated by Fisher and Wright. This phase of theoretical development began, somewhat retroactively, in 1948 with the publication of Gustave Malécot's book *Les Mathématiques de l'Hérédité*. Malécot's contributions to theoretical population genetics were slow to be appreciated by the wider community because he published in French and his book was not translated into English until 1969 (Epperson, 1999). Malécot put much of the stochastic theory initially developed by Fisher and Wright onto rigorous probabilistic footing. He developed the concept of identity by descent of gene copies (as did Cotterman, independently, in 1940). This concept clarified the relationship between inbreeding and random genetic drift, over which Fisher and Wright were bitterly divided. Much of the theory for the effects of migration, gene flow, and population subdivision is due to Malécot. His work anticipated coalescent theory (Slatkin and Veuille, 2002) and he was the first to develop the so-called infinite alleles model of mutation (Epperson, 1999).

The expansion of stochastic population genetic theory accelerated through the work of Motoo Kimura, whose broad contributions to evolutionary genetics are second only to Fisher's (see Takahata, 1994). In 1955, he published the first complete mathematical solution to the process of random genetic drift, and in subsequent papers he extended that treatment to drift with mutation, various forms of migration, and selection (Kimura, 1955, 1962). In essence, Kimura finished what Fisher had begun 40 years earlier: the Wright–Fisher model was now a general model of evolution.

Kimura also led the exploration of the second broad topic in this second wave, the evolutionary dynamics of multilocus systems. In 1956, he produced what might be considered the first investigation of the evolution of the genome by finding the conditions under which linkage between selected loci would evolve (Kimura, 1956). Kimura (Kimura and Crow, 1964) also showed that if epistasis and linkage are weak, that a population under selection attains a state of "quasi-linkage equilibrium," in which case the additive genetic variance is the best predictor of evolutionary change under selection. This result was far-reaching because it validated the standard quantitative genetics practice of using only the additive genetic variance to predict the response to selection (Crow, 1995). And in 1960, Lewontin and Kojima introduced a formal analysis of polymorphism in two-locus systems and initiated an investigation of the role of epistasis in maintaining genetic variation (Lewontin and Kojima, 1960).

An even more fundamental discovery about multilocus systems emerged from the work of Alan Robertson and William Hill (Robertson, 1960, 1967). They described how selection at one locus would reduce the efficiency of selection at all other linked loci (the so-called Hill–Robertson effect). That finding ranks among the most profound in evolutionary genetics, with ramifications for the evolution of sex and recombination (Felsenstein, 1974; Keightley and Otto, 2006), the maintenance of genetic variation, and the relationship of polymorphism within species to the divergence among species (Comeron *et al.*, 2008).

The third great stream of postwar evolutionary genetics involved what has come to be called 'levels of selection.' This set of ideas begins with the premise that what is favored by selection at one hierarchical level (e.g., the gene) may be opposed by selection at some other level (e.g., the individual organism). This question came into sharp focus initially in considering the evolution of sociality, explaining the evolution of altruistic behavior in which individuals sacrifice opportunities for reproduction in order to increase the fitness of other individuals or the overall fitness of the group, family, or colony within which they live.

While the arguments on this topic can be traced to Darwin, Fisher, and Wright (see Williams, 1966), it was the great English biologist W. D. Hamilton who translated them into mathematical theory. Hamilton demonstrated that the marginal fitness of an allele is a function not only of its effects in the focal individual carrying that allele but of its effects in all other individuals carrying that same allele with which the focal individual interacts – i.e., the individual's relatives. Hamilton referred to this phenomenon as inclusive fitness and showed that an altruistic trait can evolve if the indirect fitness benefit to the altruistic individual's relatives outweighs the direct fitness cost borne by the altruistic individual (Hamilton, 1963, 1964). The more general conclusion was that selection operating at different hierarchical levels can lead to counterintuitive evolutionary outcomes. This line of reasoning has proven hugely influential in evolutionary biology, not only with respect to understanding the evolution of sociality but also to more overtly genetic problems concerning the evolution of 'selfish' genetic elements.

Empirical Discoveries Challenge Theory: New Problems or Deeper Questions?

In the early 1960s, evolutionary genetics felt the impact of the revolution in molecular biology. Previously, the genetic characters chosen for empirical study were a highly nonrandom subset, usually chosen because they produced visually conspicuous phenotypes. This made the distribution and dynamics of these characters easily studied. But convenience carried an epistemological cost because it was impossible to know whether the levels of genetic variation for such characters, or the magnitude of selection on their associated genotypes, were representative of the genome as a whole. As biologists became adept at determining the sequence of amino acids in proteins and identifying allozymic forms of proteins, it became possible to study a largely unbiased sample of genetic variation.

The results ignited an intellectual revolution. In 1962, Zuckerkandl and Pauling observed that the rate of amino acid substitutions in hemoglobin, inferred from pairwise species differences and the fossil record of their separation times, appeared to be relatively constant across orders of mammals (Zuckerkandl, Pauling, 1962). Subsequent studies with other proteins and taxa reinforced that finding, leading to the suggestion that protein evolution proceeded according to a "molecular clock" (Margoliash, 1963; Zuckerkandl and Pauling, 1965). At about the same time, the first large-scale surveys of allozyme variation in proteins within species revealed unexpectedly high levels of standing variation in *Drosophila melanogaster* (Lewontin and Hubby, 1966) and *Homo sapiens* (Hopkinson and Harris, 1966).

Taken together, these observations suggested something was terribly wrong with evolutionary genetic theory. Specifically, in the context of existing theory, they implied that natural populations would be carrying impossible levels of genetic load. The rates of allelic substitution through time, inferred from the amino acid sequence data, appeared far higher than could be supported by the most generous estimates of sustainable genetic loads. Similarly, the observed levels of polymorphism at many loci simultaneously would impose a genetic load in every generation that was so large that no population could bear it.

Kimura (Kimura, 1968) was the first to explicitly connect the dots between the seemingly intolerably high rate of protein evolution and the seemingly intolerably high heterozygosity. Both observations could be explained by a single postulate, that the majority of molecular variants were selectively neutral so that their evolutionary dynamics would be governed only by mutation and drift. This was the so-called neutral theory of molecular evolution. This theory led to two important predictions. First, the substitution rate at any locus should be equal to the neutral mutation rate at that locus. Second, the level of standing genetic variation should be proportional to the product of the effective population size, a measure of how many individuals contribute genes to the next generation, and mutation rate.

Almost 50 years on, these predictions remain at the epicenter of evolutionary biology because they describe the role of random chance (mutation and drift) in creating evolutionary patterns. Distinguishing the patterns created by

natural selection from those expected from random change remains the core challenge of evolutionary biology (Felsenstein, 1985; Gillespie, 2000; Lynch, 2007).

The Syntheses of Evolutionary Genetics

Several synthetic treatments of evolutionary genetics appeared in the 30 years after Fisher's (1930) monograph. However, nearly all of them were empirically oriented. Some of these books were focused on evolution in particular groups of organisms (e.g., Anderson, 1949; Stebbins, 1950) while others were focused on the evolutionary process per se (e.g., Dobzhansky, 1951 and earlier editions; White, 1954).

There were few synthetic treatments of theory in this period. Haldane's book (Haldane, 1932) appeared in 1932, shortly after Fisher's, and Wright did not begin to publish his own synthesis until 1968 (Wright, 1968). Malecot's monograph appeared in 1948 but was not translated into English until 1969. The only comprehensive treatment of evolutionary genetic theory in this period was C. C. Li's (1955) textbook, *Population Genetics*, which was published originally in 1948 in Chinese. Li's book covered topics from the effects of inbreeding and assortative mating to the stochastic distribution of allele frequencies under the joint action of selection and drift, as it was known through about 1950.

Three books that appeared between 1960 and 1970 summarized the achievements of evolutionary genetics and laid the foundation for the next generation of theory. The mathematically oriented monographs by Moran (1962) and Ewens (1969) followed in the tradition of Malécot (1948), establishing a rigorous mathematical framework for traditional formulations and pointing toward new approaches to longstanding problems. Crow and Kimura's (1970) textbook, *An Introduction to Population Genetics Theory*, offered a synthetic presentation of the full spectrum of evolutionary genetic theory, from traditional topics like the effects of selection on variation at a single locus to the newly developed neutral theory of molecular evolution. A full third of the pages are devoted to random processes and the stochastic distribution of genetic variation, testimony to Fisher's, Wright's, and Malecot's views on evolution as a stochastic process and evidence of the mathematical sophistication that now characterized the discipline. A little over a century after Darwin articulated his hypotheses about the evolutionary process in words, evolutionary genetics, in theory and data, had validated them.

Evolutionary Medicine I. An Overview and Applications to Cancer

NA Johnson, University of Massachusetts-Amherst, Amherst, MA, USA

Glossary

Biotic interactions Environmental interactions with other organisms.
Drivers Mutations that are selectively advantageous for the tumor. These generally promote tumor growth (see also Passengers).
Genetic hitchhiking The process by which neutral or deleterious variants that are linked to an advantageous variant increase in frequency in a population.
Genomic conflict Conflict that arises among different parts of the genome of an individual because their evolutionary interests do not coincide.
Genomic imprinting Differences in DNA methylation patterns distinguishing maternally and paternally inherited alleles.
Linkage disequilibrium The correlation (association) of allele frequencies at different sites on a chromosome.
Metastasis The process by which cells from the primary tumor detach and form new tumors (metastases).
Microbiome The collection of microorganisms that live inside or on the surface of the body of an organism.
Neoplasm An abnormal growth of tissue.
Oncogene A gene, for which over-expression can lead to tumor formation or continued progression.
Passengers Mutations that are either neutral or deleterious to the tumor, but accumulate via hitchhiking with selectively advantageous mutations (drivers).
Peto's paradox The observation that rates of cancer and body size are not well correlated, despite cancer being connected to cell division.

Overview of Evolutionary Medicine

Four general principles underlie evolution.

1. Evolution is historical. Evolution has shaped features of organisms over historical time. All organisms (including humans) share an evolutionary history due to shared ancestry. Moreover, this shared history is nested hierarchically: a given organism shares more recent ancestry with some organisms than it does with others.
2. Evolution requires heredity, the transmission of information from ancestors to descendants.
3. Evolution takes place in populations, and is necessitated on the presence of variation within populations. Evolution involves changes in frequencies of variants. Natural selection, genetic drift, and other processes of evolution act on variation within populations.
4. Evolution occurs in an ecological context, involving interactions of the organism and the environment. This environment includes both abiotic (physical characteristics) and biotic (other organisms) components.

These basic evolutionary principles have implications for human health and how we treat disease. It can also inform treatment in a number of cases.

The evolutionary medicine articles in this encyclopedia each tackle at least one of these evolutionary principles. Kelly's article (see Section See also) focuses on the first principle. It explores how we employ the concept of shared (and not shared) evolutionary history between humans and nonhuman animals in biomedical research. The interaction of history, genetics, and environment is at the center of Low and Gluckman's article (see Section See also). Scarpino's article (see Section See also) involves the ecological context as well as the processes underlying evolution of populations of disease-causing microbes. Cancer, which is treated in this article, encompasses all four principles.

Why We Get Sick

Evolutionary approaches have long been applied to medically related topics. Hermann Joseph Muller, who made substantial contributions to evolutionary genetics (Carlson, 1981; Johnson, 2002), won the 1946 Nobel Prize in physiology and medicine for his pioneering studies of mutagenesis in flies. These investigations led him to consider the implications of mutations to human health and human evolution (Muller, 1950). Mutation rates and their ramifications for human health continue to interest evolutionary biologists (e.g., Lynch, 2010). The basic principles for an evolutionary theory of aging were also laid out in the 1950s and 1960s (Williams, 1957; Hamilton, 1966). In the 1970s, Cairns (1975) and Nowell (1976) put forth seminal evolutionary theories of cancer progression. Yet, prior to the 1990s, these evolutionary treatments of human health and disease were done piecemeal. A general framework was lacking.

In the 1990s, a collaboration between a psychiatrist (Randolph Neese) and an evolutionary biologist (George Williams) laid out a general framework for evolutionary treatment of human health and disease in a review article (Nesse and Williams, 1991) and then a popular book, *Why We Get Sick* (Nesse and Williams, 1996). This framework has grown into the interdisciplinary field of evolutionary (or Darwinian) medicine (e.g., Stearns *et al.*, 2010).

In their popular book *Why We Get Sick*, Nesse and Williams (1996, pp. 8–11) present their ideas about the major reasons for illness. Infection is one of the reasons, but so are side effects of our defense systems against infection. Another cause is the

 doi:10.1016/B978-0-12-800049-6.00310-3

Table 1 Possible causes of human disease

Category	*Example(s)*
Infection	Malaria (Hedrick, 2011) HIV-AIDS (Rambaut *et al.*, 2004)
Defense side effects (physiological)	Fever (Nesse and Williams, 1996, pp. 26–29) Low levels of iron (Nesse and Williams, 1996, pp. 29–31)
Defense side effects (genetic)	Sickle cell anemia as a genetic defense against malaria (Hedrick, 2011)
Mismatch	Type II diabetes prevalent when humans have a high-sugar diet (Glickman and Hanson, 2006) Cancers of certain reproductive tissues are higher in modern western societies in part because women in these societies undergo more menstrual cycles than they did throughout much of evolutionary history (Aktipis and Nesse, 2013)
Historical legacies	Inverted retinas (Nesse and Williams, 1996, pp. 127–129)
Conflicting selection pressures	Selection will generally favor alleles that increase survival when young, even if the alleles decrease survival when the individual is older (Nesse and Williams, 1996, pp. 112–118)
Genomic conflict	Prader–Willi syndrome (see main text) (Haig and Wharton, 2003)

Note: Some of these examples (notably fever and low levels of iron) are hypotheses to be tested.

mismatch between the novel environments we now inhabit and the environments in which our species evolved (see Section See also). Related to mismatch are historical legacies. Conflicting selection pressures, conflicts between different genes in our genome (genomic conflict), and design compromises also contribute to human illness. Deleterious mutations, as Muller (1950) had noted, are still a factor (see **Table 1** for a list of examples of these categories). Note that the items presented in **Table 1** are not mutually exclusive, and that some diseases may be attributed to more than one cause. For instance, sickle cell anemia is prevalent in people of African descent because heterozygotes for the sickle form of hemoglobin B have protection against malaria (Hedrick, 2011). This is an example of both genetic defense for infection and conflicting selection pressures. Note also that each of these reasons for illness involves at least one and usually more of the principles of evolution above.

Biotic Interactions and Human Health

Research in each of these categories of causes for disease that Nesse and Williams (1996) identified has continued over the last two decades. Many of these advances have focused on how our interactions with the biotic environment. Unlike features of the physical environment, other species are also subject to evolutionary pressures; thus, coevolution of humans and other species becomes a possibility. Coevolution can follow many paths, including the evolution of mutualism, wherein both the human and nonhuman populations evolve traits that benefit the other. Coevolution can also result in host–parasite arms races wherein parasites evolve traits that help them better exploit humans and humans evolve counter-measures to defend against the parasites. Understanding infectious disease and humans' responses to it in this case requires an understanding of the evolutionary history of humans and the disease-causing organism, as well as the populational processes and heredity of both species.

Coevolutionary arms races between humans and disease-causing organisms can involve tradeoffs wherein the adaptations of one species are detrimental in some way. In a fascinating study, Kaiser *et al.* (2007) showed that adaptations in humans to defend against certain viruses could have increased human vulnerability to HIV. This study used phylogenetic methods to reconstruct ancestral viruses that humans were likely exposed to and found that human immune protein TRIM5α can destroy those viruses, but at the expense of humans' being less able to defend against HIV. It is not just humans that are subject to tradeoffs; so are our natural enemies. For instance, evidence is accumulating supporting the hypothesis that the reason avian influenza is extremely difficult to be transmitted from human to human because the virus has evolved adaptations for living in domestic chickens (Long *et al.*, 2014).

Perhaps the most unexpected development in evolutionary medicine from the last decade is the increased appreciation for the role the microbiome plays in human health. The microorganisms of the microbiome (microbiota) are not just passive by-standers residing in our bodies. Instead, they play myriad roles in our physiology and, amazingly, even our psychology (see reviews in Finlay, 2013; Heintz and Mair, 2014). These studies are addressed in great detail in Knight (see Section See also). Comparative studies of the microbiota in nonhuman primates could reveal insights into the human microbiome. An interesting recent study demonstrated that social interactions, in particular grooming networks, strongly influence microbiota composition in baboons (Tung *et al.*, 2015). Note also that this work on baboon microbiota could only be done given the rich evolutionary demography studies by Jeanne and Stuart Altmann and their colleagues.

Once thought to be a vestigial organ of no current evolutionary value, the role of the appendix is being revised (Johnson *et al.*, 2012). Bollinger *et al.* (2007) contend that the appendix may be a storehouse for beneficial microbiota. Taking a phylogenetic approach to the evolution of the appendix in a variety of mammals, they find evidence supporting this role for the human appendix. Inflammation of the appendix, however, may be due to possible mismatch between current human diets and microbiota and previous environments in which we evolved (reviewed in Johnson *et al.*, 2012).

Genomic Conflict

Another recent major development in evolutionary medicine is the accumulating evidence supporting genomic conflict as a

major contributor to human disease (Haig, 2004; Crespi, 2010, 2011). Genomic conflict occurs when the evolutionary 'interests' of different parts of the genome do not perfectly coincide (Burt and Trivers, 2006; Rice, 2013). For instance, because mitochondria are strictly maternally inherited, a mitochondrial allele that benefitted daughters at the expense of sons would be evolutionarily favored. Accumulation of such male-detrimental alleles would be contrary to the evolutionary interests of autosomal genes, and thus selection would favor autosomal genes that counteract the mitochondrial alleles. Like biotic interactions, genomic conflict can lead to persistent and intense coevolutionary arms races (Crespi, 2010; Rice, 2013).

One area of genomic conflict that seems to be particularly intense is in maternal–fetal interactions and these conflicts often involve different interests regarding the allocation of resources (Haig, 2004; Burt and Trivers, 2006; Crespi, 2010, 2011; Boddy *et al.*, 2015). Evolutionary biologists have long been aware of the divergent evolutionary interests of parents and offspring (Trivers, 1972). Consider the optimal level of resources a mother should provide for her fetus (or infant). From the perspective of the fetus' interests the fetus should receive as much from the mother as possible without seriously endangering her health. Whereas, the mother's evolutionary interest will depend on her health, but also her prospects of having and supplying resources to other children. Because of this, optimal resource allocation is different for the mother than for the child (Trivers, 1972; Burt and Trivers, 2006).

Given at least some departure from strict monogamy, the evolutionary interests of mothers and fathers would diverge (Haig, 2004; Burt and Trivers, 2006). In resource allocation disputes, the father's evolutionary interests would favor more resources be given to the particular fetus than would be optimal according to the mother's evolutionary interests because he may not be the father of the mother's other current and future children. Given this conflict, the evolutionary interests of the paternal alleles of the fetus (the ones inherited from the father) would favor a higher resource allocation level than the interests of the maternal alleles of the fetus. This complex conflict has likely led to patterns of genomic imprinting wherein paternal and maternal alleles for particular genes (many of which are involved in resource allocation) are differentially methylated and differentially expressed (Haig, 2004; Burt and Trivers, 2006).

In general, the arms race associated with conflict between paternal and maternal alleles reaches resolution in an uneasy truce, but mutations can reveal the evidence of the battlefield (Haig, 2004; Burt and Trivers, 2006). Loss or reduced expression of maternal alleles results in paternal alleles exerting control, and this should lead to the fetus taking far more than the optimal level of resources from the mother. In contrast, reduced expression of paternal alleles should lead to the fetus taking far less than the optimal level of resources too little. Prader–Willi syndrome, caused by deletion of part of paternal chromosome 15, is an example of the latter (Haig and Wharton, 2003). Although the excess food-seeking behavior of postweaning Prader–Willi individuals is better publicized than other symptoms, fetuses and infants with Prader–Willi are generally lethargic and actually have reduced food intake (Haig and Wharton, 2003).

Preeclampsia, or increased blood pressure in pregnant or postpartum women, may also be due to conflicts among the mother, the father, and the fetus and may be a function of selection within the human lineage (Crespi, 2010). Although the evidence supporting an evolutionary explanation for preeclampsia is not fully established, some evidence does support this hypothesis. This evidence includes the rarity of the disorder in nonhuman primates, the increased prevalence of the disorder in first pregnancies, the association between preeclampsia and a change in sexual partners, and the positive association between increased gestational blood pressure and maternal blood flow into placental tissues (Crespi, 2010).

Related to maternal–fetal conflicts is the phenomenon of fetal microchimerism, wherein women often retain some cells from their offspring many years or even decades after their pregnancy. The overall effect of such fetal microchimerism is not quite clear, as it seems to have both apparent advantages and detriments to the woman (Boddy *et al.*, 2015). Evolutionary explanations based on conflict and those based on cooperation are being applied to address this unexpected phenomenon (Boddy *et al.*, 2015).

Genomics and Evolutionary Medicine

At the time of the publication of *Why We Get Sick*, not a single eukaryotic genome had been sequenced! As of 2014, genomes from tens of thousands of human individuals have been sequenced (Field and Davies, 2015). The accumulation of full genome sequences from many humans from multiple populations, Neanderthals and other archaic humans, and nonhuman primates is a dramatical change. Insights from this genomics revolution to evolutionary medicine are still being processed, but some interesting data and ideas have already come of it, with the promise of much more.

Due to advances in genomics, researchers can more efficiently identify associations between genes and diseases. In some cases, these advances can also tie the genetic associations with disease to our evolutionary history. Population genomics of human populations combined with comparative genomics of nonhuman primates, as well as Neanderthals and other archaic humans, enables the detection of selective forces that have operated (Johnson, 2007; Crespi, 2011).

Bernard Crespi (2010, 2011) raised the fascinating proposition that the genetic changes that 'made us human' (contributed to human-specific brain and cognitive traits) also made us sick. As suggestive evidence, he notes that genes showing signs of positive selection since humans diverged from Neanderthals are significantly more likely to be associated with a host of neurological diseases such as schizophrenia, mood disorders, and autism.

Crespi (2010) also noted that cognitive and emotional traits, reproductive traits, and traits related to the increased life span in humans are overly represented in human disease. Related to these three types of phenotypes, Crespi contends that certain tissues appear particularly vulnerable to human disease. These include brain as well as reproductive tissues (breast, ovary, placenta, testis, and prostrate). These tissues are likely to be affected by genomic conflict (see above) as well as be influenced by genes that have been under strong selective

pressures. The evolutionary changes at such genes may have strong side effects (Crespi, 2010). These ideas, while intriguing, have generally not been confirmed, but are useful as hypotheses to be tested.

Related to Crespi's hypotheses, Moalic *et al.* (2010) argue that more knowledge of the genes that show signatures of positive selection in the human lineage could be applied to drug discovery, especially for neurological diseases. The study of these genes can reveal new processes about human cognition and how it can go awry, and this knowledge can then be used to develop novel drugs.

Evolutionary Medicine and How Humans Are Evolving

The answer to the question 'Are humans still evolving?' is yes, definitively. Humans vary in traits, those traits are heritable, and are linked to differential survival and reproduction. A more interesting question is 'how are humans evolving?'

Evolutionary medicine can address this question by examining how traits affect viability and fecundity within human populations. For instance, the Framingham Heart Study has been collecting reproductive, physical, and physiological data on people (mainly European-Americans from eastern Massachusetts) since 1948. Byars *et al.* (2010) applied standard evolutionary quantitative genetics theory to the Framingham data to project changes in the population over the next 10 generations (approximately 250–300*x* years). Fertility is the major selective factor, and the fertility period is expected to continue increasing due to later menopause. Assuming that the patterns of selection and the environments remain the same, women in that population are expected to be somewhat shorter, heavier, with lower cholesterol, and blood pressures levels.

Cancer as an Evolutionary Disease

In a prescient, and far-reaching article, Peter Nowell (1976) articulated a view of cancer as an evolutionary process with each tumor usually having a unicellular origin. Nowell also envisioned bouts of selection being associated with tumor progression. In the decades since, the connections between cancer and evolutionary biology have grown substantially. Several recent reviews highlight the increasing awareness that evolutionary biology can inform the study of cancer biology and can even be of therapeutic relevance (Merlo *et al.*, 2006; Podlaha *et al.*, 2012; Pepper *et al.*, 2009; Attolini and Michor, 2009; Gerlinger and Swanton, 2010; Sprouffske *et al.*, 2012; Aktipis *et al.*, 2015). Numerous approaches from evolutionary biology are used, including phylogenetic analysis (Campbell *et al.*, 2008; Aktipis *et al.*, 2015), experimental evolution with microbes (Sprouffske *et al.*, 2012), evolutionary epidemiology (Attolini and Michor, 2009), and mathematical modeling (Attolini and Michor, 2009). Moreover, cancer inherently involves consideration of different levels of selection (e.g., cells and tissues vs. the individual organism) (Pepper *et al.*, 2007; Aktipis *et al.*, 2015), a perennial topic in evolutionary biology.

Although numerous forms of cancer exist, each with their own particular characteristics, different cancers share several commonalities (Podlaha *et al.*, 2012; Hanahan and Weinberg, 2011). Cancer tissues sustain signals to proliferate, while evading growth suppressors and resisting cell death. They bypass limits normally imposed on cell division, and thus achieving replicative immortality. In addition, they obtain a blood supply. Finally, primary tumors often invade and metastasize new regions of the body. See **Figure 1** for an overview of cancer progression.

These 'hallmarks of cancer' (Hanahan and Weinberg, 2011) involve evolutionary change during cancer's progression as well as defenses that the body has evolved for countermeasures. One possible example is the finding of certain cases wherein too much expression of some oncogene signals can lead not to progression of cancer, but to cell senescence (reviewed in Hanahan and Weinberg, 2011). Could this be the result of a mechanism that evolved to guard against cancer?

Although cancer progression is typically a multistep process involving the evolution of several genetic changes, knocking out the expression of a single oncogene often halts or retards the tumor. Because it appears tumor is dependent on the oncogene much like an addict, this phenomenon has been called 'oncogene addiction' (Weinstein and Joe, 2008). Oncogene addiction and redundancies in the pathways underlying the different hallmarks of cancer (Hanahan and Weinberg, 2011) suggest the relationship between genotype and phenotype (and fitness) in cancer progression is complicated, and that sophisticated evolutionary genetics that is becoming more adept to deal with such complexities (e.g., Weinreich *et al.*, 2013) can be useful. There are also implications for therapy as suggested by Weinstein and Joe (2008).

Why Cancer?

Biologists and medical researchers have learned much about the progression of cancer within an individual organism by viewing it an evolutionary process. Why we have cancer in the first place is also an evolutionary question.

Cancer and its suppression are outcomes of selection at different levels (Aktipis *et al.*, 2015). Evolution via natural selection will occur provided (1) variation exists among entities that affect their survival and/or reproduction and (2) offspring inherit the traits of their parents. The entities need not even be biological as computer programs can evolve via these principles (Lenski *et al.*, 2003). Thus, selection can occur on cell lineages: those replicate more and ones that do not respond to cues to stop replicating would have a selective advantage, and would increase in frequency. This selection within the organism is at odds with the evolutionary interests of the multicellular organism, which would be under selective pressure to suppress potential cancers. Examining the outcomes when different forms of selection are acting at different levels is a mainstay of evolutionary biology (Wade, 1978; Michod, 1999; Novak, 2006) that can be applied to understanding both why cancer occurs and why it is rare (Aktipis *et al.*, 2015).

Cancer is a consequence of breakdowns in the cooperation needed to sustain multicellularity (Aktipis *et al.*, 2015). Multicellular organisms have evolved multiple and independent times in the evolution of life, and cancer and/or cancer-like phenomena are found in each of the independent lineages that evolved multicellularity (Aktipis *et al.*, 2015). Multicellular organisms require cooperation among the

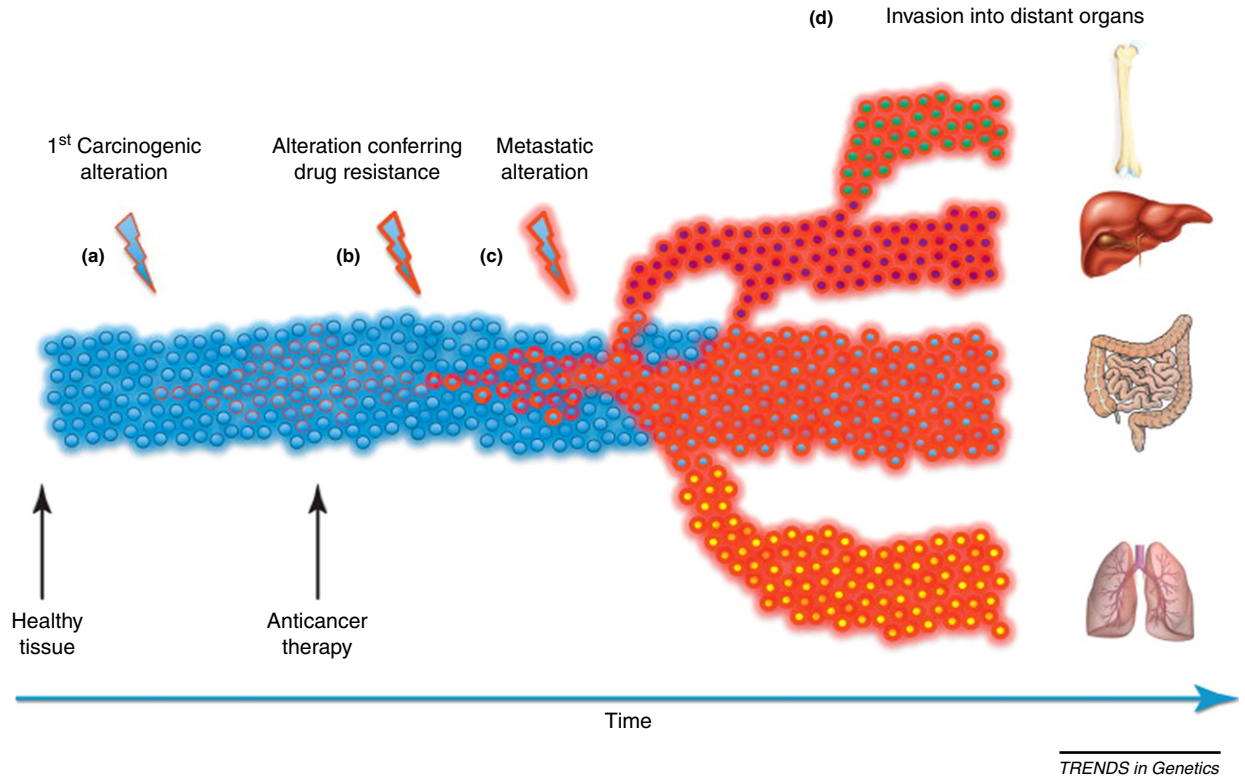

Figure 1 Key steps in the progression of cancer. Adapted from Podlaha, D., Riester, M., De, S., Michor, F., 2012. Evolution of the cancer genome. Trends in Genetics 26, 155–163.

different cell lineages in each individual organism (Michod, 1999). In a multicellular organism, cell division patterns of each particular cell lineage need to be tightly controlled. Multicellular organisms also require particular cells to undergo programmed cell death on schedule. Proper functioning also requires appropriate allocation of resources within the organism (Aktipis *et al.*, 2015).

The hallmarks of cancer (Hanahan and Weinberg, 2011) reflect different types of breakdowns – 'cheating' – of the cooperation (Aktipis *et al.*, 2015). Cancer progression is marked by continued proliferation and failure to respond to signals to undergo programmed cell death. This is an example of demographic cheating, in the terminology of Aktipis *et al.* (2015). Another hallmark of cancer is the diversion of blood supply by the growing tumor for its own use – a form of economic cheating (Aktipis *et al.*, 2015). Examining these forms of cheating as well as how they are countered by the organism should lead to better understanding of cancer.

Cancer Susceptibility

Lifetime risk of cancer in developed countries is about 40% in men and 30% in women (Varki and Varki, 2015). There are two main questions about cancer susceptibility and evolutionary genetics: (1) Why are humans more or less susceptible than other animals? and (2) Why are some genotypes within humans more susceptible than others?

As noted above, cancer is a disease of cell lineages failing to cooperate with the rest of the organism. With each cell replication, the possibility of progression to cancer exists. Yet, the relationship between body size and cancer incidence is weak at best; for example, humans and mice have similar lifetime cancer risks, despite the gigantic differences in size and number of cell divisions (Caulin and Maley, 2011; Aktipis *et al.*, 2015) This puzzling pattern is known as Peto's paradox. A likely explanation is that larger organisms have evolved various mechanisms to suppress cancer (Caulin and Maley, 2011; Aktipis *et al.*, 2015). A prediction of this explanation is that animals much larger than humans (e.g., whales and elephants) should have evolved even better cancer suppression systems.

Despite the general lack of correlation between size and cancer risk among species, variation in size within species is associated with cancer risk. In humans, a 10-cm increase in height results in a 10–15% increased cancer risk, and similar patterns exist in other mammals (Aktipis and Nesse, 2013). The association of cancer risk with size within species suggests that the cancer suppression mechanisms are not genetically linked to size within species.

Mammals appear to have higher overall cancer rates compared with birds and reptiles (Aktipis *et al.*, 2015). Within mammals, cancer rates also vary: at one extreme, mole rats appear to have extraordinarily low cancer rates (Seluanov *et al.*, 2009; Aktipis *et al.*, 2015); at the other, most Tasmanian devils (which are carnivorous marsupials) have an infectious cancer that is usually transmitted via biting (Grueber *et al.*, 2015).

Unfortunately, we know little about the cancer in nonhuman primates. Although the incidence of carcinomas (malignancies arising from epithelial cells) appears to be very low in captive apes, insufficient data precludes a conclusive finding (Varki and Varki, 2015). There are hints of genetic differences that may underlie cancer susceptibility differences between humans and other primates, but nothing definitive has been established. One such putative reason for the likely increased cancer susceptibility in humans is in the differences between humans and other primates in the siglecs, the sialic-acid-binding immunoglobulin-like lectins that have immunological and other functions (Varki and Varki, 2015). Clearly, much more study in nonhuman primates is needed, especially on the quantification of cancer and its genetic basis.

Numerous susceptibility genes have been located. Some of these show signatures of selection in the human lineage. For instance, Ding *et al.* (2008) show an association for both the signature of selection and increased cancer susceptibility in fragile histidine triad gene (FHIT). This is a tumor suppressor gene that is involved in apoptosis after environmental damage (e.g., radiation exposure). In many human cancers, its protein expression is diminished or lost. Moreover, single nucleotide polymorphisms (SNPs) have been found that affect prostrate cancer risk. Ding *et al.* (2008) found a complex pattern of selection operating on the gene, with some SNPs showing signatures of positive selection in one or more populations, and other SNPs showing signals of balancing selection. They did find an association between the variant in the intron of FHIT associated with both enhanced prostrate cancer risk and also positive selection in European-American and Japanese populations.

Crespi (2010) notes a negative correlation between incidence of three human-specific diseases (Parkinson's disease, Alzheimer's disease, and schizophrenia) and cancer risk. As these diseases are likely involved in the evolution of the social brain of modern humans, the epidemiological link to cancer is most intriguing.

Tumor Heterogeneity

Although tumors usually originate as a single cell, different cells in most human tumors generally vary considerably in morphology, gene expression patterns, cell surface receptor expression, and numerous other phenotypic ways. This tumor heterogeneity presents challenges to cancer biology, but also illustrates the value of viewing cancer from an evolutionary perspective (Marusyk and Polyak, 2010). Heterogeneity is just another word for variation, and evolutionary genetics has intensely studied the causes and consequences of variation since its conception (e.g., Dobzhansky, 1937; Lewontin, 1974; Hartl and Clark, 2007; Corbett-Detig *et al.*, 2015).

Although much of tumor heterogeneity is due to genetic changes, some of it arises from environmental differences (Park *et al.*, 2000; Marusyk and Polyak, 2010). For instance, in addition to causing genetic mutations, ionizing radiation may be carcinogenic due to its remodeling of the extracellular matrix (Park *et al.*, 2000). The phenomenon of the same genotype leading to different phenotypes is known as phenotypic plasticity, an area of intense research in evolutionary genetics. This research shows that the extent of phenotypic plasticity is both of a product of past evolution and can influence future evolutionary trajectories (e.g., Pigliucci, 2001; West-Eberhard, 2003).

Coevolution between the tumor cells and cells in surrounding tissues often occurs, with each influencing the other's evolutionary trajectory (Polyak *et al.*, 2009). The 'normal' cells in the microenvironment of a potential tumor often participate in the evolution of cancer due to the signals they produce. For instance, circulating levels of signaling proteins such as integrins and transforming growth factor-*B* appears to influence the early stages of tumor progression (Marusyk and Polyak, 2010). The tumor cells likewise influence the surrounding tissue (Polyak *et al.*, 2009). Coevolution is a vital area of mainstream evolutionary biology, and studies of such coevolution could be useful for studying cancer.

Examining and quantifying tumor heterogeneity poses challenges in sampling the variation (Marusyk and Polyak, 2010). These challenges are similar in some respects to those of evolutionary biologists sampling variation, especially those engaged in metagenomics (e.g., Kembel *et al.*, 2011).

In some cases, the extent of heterogeneity strongly correlates with tumor progression, and thus can be used as a predictive clinical biomarker (Pepper *et al.*, 2009; Marusyk and Polyak, 2010). One such case is Barrett's esophagus, a premalignant neoplasm that arises from chronic inflammation. Some people who have Barrett's esophagus develop malignancies, but most do not. Maley *et al.* (2006) used measures of clonal diversity commonly used by ecologists and evolutionary geneticists and found that indeed, higher levels of clonal diversity were predictive of progression to cancer, even after controlling for other risk factors. They also hypothesized that genomic instability from telomere shortening led to increased genetic diversity. Consistent with their hypothesis, telomere length was negatively correlated with one of the metrics of clonal diversity, the Shannon index (Maley *et al.*, 2006). In general, this and similar studies highlight how an evolutionary perspective can inform when malignancies will develop (Pepper *et al.*, 2009). Tumors are generally spatially heterogeneous. This heterogeneity sets up the prospect of selection pressures varying in different locations, and the heterogeneous selection pressure would likely lead to yet more heterogeneity (Marusyk and Polyak, 2010). This feedback loop is similar to what was seen in an experimental ecosystem of microbes (Rainey and Travisano, 1998).

Drivers and Passengers

Not all of the genetic changes that occur during the evolution of a tumor are advantageous to the tumor. Indeed, most are neutral or somewhat deleterious. Cancer biologists call the mutations that are driven to high frequency by selection 'drivers,' and the neutral and deleterious mutations that also accumulate 'passengers' (see references in Attolini and Michor, 2009; Sprouffske *et al.*, 2012; McFarland *et al.*, 2014).

The idea that neutral or even deleterious variants can accumulate in populations undergoing adaptation along with advantageous ones is an old idea in evolutionary genetics, and was coined 'hitchhiking' by Maynard Smith and Haigh (1974).

The reason that hitchhiking occurs is that some neutral/deleterious variants are associated with the advantageous variants. This association is known as linkage disequilibrium. Even though recombination erodes linkage disequilibrium each generation, selection increases the frequency of both the advantageous variant and variants that are in linkage disequilibrium with it. Linkage disequilibrium is very important in evolutionary genetics as well as in applied field (Hartl and Clark, 2007; Slatkin, 2008).

Cancer is a largely clonal process, and recombination is generally absent. With the absence of recombination, hitchhiking should be very common and many passengers would be expected to accumulate (Hartl and Clark, 2007). The accumulation of passengers can be important, especially to the extent that genotype-by-environment ($G \times E$) interactions are common in tumor progression. With considerable $G \times E$ interactions, passenger mutations might be fuel for further change in the selective environment of the tumor.

In actuality, most passengers should not be neutral, but actually somewhat deleterious on average. Although most theory has treated passengers as neutral, a recent treatment models the evolution of tumors assuming deleterious passengers (McFarland *et al.*, 2014). This model found that cancer progression is often a tug-of-war between accumulation of drivers that promote tumor growth and accumulation of passengers that retard it (McFarland *et al.*, 2014). Under considerable parameter space, a critical threshold for tumor size exists. Below the threshold, tumors eventually go extinct. Above the threshold, a macroscopic malignant tumor is expected to form. The model also found an optimal range of mutation for tumor growth. With low a mutation rate, insufficient drivers evolve, and the critical size is not reacted. Too high a mutation rate leads to mutational meltdown. McFarland *et al.* (2014) note possible therapy applications based on this model, which are discussed in brief in the 'Evolutionary Applications for Cancer Therapy' part of this article. How can we distinguish drivers from passengers? Frequent occurrences of the same genetic changes in independent cases would be strong evidence that those changes arose due to selection favoring them (Sprouffske *et al.*, 2012). For this reason, evolutionary geneticists are particularly interested in convergent evolution (Tenaillon *et al.*, 2012). Similar logic can be used to find drivers in cancer evolution.

Evolutionary geneticists have developed a plethora of statistical tests designed to infer selection (Johnson, 2007; Hartl and Clark, 2007). Although such tests can be and are used to infer drivers in cancer progression, Sprouffske *et al.* (2012) note the statistical complications involved with these tests. Further development is necessary. Experimental evolution approaches are another possible way to distinguish drivers from passengers (Sprouffske *et al.*, 2012).

Metastasis

Metastasis occurs when cells from the primary tumor detach and form new tumors (metastases). Much of the mortality from cancer comes not from the primary tumor, but from the metastases that later appear. One estimate places the metastases contribution to cancer deaths at 90% (Mehlen and Puisieux, 2006). An evolutionary understanding of metastasis is thus a major part of studies of the evolution of cancer.

Metastasis inherently involves the evolutionary ecology processes of dispersal and colonization (Fidler, 2003; Merlo *et al.*, 2006; Talmadge and Fidler, 2010). In the late nineteenth century, a British surgeon named Stephen Paget proposed what would be called 'the seed and soil hypothesis' for cancer metastasis. Paget used the analogy of a plant shedding its seeds to explain his view of metastasis. He noted, "When a plant goes to seed, its seeds are carried in all directions, but they can only live and grow if they fall on congenial soil" (quoted in Talmadge and Fidler, 2010, p. 5650). With respect to metastasis, the seed and soil represent respectively propagules from the primary tumor and prospective locations and tissue types for metastases. Despite considerable controversy during the twentieth century, substantial evidence now supports a version of the seed and soil hypothesis (Fidler, 2003; Merlo *et al.*, 2006; Talmadge and Fidler, 2010).

What is known about the clonal relationship between tumor cells in primary tumors and metastatic sites? Marusyk and Polyak (2010) note conflicting evidence, with the extent to which metastases have diverged from the primary tumor being still controversial. Still, metastases often do resemble primary tumors. Weigelt *et al.* (2003) found that the gene expression profiles of primary breast tumors and metastases from the same patient usually clustered together, distinct from the tumors of other patients. Moreover, in some patients, the gene expression pattern in the primary tumor was practically indistinguishable from the metastases. Some evidence supports metastases occurring much earlier than previously thought during tumor progression, and that genetic differentiation may increase between the primary and metastatic tumors during subsequent evolution (Marusyk and Polyak, 2010).

Evolutionary Applications for Cancer Therapy

The potential applications of evolutionary biology to cancer therapies are many and varied. Increasingly, the evolutionary ecology approach of using other organisms to mediate cancer is being used in therapy (Pepper *et al.*, 2009). Dang *et al.* (2001) presented an interesting example of such bacterial therapy. They were motivated by the observation that growth of tumor often outpaces growth of blood supply leaving large parts of the tumor hypoxic. Anaerobic bacteria would be expected to thrive in such conditions. Dang *et al.* (2001) searched for bacteria that would not only grow under these conditions, but would selectively kill tumor cells in adjacent regions, They found such an agent in *Clostridium novyi*. After genetic modifications of this bacterium to reduce toxicity to the mouse host and other modifications, this bacterium in combination with traditional chemotherapy can result in dramatic regression of mouse tumors. Use of other organisms in therapy is complicated by the fact that these organisms themselves evolve. This evolution 'a double-edged sword': it can be advantageous considering that the organisms can coevolve measures against the defenses tumor cells may evolve, but this evolution can also have potential negative side effects (Pepper *et al.*, 2009). The evolutionary potential of these

biological agents need to be considered in the development of therapies.

Evolutionary quantitative genetics theory may provide insights into cancer therapy. For instance, consider therapy that involves giving patients combinations of drugs. When would such combination therapy be most likely to be more effective than single therapies? Evolutionary quantitative theory (e.g., Roff, 2006) would predict that such treatment would be most effective when the tumor's resistance to one drug comes at a cost of being less resistant to other drugs. The next most likely case for combination therapy to be effective is when resistance to one drug evolves with little or no cross-resistance. Combination therapy is not expected to be effective when the evolution resistance to one drug also results to resistance to other drugs (see also Pepper *et al.*, 2009).

Pepper *et al.* (2009) and others have suggested that we should think about therapies based on evolutionary rates. The McFarland *et al.* (2014) model of deleterious passengers has similar applications for treatment. Recall that this model predicted an optimal range for mutation rates. For most neoplasmas that have yet to become malignant, reducing mutation rates would limit progression. One way to reduce mutation rate would be to suppressing inflammation. Vaughan *et al.* (2005) has found that the use of aspirin and other NASIDs limit progression of Barrett's esophagus to malignant esophageal adenocarcinoma, presumably by limiting inflammation. In contrast, malignant tumors are already beyond the size threshold. Here, raising the mutation rate so as to generate a mutational meltdown might be the best strategy. McFarland *et al.* (2014) provide further details.

A related consideration is the number of cell division. Higher numbers of cell division could increase the risk of cancer. This supposition is consistent with the general increase incidence of cancer with age (Attolini and Michor, 2009). Wodarz and Komarova (2007) proposed that high rates of apoptosis increase cell turnover, thus generating more mutants and increasing the probability of cancer progression. They suggest limiting apoptosis might reduce cancer risk, but such a strategy has yet to be put into practice.

Finally, some cancer experts are considering adaptive therapy, a treatment strategy where the aim is to manage a stable tumor population rather than trying to kill as many cancer cells as possible (Gatenby *et al.*, 2009). Its use is still in development.

Outstanding Questions

1. The nonhuman animals that have been used as models for cancer research have evolved differences from humans in the way cell physiology and thus, cancer works. For instance, the role of telomerase differs in cancer progression in human and mice (reviewed in Hanahan and Weinberg, 2011). How well do animal models of cancer suffice? How can we use evolutionary principles and data to improve the use of the models?
2. Cancer biologists have postulated for a long time that only some cells – cancer stem cells – retain the potential to evolve into tumors (Cairns, 1975). The exact role of cancer stem cells remains unclear (Hanahan and Weinberg, 2011). The extent to which only some cells can retain the potential to form tumors affects several aspects, including the effective population size, of tumor evolution (Attolini and Michor, 2009).
3. What are the rates of cancer in other mammals, especially nonhuman primates? What are the genetic mechanisms that underlie the supposedly better cancer suppression mechanisms in very large animals, and can we exploit them to reduce cancer incidence and progression in humans?
4. Some evidence suggests the presence of tradeoffs between wound healing capacity and cancer suppression (Aktipis and Nesse, 2013). What is the nature of these tradeoffs? What genes are involved? How can we exploit this information to develop better therapies?

Evolutionary Medicine II. Use of the Comparative Method and The Animal Model

DA Kelly, University of Massachusetts, Amherst, MA, USA

Medical research tries to find treatments for human diseases, often by exploring the underpinnings of basic human biology, but most experiments are not carried out on humans or in human tissues. Instead, experimental work typically uses animal models: nonhuman animals that serve as proxies for human biology. Animal models allow scientists to conduct studies that would be impossible to complete in humans: experiments involving surgery, tissue manipulations, or breeding controls that would be unethical to try on people. Humans are also poor subjects for research into heredity because they have a long gestation period and take many years to grow to maturity. As a result, animal models have become powerful tools behind advances in all aspects of human biology, including physiology, functional anatomy, embryonic development, cell biology, genetics, and biochemistry (Rand, 2008).

Experimental studies in biology and medicine have been dominated by a short list of animal models, including the fruit fly (*Drosophila melanogaster*), nematode worm (*Caenorhabditis elegans*), zebrafish (*Danio rerio*), mouse (*Mus musculus*), and Norway rat (*Rattus norvegicus*). All became popular models because they have characteristics that make them convenient to use in a laboratory (Bolker, 2012). As a rule, they are small, robust, and easy to care for in captivity. They also grow to maturity quickly and breed frequently, making it possible to conduct experiments that span multiple generations over a relatively short period of time. Many model animals also have traits that make them particularly amenable to specific types of research: for example, the nematode *C. elegans* has a fixed developmental pattern that allows researchers to trace the fate of every cell in its body (Kenyon, 1988), and zebrafish are transparent as embryos, making it possible to use protein markers and fluorescent dyes to track cell movement and changes in gene expression *in vivo* (Gilbert, 2013). In addition, researchers have bred mutant varieties of these model animals or deliberately altered their genomes in order to track and determine the function of specific genes (Rubin, 1988; Jennings, 2011), neither of which would be possible in humans.

But while practical considerations were instrumental in making these species popular proxies for humans, it is their shared evolutionary history that makes correlations with human biology possible. Every model animal is a branch off the same family tree; although each has a unique evolutionary history, they also shared a common ancestor with humans at some point in the past (Dunn *et al.*, 2014). Common ancestry means they will share at least some aspects of their physiology with humans. Choosing a model animal should therefore include a consideration of its specific evolutionary history, to determine whether it will be a good analog for the human condition of interest. For some studies, fidelity between human and model characteristics is most desirable (Rand, 2008); in others, unique traits of the model species may be effective reflections of human tissues or disease states (Maher, 2009).

Deep Homology, Distant Relatives, and the Persistence of Ancestral Traits

Evolutionary relationships among species can be drawn as a series of nested branches called a phylogeny (**Figure 1**). Branches fork at speciation events, where two descendant groups are derived from a hypothetical common ancestor. Any traits that are unique to the hypothetical ancestor may be inherited by its descendant taxa, producing a group of species called a clade that share these derived characteristics, or synapomorphies (Harvey and Pagel, 1991; Brooks and McLennan, 1991).

This pattern of inheritance with modification underlies why many discoveries made in model animals are applicable to human biology: when humans and an animal model both inherit versions of a trait from a common ancestor, the traits are homologous and may retain similarities in genetic sequence, phenetic expression, and physiological function (Lauder, 1994). By manipulating these shared features in a

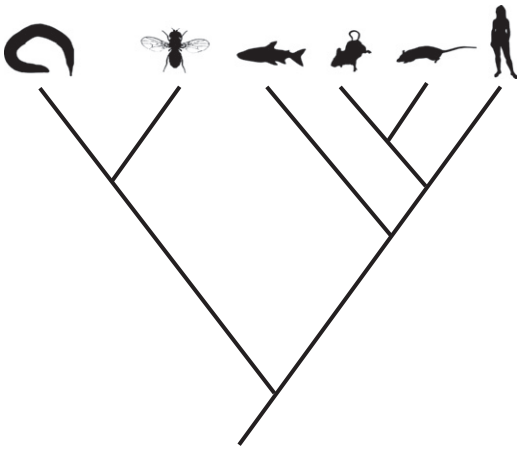

Figure 1 The phylogenetic relationships of the five most commonly used animal model species relative to humans. From left to right, species illustrated are *Caenorhabditis elegans* (roundworm), *Drosophila melanogaster* (fruit fly), *Danio rerio* (zebrafish), *Mus musculus* (mouse), *Rattus norvegicus* (rat), and *Homo sapiens* (human). Note that the laboratory mouse and rat are more closely related to one another than either is to humans. Although they are not particularly closely related, *C elegans* and *D. melanogaster* are still more closely related to one another than either is to any of the vertebrate animal models. Animal icons adapted from PhyloPic.org by Frank Förster (*C. elegans*), David Liao (*M. musculus*), Rebecca Groom (*R. norvegicus*) used via CC BY-SA 3.0, all others public domain.

model animal, we can obtain insights that are applicable to human biology.

A fruit fly, for example, looks nothing like a human. It is grossly different in size, body plan, internal anatomy, and developmental patterning: unsurprising, as molecular clock estimates suggest its lineage diverged from the lineage that includes humans more than 700 million years ago (Wray *et al.*, 1996; Wang *et al.*, 1999). But as an animal model, fruit flies have been instrumental in advancing our understanding of human heredity, gene expression, protein function, and the regulation of embryonic development (Rubin, 1988; Roberts, 2006) because flies and humans both inherited genes critical to cell survival and differentiation from an ancient common ancestor (Liebeskind *et al.*, 2011; Ramos *et al.*, 2012). Aspects of the genes that code for these traits have diverged over time, as humans and flies evolved significant differences in body plan (Gilbert, 2013). But their genes still have a deep homology (Bejerano *et al.*, 2004), and have retained enough functional similarities that experimental manipulations in flies can illuminate how the homologous human version works.

Closer Relationships, Greater Fidelity

Fruit flies and nematode worms have been excellent models for understanding genetics and development, but would be inappropriate for examining physiological systems such as the adaptive immune system – which is only found in vertebrates (Flajnik and Kasahara, 2010), or mammary glands – which are only found in mammals (Liem *et al.*, 2001). In cases like these, the best model animals share a more recent common ancestry with humans.

Species with recent common ancestry will be nested more deeply in a phylogenetic tree and share more synapomorphies than species that are more distantly related. For example, humans, mice, and zebrafish are all members of a clade descended from ancient bony fish. As such, they share a suite of derived characteristics that includes two pairs of lateral appendages and specialized tissues such as bone and enamel (Liem *et al.*, 2001; Hall and Witten, 2007). But humans and mice share a more recent common ancestry – they are both members of a clade that descended from early mammals – and as such they share additional derived characteristics that are not found in zebrafish: including hair, the ability to secrete milk, and facial morphology associated with chewing (Liem *et al.*, 2001). Closely related lineages share more derived characteristics, increasing the similarity of their anatomy, physiology, and their responses to disease and medical interventions.

This nested pattern of relationships and synapomorphies is why researchers use rodents as models in early-stage biomedical research, but switch to nonhuman primates as the final model animal when testing the efficacy of new drugs and medical treatments. Primates are far more difficult to maintain in the laboratory than mammalian models like rats and mice (King *et al.*, 1988; Shanks and Pyles, 2007), but their more recent common ancestry with humans also gives them more genetic and physiological similarities to humans. Physiological similarities between humans and their primate relatives make it possible to identify side effects that may not appear in more distantly related model species, or determine whether a treatment that worked in mice or rats remains effective in humans (Johnsen *et al.*, 2012).

Common Ancestry, Unique Histories

Many medical conditions are widespread among vertebrates: examples include cancer, infertility, obesity, and heart disease (Natterson-Horowitz and Bowers, 2012). The ubiquity of these conditions probably comes from the common ancestry of the clade – if the anatomy and physiology of a common ancestor left it susceptible to these conditions, its descendants can inherit that susceptibility as well as its other traits.

But although vertebrates suffer from similar illnesses, many treatments developed using model animals fail to translate to human biology (Shanks and Pyles, 2007; Seok *et al.*, 2013). While some failures can stem from methodological problems in experimental design, including small sample sizes, insufficient blinding, and inappropriate choices of model species (Pound *et al.*, 2004; van der Worp *et al.*, 2010), others may be a result of characteristics that are unique to the model species' lineage. The model animals still become ill. But aspects of their physiology can differ from humans, and these differences can affect their susceptibility to disease and their metabolic response to experimental treatments (Shanks and Pyles, 2007).

Evolution is ongoing, and after a speciation event each sister-lineage continues to accrue new characteristics. As a result, every model animal has traits unique to its own lineage, even while it shares other similarities with humans. Those differences make correlating model and human physiologies an imperfect process. For example, in recent years zebrafish have become a promising model animal for understanding bone formation (Spoorendonk *et al.*, 2008; Apschner *et al.*, 2011; Asharani *et al.*, 2012) – results from these studies are broadly applicable to mammals because the characteristics under investigation are conserved throughout vertebrates. But all vertebrate bone is not identical. Zebrafish, like other advanced teleost fish, have lost the ability to make osteocytes (Apschner *et al.*, 2011). Because osteocytes are the cells responsible for bone remodeling in other vertebrates, this teleost synapomorphy makes the zebrafish an inappropriate model for studies of bone remodeling, even as they remain a useful model for investigating more ancestral characteristics.

Evolutionary Mutants, Convergent Traits, and Unique Inventions

In some cases, model animals are chosen for study because they have traits that differ from normal human biology. For example, instead of using mutant strains of 'standard' model animals like flies or zebrafish, researchers may choose more unusual species whose normal phenotypes mimic human diseases. These evolutionary mutant models (Albertson *et al.*, 2009) can come from a broad range of taxa: examples include blind cavefish, which have naturally regressive eye loss and have been used as models for human retinal degeneration (Jeffery, 2001); and more recently turtles, whose phallus normally develops with an open groove for sperm transport, have served as a model for hypospadias, a congenital pathology

where the mammalian urethra fails to close along its midline (Larkins and Cohn, 2015). By examining normal developmental pathways in these model animals, researchers hope to determine how their traits are produced and ultimately develop a nuanced understanding of how differences in the regulatory regions of genes can affect phenotype (Albertson *et al.*, 2009).

Another tactic takes advantage of convergent evolution: choosing a model animal that independently evolved a trait similar to one found in humans. In this case, the model and human traits will not be identical, but they may share functional similarities that let the model's behavior provide insights about human function. For example, humans and songbirds independently evolved the ability to reproduce meaningful sounds by imitating adults; the process shares many functional similarities in both taxa including characteristic immature vocalizations ('babbling'), a dependence on social cues, and an interplay between vocal muscle activation and auditory feedback (Doupe and Kuhl, 1999; Knudsen, 2013). The zebra finch (*Taeniopygia guttata*) has been a particularly valuable model for exploring the neural underpinnings of this convergent system (Mello, 2014). There is nothing fundamentally different about the physiology of individual nerves in humans and birds. But songbirds have markedly different cerebrum anatomy than humans (Proctor and Lynch, 1993; Liem *et al.*, 2001), which means they comprise a second evolutionary experiment in neural circuitry for effective learning and song production. Researchers hope that examining the anatomical organization and neurochemical function of these circuits will unearth common organizational principals that can be applied to analogous regions in the human brain.

Sometimes a model animal has a unique trait that improves our ability to investigate a fundamental biochemical or physiological system. A classic example is the use of the squid genus *Loligo* for examining neuron function during the first half of the twentieth century. Squid have giant neurons in their mantle that control escape behaviors (Young, 1938). Mammals have no equivalent to these giant axons (Hill *et al.*, 2004), but the sensors available at the time were too large to fit inside a vertebrate neuron. Squid giant axons were easier to manipulate, and because they are much larger than vertebrate neurons – up to 1 mm in diameter – they could accommodate sensors to measure voltages inside their cell membrane. These experiments were instrumental to our understanding of how action potentials are produced (Hodgkin and Huxley, 1939), and were ultimately applicable to vertebrate neurons due to their common ancestry with squid (Dunn *et al.*, 2014). Although the morphology of squid and vertebrate neurons had diverged, the underlying cellular machinery for electrical conduction, inherited from a common ancestor (Liebeskind *et al.*, 2011), remained essentially the same.

The Challenge of Extrapolating from Models

Experiments in model animal systems have been integral to developing our understanding of scores of basic biological processes, but paradoxically, clinical treatments developed in animal models are sometimes ineffective in humans (Shanks and Pyles, 2007; Seok *et al.*, 2013). These failures occur often enough that some authors have suggested direct assays of human biomarkers could be a more useful method of predicting drug efficacy (Littman and Williams, 2005). Indeed, one challenge of extrapolating from any biological model, whether animal proxy or human genetic assay, is navigating the complex relationship between genetic differences and the morphological and physiological changes that cascade from them. Depending on their specific role in physiology or development, some genes simply drive more significant changes than others (Haag and True, 2001).

It is particularly important to remember that species sharing a high degree of morphological homology do not always share the same degree of physiological similarity (Burggren and Bemis, 1990). For example, although chimpanzees and humans are closely related, share many homologous traits, and can both be infected by HIV, chimpanzees are a poor model for studying the effect of the virus because they do not become ill the way humans do. Selecting the best animal model for a medical study is not simply a matter of getting as 'close' to humans as possible. An effective animal model for a human disease state will ideally replicate how the disease behaves in humans at some measureable level, whether genetic, or the development of symptoms, or the process of recovery (Pouladi *et al.*, 2013).

But any one animal model does not have to replicate every detail of the condition in question: it only has to accurately reflect the specific details that a study is interested in. In the case of HIV, cats turned out to be an effective model system for studying how the virus attacks the human immune system. Cats are more distantly related to humans than chimpanzees and have fewer morphological and physiological similarities, but the feline response to FIV, a virus in the same retroviral family as HIV, closely matched the human response to HIV.

Conclusions

Choosing a model animal for a study should not stop at practical considerations of cost and convenience. In medical research, the phylogenetic relationship of the model to humans is also important. Considering the evolutionary history of a potential model organism can help pinpoint which traits of interest may share similarities with humans, and which have diverged over time. The closeness of the relationship, the presence of homologous traits, and the unique traits bequeathed by the model's lineage are as critical to consider as the availability of mutant strains or the ease of breeding. Studies that aim to explain basic biological processes that are ancestral and maintained in many animals may be able to select from a much broader array of animal models than either studies focused on the progression of disease inside a closely related group of animals or studies that aim to identify effective treatments for a human disease.

It is also important to remember that closely related species are not always the best model for some aspects of human physiology. Researchers should look for a model species that is a good match for the 'specific traits of interest,' considering whether that species has retained those traits from a shared ancestor or evolved them independently. Different species are

likely to be better suited for modeling different aspects of a complex problem. Indeed, simply picking a species from a short list of 'standard' animal models may unnecessarily limit the types of questions we are capable of answering. We should be open to developing new animal models, each carefully chosen to effectively mirror a particular trait.

Evolutionary Medicine III. Mismatch

FM Low and PD Gluckman, The University of Auckland, Auckland, New Zealand

Glossary

Antagonistic pleiotropy Concept where a trait has beneficial, fitness promoting effects in early life but may incur costs later in life.

Developmental plasticity Processes of potential adaptive value in which an organism uses environmental cues to tune its phenotypic development to enhance fitness in a particular environment.

Maternal constraint Maternal and utero-placental factors that operate to limit fetal growth in the mammal.

Introduction

The emerging research domain of evolutionary medicine is concerned with the application of evolutionary principles to understanding human health and disease. It infuses traditional medical thinking, which primarily centers on proximate explanations and reductionist approaches, with evolutionary concepts to offer ultimate explanations for why disease may occur, thus providing a more complete framework for understanding the origins of disease risk. Formalized as a discipline less than three decades ago, it has rapidly gained traction in recent years (Alcock, 2012). This reflects the growing appreciation of how it complements clinical/biomedical approaches, providing a better understanding of human disease vulnerability at the levels of both the individual and the population.

Evolutionary medicine aims to address why, despite millennia of evolutionary history for selection pressures to operate, the human body is still vulnerable to disease. Nesse and Stearns (2008) identified six pathways by which evolutionary processes can influence disease susceptibility in humans. We expanded on these by further incorporating several aspects of population genetics (Gluckman *et al.*, 2009; **Table 1**).

In this article we focus on two major pathways to disease risk: evolutionary mismatch, and life history-associated factors underlying developmental mismatch. As both pathways involve aspects of the 'mismatch' concept, it is important to recognize the nuanced differences between the two. The basis for evolutionary mismatch is the dramatic change in contemporary environments and lifestyles compared to those during which the majority of selective processes giving rise to the modern human genotype have operated. On the other hand, developmental mismatch is underpinned by the evolved processes of developmental plasticity that operate early in the life course and influence the mature phenotype and, hence, disease risk in a particular context. Central to both pathways is the key principle that selection operates to maintain and promote Darwinian fitness, and is essentially heedless of quality of health past the age of peak reproduction. It should also be noted that evolutionary and developmental histories are not causative of disease per se, but instead mediate disease risk.

Evolutionary Mismatch

Evolutionary mismatch arises when the environments in which contemporary populations now live have deviated from that experienced during most of our evolutionary history. While numerous species demonstrate environment-altering behaviors to sustain their fitness (a process known as niche construction), humans are unique for their capacity to dramatically and rapidly change their built, sociocultural and nutritional environments, and much of this change has occurred relatively recently in evolutionary terms, spurred by the Agricultural and Industrial Revolutions (Fogel, 2004). The processes of selection generally operate over timescales of multiple generations to millennia, gradually changing the allelic frequency within a population. Yet, the genetic substrate for selective processes to act upon is somewhat limited by the range of environments previously experienced by the lineage. The slow tempo at which selection operates has become far outpaced by the speed of environmental change, and this lag has left our bodies mismatched and unable to adequately cope with consequent deleterious effects on health (Gluckman and Hanson, 2006a).

Evolutionary Novelty

The nature of the environment that can give rise to evolutionary mismatch can be distinguished in two ways. The first is when an individual encounters a wholly novel exposure. This may be in the form of a toxicant such as asbestos, to which humans have had minimal exposure and thus lack evolved detoxification mechanisms. Widespread mining and industrial use of asbestos from the late nineteenth century led to chronic inhalation of asbestos in many individuals, hence resulting in an epidemic of pleural mesothelioma, a rare cancer of the cells that surround the lungs and line the chest wall.

Exposure to a novel environment is another example of evolutionary novelty leading to mismatch. For example, scurvy, a disease clinically characterized by inflamed and bleeding gums, anemia, and skin hemorrhages, results from lack of dietary ascorbic acid. Humans are among the few primates that have lost the ability to synthesize ascorbic acid due to a mutation in *GULO*, which encodes the enzyme responsible for the committed step in the biosynthetic pathway. It is thought that this was an initially neutral mutation that arose in a frugivorous cladal ancestor. However, it only has a detrimental impact upon exposure to a novel dietary environment lacking in vitamin C, such as that experienced by eighteenth-century sailors undertaking long voyages (Buklijas *et al.*, 2011).

Table 1 Eight pathways by which evolutionary processes can modulate disease vulnerability

Pathway	*Conceptual basis*	*Clinical examples*
Mismatch	Exposure to an environment of evolutionary novelty (in entirety, or in extent)	Myopia; metabolic mismatch
Life history-associated factors	Trade-offs and antagonistic pleiotropy	Developmental mismatch: poor early life nutrition leading to obesity and metabolic dysfunction in adulthood
Excessive defense mechanisms	Dysregulation of normally adaptive defense activity	Extreme pyrexia; fear
Human–pathogen coevolution	Rapid rate of microbial evolution relative to that of humans	Antibiotic resistance
Evolutionary constraints	Consequences of human evolutionary history giving rise to certain anatomical features	Bipedalism underpinning back pain; ancestral herbivorism requiring a now-defunct appendix that is prone to inflammation
Sexual selection	Competition between males, and possibly certain sexually dimorphic biological characteristics such as higher testosterone	Greater extrinsic and intrinsic mortality among males
Balancing selection	Heterozygote advantage enabling the persistence of an apparently deleterious allele	Sickle cell anemia
Demographic history	Population bottlenecks, founder effects	Modern Finnish population demonstrating differential susceptibility to a range of diseases compared to rest of Europe

Note: The authors note that these categories are not discrete, and that many diseases will draw on multiple pathways.

Juvenile-onset myopia refers to near-sightedness resulting from refractive error that occurs around age 8 to 14. Myopia has a genetic component: having a myopic parent increases a child's risk of developing the same condition, and recently a mutation responsible for its onset has been identified in members of an Israeli tribe (Mordechai *et al.*, 2011). However, there is clearly strong environmental and cultural contribution to its development in the wider population. Risk factors implicated in its etiology include urbanization, increased education, being indoors, reading and close-up work, and underuse of peripheral vision (You *et al.*, 2012; Goldschmidt and Jacobsen, 2014), all of which are components of evolutionarily novel built environments. This, in turn, has led to preventative strategies being evaluated which encourage young children to spend time outdoors during this critical period of ocular development (French *et al.*, 2013). It appears that some populations may be predisposed to development of myopia, but that the condition is only revealed upon exposure to a 'myopigenic' environment. For example, rates of myopia are relatively low among Indians residing in India, but high among Singaporean Indians exposed to multiple environmental risk factors (Morgan and Rose, 2005).

The mismatch concept has a broad scope and can illuminate upon aspects of both physiological and mental health. Humans are exceedingly social animals, but while we have evolved to live in simple societies in groups of 100–150 (Dunbar, 2003), the modern day societal structure is characterized by large social groups, complex social hierarchies and stratification, democratization enabling greater autonomy, and myriad interactions involving personal and nonpersonal social networks and communication methods. The confluence of these evolutionarily novel environmental attributes may exceed the evolved cognitive and emotional adaptive capacities of some individuals, contributing to mental health disorders. It is perhaps telling that forecasts by the World Health Organization of morbidity causes in 2030 have pinpointed depression as the second highest contributor worldwide, and as the largest cause in high-income countries (Mathers and Loncar, 2006). There are some provocative human data linking social environment with mental illness, suggesting that urbanicity is associated with increased amygdala responses to social stress (Lederbogen *et al.*, 2011). Other studies have demonstrated correlations between real-world social network size and amygdala volume (Bickart *et al.*, 2011), and online social network size with gray matter density in brain regions involved in social cognition (Kanai *et al.*, 2011).

Mismatch between the ages of reproductive maturation and of psychosocial competence can also raise the risk of mental health disorders. Adolescence refers to the period from the onset of puberty to that when social recognition as an adult is attained, and the post-pubertal phase of adolescence is essentially an evolutionarily novel social construct. While the age of pubertal onset in the Paleolithic is unknown it may have been around 7–13 years, with full reproductive capacity being reached at perhaps age 9–14 (Gluckman and Hanson, 2006b) given that in modern hunter-gatherer populations the age at menarche is lowest in populations with high extrinsic mortality (Walker *et al.*, 2006). Further, competence in parenthood and as an adult within the simple small-scale societies necessitates psychosocial maturity, and it is likely that the age at which this was reached would have evolved to coincide with that of reproductive capacity for maximum fitness advantage (Gluckman and Hanson, 2006b). The advent of agriculture and settlement, and the associated increases in childhood morbidity and undernutrition then delayed age at menarche, but this was again matched by the increased societal complexities brought about by population aggregation. Then, improved standards of living and healthcare

accompanying the enlightenment facilitated the modern secular decline in the age at menarche. Other pre- and postnatal factors such as being born small with rapid postnatal weight gain can accelerate puberty (Sloboda *et al.*, 2007).

However, as discussed earlier, the complexities of the social environment have only increased since, and exponentially so since the arrival of the information age. Further, neuroimaging data and functional studies demonstrate that it is not until the third decade of life that brain regions associated with impulse control and judgment become fully mature (Lebel and Beaulieu, 2011; Cauffman and Steinberg, 2000). It is unclear whether late brain maturation is a modern day phenomenon resulting from increased societal complexity, from societal reticence in treating adolescents as adults upon biological maturity, or whether it is simply an evolved aspect that has adverse consequences in the modern world. Indeed, changing cultural norms in contemporary Western societies have led to prolongation of the period before youth become accepted as adults. Evidence suggests that those who experienced earlier puberty are at greater risk of exhibiting acting-out behaviors, depression, substance abuse, and suicidal attempts (Michaud *et al.*, 2006; Kaltiala-Heino *et al.*, 2003). Thus, it may be that the asynchronous timing of biological and of psychosocial maturation has consequences reflected in greater morbidity and mortality among adolescents (Office of the Prime Minister's Science Advisory Committee, 2011).

Evolutionarily Novel Range of Exposures

The second way by which evolutionary mismatch can arise is when exposure to a particular aspect of the environment is beyond the range previously experienced by the lineage. An excess of nutrition in the modern affluent world, leading to metabolic mismatch and contributing to the epidemics of obesity and metabolic disorders, is an illustrative example of this. The relatively recent beginnings of agriculture, compared to the appearance of the earliest members of genus *Homo*, suggests that humans and their hominin ancestors lived the bulk of their existence as hunter-foragers, and it is this lifestyle that has served as the template on which human biology and metabolism have been molded. Estimates of the likely dietary composition that prevailed in the Paleolithic indicate that it differed markedly from that in modern day societies: it was likely to have been highly varied and not reliant on a few cereal grains as dietary staples; intake of lean protein, fiber, and micronutrients such as calcium and ascorbic acid was higher, while that of fat and sodium was lower (Eaton and Konner, 1985; Eaton *et al.*, 1988). The major and progressively escalating driver of these changes has been the development of agriculture, industrialization, and extensive processing of food, underpinned by rapid cultural changes and technological advances (Lucock *et al.*, 2014). The contemporary obesogenic environment is characterized by a hypercaloric diet of readily available, palatable food and drink high in refined carbohydrates, sugar, sodium, and evolutionarily novel *trans*-fats, and a lifestyle of increased sedentariness. These pronounced changes in our nutritional and energetic patterns may overwhelm our evolved metabolic physiology and adaptive capacity. Accordingly, susceptibility to nutrition-related disease phenotypes such as obesity and type 2 diabetes mellitus is increased (Gluckman and Hanson, 2006a; **Figure 1(a)**).

Although humans as a species are vulnerable to metabolic mismatch, a degree of variation in disease risk exists at the level of the individual or population. For example, type 2 diabetes risk appears to be ethnicity-specific; it is greater in South Asian, Chinese, and Black populations than in Caucasians throughout the entire range of BMIs. Indeed, at a BMI of 24, clinically defined as normal, there is a greater than fourfold incidence of diabetes among South Asians than in those of Caucasian descent (Chiu *et al.*, 2011). The genetic component explaining variance in risk of obesity and its complications is small (McCarthy, 2010; Speliotes *et al.*, 2010), and there is now increasing evidence implicating developmental factors as a key contributor (see section Developmental Mismatch).

Developmental Mismatch

Developmental Plasticity

Developmental plasticity refers to the evolved and ubiquitous ability to adjust phenotypic development in response to environmental cues experienced in the more plastic early stages of development (Bateson *et al.*, 2004). It is the basis by which multiple phenotypes may be generated from a single genotype. Developmental plasticity may be induced by cues that generally fall within the normal range of physiological and ecological conditions, such as quantitative and qualitative aspects of, in mammals, maternal nutrition, maternal stress, and predator risk. The processes underpinning adaptive developmental plasticity evolved to promote fitness; they confer potential adaptive benefit by enabling the organism to exploit external cues to tune its phenotype to better survive stresses and match its environment.

However, the inherent constraints and energetic costs of maintaining plasticity limit much plasticity to the early period in life, although there may be *trans*-generational legacies (Gluckman *et al.*, 2007a). Because of this constraint, responses may be made not just for immediate survival advantage concurrent with the environmental challenge, but also for anticipated conditions later in life for delayed adaptive advantage. The latter type of response has been termed predictive adaptive responses (PARs) (Gluckman *et al.*, 2005a). For example, a fetus may gain information about the nutritional characteristics of the environment into which it will be born based on the nature of nutrition received from its mother; suboptimal maternal nutrition may induce PARs and thus signaling the adoption of an energy conserving phenotype to best adapt to a poor postnatal nutritional environment. These do not necessarily lead to apparent changes in phenotype or adaptive advantage *in utero* or at birth, but later in life. The biology and conceptual framework underlying PARs has been reviewed in detail (Bateson *et al.*, 2014; Bateson and Gluckman, 2011; Hanson and Gluckman, 2014).

The anticipatory strategy of PARs is not inerrant. Erroneous predictions, for example due to inaccurate transmission of cues, or to significant changes in the environment subsequent to the establishment of PARs, can result in the organism

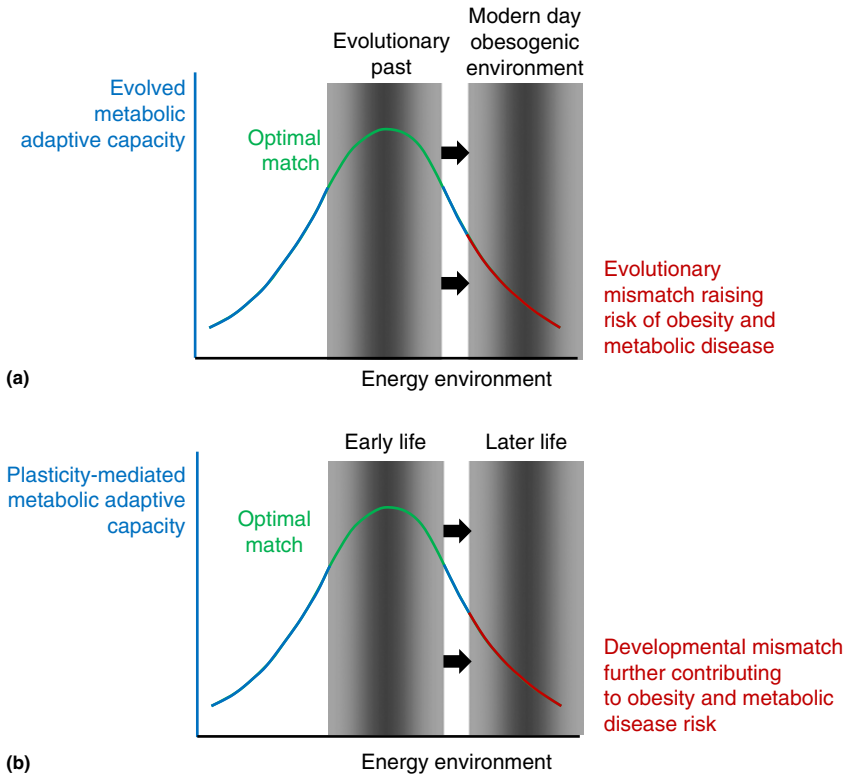

Figure 1 Our metabolic adaptive capacity as shaped by the energy environments experienced during our (a) evolutionary and (b) developmental histories can become mismatched to the modern day or later life planes of nutrition, leading to increased risk of obesity and its complications.

possessing a phenotype that is discordant with the mature environment. This leads to a situation of developmental mismatch wherein risk of chronic noncommunicable disease is increased. Since selection operates to maximize reproductive fitness and not health or longevity, and – at least with respect to most noncommunicable disease – the increased disease risk likely manifests after the period of peak reproduction has passed, inaccurate anticipatory responses will generally have little impact on reproductive success. This, therefore, provides little impetus for negative selection to operate, enabling the evolutionary retention of developmental plasticity and PARs in spite of the potentially deleterious later life consequences. Modeling work has also shown that even under conditions of environmental stochasticity, persistence of induced phenotypes over several generations offers adaptive advantage over both non- or fully plastic strategies (Jablonka *et al.*, 1995).

Another factor that may play a role in why PARs are conserved may relate to maternal care seen in mammals, birds, and some other taxa. In mammals, the cues of most relevance are prenatal, and forecast, for example, poor postnatal nutrition, even though the infant will undergo a protected period of postnatal maternal care before becoming autonomous. To induce the physiology appropriate to autonomous life in poorly nourished circumstances may be disadvantageous while being suckled. Indeed, it is well established experimentally and clinically that signals of poor intrauterine nutrition lead to long-term induction of insulin resistance with its survival value in postweaning poor nutritional circumstances (Duque-Guimarães and Ozanne, 2013). However, to be insulin resistant during the period of high-fat milk feeding would reduce adipose deposition and thus make the growing individual more likely to be unable to buffer the energetic demands of the rapidly growing brain after weaning under conditions of malnutrition or infection (Kuzawa, 2010). Such data explain why children born with growth retardation only become insulin resistant at about the age of 3 years (Mericq *et al.*, 2005), which is coincident with likely past weaning behaviors.

Developmental Origins of Obesity and Its Complications

Although the literature is dotted with sporadic reports as far back as the 1930s hinting at the role of early life pathways in disease risk, it was not until David Barker and associates' meticulous work on a large UK cohort in the 1980s, showing that low birth weight correlated with increased risk of death from ischemic heart disease in middle-age, that the role of development as a determinant of later life disease risk gained sustained attention (Barker *et al.*, 1989; Gluckman and Buklijas, 2014). Articulations of this phenomenon into a viable conceptual framework (Gluckman *et al.*, 2005a,b), together with progress in epigenetic biology (Gluckman and Buklijas, 2014; Hanson and Gluckman, 2014), helped give wider credence to the idea that events occurring at the very earliest stages of life could have lifelong health sequelae. There is now a substantial corpus of research from domains spanning epidemiology through to clinical medicine and animal experimental work, showing that risk of noncommunicable disease

in later life is modulated by early life events. By positioning developmental factors as a key determinant of disease risk, this framework, formalized as the developmental origins of health and disease (DOHaD) (Gluckman and Hanson, 2006c), has significantly advanced our understanding of human morbidity in the context of modern day environments.

Much of the DOHaD literature has focused on how developmental influences have shaped risk of adiposity, cardiovascular, and metabolic diseases, including insulin resistance, type 2 diabetes, and hypertension. Experimental work using rodent models has demonstrated that a maternal low-protein diet during pregnancy induces hypertension, dysregulations in vascular endothelial function and lipid metabolism, and a preference for high-fat food in adult offspring (Langley-Evans *et al.*, 2006). Fetal exposure to maternal undernutrition influences intermediary metabolism and appetite control, leading to obesity, insulin resistance, decreased physical activity, hyperphagia, and dietary fat preference in adulthood (Vickers *et al.*, 2000, 2003). Crucially, increasing the degree of developmental mismatch through a high-fat postnatal diet amplifies these phenotypic effects. Hence, in this model, fetally undernourished offspring appear to have adopted an integrated, energy conserving phenotype to cope with an anticipated low postnatal plane of nutrition. This metabolic physiology is rendered inappropriate upon exposure to an obesogenic environment to which the offspring are developmentally mismatched, thus leading to increased disease vulnerability. An equivalent situation in humans has been well studied using cohorts of descendants of famine survivors. For example, offspring of women who were pregnant during the wartime famine of 1944–45 in the Netherlands were at higher risk of coronary heart disease, dyslipidemia, glucose intolerance, and (in women) adiposity at age 50–58 compared to unexposed individuals (Roseboom *et al.*, 2006). Dietary preference for fat has also been observed (Lussana *et al.*, 2008). *In utero* exposure to the Chinese famine of 1959–61 was associated with hyperglycemia and clinical indicators of metabolic syndrome (Li *et al.*, 2010, 2011), while exposure to the Nigerian civil war famine of 1967–70 during fetal life and infancy increased risk of hypertension and impaired glucose tolerance at age 40 (Hult *et al.*, 2010).

While famine serves as a regrettable natural experiment to investigate DOHaD in humans, they are relatively rare and extreme. Indeed, recent work shows that developmental induction of long-term consequences can occur within quite normative exposures *in utero* which do not lead to changes in birth weight (Gale *et al.*, 2006; Godfrey *et al.*, 2011), emphasizing the subtle and likely adaptive nature of plasticity. In humans, there are multiple situations by which developmental mismatch can arise that may affect much of the population and thus have profound public health implications. A major pathway, particularly relevant to developing countries experiencing economic prosperity, is the rapid transition to an obesogenic environment of nutritional plenitude and associated decreases in energy expenditure. Relatedly, increased urbanization, rural-to-urban migration, and emigration to more prosperous countries may leave the individual – who has likely experienced a low plane of nutrition early in life – ill equipped to handle the nutritionally overloaded environment encountered (Ebrahim *et al.*, 2010; Shan *et al.*, 2011). Cultural factors may also contribute. Decreasing family size in many countries has led to corresponding increases in proportion of first-borns who, owing to the processes of maternal constraint that limit fetal growth and operate to a greater extent in primiparous pregnancies, are more likely to be born smaller than later-born siblings, be more insulin resistant in later childhood, and more adipose in adulthood (Ayyavoo *et al.*, 2013; Reynolds *et al.*, 2010). The introduction of formula feeding as an alternative to breastmilk is another factor that has been linked to increased obesity risk (Jwa *et al.*, 2014; Harder *et al.*, 2005).

Extensive epidemiological data have shown that there is a clear gradation in the relationship between early life cues and later disease risk (Rich-Edwards *et al.*, 2005; Harder *et al.*, 2007; Osmond *et al.*, 1993). This indicates that plasticity operates across the normal range of exposures, and that normative developmental experiences can still be associated with adverse health outcomes. Thus it would be fallacious to dichotomize populations into low versus at-risk, as disease risk arguably applies across the entire population. It should also be noted that individuals experiencing nutritional developmental mismatch are also subject to evolutionary metabolic mismatch; in this way, the effects of the former compound those of the latter (**Figure 1(b)**).

Molecular Basis of DOHaD

There is strong evidence from investigations in animals, and emerging evidence in humans, that epigenetic mechanisms play a key role in mediating the processes of developmental plasticity. Epigenetic mechanisms are the molecular processes that establish and maintain mitotically heritable patterns of gene expression in a DNA sequence-independent manner. Key mechanisms include DNA methylation, covalent modifications of histone protein tails that induce chromatin reconfiguration, and the gene expression-regulating activity of noncoding RNA. In the previously described rat model of fetal undernourishment, decreased expression of *Ppara*, encoding a fatty acid oxidation regulator, in offspring hepatic tissue was concordant with hypermethylation at its promoter region. Importantly, neonatal administration of leptin to these pups normalized epigenetic and gene expression changes and completely prevented development of the primed phenotype (Vickers *et al.*, 2005; Gluckman *et al.*, 2007b). Similarly, in a model of maternal protein-restriction in which offspring become hypertensive as adults and show dysregulations in lipid metabolism and vascular endothelial function, increased expression of *Ppara* and *GR* was observed together hypomethylation at the promoter regions (Lillycrop *et al.*, 2005). Furthermore, offspring from rat dams that received folic acid supplementation were spared the metabolic dysfunction phenotype, and methylation and gene expression levels were restored to those of controls (Lillycrop *et al.*, 2005).

The famine cohort studies have provided support for the tractability of epigenetic marks in response to early life events in humans. Differential methylation at *IGF2*, a maternally imprinted gene central to growth and development, and at several candidate genes involved in metabolic and cardiovascular disease was seen in gestationally exposed individuals

in their sixth decade of life (Heijmans *et al.*, 2008; Tobi *et al.*, 2009). The effect sizes were small, but these studies clearly demonstrate the temporal stability of the molecular memory arising from a transitory environmental exposure. The recognition that the epigenome may serve as a molecular transducer of information from environment to genome has prompted the establishment of multiple prospective cohort studies investigating the epigenetic underpinnings of developmentally influenced disease risk in normal populations (Ng *et al.*, 2012; Soh *et al.*, 2013; Saffery *et al.*, 2012). Early data have already linked the epigenome to later phenotypic variation of clinical relevance. For example, degree of methylation at specific sites of the *RXRA* promoter measured at birth correlated with adiposity of the child at age 6–9 years and explained a significant component of the variance in BMI at that age (Godfrey *et al.*, 2011). Methylation levels were further inversely associated with maternal carbohydrate intake in early pregnancy, demonstrating that even subtle changes in the nature of nutrition received *in utero* affects epigenetic regulation.

Implications for Human Health

We have described how disease risk is influenced by both the evolutionary and developmental histories of the individual, and thus a greater understanding of human health and disease from these perspectives has considerable value in devising interventional strategies. In the case of evolutionary mismatch, given the inherent temporal limitations of our genetic repertoire in adapting to environmental novelties, it seems likely that our recourse is to change the environment, and/or adapt our behaviors to the changed environment. With respect to nutrition, some studies on native peoples have supported the notion that dietary modifications in favor of varied and healthful foods may have beneficial effects. For example, diabetic Australian Aboriginal people who maintained a traditional hunter-gatherer diet and lifestyle for 7 weeks showed substantial improvements in several metabolic parameters (O'Dea, 1984), while observational studies have shown that rates of obesity and type 2 diabetes among Pima Indians living in remote mountainous regions of Mexico are markedly lower than for those residing in the United States (Schulz *et al.*, 2006). Nevertheless, despite the recent popularity of the so-called 'Paleolithic diet' attempting to emulate the presumed diet of our preagricultural hunter-gatherer ancestors, there are few well-controlled studies of its long-term efficacy, and there is unlikely to be a single diet that is appropriate for all individuals due to variations in our metabolic physiology as influenced by our genetic and developmental backgrounds.

In light of the unabated rise in rates of overweight, obesity, and associated chronic diseases in both high and low-middle income countries (Ng *et al.*, 2014; International Diabetes Federation, 2013), it is becoming evident that voluntary lifestyle modifications in adulthood, which have been the mainstay of public health strategies targeting obesity, are ineffective. Alternative strategies based on recent scientific advances underscoring the role of development in disease risk have been well canvassed (Gluckman *et al.*, 2011) – these recognize the value of exploiting the period early in the life course when physiological set-points for metabolism, appetite and satiety are being established. Exciting research is now accruing from the field of developmental epigenetics showing that risk markers of adiposity (Godfrey *et al.*, 2011; Perkins *et al.*, 2012) and of metabolic syndrome (Yoo *et al.*, 2014) may be measurable at birth. This suggests the potential for the use of prognostic biomarkers to identify at-risk infants for early intervention, although it is imperative that such studies incorporate within- and between-cohort replications to validate findings. Ample experimental evidence that developmentally primed phenotypes can be reversed by endocrinological, dietary, and pharmacological means (Vickers and Sloboda, 2012) offers proof of concept that a poor start to life need not have immutably deleterious effects. What is clear is that the focus should be on optimizing an individual's diet and health, starting from as early as the preconceptual period via maternal well-being, through to the neonatal life, infancy and childhood.

Evolutionary Medicine IV. Evolution and Emergence of Novel Pathogens

SV Scarpino, Santa Fe Institute, Santa Fe, NM, USA

Glossary

Coalescent theory A retrospective, mathematical framework for relating genetic variation to historical evolutionary and demographic processes.

***De novo* phenotypes** New traits, which are present for the first time in a population.

Glycoprotein A molecule that consists of a carbohydrate and a protein bound together.

Influenza hemagglutinin One of the surface glycoproteins found on influenza viruses. Its primary function is for binding the virus to sialic acid binding sites.

Microparasites Parasites that can complete their life cycle within a single host and can be transmitted directly to other hosts of the same species, for example, influenza, HIV, and Ebola.

Phylodynamic models Theoretical population genetic models relating the complex demographics of pathogens to the structure of their phylogenetic trees.

Sialic acid Nitrogen or oxygen substituted derivatives of the nine-carbon monosaccharide, neuraminic acid.

Social contact networks A social structure made up of individuals and the contacts between them, which are often visualized as graphs.

Introduction

The evolutionary history of humans is characterized by dynamic shifts in population density and the structure of our social contact networks. Agriculture, the advent of City-States, European expansionism, and modern globalization have all had profound effects on the ecology of humans (Mcmichael, 2004). Our changing dispersal, demographic, and contact patterns have impacted both commensal and pathogenic organisms. Fruit flies in the genus *Drosophila*, numerous Yeast species, *Escherichia coli* and other human commensals tracked our expansion throughout the world (Keller, 2007; Pamer, 2007). However, pathogenic species followed too. In the 1700s and 1800s, smallpox and measles – spread to the Americas by European explorers – decimated indigenous populations (Mcmichael, 2004; Cliff *et al.*, 1993). At the turn of the last century, the 1918 flu killed between 20 and 40 million people worldwide in little over a year (Noymer and Garenne, 2000). Troop movement during WWI played a critical role in the emergence and spread of that virus (Oxford *et al.*, 2002). Today, we are beset by the human immunodeficiency virus infection and acquired immune deficiency syndrome (HIV/AIDS) epidemic, the threat of pandemic avian influenza, hepatitis C, Ebola, tuberculosis, and myriad neglected tropical diseases (Mcmichael, 2004; Morse, 1995; Worobey *et al.*, 2008; Hotez, 2014). The critical factors uniting the spread of commensal and pathogenic species, the emergence of new diseases, and the rapid spread of pandemic strains are the increasing density and connectivity of our populations, coupled with the evolutionary lability of many parasites, for example, bacteria and viruses (Scarpino *et al.*, 2015; Galvani and May, 2005; Pourbohloul *et al.*, 2009; Stoddard *et al.*, 2009).

Modern travel patterns, heterogeneity in population density, variable immunity, and changing proximities to wild and domesticated animals interact to drive complex patterns of disease transmission and emergence (Galvani and May, 2005). SARS and SO-H1N1 spread rapidly around the globe, but because of heterogeneity in contact patterns and immunity, these diseases were not the disasters predicted early in the epidemics (Pourbohloul *et al.*, 2009; Meyers *et al.*, 2005). A similar situation also occurred during the 2014–15 Ebola outbreak in West Africa, where models with more realistic human contact patterns predicted yielded more accurate predictions (Scarpino *et al.*, 2015). The threat of wildlife disease and its spillover to humans and our food is also becoming an increasing concern (Weiss and McMichae, 2004; Frenzen, 2004; Chua *et al.*, 1999; Daszak, 2000). Changes in hunting and agricultural practices alter contact patterns between wildlife and domesticated animals (Daszak, 2000; Köndgen *et al.*, 2008). The result has been both the spillover of highly virulent diseases, such as Nipah virus and Ebola, and recombination between human and animal strains of influenza (Weiss and McMichae, 2004; Chua *et al.*, 1999; Daszak, 2000).

The emergence of HIV in central Africa illustrates both the importance of evolution and changing ecology on the epidemic potential of novel pathogens. The European reorganization of central Africa – from a dispersed collection of villages to a system with large urban areas – fundamentally changed human social contact patterns in the region (**Figure 1**; Hance, 1970; Worobey *et al.*, 2008). Recent genetic evidence suggests that in some of these emerging cities, HIV epidemics were raging by the late 1950s or early 1960s (Worobey *et al.*, 2008). Using historical census data (Hance, 1970), the author compared the rates of population growth, urbanization, and HIV infection – as reconstructed from HIV genomic data by Worobey *et al.* (2008) – in the Democratic Republic of the Congo (DRC), the Republic of Congo, the Central African Republic, and Gabon. Strikingly, the rate of increase in HIV infections lags the rate of urban growth, while the rate of population growth remains essentially constant (**Figure 2**). This result highlights the importance of both changing host ecology, in this case the urbanization of central Africa, and pathogen evolution in the emergence of new diseases (Schrag and Wiener, 1995; Antia *et al.*, 2003; Weiss and McMichae, 2004; Holmes, 2009). In the next section, the author discusses

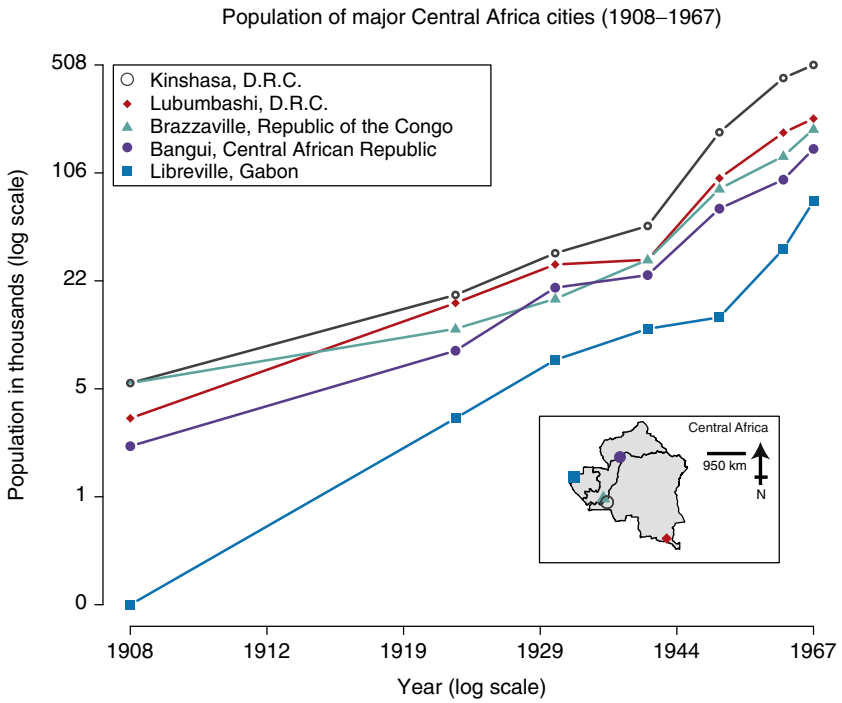

Figure 1 Between 1900 and 1970, the population size of the five largest central African cities grew by over 100-fold. This dramatic increase in size was due mostly to urbanization, where individuals migrated from rural areas to the cities, as opposed to population growth.

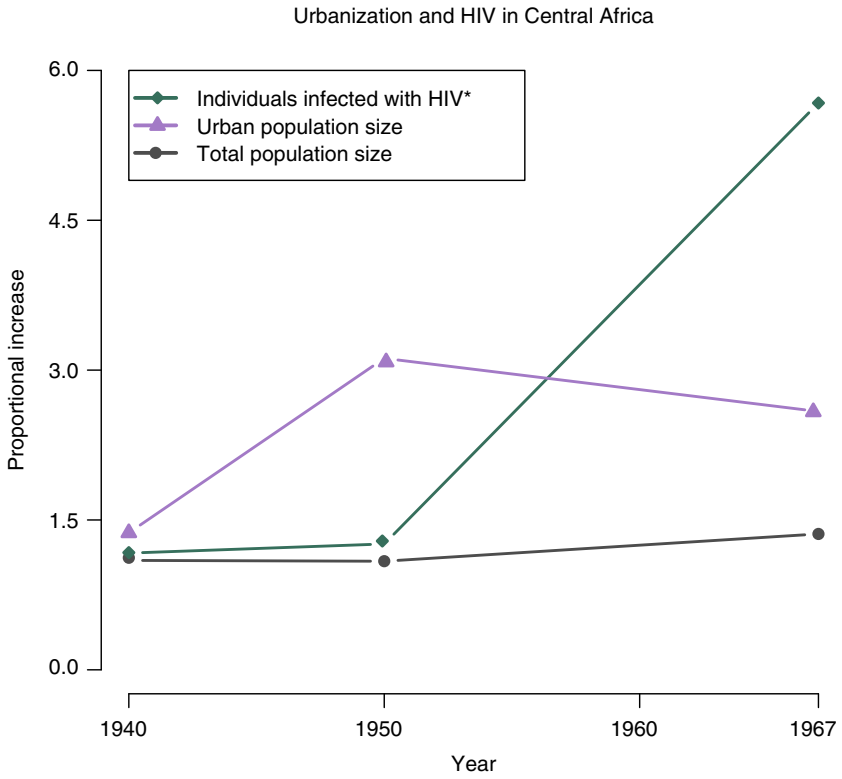

Figure 2 Estimates from genomic data suggest that HIV was already spreading rapidly in central Africa by the 1960s. As predicted by theory from epidemiology, there is evidence for a role of urbanization in the spread of HIV. The figure plots the proportional increase in growth rate by decade for individuals infected with HIV (green), urban population size (purple), and total population size (black). Note how the HIV epidemic lags urbanization, while the population growth rate remains essentially constant.

modern methods for studying the dynamics of infectious diseases using genomic data and then in the following sections the author illustrates the role of these new methods in studying emerging infectious diseases.

The Phylodynamics of Emerging Infectious Diseases

Pathogen host shifts are responsible for outbreaks of severe disease in wildlife, livestock, and human populations (Antia *et al.*, 2003; Dobson and Foufopoulos, 2001; Morens *et al.*, 2004; Daszak *et al.*, 2000b; Altizer *et al.*, 2003). Despite the biological importance of such host shifts, many gaps remain in our understanding of how and why they occur. Because many pathogens – especially RNA viruses – mutate so rapidly, their evolutionary and ecological processes are inextricably linked (Antia *et al.*, 2003; Koelle *et al.*, 2009; Pybus and Rambaut, 2009; Levin, 1999). Therefore, studying epidemics requires models able to connect evolution to ecology. The emerging field of phylodynamics seeks to leverage the genetic variation of pathogens to investigate their complex, epidemiological dynamics through the use of mathematical transmission models (Grenfell, 2004; Holmes and Grenfell, 2009; Volz *et al.*, 2009). Linking these models with the genetic sequence data – now routinely collected during disease outbreaks – provides an unprecedented opportunity to advance our scientific understanding of how evolution affects epidemics and pathogen establishment (Antia *et al.*, 2003; Holmes and Grenfell, 2009; Pybus and Rambaut, 2009; Leventhal *et al.*, 2015; Woolhouse *et al.*, 2005).

What are the drivers of pathogen emergence and reemergence? How are microparasites able to cause epidemics in novel hosts? These questions have been the focus of epidemiology since its inception and remain of immediate importance for wildlife, human, and livestock populations (Anderson and May, 1992; Daszak *et al.*, 2000a). It has become clear that answering these questions requires an understanding of how rapid evolution contributes to epidemic potential (Antia *et al.*, 2003; Pepin *et al.*, 2010; Pybus and Rambaut, 2009; Leventhal *et al.*, 2015; Woolhouse *et al.*, 2005). For emerging infectious diseases, the key evolutionary event is often the generation of *de novo* phenotypes in pathogens (Altizer *et al.*, 2003; Woolhouse *et al.*, 2005; Parrish *et al.*, 2008). These phenotypes might include a strain with increased transmissibility, or immune escape variants. Because of the large population sizes and high mutation rates of many viruses, it is hypothesized that selection on *de novo* variation may be a critical factor during viral adaptation to novel hosts and coevolution with existing hosts (Crill *et al.*, 2000; Eshelman *et al.*, 2010; Pybus and Rambaut, 2009; Altizer *et al.*, 2003; Woolhouse *et al.*, 2005; Parrish *et al.*, 2008).

Since its inception, the field of phylodynamics has seen significant advances in theoretical population genetic models relating the complex demographics of pathogens to the structure of their phylogenetic trees (Koelle *et al.*, 2006; Norström *et al.*, 2012; Volz *et al.*, 2009). These include mathematical models describing how deterministic epidemic dynamics shape neutral genetic variation (Volz, 2012), models describing how rates of coalescence can be related to epidemiological model structures (Koelle and Rasmussen, 2012), and powerful statistical models to estimate the parameters of those mathematical models (Rasmussen *et al.*, 2011). However, the existing mathematical models are insufficient for investigating the role of *de novo* evolution in epidemics. The emergence of novel pathogen phenotypes, such as a strain with higher transmissibility or increased virulence, during an outbreak necessitates a dynamic model structure. Although capable of incorporating selection and allowing for stochasticity, the current models have a static structure and are thus unable to account for newly arising phenotypic variants (Koelle and Rasmussen, 2012; Rasmussen *et al.*, 2011; Volz, 2012).

A Short Primer on the Coalescent

The primary tool for modern population genetic inference is coalescent theory, which provides a retrospective, mathematical framework for relating genetic variation to historical evolutionary processes (Wakeley, 2008). Coalescent theory permits the study of the evolutionary history of a population by sampling individuals in the present (Drummond *et al.*, 2005; Wakeley, 2004, 2008). Consider a population in which individuals are related by a shared ancestry rooted at their 'most recent common ancestor (MRCA).' Going forward in time and starting from the MRCA, the population diverges with lineages forming and dying. Looking backwards, lineages fuse, reducing in number until only a single lineage remains; the coalescent is a quantitative, probabilistic framework for determining when lineages join, or 'coalesce,' backwards in time (Wakeley, 2008; Fu and Li, 1999). Because the coalescent considers neutral genetic variation, all pairs of existing lineages are equally likely to coalesce (Wakeley, 2008; Kingman, 1982a,b). The result is a genealogy tracing the current individuals backwards in time to the MRCA. The parameters of a coalescent model describe this stochastic, genealogical process. The rate that these lineages are born and die is also a function of the nonneutral evolutionary forces acting on the population and demographic processes (Wakeley, 2008). Therefore, selection, demography, and other evolutionary processes will leave signatures in the shape of genealogies (Wakeley, 2008; Drummond *et al.*, 2005; Parsch *et al.*, 2001; Nei and Takahata, 1993). The expected coalescent time and the rate of coalescent are both highly sensitive to changes in ecological and evolutionary dynamics. As a result, coalescent theory can be used to extract information about phenotypic evolution from the genetic variability of populations.

The Coalescent and Infectious Diseases

Applying coalescent theory to the study of infectious disease dynamics presents a number of challenges (Frost *et al.*, 2015). First, sequences are typically sampled serially, as opposed to the classical application of coalescent theory where sequences are collected from a single time-point (Koelle and Rasmussen, 2012; Volz, 2012; Stadler *et al.*, 2012). Second, unlike many traditional applications, often a large fraction of infected individuals are sampled (Volz, 2012). Third, complex population dynamics emerge from an epidemic process. In two recent papers, Volz *et al.* (2009) and Volz (2012) derived the coalescent for structured pathogens undergoing complex population dynamics. The models in (Volz, 2012; Volz *et al.*, 2009) allowed for: (1) the nonlinear growth rate of pathogen populations during

epidemics, (2) birth and transmission rates that change during an epidemic and are not always proportional to population size, and (3) the changing variance in the number of transmissions per infected individual. Using the novel coalescent framework developed by Volz *et al.* (2009), Rasmussen *et al.* (2011) demonstrated that with a model for the rate of coalescence, it was possible to infer historical epidemiological patterns from simulated sequence data. The statistical methods developed by Rasmussen *et al.* (2011) are Bayesian particle filter methods, which, once an equation exists for the rate of coalescence, can approximate the likelihood of a model given a genealogy.

Selection acting on genetic variants arising from *de novo* phenotypic evolution adds an additional layer of complexity to the coalescent process (Frost *et al.*, 2015). This form of evolution will result in new disease model compartments that arise stochastically. Therefore, modeling selection on *de novo* variation requires a dynamic model structure. The Volz *et al.* (2009) and Volz (2012) coalescent models can have arbitrary structure, but critically this structure must be static during the course of evolution. Consider a mutation increasing the transmissibility of a pathogen. As this mutation spreads, the transmission dynamics change. This effect can be easily visualized in the transmission tree, where hosts are connected if one host's pathogens seeds infection in an uninfected host (**Figure 3**). Because two pathogen lineages cannot coalesce unless they come from a shared host, changes in the transmission tree will affect the rate of coalescence for pathogens.

How Does Selection for Increased Transmissibility Affect Influenza Phylogenies?

In 2004, an influenza outbreak in greyhound dogs had a case fatality rate close to 40% (Crawford, 2005). Sequencing of viral isolates determined that the virus responsible for this outbreak, influenza A/H3N8, arose from a recent spillover from horse populations (Crawford, 2005). Subsequent phylogenetic analysis provided early evidence for viral evolution during adaptation to a novel host. Molecular changes in the A/H3N8 hemagglutinin gene, encoding the viral surface glycoprotein, indicated evolution of increased transmissibility in canines (Crawford, 2005).

Over the period of 4 months in 2011, nearly 200 New England harbor seals died of pneumonia caused by an avian influenza, also of the influenza A/H3N8 subtype (Anthony *et al.*, 2012). The H3N8 strain had acquired a mutation that increased its ability to transmit between mammalian hosts (Anthony *et al.*, 2012). Because influenza infects the gastrointestinal tract of birds and the upper respiratory track in mammals, transmissibility had been a barrier to species jumping. Variation in infection location is primarily caused by differences in the sialic acid binding site of influenza infecting avian and mammalian hosts (Fergusson *et al.*, 2003; Smith *et al.*, 2009; Suzuki *et al.*, 2000). However, reassortment of influenza strains with different cell-type specificity and evolution in hosts with mixed sialic acid types, such as pigs, can facilitate spillover (Fergusson *et al.*, 2003; Smith *et al.*, 2009; Suzuki *et al.*, 2000). Sequence data from the harbor seal outbreak suggests this as a mechanism for increased transmissibility (Anthony *et al.*, 2012).

Using Phylodyanmics to Study Disease Reporting During the 2014 Ebola Outbreak

Infectious disease surveillance data can be unreliable during unfolding crises in which resources are limited and public health authorities have poor access to affected communities. During the 2014–15 Ebola outbreak in West Africa, surveillance efforts primarily detected cases that were treated in healthcare facilities, and may have missed a sizable fraction of infections (Meltzer *et al.*, 2014; WHO Ebola Virus Response Team, 2014). Initially, the CDC estimated for every Ebola case reported in Sierra Leone and Liberia, as many as 2.5 times as many cases went unreported (Meltzer *et al.*, 2014). Accurate outbreak projections and assessments of intervention strategies depend on reliable estimates of underreporting rates. However, underreporting can be a very dynamic process, potentially varying in time, space, and/or with outbreak size, and driven by intrinsic properties of the pathogen, human behavior, diagnostic practices, and the healthcare infrastructure.

The primary difficulty the public health community faced in estimating underreporting is the limited data commonly available during an outbreak, namely confirmed and suspected cases and mortalities. From these data alone, one cannot estimate the rate of underreporting without making strong modeling assumptions and, even with such assumptions, we often lack statistical power to make precise estimates.

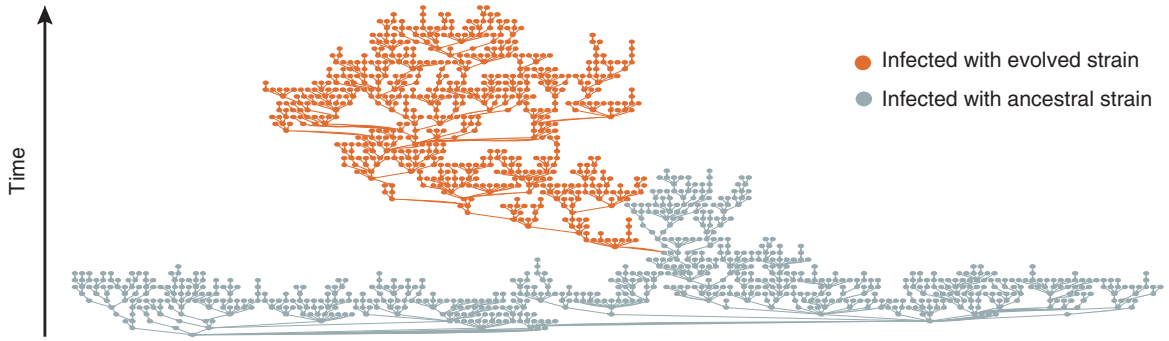

Figure 3 The results from a computer simulated emerging infectious disease outbreak. Hosts are represented as circles, with lines connecting individuals who infected each other. Time starts at the bottom of the plot. Approximately one-third of the way through the outbreak, a mutation occurred that increased the transmissibility of the pathogen. Individuals infected with this new strain are colored in orange.

However, underreporting can cause a mismatch between incidence estimated from case data and incidence reconstructed from genetic data using phylodynamic methods. For example, if there is a constant level of underreporting, case count data will reflect lower transmission rates and lead to underestimation proportional to the underreporting rate. However, the extent of genetic variation among viral sequences taken from the same set of cases will reflect the true, larger population size of circulating viruses, and lead to estimates closer to the true incidence. This is true even if viral sequences are only collected from reported individuals, assuming reported and unreported individuals are mixing with each other. In a phylodynamic analysis of Ebola virus genome sequences, Scarpino *et al.* (2015) estimated that underreporting of cases may be between 0–70%, with the most likely value being 17%.

Beyond underreporting, leveraging phylodynamic methods during emerging infectious disease outbreaks can potentially address a range of important, but historically challenging, questions. These include, but are certainly not limited to, the potential for evolution to alter the virulence or transmissibility of the pathogen, the role of subclinical or asymptomatic infections in transmission, the importance of cross-border transmission, and the relative role of various transmission routes in sustaining an outbreak. During the next pandemic, or emerging infectious disease outbreak, deploying phylodynamic methods and next-generation sequencing to improve surveillance and decision-making will be essential.

Conclusions

In this article we have seen the emergence of novel pathogens is a complex process and one affected by host ecology and behavior, as well as, pathogen evolution (Leventhal *et al.*, 2015; Woolhouse *et al.*, 2005). For some diseases, such as influenza, it seems clear that the most important determinant is pathogen evolution. However, for others, such as SARS, Ebola, and Middle East respiratory syndrome corona virus host factors seem to play a larger role in regulating spread. Although a pathogen's often rapid rate of evolution can contribute to its epidemic potential, these high rates also facilitate the application of phylodynamic methods to the study of emerging infectious diseases. Future work in the rapidly expanding field of evolution and the emergence of novel pathogens will undoubtedly provide numerous scientific insights, but hopefully, better prepare us for the next pandemic.

Evolvability, Quantitative Genetics of

TF Hansen, University of Oslo, Oslo, Norway

Introduction

The concept of evolvability came late to evolutionary biology. This may be a symptom of the much-discussed blackboxing of development and the genotype–phenotype relation during the modern synthesis (Gould, 2002; Amundson, 2005). A core assumption of the synthesis and the adaptationist program was that selection is always provisioned with sufficient genetic variation to operate. Evolvability was taken for granted, a given premise, and was not itself a focus of research. This started to change in the 1970s and 1980s driven by a renewed interest in evolutionary constraints. Concepts such as allometry and heterochrony were used to study the structuring of variation (e.g., Gould, 1977). The emergence of evolutionary quantitative genetics provided statistical tools for studying patterns of genetic variation in natural populations, and researchers began testing the premise of 'unlimited' genetic variation. The blackboxing of the genotype–phenotype map was still in place, however, as mutation rates and allelic effects were treated as fixed, non-evolving parameters. The real breakthrough in the study of evolvability came with the emergence of evolutionary developmental biology in the 1990s. Almost from the start 'evodevo' researchers were talking about evolvability and many see the study of evolvability as the key contribution of evodevo to evolutionary biology (e.g., Von Dassow and Munro, 1999; Hendrikse *et al.*, 2007).

Today, the term evolvability is routinely used as a label for much research in evodevo, evolutionary quantitative genetics, and other fields in evolutionary biology. While an ISI search on 1 July 2014 turned up 1 hit for 'Evolvability' before 1990 (and that 1 is from computer science), and 70 for 1990–99, it gave 785 hits for 2000–09, and 728 for 2010–14.

Definitions and Origins of the Concept

The term evolvability was practically never used before 1990. It is interesting that one of the first uses was by Richard Dawkins, who in an article entitled 'The evolution of evolvability' starts out by saying that "A title like [this] ought to be anathema to a dyedin-the-wool, radical neo-Darwinian like me!" (Dawkins, 1988, p. 201). This reflects the attitude that evolutionary biology is about what happens when the conditions for evolution by selection are fulfilled and not about what makes these conditions in the first place. It is not clear what role Dawkins' article had in establishing interest in evolvability, but together with a chapter in Dawkins (1996) it may have helped ease acceptance of the concept among mainstream evolutionary biologists. Arnold *et al.* (1989) and Alberch (1991) are possible entry points for Dawkins' ideas to the communities that later embraced the term 'Evolvability.'

Even if the term 'Evolvability' was not used, interest in the origin and evolution of variation date back to Waddington and other critics of the neo-Darwinian blackboxing of development, and to an increasing interest in evolutionary constraints. Olson and Miller (1958) initiated a 'morphological integration' research program focused on the origin of patterns of variation and their relation to functional interrelationships between traits. Riedl's (1978) influential *Order in Living Organisms* argued that organisms were structured to facilitate variation along functional lines. In the 1980s, many theorists discussed evolvability under other labels. Layzer (1980) and Conrad (1983), and also Waddington (1957), discussed 'adaptability,' Wagner (1984) 'adaptive versatility,' and Campbell (1987) 'evolutionary drivers.' Lewontin's (1978) Scientific American article on 'Adaptation' had a prescient discussion on the prerequisites for adaptive evolution, which he suggested depended on the two properties of 'continuity' and 'quasi-independence.' The former referring to the standard neo-Darwinian assumption that small changes in a trait must lead to small changes in fitness and the second to the possibility of changing traits without messing up other traits.

Interest in the ability of complex systems to change had also emerged in computer science. Kauffman (1990, p. 135) explicitly defined evolvability in this context as the ability to 'successively accumulate useful variations.' His 1993 book *The Origins of Order* played a key role in raising interest in evolvability among biologists and philosophers alike (Kauffman, 1993).

It is hard to pinpoint the exact emergence of the evolvability concept within evolutionary developmental biology. Perhaps the focal idea in evodevo is to study how development structures variation so as to provide evolvability. Theoretically this is conceptualized with the genotype–phenotype map. Alberch (1991) is among the first to state this explicitly, but elements of the idea can be found, for example, in Waddington (1957), Lewontin (1974), Riedl (1978), and Raff and Kaufman (1983). The influential review by Wagner and Altenberg (1996) firmly establishes the genotype–phenotype map at the focus of evolvability studies. They start by defining evolvability as "… the ability of random variations to sometimes produce improvement" (p. 967), and then narrow this to a property of the genotype–phenotype map, the 'genetic system,' when they write: "Evolvability is the genome's ability to produce adaptive variants when acted upon by the genetic system" (p. 970). They then focus on 'modularity,' the variational (quasi-)independence of traits, as the key prerequisite of evolvability. In their view, the main problem in maintaining evolvability of a complex organism is to avoid everything being tangled together in 'unbounded pleiotropy.' The evodevo solution to this is that evolution is driven by changes in *cis*-regulatory modules with restricted spatio-temporal expression. Early versions of this idea were expressed by Jacob (1977) and Dickinson (1990) and it was firmly established by the second half of the 1990s (reviewed in Stern, 2000; Davidson, 2001; Carroll, 2008).

Many specific definitions of evolvability have been given, see Love (2003), Schlichting and Murren (2004), Hansen (2006), Pigliucci (2008), Brookfield (2009), Pavlicev and Wagner (2012), Kopp and Matuszewski (2014) for examples,

reviews, and discussions of these. Most of these put emphasis on the ability for adaptive evolution, but Schlichting and Murren (2004) explicitly want to include capacity for non-adaptive evolution.

Evolvability in Quantitative Genetics

The term evolvability was introduced to quantitative genetics by Houle (1992), who operationalized it as the expected response to selection. Houle criticized the standard use of heritability as a measure of evolutionary potential, and suggested instead the use of mean-scaled additive variation as a comparative measure of 'evolvability.' Houle (1992) worked with the standard deviation divided by the mean (the coefficient of variation), but the variance divided by the mean squared is a more direct measure of evolvability because the change in the trait mean per generation under directional selection measured by a selection gradient β is

$$\Delta\bar{z} = V_A\beta$$

where V_A is the additive genetic variance. Hence, if evolvability is to be measured as the response to selection per strength of selection, the evolvability becomes

$$e = \frac{\Delta\bar{z}}{\beta} = V_A$$

Standardizing this with the mean yields the mean-scaled evolvability,

$$e_\mu = \frac{V_A}{\bar{z}^2}$$

as indeed suggested by Houle (1992) for traits under directional selection. Hoffmann and Parsons (1997) and Hansen *et al.* (2003a, 2011) have argued that e_μ is usually the best measure of evolvability for quantitative traits, but with the caveat that mean-scaled measures should not be used for traits on ordinal, interval, or proportional scales. See also Garcia-Gonzalez *et al.* (2012) for common errors in using these measures. The e_μ measure is practically equivalent to the additive variance on log scale.

Table 1 summarizes the results from literature compilations of univariate evolvability and heritability estimates. One insight is that evolvabilities of complex traits such as life histories, behaviors, and 3D size measures can be an order of magnitude higher than the evolvabilities of simpler traits such as linear morphological measurements. Still, even an evolvability of a tenth of a percent, about the median for linear morphological measurement, can support rapid evolution. With this evolvability, a trait under unit selection (mean-scaled selection gradient of one) would double in 694 generations, and with 1% evolvability, as is common for complex traits, the trait could double in 70 generations. Hence, most univariate evolvabilities are large enough to propel essentially instantaneous adaptation on geological time scales.

Table 1 also summarizes mean-scaled mutational variances. These are obtained from mutation-accumulation experiments (Halligan and Keightley, 2009), and reflect the amount of additive genetic variance that arises in each generation by new mutations. These estimates are no more than 2–3 orders of magnitude below corresponding measures of standing variation, which implies that standing evolvabilities can be replaced over a few hundred generations (Houle, 1998), and the supply of mutations does not appear very limiting for the evolvability of univariate traits. Life-history traits tend to have more than an order of magnitude higher mutational evolvability than morphological traits. The high evolvability of life history and other complex traits may therefore be caused by their higher mutability. Houle (1998) suggested that this is due to a larger mutational target size, as more genes may have an effect on more complex traits.

Table 1 Median evolvabilities (mean-scaled additive variances), e_μ, and heritabilities, h^2, for univariate traits

Trait group	e_μ	h^2	*Source*	n
All traits	0.25%	0.33	H92	842
	0.26%	0.29	HPH11	960
	1.28%[a]	–	GG12	35
Life history	0.80%	0.20	H92	131
	0.95%	0.16	HPH11	149
	1.42%	–	GG12	10
Morphological	0.15%	0.39	H92	545
Linear morphological	0.09%	0.35	HPH11	394
	0.14%	–	GG12	7
Weight and volume	0.94%	0.27	HPH11	125
	1.13%	–	GG12	10
Morphological counts	0.21%	0.40	HPH11	50
Shape	0.37%	0.29	HPH11	42
Growth	1.00%	0.28	H92	163
Physiological	0.49%	0.12	HPH11	89
	2.60%	–	GG12	3
Behavior	1.93%	0.26	HPH11	44
	2.60%	–	GG12	4
Developmental stability	0.05%	0.03	HPH11	28
Mutation evolvability				
All traits	0.0032%	0.0023	HML96	57 (56)
Life history	0.0190%	0.0012	HML96	17 (16)
Life history	0.0257%	0.0012	HK09	34 (19)
Morphological	0.00072%	0.0032	HML96	26
Growth	0.0025%	0.0023	HML96	10

[a]This higher total is influenced by a lower proportion of linear traits in this study. Based on published reviews of additive or mutational genetic variances from which median evolvabilities could be computed: H92 is Houle (1992), HML96 is Table 1 from Houle *et al.* (1996), HK09 is Table 1 from Halligan and Keightley (2009) not including virus, HPH11 is Hansen *et al.* (2011), GG12 are error-corrected estimates from appendix 1 in Garcia-Gonzalez *et al.* (2012). Trait categories follows source except for Garcia-Gonzalez *et al.* (2012) that were grouped according to the criteria in Hansen *et al.* (2011). The h^2 for mutational traits is relative to the environmental variance in the lab experiment. Sample sizes in parentheses are for heritabilities if different from evolvabilities.

Evolvability and Heritability

The classic and still most commonly used measure of evolutionary potential in quantitative genetics is the narrow-sense

heritability,

$$h^2 = \frac{V_A}{V_P}$$

where V_P is the total phenotypic variance in the population. Under certain assumptions this determines the slope of the parent–offspring regression (Lynch and Walsh, 1998). The heritability is related to evolutionary potential because it quantifies parent–offspring similarity, a core element of evolution by natural selection. Also, the 'breeder's equation,'

$$\Delta\bar{z} = h^2 S$$

where S is the selection differential, suggests that heritability is a useful measure of evolvability in Houle's sense of predicting the response to selection if selection is measured by a differential and not by a gradient. The two formulations are mathematically equivalent because

$$\Delta\bar{z} = h^2 S = \left(\frac{V_A}{V_P}\right) S = V_A \left(\frac{S}{V_P}\right) = V_A \beta$$

since the selection gradient equals the selection differential divided by the phenotypic variance. Mathematical equivalence does not equal biological equivalence, however, and the two formulations make radically different assumptions as to what variables can be treated as independent biological entities.

Houle (1992) argued that most variation in heritabilities is due to variation in the environmental component of the phenotypic variance and less to variation in additive variances. A consequence of this was an overturning of the established generalization that life-history traits and fitness components had little additive genetic variance while morphological traits had more. Life-history traits indeed have lower heritabilities than morphological traits (**Table 1**), but this is due to higher levels of environmental variance and not to lower levels of additive variance.

Hansen *et al.* (2011) showed that heritabilities and (mean-scaled) additive genetic variances are almost completely uncorrelated with each other. This puzzling result comes from the fact that the additive genetic variance tends to covary with other components of variance. It can be shown theoretically that levels of additive genetic variance scale positively with levels of dominance and epistatic variance, and there is a strong empirical correlation between genetic and environmental variances. Traits that are sensitive to genetic perturbances also tend to be sensitive to environmental perturbances. When heritabilities are used to measure additive genetic variance we are in effect using a measuring stick (the phenotypic variance) that is strongly correlated with what we want to measure. The effect of this 'rubber measure' is to remove essentially all correlation between the two.

In itself this observation does not establish the correct measure of 'evolvability,' but it does show that heritabilities cannot be used interchangeably with additive genetic variances that are either mean standardized or unstandardized.

Evolvability for Multivariate Traits

Evolutionary quantitative genetics describe the evolutionary response in a trait vector, $\mathbf{z}$, as

$$\Delta\bar{\mathbf{z}} = \mathbf{G}\boldsymbol{\beta}$$

where $\boldsymbol{\beta}$ is the selection gradient, a vector consisting of partial regression coefficients of relative fitness on the traits, and $\mathbf{G}$ is the additive genetic variance matrix with variances along the diagonal and covariances on the off diagonals (e.g., Lande and Arnold, 1983). The possibility of studying genetic constraints through the G-matrix was part of the attraction of evolutionary quantitative genetics (e.g., Cheverud, 1984; Arnold, 1992). The G-matrix quantifies the role of genetic covariance in impeding or channeling evolutionary change. The response to selection may deviate from the direction of the selection gradient toward directions with more additive genetic variation (higher evolvability).

Strictly speaking, this equation describes evolution on a planar fitness surface (linear directional selection). This is usually a good approximation for a few generations, but over time nonlinearities in the fitness landscape will change the gradient, as the population evolves into more or less steep parts of the landscape.

For example, if the population evolves on a conical fitness landscape then the selection gradient will get more shallow and eventually approach zero as the summit is reached. This means that the summit of a single-peaked fitness landscape will always be reached, even if in a roundabout way, as long as there is positive evolvability in all directions (i.e., $\mathbf{G}$ is of full rank). With alternative peaks, however, patterns of evolvability may influence which optimum is reached.

Hansen and Houle (2008) proposed to measure evolvability in (vector) direction $\mathbf{x}$ as the length of the projection on $\mathbf{x}$ of the response to a (unit) gradient in direction $\mathbf{x}$. This yields an evolvability, $e(\mathbf{x}) = \mathbf{x}^{\mathrm{T}}\mathbf{G}\mathbf{x}$, where T denotes transpose and $\mathbf{x}$ is normalized to unit length. This measure is equivalent to the additive genetic variance in direction $\mathbf{x}$ (Lin and Allaire, 1977), and also proportional to the increase in fitness (Agrawal and Stinchcombe, 2009; Chevin, 2013).

Several related measures focus on how genetic covariances affect evolvability. Agrawal and Stinchcombe (2009) suggested comparing evolvabilities, $e(\mathbf{x})$, with and without genetic covariances set to zero, and Kirkpatrick (2009) presented a decomposition of the response into a correlation matrix and single trait evolvabilities. Marroig *et al.* (2009) proposed to use evolutionary flexibility, which is measured with the cosine of the angle between a selection gradient and the response it induces. A population that tracks closer to the direction of selection is more 'flexible.'

These measures do not capture constraints from stabilizing selection on other characters. Hansen *et al.* (2003b) proposed to study selective constraints with 'conditional evolvability' defined as the evolvability of a character when other defined characters are kept invariant. They showed that this equals the additive genetic variance of the residuals from a regression on the constraining variables (the conditional variance). Hansen and Houle (2008) showed that the conditional evolvability along a (vector) direction $\mathbf{x}$ when the traits are constrained to

evolve only in this direction is $c(\mathbf{x}) = (\mathbf{x}^T\mathbf{G}^{-1}\mathbf{x})^{-1}$, with $\mathbf{x}$ normalized to unit length.

Does Evolvability Affect Evolution?

If univariate evolvabilities are not limiting on geological time scales as indicated by **Table 1**, we expect trait evolution to be governed by selection and adaptation, and genetic constraints to be unimportant. This view approached a consensus, but has come under scrutiny. Hansen and Houle (2004, 2008), Blows and Hoffmann (2005), Kirkpatrick (2009, 2010), Gomulkiewicz and Houle (2009), and Walsh and Blows (2009) are among those who have raised questions. The arguments are concerned with multivariate constraints. Even if individual traits appear evolvable, the variation they display may be tangled up with other characters or based on alleles with generally deleterious effects on fitness. Conditional evolvabilities may be much smaller than unconditional evolvabilities.

Starting with Schluter (1996), comparing the direction of maximal evolvability (aka genetic line of least resistance) with direction of species divergence has been a standard test for genetic constraints. This approach suffers from methodological difficulties, and has not yielded conclusive results. More recent tests based on direct measures of evolvability seem to support a correlation between evolvability and rates and directions of change, but this is far from conclusive (Bolstad *et al.*, 2014).

Lee and Gelembiuk (2008) argue that invasive species often have high evolvability and are able to rapidly adapt to novel environments. There is also evidence that species in stressful environments or with wide ranges are more evolvable (Hoffmann and Parsons, 1997; Hoffmann *et al.*, 2003; Kellermann *et al.*, 2012). Evolvability may be an important predictor of the ability of species to survive climate change (Hoffmann and Sgro, 2011; Hoffmann *et al.*, 2013).

Determinants of Evolvability

Most research on evolvability is qualitative and usually related to the structure of the genotype–phenotype map. "Evolvability is the ability of the genetic system to produce and maintain adaptive genetic variants" (Hansen, 2006, p. 129), and the question is what properties the 'genetic system' needs to achieve this. The following is a list of such properties. Raff (1996), Gerhart and Kirschner (1997), Budd (2006), and Hansen (2006) are general reviews from this point of view.

Determinants of Evolvability: Continuity

Continuity of the genotype–phenotype-fitness relation was one of Lewontin's (1978) criteria for evolution to be possible. The argument, which goes back to Fisher (1930) and even to Darwin's gradualism, is that evolvability requires improvements in small steps. It must always be possible to make small changes in phenotype with small changes in genotype, and there must be paths of fitness improvements with small steps. Dawkins (1996) gives an elegant discussion of this point.

Determinants of Evolvability: Modularity

Lewontin's (1978) other requirement was 'quasi-independence,' which means that it must be possible to change a character without destroying the adaptations of other characters. Wagner and Altenberg (1996) identified the combinatorial explosion of interactions between parts as the primary problem of complex adaptation, and argued that the solution must be a modular structuring of the genotype–phenotype map that restricted pleiotropic interactions to happen within and not between modules. This idea connected well with observations of developmental modularity where many organs after their initiation are internally regulated and able to develop independently of the rest of the organism (e.g., Raff, 1996). In evolutionary developmental biology, modularity almost appears as a synonym of evolvability. This is manifest both in the idea of evolution being driven by changes in *cis*-regulatory 'modules' (Carroll, 2008), and in the treatment of organs and gene networks as autonomous units, as for example, seen in the studies of butterfly eyespots and their patterning gene networks (Brakefield and Roskam, 2006).

Modularity is often measured as a lack of pleiotropic links between modules. Variational independence may also be achieved with compensatory pleiotropic effects, however, a degree of pleiotropy may even increase conditional evolvability (Hansen, 2003; Pavlicev and Hansen, 2011).

Determinants of Evolvability: Coordination and Integration

If mutations affect traits in a coordinated manner they are more likely to fulfill an adaptive need and less likely to produce maladaptive side effects. For example, left–right symmetries in bilaterians increase the probability that mutations will affect paired appendages in a coordinated manner (Dawkins, 1996). The flip side is that asymmetries become harder to evolve. Integration increases evolvability in some directions at the cost of other directions. Olson and Miller (1958), Riedl (1978), Cheverud (1984), Jones *et al.* (2007), and Pavlicev *et al.* (2011) are among those who have argued organisms are structured or integrated so as to produce coordinated variation that reflects functional integration.

Determinants of Evolvability: Robustness

Genetic robustness is the ability to maintain an appropriate phenotype when experiencing mutation or other genetic changes. Since evolvability depends on the ability to express variation, the immediate expectation is that canalization and robustness will decrease evolvability. 'Hidden' variation may accumulate in robust systems, however, the expressed variation in mutation-selection balance is not necessarily reduced (as in the 'Haldane–Muller principle'). Robust systems may also be able to boost evolvability by releasing hidden variation if they become decanalized (Hermisson and Wagner, 2004). Rutherford and Lindquist (1998) suggested that the ability to decanalize in periods of stress may exist as an adaptation for evolvability if the stress is caused by a changing environment.

They further presented evidence that the heat-shock protein Hsp90 may act as a 'capacitor' to release variation under stress. Although the evolution of capacitors is possible (Masel, 2005), the release of hidden variation under disturbance is a generic property of genetic systems (Hermisson and Wagner, 2004), which makes it hard to assess whether observed 'capacitors' are adaptations for evolvability.

A positive relation between robustness and evolvability has been found in some genetic systems (reviewed in Wagner, 2005). For example, models of secondary RNA-folding configurations has the property that the more robust configurations are also those with the largest set of neighboring configurations, and through neutral drift among equivalent genotypes that make the same configuration it can be easier to evolve to a new configuration from a robust configuration (Wagner, 2008).

Determinants of Evolvability: Mutability

Mutation is a necessary prerequisite for long-term evolvability. Although levels of standing additive variance in mutation-selection balance depend nonlinearly on strength of selection, population size, number of loci, epistasis, pleiotropy, mutation rate, and mutational effect sizes, and is thus hard to predict, the estimates in **Table 1** indicate that the supply of new variation through mutation is unlikely to severely constrain the evolvability of quantitative traits. Similarly, estimates of molecular rates of mutation including base-pair substitutions, as well as duplications, deletions, and transpositions of larger bits of DNA are often surprisingly high in complex organisms (Lynch, 2007).

Duplication and subsequent divergence through subfunctionalization or neofunctionalization is an important mechanism of gene and genome evolution (Force *et al.*, 1999; Lynch, 2007). It is also important on the morphological level as in the classical model of how segmentation can give rise to segments with new specialized functions (e.g., Raff, 1996). Duplication and also co-option of genes and structures for new functions is made possible by the modularity and robustness of the genetic and developmental systems.

If evolution is mutation limited, we would expect population size to be an important determinant of evolvability. This does not seem to be the case except in very small populations (Willi *et al.*, 2006).

Determinants of Evolvability: Recombination

The realization that recombination of Mendelian genes generates new variants and provides a potential for a population to evolve far outside its initial range of variation dates back to the beginning of the twentieth century and was instrumental in establishing natural selection as a force capable of producing large differences between species. Since then, the origin and maintenance of sex and recombination has been a major topic of research (Williams, 1975; Bell, 1982). Sexual reproduction allows the bringing together of advantageous mutations that happen in different individuals and give massive boosts to evolvability when evolution is mutation limited (as in small populations). It also allows the purging of deleterious variants and is instrumental in maintaining adaptation in small populations.

Determinants of Evolvability: Epistasis

Short-term evolvability depends on additive genetic variance and covariance, but nonlinearities in the genotype–phenotype map will soon start to change gene effects and consequently patterns of variation (**Figure 1**). Epistasis, in the sense of a dependence of gene effects on genetic background, describes such nonlinearities, and if there are systematic patterns of gene interaction, systematic changes in evolvability may ensue (Rice, 1998; Hansen, 2006, 2015). In particular, Carter *et al.* (2005) have shown that positive directional epistasis, where allele substitutions with positive effects on the trait tend to elevate the effects of other positive allele substitutions (including mutations), will elevate evolvability under directional selection, whereas negative directional epistasis, where the effects of other positive substitutions are decreased, will lead to canalization and reduced evolvability. Hence, it is not epistasis per se that is important, but the patterns of gene interaction. The traditional epistatic variance components from statistical genetics are uninformative about (relevant) patterns of epistasis, and thus uninformative about evolvability (Hansen, 2013).

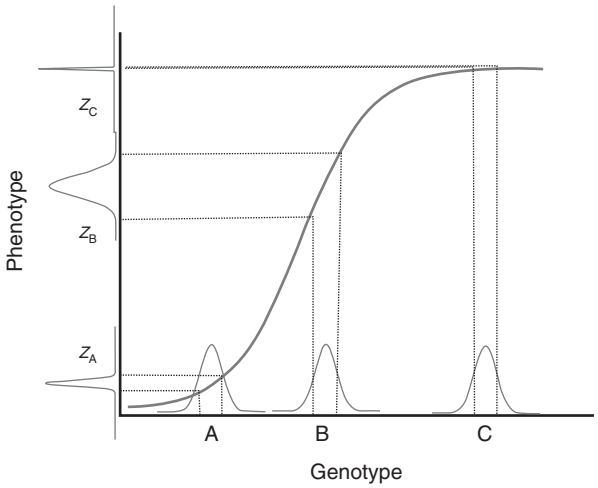

Figure 1 The genotype–phenotype map, epistasis, and the evolution of evolvability. Similar amounts of 'molecular' genetic variation is shown around three positions (A, B, C) in genotype space on the *x*-axis, but these are mapped to very different levels of expressed (additive genetic) variation on the phenotype axis. Evolution from left to right in genotype space will first increase evolvability due to positive curvature in the genotype–phenotype map from A to B and then 'canalize' due to negative curvature from B to C (e.g., Rice, 1998). Positive curvature will be expressed as positive directional epistasis because gene effects increase when the genetic background change from A to B, and negative curvature will be expressed as negative directional epistasis. Hence, directional epistasis makes the genetic variance evolve (Carter *et al.*, 2005). Modified from Hansen, T. F., 2015. Measuring gene interaction. In: Moore, J.H., Williams, S.M., (Eds.), Epistasis: Methods and Protocols. New York, NY: Humana Press, pp. 115–143.

The Evolution of Evolvability

Gould (2002, p. 1270) presented the 'paradox of evolvability' in terms of the question, How can something evolve that is not of immediate use? This is not much of a paradox as stated, because there is no doubt evolvability will evolve when the genetic system evolves (Pigliucci, 2008), but the paradox illustrates skepticism toward individual-level adaptations for evolvability. Many find it more plausible that evolvability is a group- or species-level adaptation (e.g., Waddington, 1957; Gerhart and Kirschner, 1997; and even Dawkins, 1996). Others favor nonadaptive evolution as a side effect of selection on the evolvable trait (Hansen, 2011), canalizing selection on variation or robustness (Layzer, 1980; Le Rouzic *et al.*, 2013), or more general organizational changes in the genetic system (Maynard Smith and Szathmáry, 1995; Budd, 2006). Yet others favor neutral evolution of evolvability due to 'systems drift' (True and Haag, 2001; Wagner, 2005), or due to weak selection against changes in genome architecture in finite populations (Lynch, 2005, 2007). A form of individual-level adaptation for evolvability is also possible in that it may benefit an individual to make variable offspring to allow selection to pick the best adapted, as exemplified by the tangled-bank hypothesis for maintenance of sex (Ghiselin, 1974; Bell, 1982). Unfortunately, much work on the evolution of evolvability does not separate evolution and adaptation (Gardner and Zuidema, 2003; Hansen, 2011).

Founder Speciation

DR Matute, University of North Carolina, Chapel Hill, NC, USA

Introduction

When colonizing new areas, species may discover new niches, be subjected to a novel selection regime, and evolve new traits that differentiate them from their ancestors (Thomas *et al.*, 2001; Gillespie and Roderick, 2002; Kawecki, 2008; Sexton *et al.*, 2009). If the colonizing population is small, its genetic composition may only contain a subset of the genetic variance from the parental population. Through further sub-sampling in subsequent generations, these *founder events* might cause a significant reduction of the effective population size. The loss of genetic variation and the rescaling of allele frequencies that occurs throughout the genome during the colonization process is known as a *founder effect* (Templeton, 1980; Coyne, 1994).

Founder effects can have three consequences for the evolutionary potential of a population. If the amount and nature of the remaining genetic variation of the founders is low and the bottleneck catastrophically reduces the levels of genetic variance, the founder effect might lead to extinction of the population (Frankham, 1995, 1998). A second possibility is that the new population will suffer from inbreeding depression. Natural selection acts more expediently on larger populations, so founder events might constrain the evolution of founder populations simply because there will be a lag period before new mutations accumulate for selection to act on (Hoffmann *et al.*, 2003; Willi *et al.*, 2006; Killermann *et al.*, 2006; Hill *et al.*, 2006). Finally, high degrees of inbreeding can reallocate the amount of additive genetic variance and lead to trait decanalization, thereby overcoming genetic constraints that could not otherwise be overcome in a larger population (Cheverud and Routman, 1996; Turelli and Barton, 2006). One of the mechanisms by which this can occur is when inbreeding uncovers and perpetuates combinations of alleles that would be selected against, or simply remain cryptic, in large populations (Carson, 1990; Gibson and Dworkin, 2004; Schlichting, 2008). Occurrences of the first two scenarios – extinction and inbreeding depression – have been extensively documented (Hedrick and Kalinowski, 2000; Pekkala *et al.*, 2014). The prevalence of the third possible outcome remains debated. While it has been shown that inbreeding can lead to significant changes in the phenotypic average and an increase in the additive component of the total phenotypic variance for a variety of morphological, physiological, sexual, and life history traits (Goodnight, 1987; Lopez-Fanjul and Villaverde, 1989; Garcia *et al.*, 1994), it is unclear how much of this increase in phenotypic variance is really heritable and thus relevant to evolution (Bryant *et al.*, 1986; Lopez-Fanjul and Villaverde, 1989; Garcia *et al.*, 1994; Wade *et al.*, 1996; Whitlock and Fowler, 1999).

Founder events may also lead to changes in traits potentially involved in reproductive isolation and generate reproductive isolating mechanisms. This process, termed *founder speciation*, hypothesizes that small population size could foster the evolution of reproductive isolation, and ultimately result in new species (Templeton, 1980). Support for founder speciation is ambiguous. Theoretical treatments have suggested founder speciation is likely in some cases and unlikely in others. Even though the majority of founder speciation models are unrealistic and all models of founder speciation are regarded as unfeasible (Charlesworth, 1997; Coyne and Orr, 2004), a subset of models does work, yet remains largely untested (Slatkin, 1997; Uyeda *et al.*, 2009).

Laboratory experiments have also found support both for and against founder speciation. As a result, one camp of evolutionary biologists argues that founder effects might be the driving force in evolutionary biology and the most prevalent form of speciation (Templeton, 2008). Others have declared the topic solved, stating that founder effects play no role in the evolution of new species (Charlesworth, 1997; Coyne and Orr, 2004). The relative importance of the process likely resides between these two views. It is, therefore, important to evaluate if founder speciation is possible in actual biological systems. The outstanding question is thus more empirical than theoretical. Here, evidence both for and against founder speciation is compiled and its implications investigated.

Theoretical Support

Founder speciation has been proposed to explain how island and high-altitude endemic species might have originated from small parental populations (Vermeij, 1987; Paulay and Meyer, 2002). The main support for the founder speciation hypothesis comes from theoretical efforts that have modeled how quickly allele frequency changes induced by genetic drift can result in reproductive isolation (Gavrilets and Hastings, 1996).

 doi:10.1016/B978-0-12-800049-6.00078-0

Ernst Mayr proposed the first model of founder speciation (Mayr, 1942, 1954; Provine, 1989; Coyne, 1994). His verbal proposition stated that genetic drift could affect the level of genetic variance in a system in such a way that it would determine how selection could act, thus making founder effects important in the origin of new species. The premise of the model is quite simple: given that epistasis is rampant across the genome, the selective value of an allele involved in reproductive isolation is contingent on the genetic backgrounds present in the ancestral population. When such a population undergoes a population size decrease, a fast change of the genetic environment might occur, simply because the allele frequencies of the founding population might have changed. Those changes might lead to changes at other loci similar to a chain reaction (i.e., genetic revolution). Finally, changes across the genome might lead to a new state of equilibrium which in turn might give rise to a population that is reproductively isolated from the parental population. This model, known as *genetic revolutions* was inspired by "the conspicuous difference of most peripherally isolated populations of species" (Mayr, 1954). Mayr's idea was controversial among geneticists (e.g., Haldane, 1964 reviewed in Provine, 2004) and fell out of favor because of its vagueness, and the lack of evidence supporting any of the components for the process (Lewontin, 1965; Lande, 1980; reviewed in Provine, 2004; Nei, 2005).

Mayr's genetic revolutions model may not be a prevalent mode of speciation, but it is an appealing hypothesis because it relies on two simple, testable ideas. First, alleles with the potential to cause reproductive isolation must be segregating within species. Thorough scans for within-species incompatibilities have discovered them in several taxa (Charlesworth and Laporte, 1998; Reed and Markow, 2004; Good *et al.*, 2008; Cutter, 2012; Corbett-Detig *et al.*, 2013). Second, the effect of such an allele must be contingent on the genetic background (Good *et al.*, 2008; Matute *et al.*, 2014). The results from several studies suggest that background-specific effects are not only real but also pervasive, even for such extreme phenotypes as hybrid sterility and inviability. Thus, as occurs with most (if not all) phenotypes (Gibson and Dworkin, 2004; Chari and Dworkin, 2013), the genetic background can modify the penetrance of alleles involved in reproductive isolation.

A second model proposed by Hampton Carson, dubbed *founder-flush speciation*, requires not only a founder event but also the colonization of a new habitat (Carson, 1968, 1971, 1975; Carson and Templeton, 1984). In this model, the founder event reduces the effective population size, leading to changes in allele frequencies along the genome. Recombination in the newly arisen population will generate new allelic combinations that might not have survived in the ancestral population. Natural selection by the new ecological environment then locks together new allelic combinations, which might lead to the origin of new reproductive barriers. Carson was heavily influenced by the spectacularly diverse Hawaiian *Drosophila* and proposed that these species might have arisen through several rounds of founder-flush speciation (Carson and Kaneshiro, 1976; Mueller-Dombois *et al.*, 1981). Even though these *Drosophila* island endemics are frequently cited as the prime examples of founder speciation (Kaneshiro, 1976; Carson and Kaneshiro, 1976; Carson, 1982; DeSalle and Templeton, 1988; Hollocher and Williamson, 1996), the connection between island colonization and the origin of new reproductive isolating mechanisms remains to be explored.

Despite founder speciation being disregarded by some due to its presumed slow speed of action, there are theoretical arguments suggesting drift can promote rapid divergence (Nei, 1976; Nei *et al.*, 1983; Slatkin, 1996). Theoretical models have shown that drift can promote rapid divergence in sexually selected traits and that the time required for inducing reproductive isolation is relatively short if inbreeding is strong (Lande, 1981; Wu, 1985; Uyeda *et al.*, 2009). These simulations also suggest that the evolution of sexual isolation by sexual selection is stochastic in small populations. In groups of large animals (i.e., vertebrates), the effective population size might commonly be small and stochastic changes might play a role in the divergence of mating preferences and reproductive isolation.

Theoretical Challenges

Theories of founder speciation have been strongly scrutinized since their inception (Barton and Charlesworth, 1984; Barton, 1989; Gavrilets and Hastings, 1996; Charlesworth, 1997; Slatkin, 1997). The main, and most cited, criticism is that founder speciation requires very specific conditions to take place, thus rendering it unlikely to be an important mechanism of speciation. Some simulations have found that reproductive isolation can evolve through drift, though other models have found that drift can constrain the evolution of the same types of isolating barriers if starting conditions are slightly different (i.e., Charlesworth and Smith, 1982; Uyeda *et al.*, 2009). Several authors have proposed that models of founder speciation are unrealistic because of two general principles in population genetics. First, reproductive isolation is more likely to evolve through gradual evolution than through large abrupt changes like founder events (Barton and Charlesworth, 1984; Barton, 1989; Coyne and Orr, 2004). Second, most models require genetic drift to act for a long time, rather than just in the founding generation, in order to generate new species (Rice and Hostert, 1993; Gavrilets and Hastings, 1996; Gavrilets, 2003; Futuyma, 2006). The ensuing prolonged inbreeding will result in founder populations with low genetic variability and limited capacity to respond to selection, which in turn might hamper their establishment on new environments (Willi *et al.*, 2006; Kawecki, 2008; Kawecki *et al.*, 2012).

A second group of critiques of founder speciation is aiming at the fact that all the original formulations argued that large populations were not likely to split into new species because large populations supposedly had little potential to evolve new traits (Mayr, 1954; Carson and Templeton, 1984; Provine, 1989). Both, theoretical models and experimental results have shown that large populations do not lack evolutionary potential, and if anything, they have a more pronounced response to selection; it is in small populations where drift, or its interaction with selection, plays a larger role in shaping genetic composition (Hill and Caballero, 1992; Kawecki, 2008; Jones *et al.*, 2014).

A final criticism of founder speciation hypotheses is that, even if drift could drive the evolution of reproductive

isolation, the process would be extremely slow and, more often than not, natural selection would be the faster-acting and therefore the prevalent force within the evolving system (reviewed in Coyne and Orr, 2004). The conclusions of simulation efforts (Lande, 1981; Wu, 1985; Uyeda *et al.*, 2009) and the evidence from experimental evolution experiments (see below) have suggested that founder speciation can occur quickly and that ignoring the process because of its supposed glacial pace is short-sighted.

Experimental Evidence

While founder speciation is a longstanding theory, few direct tests have been made of either its validity or prevalence. Evidence for it can be divided into two categories: experimental evolution and natural assessments.

Evidence I: Experimental Evolution

The premise of testing founder speciation with experimental evolution is simple: if founder speciation proceeds quickly and a species has the potential to originate through founder effects, then applying strong inbreeding in laboratory conditions should give rise to reproductive isolation from the original population.

The first such experiments were the results of accidental bottlenecks. An accidental test was performed in *Nereis acuminata*. A single population of this marine polychaete underwent serial bottlenecks following collection and maintenance in the laboratory (Weinberg *et al.*, 1992). Even though the authors observed reproductive isolation between the founded population and the putative parental population, the results might signal cryptic population stratification: the 'founder population' could have been just part of a population of *N. acuminata* that at the time of collection was already reproductively isolated from the putative parental population (Rodriguez-Trelles *et al.*, 1996).

A second type of experiment addressed the effects of bottlenecks in a more controlled manner. In particular, several flush and crash experiments have tested the evolution of reproductive isolation. Large populations of flies (*Drosophila* and *Musca*) were subjected to extreme levels of inbreeding (e.g., cages with hundreds or thousands of individuals were reduced to a single mated female) and levels of reproductive isolation were measured after several such crashes (reviewed in Rice and Hostert, 1993 and Powell, 1997). The rationale behind these experiments is that extreme cases of inbreeding might create the conditions for genetic drift to induce the evolution of reproductive isolation in founder populations (Carson, 1971). These experiments, carried out in at least five different species, demonstrate that reproductive isolation can evolve after two steps: a strong founder event (crash and inbreeding) and a subsequent population expansion (flush; Powell, 1978; Dodd and Powell, 1985; Ringo *et al.*, 1985, 1986; Dodd, 1989; Bryant and Meffert, 1993 but see Galiana *et al.*, 1993; Moya *et al.*, 1986). A second general pattern is that the increased reproductive isolation detected between the parental population and the inbred/flushed populations is usually asymmetric and it is almost always in the form of stronger female choice from the parental population discriminating against males from the inbred/flushed populations (Powell, 1978).

All these studies, however, have two common, yet understandable, caveats. The first one is that all the experiments have been carried out in flies, and it is unclear to what extent the results from flies can be expanded to other organisms. The second is that, in all of these experiments, the number of replicates has always been low (<50 replicates) and consequently, they have little power to determine how frequently founder events lead to the origin of reproductive isolation.

The study of founder speciation using experimental evolution has been formally criticized on three major grounds (Rice and Hostert, 1993; Coyne, 1994; Mooers *et al.*, 1999). First, founder-crash experiments usually involve newly collected lines from different geographic localities. Cryptic population stratification among collected individuals might result in differential adaptation to laboratory conditions with reproductive isolation arising as a by-product (Ödeen and Florin, 2000; Rundle, 2003).

Second, the biological parameters that crash experiments depend on are likely to be unrealistic. The most commonly used scheme involves crossing a single pair of flies in a brother–sister mating at every generation, resulting in extreme inbreeding. These conditions likely do not reflect the true nature of a founder effect, though it remains largely unknown how founder population size affects the evolution of reproductive isolation (Powell, 1978, but see Galiana *et al.*, 1993). Only one experimental approach has addressed this question by using multiple pairs of flies instead of one brother–sister pair to start every generation. Galiana *et al.* (1993) used *D. melanogaster* to assess the likelihood of founder speciation under different inbreeding schemes. Experimental populations were started with different numbers of founders, and the resulting populations were assessed for their levels of behavioral isolation toward the ancestral population. Populations with fewer founding individuals tended to be more reproductively isolated from the parental population than those with more founders. This conclusion remains provocative, but larger experiments with more statistical power will be required to establish whether the size of the founder population is correlated with the likelihood of founder speciation. Regardless of the actual population sizes achieved after inbreeding founding a natural founder event, these experiments showed that reproductive isolation can evolve as a result of severe reductions in population size, and also demonstrated the feasibility of studying founder effects (and the origin of reproductive isolation) in laboratory settings.

A third and final criticism of the crash and flush experiments is the unstable nature of the resulting reproductive isolation (Powell, 1978; Ringo *et al.*, 1985; Moya *et al.*, 1986 but see Dodd and Powell, 1985). The strength of reproductive isolation attained after experimental bottlenecks waxes and wanes over time in the vast majority of reports (Coyne and Orr, 2004). Once the experimental scheme is relaxed, reproductive isolation does not persist in the crashed populations. This is not a surprising result, as it is predicted by models of reproductive isolation driven by drift (Uyeda *et al.*, 2009). The unstable nature of reproductive isolation in experimental settings suggests that although founder effects can give rise to

reproductive isolation, other forces such as sexual selection, natural selection through reinforcement, or genetic assimilation might be necessary to stabilize the trait.

Criticism of founder speciation reduced enthusiasm for the process, and its study dwindled over the last decades of the twenty-first century. However, a new generation of theoretical and comparative studies has revitalized interest in founder speciation (Templeton, 2014). One of the most comprehensive studies on this subject has been performed in *Anolis* lizards. Schoener and Schoener (1983) were interested in extinction and experimentally introduced *Anolis* lizards (*Anolis sagrei*) in pairs of islands that were previously stratified by habitat. A few years later, they also introduced *Anolis carolinensis* in a subset of the islands. Much to Schoener and Schoener' surprise, the populations persisted in all but the smallest islands, and in some cases, they even attained a population size of hundreds of individuals. These controlled introductions constitute a replicated experiment of the effect of new habitats on small founding populations. Years after the introduction, *A. sagrei* and *A. carolinensis* showed morphological changes that persisted for many generations (Losos *et al.*, 1997, 2001; Kolbe *et al.*, 2012). These morphological changes indicate that the joint action of founder effects and natural selection can be a powerful driver of trait evolution of not only flies, but also anoles.

In another recent study, Matute (2013) used 1000 parallel populations of *Drosophila yakuba* that underwent a strong bottleneck to study whether founder effects could lead to reproductive isolation between the inbred lines and the parental population of *D. yakuba*. As expected, the most common outcome of this extreme inbreeding was extinction of the experimental population. Nonetheless, in a small proportion of cases, founder effects led to a significant level of premating reproductive isolation toward the parental stock. This experiment showed that both the mean behavioral isolation and its variance within lines were much larger in inbred populations than in populations that did not undergo a bottleneck. Finally, Matute also carried out artificial selection experiments on the inbred populations to determine whether the high phenotypic variance in reproductive isolation was caused by large genetic variance. In this study, the increase in phenotypic variance did not confer an increase in the response to selection for reproductive isolation in artificial selection experiments, indicating that the increased phenotypic variance is not caused by increases in additive genetic variance.

These two recent studies have two implications. First, they add to the body of evidence that suggest that founder effects might be important for evolution in two different biological systems but under a particular demographic regime (i.e., very strong bottlenecks). Second, they show that the interest in the experimental study of founder effects has not vanished and has the potential to be rekindled.

Evidence II: Natural Variation

An alternative approach to study the role of founder speciation has been to assess insular or isolated populations and look for evidence that they experienced a population bottleneck in the past. Three different methods have been applied to this end: range comparisons in sister species, phylogenetic methods, and demographic methods. The first approach in order of historical appearance is range comparisons in sister species. These studies have tried to determine the importance of founder effects by using pairwise comparisons between the range sizes of sister species to infer the relative frequency of founder, vicariant, and sympatric speciation (Lynch, 1989; Friesen and Anderson, 1997; Losos and Glor, 2003). If two sister species show very dissimilar geographic ranges, then it is considered likely that speciation occurred through founder effects; species with neighboring ranges of similar size are thought to have diverged via vicariance, and those with overlapping ranges potentially diverged in sympatry. This method, however, should be taken with reservations because it assumes that current geographic ranges reflect the ancestral ranges when speciation occurred, an assumption that remains largely untested (Losos and Glor, 2003; Richards and Carstens, 2007). Lynch (1989) applied this method to 66 frog species pairs, and 10 speciation events were best explained by founder speciation. Chesser and Zink (1994) evaluated geographic ranges of 20 pairs of North American species and inferred that two of them might have occurred through founder speciation. In line with the results from experimental evolution studies, both surveys of natural diversity suggested that small populations can indeed give rise to new species but that the relative occurrence of founder speciation is not as common as vicariant speciation.

A second family of comparative analyses has used phylogenetic models to investigate the role of geography in speciation (Barraclough and Vogler, 2000; Barraclough and Nee, 2001). These efforts are also based on analyzing the geography of sister clades but additionally incorporate phylogenetic uncertainty by studying all nodes in a species-level phylogeny. The premise, as in pairwise comparisons, is to use current species range to establish whether speciation occurred through colonization of a new and small habitat, or by the splitting of an ancestral habitat in two equivalent partitions. Again, these approaches find support for founder speciation in a small proportion of cases. This phylogenetic framework is superior to the use of pairs of species alone but still has its caveats. First, range asymmetry may result from the shape of the landscape, for example when a mountain range is located near the edge of a continent (e.g., the Andes). Second, as was a concern with the previous method, geographical ranges may have changed since speciation, a particular concern for areas with no historical record of species distributions (Barraclough and Vogler, 2000, Warren *et al.*, 2014).

Finally, a third approach has used a coalescent framework (i.e., isolation–migration models) to estimate a proxy of the effective population sizes during speciation. Estimation of ancestral population size is probably the most used approach (Baker and Moeed, 1987; Vincek *et al.*, 1997; Walsh *et al.*, 2005; Yeung *et al.*, 2011; Lane and Shine, 2011; Yoshida *et al.*, 2014). These demographic methods, however, are fraught with problems that limit the interpretation of the role of founder events (Becquet and Przeworski, 2009). Notably, changes in population structure over time may affect coalescent rate estimates and, as a consequence, influence effective population size estimates. To overcome these issues, a series of population genetics approaches have been developed to calculate changes

in the effective population size over time using whole genome data (Li and Durbin, 2011; Sheehan *et al.*, 2013). Even if such demographic approaches detect a significant reduction in past effective population size, it does not reveal anything about either its effect on the origin of reproductive isolation or the presence of a founder effect. Problems interpreting these results thus limit the possible application of purely demographic studies to establish the likelihood and importance of founder speciation.

Conclusions

The importance of founder speciation in the evolution of new species remains a contentious issue in evolutionary biology (Templeton, 2008). Theoretical studies have proposed that founder speciation is possible in certain biological contexts. Experimental evolution studies have shown that bottlenecks can lead to changes in reproductive isolation in the same manner that inbreeding affects other phenotypic traits: a displacement of the mean phenotypic value and a substantial increase in the between-population phenotypic variance (Powell, 1997). Comparative and phylogenetic analyses have also lent support for the evolution of new species after habitat shifts and founder events. The combination of these results has changed the focus of study from whether founder speciation is possible (it is) to the biological conditions that affect its efficacy and frequency. The current evidence suggests that founder speciation might be rare. Rarity, however, does not equal unimportance, and in cases such as the colonization of new environments, founder speciation might be more important than is currently appreciated. Only an integrated framework of comparative phylogenetics, population genetics, and experimental evolution will be able to disentangle the relative importance of founder speciation and its alternatives.

Fungal Evolution: Aquatic–Terrestrial Transitions

C Strullu-Derrien, The Natural History Museum, London, UK; and INRA-Nancy, Champenoux, France

Glossary

Arbuscular mycorrhizal symbiosis Symbiotic association between a plant and a fungus of the phylum Glomeromycota. Nutrient transport occurs through a structure called arbuscule inside the plant cells.
Cryptogamic Formed by bryophytes (mosses, liverworts, and hornworts), ferns, horsetails, lichens, and algae.
Dikarya Clade containing Ascomycota and Basidiomycota.
Dikaryon A type of hypha that is formed after sexual reproduction in some fungi, in which each cell has two unfused nuclei.
Environmental DNA Genetic material obtained directly from environmental samples (soil, sediment, water, etc.) without any obvious signs of biological source material (Thomsen and Willerslev, 2015).
Hypha A long branching filamentous structure with rigid walls that may be reinforced by perforated cross-wall septa. Hyphae form a network called a mycelium.
Mating types Molecular mechanisms that regulate compatibility in sexually reproducing organisms, often referred to by numbers, letters, or simply '+' and '−.'
Pectinase enzymes Collective term for a group of enzymes that are able to break down or to transform pectins contained in the primary cell walls of terrestrial plants.
Perithecium A small flask-shaped fruiting body in some ascomycete fungi containing the asci (in which the spores are produced).
Rhizoids Hair-like filaments in Fungi and some plants.
Thallus Vegetative body of a fungus (or alga, lichen, bryophyte).
Yeasts Single-celled Fungi.
Zoospores Spores which are self-propelled by means of flagella.

Fungi and Fungal-Like Microoorganisms

Abundant and cosmopolitan, fungi are a major component of terrestrial ecosystems. Phylogenetic analyses of multiple nuclear genes have challenged the traditional division of Fungi (Eumycota) into four main groups – Ascomycota, Basidiomycota, Zygomycota, Chytridiomycota – and a major reclassification of this kingdom has been proposed (Hibbett *et al.*, 2007; **Figure 1**). The most notable changes concern the Chytridiomycota and Zygomycota. Both have been shown to be polyphyletic; Chytridiomycota has been redefined and Zygomycota is no longer a recognized group. In addition, Microsporidia, unicellular parasites, are now included in the Fungi, and several 'basal' genera are not grouped in higher taxa (Blair, 2009). This classification is currently under revision. Cryptomycota (Jones *et al.*, 2011; not shown in **Figure 1**) is a newly recognized group, which has been united with the Microsporidia, based on phylogenomics and shared genomic traits (James *et al.*, 2013). The resolution of branching order in the deepest parts of kingdom Fungi remains uncertain and instead of converging on a single solution, recent studies of early Fungi have produced conflicting phylogenies (Sekimoto *et al.*, 2011).

In addition, some lineages conventionally associated with Fungi based on morphological similarities and similar ways of life (e.g., oomycetes, slime molds) have been reclassified into separate eukaryotic supergroups (Blair, 2009). The oomycetes and hyphochytrids, together with some marine flagellates, form part of the clade defined by Cavalier-Smith and Chao (2006) as the phylum 'Pseudofungi,' which is a sister to the photosynthetic chromistan (golden-brown) algae and belongs to the stramenopiles lineage that otherwise includes brown algae (Beakes *et al.*, 2012).

An Aquatic Origin for the Fungal Lineage

Molecular data shows that the oomycetes (fungus-like organisms no longer included in Fungi) have their evolutionary roots in the sea and that a number of predominantly marine taxa appear to diverge before the two main terrestrial lineages of oomycetes (Saprolegniales and Peronosporales; **Figure 2**; Beakes *et al.*, 2012). Interestingly the changes in thallus morphology that occurred during oomycete evolution, as summarized by Beakes *et al.* (2015), appear similar to the morphological sequence in Fungi. However, while evolutionary transitions from marine to freshwater or terrestrial environments can be traced for oomycetes, transitions to land in the Fungi are less clear:

1. The question of whether the Fungi are marine in origin needs more investigation. Kis-Papo (2005) reported the difficulty encountered in defining marine fungi – the definition is based on ecological and physiological requirements and not on taxonomic relationships – and suggested that they probably had diverse terrestrial origins, subsequently adapting convergently to similar marine ecological niches. In contrast, a study by Le Calvez *et al.* (2009), based on an inventory of fungal diversity in deep-sea hydrothermal environments, concluded that the emergence and initial diversification of Fungi occurred in a marine environment even if the data are not fully conclusive. This study reported an unexpected diversity in three phyla (Chytridiomycota, Ascomycota, and Basidiomycota) and also a distinctive yet previously unknown ancient Chytridiomycota lineage. To explore the diversity of marine fungi, Richards *et al.* (2012) took an environmental

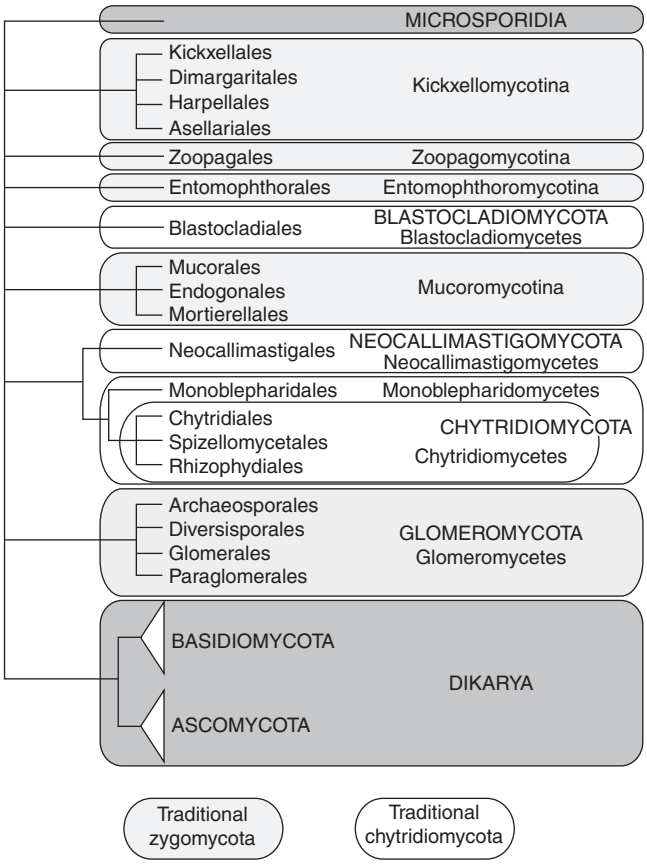

Figure 1 Phylogeny and classification of Fungi (currently under revision) (courtesy of David Hibbett; reproduced from Hibbett, D.S., Binder, M., Bischoff, J.F., *et al.*, 2007. A higher-level phylogenetic classification of the fungi. Mycological Research 111, 509–547, with permission).

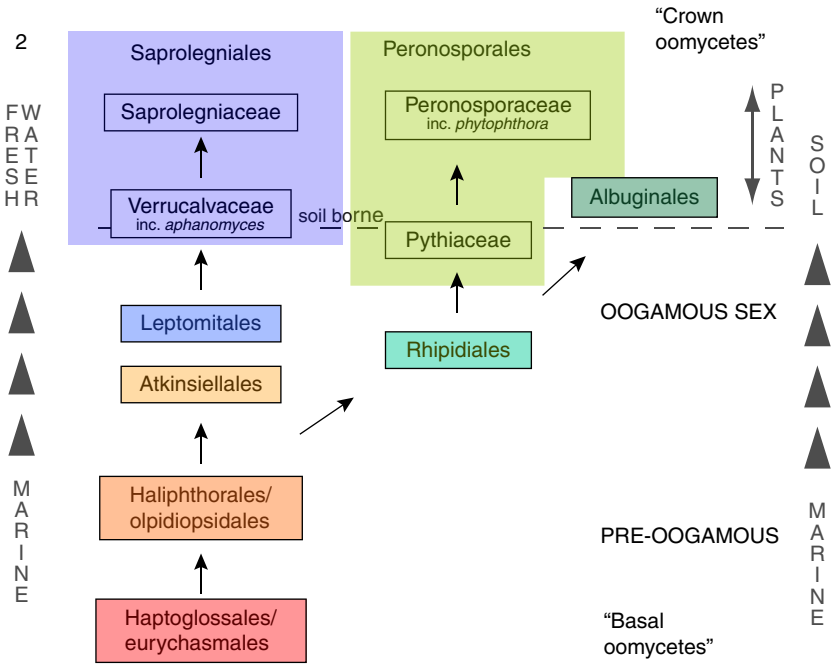

Figure 2 A schematic summary of the possible phylogenetic relationships between the main oomycete orders and families, based on current molecular data and their ecology (courtesy of Gordon Beakes; reproduced from Beakes, G.W., Glockling, S.L., Sekimoto, S., 2012. The evolutionary phylogeny of the oomycete "fungi". Protoplasma 249, 3–19, with permission from Springer).

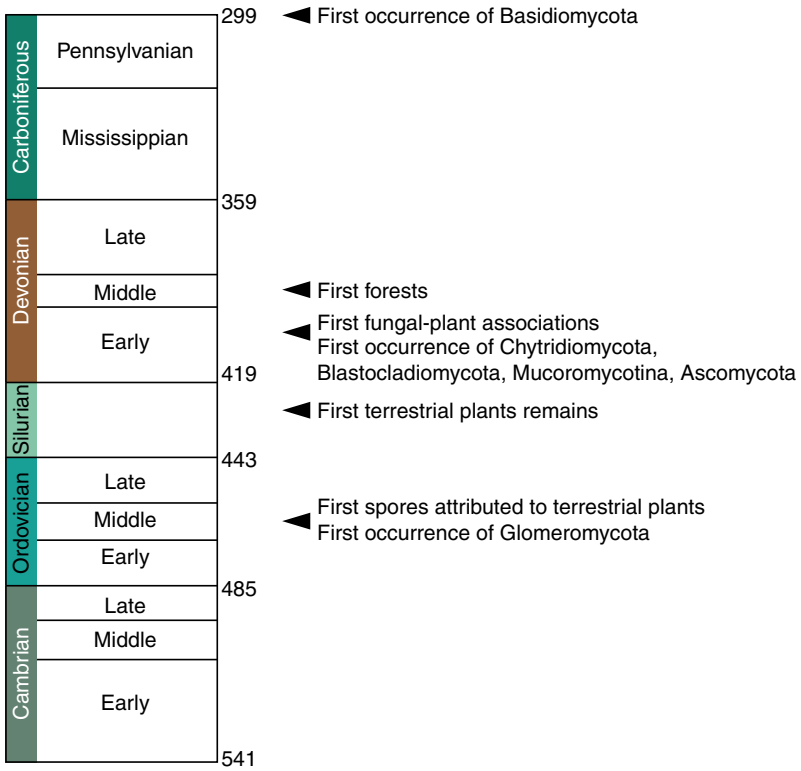

Figure 3 Earliest occurrences of Fungi and plants in Paleozoic times. Ages in millions of years are taken from the International Chronographic Chart of the International Commission on Stratigraphy, 2014.

DNA approach for phylogenetic analyses. They found that fungal sequences detected in marine environments encompass a large diversity of forms and lineages, including chytrids, filamentous hyphal types, and multicellular forms. However, the majority of the sequences clustered with the more-derived Ascomycota and Basidiomycota yeasts. An investigation of the genome of diverse Fungi from marine environments could help to make more precise phylogenetic hypotheses and answer the question of marine ancestry.

2. An aquatic (freshwater) or semi-aquatic origin of Chytridiomycota seems likely, followed by the diversification of the major phyla of Fungi in terrestrial environments. Several lines of evidence point to this hypothesis:

- The phylogeny by James *et al.* (2006), using data from six gene regions and nearly 200 species, shows that the early-diverging fungal lineages consist of a grade of zoosporic fungi, suggesting that the earliest fungi were primarily aquatic and lacked aerial spore dispersal. Subsequent losses of motile spores, which occurred at least four times, parallel the evolution of new mechanisms of spore dispersal, such as aerial dispersal in mycelial groups (e.g., Ascomycota and Basidiomycota) and eversion of the polar tube (an extrusion apparatus that evaginates during spore .discharge) in the Microsporidia.
- Recently, using a phylogeny based on 40 fungal genomes, Chang *et al.* (2015) showed that pectinases, enzymes for degrading plant cell walls, duplicated in an ancestral fungus that probably still lived in freshwater in association with streptophyte algae (= charophytes). As a result the authors considered that early terrestrial fungi might have evolved in semi-aquatic microbial slime, with the ancestors of the Zygomyceta tracking arthropods or other animals onto land, while the ancestors of the Dikarya followed plants.
- Extant Glomeromycota live as obligate symbionts of bryophytes, vascular plants, and cyanobacteria. This raised the possibility that terrestrial members of the Glomeromycota living symbiotically with cyanobacteria or algae in semi-aquatic and humid habitats later became the symbiotic partners of early land plants (Schüßler, 2002). Alternatively a transition to land as plant partners has also been proposed (Selosse and Le Tacon, 1998).
- Research on the origin of the genes acting in the fungal symbiotic pathway (arbuscular mycorrhizal symbiosis involving Glomeromycota) also focuses on algal lineages, such as charophytes, that are related to land plants. A stepwise evolution of the plant symbiotic 'toolkit' (i.e., the set of genes required for symbiosis) in algal ancestors, with several components predating the first land plants, has been recently proposed (Delaux *et al.*, 2012, 2013). Elements of this 'toolkit' may, therefore, have facilitated the interactions between aquatic charophyte-like ancestral algae and diverse symbiotic microorganisms, later being recruited and further developed for mycorrhizal evolution on land.

New Phytologist 203, 964–979, with permission from John Wiley and Sons).

Aquatic to Terrestrial Environments – Fossil Evidence of Fungi

Molecular clock studies have produced a range of time estimates for the origin and diversification of Fungi. As a result the molecular timetree shows that, while some phylogenetic uncertainty exists, major lineages of Fungi likely originated in the Neoproterozoic (1000–541 Ma), which is much earlier than the evidence provided by the fossil record (Blair, 2009; Berbee and Taylor, 2010). Microfossils in rocks of the mid Ordovician Period (ca 460–470 Ma) provide the earliest evidence of both fossil plants (earliest spores) and fossil fungi (Glomeromycota) (Rubinstein *et al.*, 2010; Redecker *et al.*, 2000; **Figure 3**), but no direct links between these organisms from that period have been proven. Fungal fossils become more common in the early Devonian (around 400 Ma) (**Figure 3**). The earliest direct evidence of Fungi associated with plant or plant remains is based on organisms fossilized in situ in the 407 million year old Rhynie Chert (Trewin and Rice, 2004). This fossil site is characterized by the occurrence of both aquatic and terrestrial environments. Among the Fungi, zoosporic species, in particular chytrids, were some of the most diverse elements. Rhynie chert Chytridiomycota have been documented inside algae, various plant, or fungal spores and plant tissues. Blastocladiomycota, previously considered a group of Chytridiomycota (**Figure 1**), also occurred associated with plant organs (see Table 1 in Strullu-Derrien *et al.*, 2015). These fungi colonized aquatic freshwater and wet terrestrial environments, and developed either as saprophytes or parasites.

Associations of the arbuscular mycorrhizal type (involving Glomeromycota) have also been described in several plants from the Rhynie chert (e.g., Remy *et al.*, 1994; Taylor *et al.*, 2005; Krings *et al.*, 2007; Strullu-Derrien *et al.*, 2014). Recently a dual colonization involving Glomeromycota and Mucoromycotina (**Figure 1**) was described in one of these plants, indicating that early fungal symbioses were more diverse than assumed hitherto, and overturning the long-held paradigm that the early mycorrhizal partners were exclusively Glomeromycota (Strullu-Derrien *et al.*, 2014; **Figure 4**). In contrast to chytrids in aquatic and wet habitats, symbiotic mutualistic associations with other fungal groups developed with plants living in terrestrial environments (Strullu-Derrien *et al.*, 2014; Taylor *et al.*, 2015). In the early terrestrial environments, Glomeromycota (and possibly also Mucoromycotina) appear to have developed as obligate symbionts of plants, a role that they still occupy today (see above the hypothesis concerning the transition from freshwater to terrestrial concerning Glomeromycota). In the Mucoromycotina, however, the earliest symbionts may have also been saprotrophic.

One fungus from the Rhynie chert has been attributed to Ascomycota (Taylor *et al.*, 1999). This fossil consists of

perithecia immersed within the aerial axes of one of the plants, however it does not fit comfortably within an extant taxonomic group (Berbee and Taylor, 2010) and its habitat (freshwater/terrestrial) has not been explored. During the early phases of land colonization by plants, root systems evolved into a broad range of complex multicellular organs specialized in anchorage and nutrient acquisition, and the size of the plants increased. Unlike the relationships between Fungi and early plants, the history of those involving trees is still not documented (**Figure 3**). One structural feature that has been used to identify fossil Basidiomycota in the absence of sexual reproductive organs is the clamp connection, a distinctive structure formed by growing hyphal cells. The first accepted Basidiomycota based on this feature occurs within a structurally preserved fern from the Carboniferous (ca 330 Ma) (Krings *et al.*, 2011), 80 Ma after the earliest putative occurrence of Ascomycota. Ancestors of all modern groups of Fungi were likely present by the end of the Carboniferous (**Figure 3**) however little is currently known about the transition to land for the most derived groups (i.e., Ascomycota and Basidiomycota).

Evolution of Traits from Primitive to More-Derived Fungi

Several traits should be considered in deciphering the aquatic (freshwater)–terrestrial transition in Fungi. We have chosen to focus on three: aquatic traits, hyphal habit, and sexual reproduction, which illustrate how Fungi evolved from zoosporic ancestors living in aquatic environments to highly adapted terrestrial groups (i.e., Ascomycota and Basidiomycota).

Aquatic Traits (Motile Spores, Non-Hyphal Growth form, Reproduction)

Chytrids represent an ancestral form of Fungi with motile spores, mostly non-hyphal growth form, and predominantly asexual reproduction. Chytrids reproduce through the production of motile spores (zoospores), typically propelled by a single, posteriorly directed flagellum. They are mostly aquatic (freshwater) or, if terrestrial, rely on water for dispersal or infection (Webster and Weber, 2007). Chytridiomycota are mostly non-hyphal Fungi; the simplest form of thallus is a sac-like, multinucleate cell with no appendages or branches. More sophisticated forms have branching rhizoids attached to the thallus body, which may be itself simple or branched (Griffin, 1996). Members of Chytridiomycota are predominantly asexual, with dehiscence and discharge of thin-walled zoospores from sporangial openings. Ultimately zoospores withdraw their flagellum into their body, deposit a cell wall, and develop into a sessile thallus. Asexually produced thick-walled resting sporangia may form (Powell, 2009). Sexual reproduction of Chytridiomycota is speculative, based on only a few studies, but sexual reproduction may be difficult to recognize or observe rather than truly absent. A thick-walled resting sporangium is likely to be the site of meiosis. In Blastocladiomycota, a clade of flagellated Fungi for which the phylogenetic position is not fully resolved (**Figure 1**), the resting sporangia form in water but can resist drying and will germinate with meiosis, releasing haploid zoospores when water is added. The same may be true for resting sporangia of Chytridiomycota (Miller and Dylewsky, 1981; Berbee, personal comm.). Fungi such as chytrids with motile spores are wholly or partly aquatic and require water for dispersal. This trait is lost in terrestrial species, which disperse aerially. In addition, aquatic Fungi are mostly non-hyphal, whereas hyphae developed in more-derived terrestrial groups. Finally, the mode of reproduction (see below) appears to have changed in correlation with the aquatic–terrestrial transition.

Hyphal Habit

The evolution of filamentous hyphae underlies an astounding diversity of fungal form and function, however little is known about diversification among hyphae. For example, recent work from Dee *et al.* (2015) demonstrated multiple independent origins of the hyphal habit by studying the cellular structure and evolutionary origins of the hyphal filamentous form in the Monoblepharidomycetes (Chytridiomycota) (**Figure 1**). Most members of this clade are found in freshwater environments. Hyphal Monoblepharidomycetes are an early-diverging fungal lineage, a clade sister to the genera without hyphae. Reconstruction of ancestral states indicates that hyphae arose independently within this lineage and in at least two other lineages (Ascomycota and Basidiomycota).

Most of the Fungi develop hyphae, which can be siphons (coenocytic hyphae), and which do not form multicellular structures or septate (multicellular) hyphae. In a recent article on the evolution of multicellularity, Niklas (2014) discussed the advantages of developing siphonous and multicellular body plans. The siphonous body plan might have conferred a selective advantage by permitting a single cell to achieve a large size and thus explore nutritionally variable landscapes (e.g., Sekimoto *et al.*, 2011; Niklas, 2014). Achieving a larger size could also have allowed more independent functioning in the face of a hostile environment likely to damage the hyphae, increasing the chance that some portion of an organism survived. The evolution of multicellularity requires the acquisition of a mechanism to partition cytoplasm into uni- or multinucleated cellular units and a mechanism for coordinating cytokinesis with cell wall deposition (Niklas, 2014). However the relationship between cell size, nuclear number, and nuclear division and cell division in fungi is different from plants or animals. In fungi, cytokinesis, partitioning cytoplasm, and cell wall deposition are linked in the dikaryon, but not in the monokaryon where cells can be multinucleate and septa form in response to cells size, not nuclear number. Multicellularity has several advantages. It allows the encapsulation of nuclei into separate but cytoplasmically connected cells (i.e., the establishment of physiological boundaries permitting isolation or coordination of metabolic processes). Also, it might evolve as a life-history strategy to allow an organism to explore space and persist through time until an optimal window of opportunity for reproduction arises (Niklas, 2014). Hyphae of Fungi that do exhibit complex developmental pathways form septa at regular intervals, though the septa usually have a central pore (Moore *et al.*, 2011)

allowing intercellular communication. The Ascomycota and Basidiomycota represent major derived lineages, which evolved from a common ancestor with septate hyphae (multicellularity).

The evolution of hyphae may have coincided with the rise of larger, multicellular food sources over half a billion years ago, when Chytridiomycota diverged from the other fungi. Data provided by Dee *et al.* (2015) suggest that both siphonous hyphae and septate hyphae arose independently from a single-cell predecessor living in freshwater environment. Early soils were formed by cryptogamic ground covers (Edwards and Kenrick, 2015) dominated by communities of cyanobacteria, basal eukaryotes of various sorts as well as small bryophyte-like organisms. Fungi likely moved from water to land to colonize these plants. Ground covers changed to biomass-rich covered mature soils as eukaryote organisms (plants and animals) diversified, providing new ecological niches for the evolution of Fungi.

Sexual Reproduction = An Ancestral Character in Terrestrial Fungi

A sexual cycle is considered to be ancestral in Fungi. Members of most of the traditional 'Zygomycota,' except Glomeromycota (**Figure 1**), share a sexual mode of reproduction through the fusion or conjugation of two hyphal branches (gametangia) to form a zygote, which undergoes meiosis and eventually germinates into a zygosporangium, which produces spores. Gametangia arise from hyphae of a single mycelium or from different but sexually compatible mycelia (Moore *et al.*, 2011). Ascomycota and Basidiomycota also reproduce sexually. In most Ascomycota, cytoplasmic fusion leads to dikaryons that form meiotic spores within a characteristic sac-like structure, the ascus. In Basidiomycota, dikaryons also form, but meiotic spores are produced on reproductive structures called basidia. A recent article of the evolution of fungal sexual reproduction (mainly focusing on a particular group of closely aligned species in the Basidiomycota) by Heitman *et al.* (2013) led the authors to suggest that unisexual reproduction could have been ancestral: perhaps sex was first a selfing mode of reproduction, generating diversity and eliminating deleterious mutations. The more complex versions of sexual reproduction, involving mating types and sexes, appeared later. Ascomycota usually have two mating types while Basidiomycota can have thousands of different mating types (Casselton, 2002). The sexual mode of reproduction characterizes the terrestrial Fungi, but sexual reproduction is known for so few members of the aquatic Chytridiomycota as to raise the possibility of its loss in some clades of this phylum. However this should not be overstated due to missing data.

When early plants colonized land, they evolved organ systems with multiple adaptations to rooting functions and physiological adaptations to growth in soils, gradually colonizing different types of environments. The development of larger plants was a key prerequisite for feeding in larger animals but also for the diversification of Fungi, which were able to evolve a wider range of enzyme activities (e.g., for wood decomposition). The combination of paleontological and genomic approaches is providing insights into the coevolution of plants and Fungi over >400 Ma, and how this has shaped their respective evolution and the geochemistry of earth, ocean, and atmosphere (Selosse *et al.*, 2015). Several key areas (e.g., relevance of the fossil record for improved timetree calibrations, better knowledge of fungal interactions in extant aquatic environments) would benefit from further cross-disciplinary developments to increase our knowledge on the origin and evolution of the fungal lineage.

Acknowledgments

CSD thanks Marc-André Selosse (MNHN Paris, France), Paul Kenrick (NHM Londres, UK), Mary Berbee (University of British Columbia, Canada), Francis Martin (INRA Nancy, France), and Amy Litt (University of California, Riverside, USA; section editor for this article) for helpful discussions concerning this manuscript. G

Gene Interactions in Evolution

CJ Goodnight, University of Vermont, Burlington, VT, USA

Glossary

Additive genetic variance Defined formally as the covariance between average effects and average excesses, from a practical perspective it is the component of the variance among individuals that is heritable and can contribute to a response to selection.

Average effect The effect that an allele has on the phenotype measured as a deviation from the population mean with the rest of the genome randomly drawn from the population.

Epistasis Interactions among alleles at two or more loci resulting in a phenotype that is different from what would be expected from the loci acting independently.

Epistatic variance Variance among individuals in a population that can be attributed to interactions among loci.

Local average effect The metapopulation extension of the average effects. The average effect that an allele has on the phenotype in a particular deme measured as a deviation from the metapopulation mean with the rest of the genome randomly drawn from a particular subpopulation.

Metapopulation A set of subpopulations connected by a low level of migration. A population of populations.

Physiological genetic effects Also known as functional or biological genetic effects. Genetic effects, including the main effects of loci, and interactions within and among loci measured for individuals without reference to the population in which it is measured. Physiological genetic effects are constant and unaffected by changes in allele frequency in a population.

Statistical genetic effects Genetic effects, including the main effects of loci and interactions within and among loci measured in the context of a particular population. Statistical genetic effects are a function of the population they are measured in and will change as allele frequencies change.

Statistical and Physiological Gene Interactions

Epistasis is an interaction among loci such that the effect of a particular genotype at one locus on the expression of a trait is dependent on the genotype at other loci (Whitlock *et al.*, 1995). An excellent example of this is found in the genetics of the coat color of Labrador retrievers (Kaelin and Barsh, 2013; **Figure 1**). In these dogs there is a 'B' locus that codes for coat color, such that B_1B_1 and B_1B_2 individuals have black coats, whereas B_2B_2 individuals have dark brown or 'chocolate' coats. However, this locus is modified by a second 'E' locus that has two alleles, one of which, the E_2 allele, prevents the deposition of melanin in the hairs. Thus, E_1E_1 and E_1E_2 individuals are black or brown depending on the genotype at the B locus, whereas E_2E_2 individuals are yellow regardless of the genotype at the B locus. Gene interactions also include dominance, which both the B locus and the E locus show. Dominance occurs when the heterozygote (e.g., B_1B_2 genotype) is not intermediate between the two homozygotes (B_1B_1 and B_2B_2 genotypes). In the case of the B locus the B_1B_1 and B_1B_2 have the same phenotype, that is different from the phenotype expressed by the B_2B_2 genotype, and the B_1 allele is said to be dominant over the B_2 allele. These examples of epistasis and dominance, where the effect of specific genotypes on the phenotype is measured against a constant scale, are often termed 'physiological' (Cheverud and Routman, 1995), 'functional' (Hansen and Wagner, 2001), or 'biological' (Moore and Williams, 2005) epistasis and dominance to distinguish them from 'statistical' gene interactions.

In quantitative genetics the phenotype, or value of traits of interest, are measured on individuals. However, the measure of interest is not the phenotype of the individual, but the variance among individuals in phenotype, V_P. The reason for the focus on the variance in phenotypes is that evolution in general, and selection in particular can only act if there is phenotypic variation in a population. Ignoring genotype by environment interactions, in standard quantitative genetics this phenotypic variance is broken up into underlying causal components. First the phenotypic variance can be divided into genetic and environmental components:

$$V_P = V_G + V_E$$

 doi:10.1016/B978-0-12-800049-6.00048-2

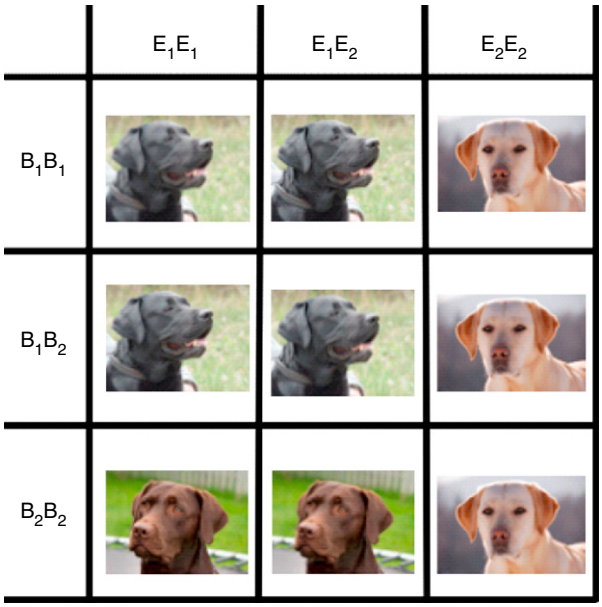

Figure 1 The genetics of coat color in Labrador Retrievers. B_1 is dominant over B_2, thus B_1B_1 and B_1B_2 individuals are black, and B_2B_2 are chocolate colored. E is epistatic with the B locus, and E_2E_2 individuals are yellow regardless of genotype at the B locus.

	A_1A_1	A_1A_2	A_2A_2	$p_A=p_B=0.5$ genotypic mean	$p_A=p_B=0.75$ genotypic mean
B_1B_1	1	0	−1	0	0.5
B_1B_2	0	0	0	0	0
B_2B_2	−1	0	1	0	−0.5
$p_A=p_B=0.5$ genotypic mean	0	0	0		
$p_A=p_B=0.75$ genotypic mean	0.5	0	−0.5		

Figure 2 Physiological and statistical epistasis example using additive-by-additive epistasis. Reproduced from Goodnight, C.J., 2014. Long term selection experiments: Epistasis and the response to selection. In: Moore, J.H., Williams, S.M. (Eds.), Epistasis: Methods and Protocals. New York, NY: Springer Science and Business Media, LLC, pp. 1–18.

where V_G is the variance in phenotype due to differences in genotype, and V_E is the variance in phenotype due to environmental influences. It is useful to further divide the genetic variance component:

$$V_G = V_A + V_D + V_{EP} + V_E$$

where V_A is the additive genetic variance, V_D is the dominance variance, and V_{EP} is the epistatic variance. The additive genetic variance, V_A, is the component of phenotypic variance that is most important for adaptive evolution. Although the formal definition is more complicated (Fisher, 1930), a practical definition of additive genetic variance is the portion of the phenotypic variance that is due to genetic effects that can be passed from parent to offspring (Falconer and Mackay, 1996). The importance of the additive genetic variance lies in the fact that it is the component that can contribute to a response to selection. The dominance variance V_D is the component of variance that can be attributed to within locus interactions (dominance), and V_{EP} is the component of variance that can be attributed to between locus interactions. The epistatic component of variance is typically further divided into specific epistatic interactions, for example, for a two locus two-allele system there are eight independent genetic variance components: additive at each locus, dominance at each locus, additive-by-additive epistasis, additive-by-dominance and dominance-by-additive epistasis, and dominance-by-dominance epistasis (Goodnight, 2000a).

The important distinction between physiological genetic effects and statistical genetic effects is that physiological genetic effects are a function of the organism's genotype that is independent of the population in which it is measured. In contrast statistical genetic effects are a function of both the organisms and the allele frequencies of the population in which they are measured (Cheverud and Routman, 1995).

Consider the simple example of additive-by-additive epistasis. In Figure 2 the values of 1, 0, and −1 in the three-by-three matrix are the physiological genetic effects. These are constants (i.e., they are fixed properties of the genotypes), and do not change regardless of the allele frequencies at the interacting loci. In the margins are the statistical genetic effects. These are the effects of one locus taken as a weighted average of the genetic backgrounds in which it is found. In this system, when the allele frequencies at both loci equals 0.5 the marginal values for both loci are all zero. Because there is no dominance in this example, the additive genetic variance is simply the variance in these marginal effects, thus the additive genetic variance is also zero, and the population is unable to respond to selection. In contrast when the allele frequencies are changed to 0.75 for both loci the weighted average for the genotypic effects are now nonzero, and the additive genetic variance is nonzero (0.187 5) (Goodnight, 2014).

Gene Interactions within Populations

Physiological dominance and epistasis are considered to be very common, if not nearly universal. The reason for this is that enzymes work in biochemical pathways where the different enzymes are the product of different loci. As a result any changes in the rate of flux through one enzyme will inevitably have effects on other enzymes in the pathway. These effects will be expressed as physiological epistasis. However, it has generally been observed that statistical epistasis tends to be a smaller component of the phenotypic variance than might be expected based on the ubiquity of physiological epistasis (Mackay, 2014). The most likely explanation for this is that statistical epistasis is maximized when all of the interacting

loci are at intermediate allele frequencies. It is reasoned that most loci are dominated by one or a few alleles at high frequencies with other, rare, alleles being at much lower frequencies (Cheverud and Routman, 1995). These are situations where the majority of genetic variance will be additive and able to contribute to a response to selection. Statistical epistasis will not be present unless there is physiological epistasis, however, the opposite need not be true. Nevertheless, genetic variance components attributable to gene interaction are frequently common enough that they must be taken into account (Roff and Emerson, 2006).

Statistical Gene Interactions and Drift

The effects of statistical gene interactions are best understood for genetic drift (e.g., Goodnight, 2006; Barton and Turelli, 2004). In an infinitely large population with no selection, allele frequencies will not change, and as a consequence the genetic variance components will remain constant. When population sizes are finite allele frequencies will change randomly due to genetic drift, with smaller populations being more strongly affected than larger populations. The accepted metric for measuring the effects of drift is the probability that two alleles are identical by descent. This is measured by Wright's inbreeding coefficient, f. In an idealized population of random mating diploid hermaphrodites the inbreeding coefficient increases in small populations:

$$f_{(t+1)} = \left(\frac{1}{2N}\right) + \left(1 - \frac{1}{2N}\right) f_{(t)}$$

where $f_{(t)}$ is the inbreeding coefficient at generation t, and N is the population size (Hedrick, 2005). This basic formula can be modified for more realistic population structures, such as separate sexes, and unequal sex ratios. More importantly for studying gene interactions, it can be modified to accommodate multiple loci and used to investigate the effects of drift on the conversion of epistatic and dominance variance to additive genetic variance (Goodnight, 1995, 2000b; **Figure 3**).

This is perhaps the most important effect of gene interactions on evolution within small populations. That is, in additive theory, a population bottleneck or period of small population size leads to a decline in the additive genetic variance. In contrast, in systems with gene interaction it is frequently the case that the additive genetic variance, and thus the ability for a population to respond to selection increases following a population bottleneck. This increase in additive genetic variance following a population bottleneck has been experimentally observed on multiple occasions (Van Buskirk and Willi, 2006).

The increase in additive genetic variance due to genetic drift warrants further discussion. In populations in linkage equilibrium the additive genetic variance is twice the variance in average effects, where the average effect of an allele is the effect of an allele on the phenotype, averaged over all possible genotypes and measured as a deviation from the population mean (Falconer and Mackay, 1996). Based on this simple definition it is apparent that there are only a few ways that the additive genetic variance can increase. It can be shown that the increase in the additive genetic variance due to changes in allele frequency when there is gene interaction is always associated with changes in the local average effects of alleles. The local average effect of an allele is defined as the effect that an allele measured in a specific subpopulation has on the phenotype taken as a deviation from the metapopulation mean (Goodnight, 1995, 2000b). Whenever there is an increase in the additive genetic variance it means that the local average effects of alleles are changing. How this occurs can be seen in **Figure 2** above. Consider a single large population with the A and B locus segregating. From this population found two new populations, one with a genotype of $A_1A_2B_1B_1$, the second with a genotype of $A_1A_2B_2B_2$. In the first population, ignoring the B locus, the A_1A_1 genotype has a genotypic value of 1, and in the second population it has a value of -1. The resulting local average effects of the A_1 allele are $+0.5$ in the first population and -0.5 in the second population. Although this is a contrived example, it demonstrates that increases in additive genetic variance are associated with changes in these local average effects, and that the increase in additive genetic variance is due to the effects of the alleles 'spreading' as the interlocus interactions become statistically

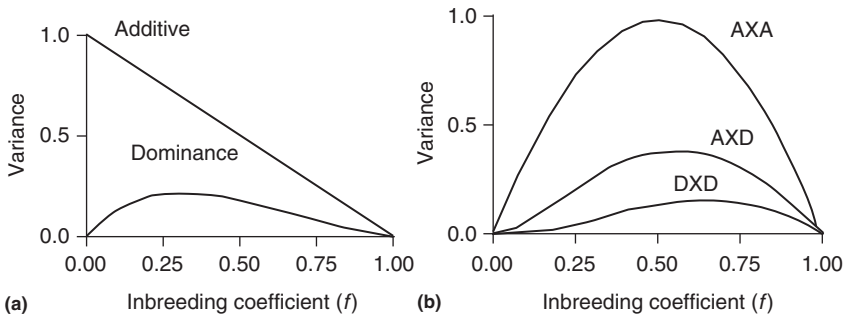

Figure 3 The additive genetic variance as a function of Wright's inbreeding coefficient. (a) Single locus genetic effects. (b) Two locus genetic effects. For additive variance the additive genetic variance declines linearly with inbreeding coefficient, whereas for variance components involving interactions the additive genetic variance is maximized at an intermediate inbreeding coefficient. Additive: single locus additive genetic variance; Dominance: Single locus dominance variance; AXA: Additive-by-additive epistatic variance; AXD: Additive-by-dominance and dominance-by-additive epistatic genetic variance; DXD: Dominance-by-dominance epistatic genetic variance. Reproduced from Goodnight, C.J., 2006. Genetics and evolution in structured populations. In: Fox, C.W., Wolf, J.B. (Eds.), Evolutionary Genetics: Concepts and Case Studies. Oxford, NY: Oxford University Press, pp. 80–100.

expressed as direct effects. Figure 4 uses a more sophisticated model and shows the expected variance in local average effects for different forms of genetic effects.

The increase in additive genetic variance coupled with the increased variance in local average effects is also associated with a decline in statistical epistatic variance within populations (Goodnight, 1988). The net result is that, due to finite population sizes, nonadditive genetic variance will frequently not be present as a measurable variance component within populations (Hill *et al.*, 2008), nevertheless it will be present between populations in the form of variance in local average effects (Goodnight, 2000b, de Brito *et al.*, 2005). Interestingly, changes in local average effects can also change over time, and under some circumstances this change can be driven by selection (Goodnight, 2004a). The result is that selection can generate, rather than consume, genetic variance. More importantly, it is possible that the adaptive value of alleles at a locus will switch over the course of selection, such that an allele that confers high fitness early in the adaptation process may be eliminated by selection later when, due to interactions with other loci, it is converted to a low fitness allele (Goodnight, 2014).

It is also important to note that the differentiation for local average effects and the differentiation for population means need not be related. When there is only additive variance, genetic drift will cause populations to differentiate for the population means, but there will be no differentiation for local average effects. In contrast, many of the interactions involving dominance have at most a small effect on the population mean, but may have substantial effects on differentiation for average effects (Goodnight, 2004b). One result of this is that populations, such as cryptic species, that are very similar in appearance, may nevertheless be highly differentiated for local average effects, and as a consequence reproductively isolated. In contrast, highly morphologically differentiated populations, such as some of the Hawaiian plant species groups, may be highly morphologically differentiated, but nevertheless not differentiated for local average effects, and as a result interfertile (Robichaux *et al.*, 1990).

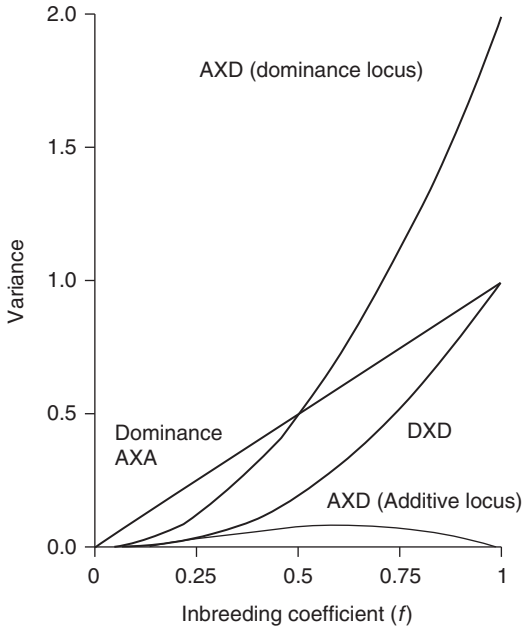

Figure 4 The variance in local average effects. The variance in local average effects for additive variance (not shown) is zero for all values of inbreeding coefficients. This means that for additive effects, regardless of how differentiated a population is the effect of an allele relative to other alleles will always be a constant. For genetic interactions the variance is always nonzero, meaning that the relative phenotypic effects of alleles will be different in different populations. Reproduced from Goodnight, C.J., 2006. Genetics and evolution in structured populations. In: Fox, C.W., Wolf, J.B. (Eds.), Evolutionary Genetics: Concepts and Case Studies. Oxford, NY: Oxford University Press, pp. 80–100.

Molecular Genetics and Physiological Epistasis

In a molecular genetic framework, interactions such as 'diminishing returns epistasis' (Maclean *et al.*, 2010), 'sign epistasis' (Weinreich *et al.*, 2005), and 'synergistic and antagonistic epistasis' (Desai *et al.*, 2007) are often discussed. These terms do not have direct parallels in the quantitative genetic framework described here, since they are referring to physiological epistasis, and the fitness effects of individual alleles rather than the statistical epistasis of the quantitative genetic variance component framework. In general, these interactions involve the order and timing of mutations in a gene network with an arbitrary number of loci, and the allelic effects are made in reference to a standard genetic background, usually the 'wild type' for the species or strain being studied (Kryazhimskiy *et al.*, 2011). The inherent polygenic nature of this approach is a distinct advantage for molecular genetic models that examine the effects of epistatic mutations at multiple loci that can accumulate over time. This molecular genetic concept and the quantitative genetic concept of epistasis are tied together through changes in variance components and changes in local average effects. For example, diminishing returns epistasis is a gene interaction in which mutations have their greatest impact on fitness when they are the sole mutation in a metabolic pathway, whereas if they are introduced into a pathway that already has mutations in it their impact will be reduced (Maclean *et al.*, 2010). From a quantitative genetic perspective this is caused by changes in local average effects that are contingent on the number of prior mutations.

Hansen (2013) gives two locus examples of 'positive,' 'negative,' and 'sign' epistasis (**Figure 5**) that are directly decomposable into quantitative genetic variance components. Positive and negative epistasis are equivalent to Desai *et al.* (2007) synergistic and antagonistic epistasis. Using the regression methods of Goodnight (2000a) positive epistasis can be shown to be a mixture of additive variance, additive-by-additive, additive-by-dominance, and dominance-by-dominance epistasis, although the relative proportions of the different components depend on the genotype frequencies. Similarly negative epistasis and sign epistasis can be shown to be mixtures of additive variance and additive-by-additive epistasis, again with the relative proportions of the two variance components dependent on gene frequency.

The examples given by Hansen (2013) are for two loci; however, the concepts of positive, negative, and sign epistasis will typically involve an arbitrary number of loci. In principle

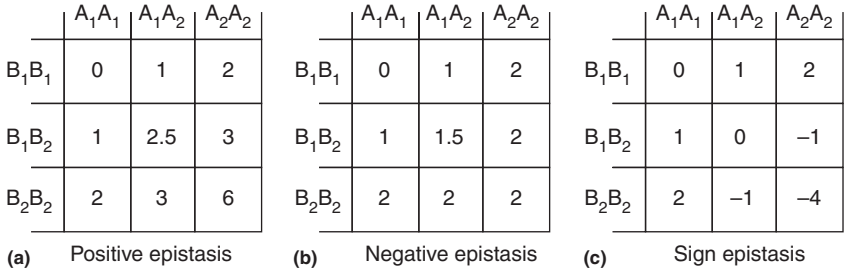

Figure 5 Examples of positive epistasis (a), negative epistasis (b), and sign epistasis (c) (Reproduced from Hansen, T.F., 2013. Why epistasis is important for selection and adaptation. Evolution 67, 3501–3511). These examples use physiological epistasis, which may be more appropriate for molecular approaches. For evolutionary studies they can be converted to quantitative genetic components. These can be found using the regression methods of Goodnight (2000a), and they will be a function of the genotype frequencies. In the case of a population in linkage equilibrium and a allele frequency of 0.5 at both loci, the positive epistasis (a) is 89% additive variance, 3.6% additive-by-additive epistasis, 3.6% additive-by-dominance epistasis, and 3.6% dominance-by-dominance epistasis. Negative epistasis (b) is 80% additive variance and 20% additive-by-additive variance, and sign epistasis (c) is 50% additive variance and 50% additive-by-additive epistasis.

this conversion from the molecular/physiological genetic approach to the quantitative genetic approach can be done for any degree of epistasis. The reality is that, for statistical reasons, there two-locus interactions will typically be adequate.

As Hansen (2013) points out, the big difference between the physiological genetic approach and the quantitative genetic approach is that with the molecular genetics approach the effects of selection on identified alleles can be followed. On the other hand, to study the effects of selection on the phenotype, some form of reckoning similar to that used in quantitative genetics needs to be done. On the other hand the quantitative genetic approach is well suited to studying the effects of selection on phenotypic change. Importantly, although the author cannot prove it, it appears that any two locus quantitative genetic system that has the same mean and gives the same variance component values as Hansen (2013) examples will also predict the same phenotypic change, although not necessarily the same allele frequency change.

Summary

Gene interaction, or physiological dominance and epistasis, is a necessary, but not sufficient, prerequisite for statistical gene interactions. Statistical genetic effects are variance components that are attributable to the underlying physiological genetic effects. Because selection requires heritable variation to be effective, it is the statistical rather than the physiological genetic effects that are important in evolution. The additive genetic variance is of primary interest in evolutionary change; however, statistical variance components due to dominance and epistasis are important because they can contribute to the additive genetic variance, and this contribution changes as allele frequencies change. Between demes this increase in additive genetic variance is associated with the shifting of the local average effects of alleles, causing populations to diverge for their effect on alleles, such that an allele that is good in one population may perform poorly in another population.

Gene Networks Driving Development, Conservation and Evolution of

VF Hinman, Carnegie Mellon University, Pittsburgh, PA, USA

Glossary

***Cis*-regulatory module (CRM)** A stretch of usually several hundred base pairs of DNA with multiple binding sites for TFs. CRMs are often located within several thousand base pairs on the gene locus or within introns. The bound TFs regulate expression of the target gene. CRMs are sometimes referred to as enhancers or *cis*-regulatory elements.

EvoDevo Short form of evolution of development. The field of biology that compares the development of different taxa to understand the basis of morphological diversity, ancestral features and the relationships between organisms.

Gene regulatory network (GRN) A network of regulatory interactions between genes. The regulatory interactions can include any of the known mechanism of gene regulation; including transcription factor regulation, signaling pathways, microRNA regulation, and other post translational mechanisms. Nodes within the GRN are genes, and edges drawn between them are the regulatory interactions.

Subcircuit A subset of usually several genes (nodes) from a GRN. Subcircuits can be considered as functional modules operating in a GRN.

Transcription factor (TF) A class of protein that binds to a DNA with sequence specificity to regulate expression of a target gene.

The Birth of Evolutionary Developmental Biology

Evolutionary developmental biology (EvoDevo), the study of the evolution of the developmental mechanisms underlying organismal morphological diversity, is a vigorous and growing field of research. The union of these areas seems so natural that it's hard to imagine that historically, evolutionary, and developmental biology were quite separate fields of investigation (e.g., Carroll, 2008; Raff, 1996, 2000). Early developmental biologists were interested in understanding subjects including how cells obtained their identity, how cells could impart properties onto other cells and how communities of cells were established (Carroll *et al.*, 2004). These studies, for instance, generated an understanding of morphogen gradients and organizing centers. Developmental biologists, primarily using the fruit fly, *Drosophila melanogaster*, as a model organism, also began to understand the genetic underpinnings of development. For instance, experiments performed in *Drosophila* revealed mutations that affected the position of appendages along the body (e.g., Lewis, 1978). Thus legs would form in the location of antennae, and two pairs of wings would from instead of one pair and one balancer pair. These experiments provided enormous insight to developmental biology, as they showed for instance that there could be genetic switches, i.e., gene products that could turn off or on an entire program or module inappropriately. Most famous of these gene mutations were to the *hox*, or homeotic genes (e.g., Gilbert, 2000). These genes are clustered along the chromosome and are expressed in overlapping domains along the anterior to posterior axis of the *Drosophila* embryo. Mutations in these genes lead to misregulation of this axis and inappropriate positional identity. Although these findings provided extraordinary insight into developmental mechanisms, it was assumed that such mechanisms and their genetic underpinnings were exclusive to *Drosophila*, or very closely related species. Hence, nothing much could be inferred about evolutionary processes. The strong assumption that distantly related organisms, and certainly species in different phyla, were constructed using different genes, indeed, that organisms were different because they used different genes, lead to the belief that little could be understood from comparative developmental genetics. The paradigm-shifting discovery in the mid-1980s that mice also had orthologs of these same homeotic genes was an enormous breakthrough (McGinnis *et al.*, 1984). The implication of this finding was that mice and *Drosophila* shared genes with sequences that were predicted to have arisen from a common gene present in their ancestor. Furthermore, the *hox* gene orthologs in mouse were also found to be clustered in the genome, expressed in overlapping domains along the anterior posterior axis, and most significantly, when mutated led to defects in axial skeletal patterning.(e.g., Graham *et al.*, 1989; McGinnis *et al.*, 1984). This initial discovery of similar uses of orthologous *hox* genes in highly disparate taxa was quickly extended to many more genes, for example, *pax6* orthologs were expressed in, and needed for the function of eyes, similarly *tinman* orthologs, for hearts, and *distalless* to extend appendages (Halder *et al.*, 1995; Olson, 2006; Panganiban *et al.*, 1997).

The Focus on Regulatory Evolution

These early findings led to the blossoming of the EvoDevo field. The burst of sequencing of genomes from across a diversity of animal taxa confirmed the initial findings that different animals have very similar sets of genes (e.g., Koonin, 2009; Putnam *et al.*, 2007; Srivastava *et al.*, 2010). Certainly expansions and taxon specific genes have evolved in specific lineages, but it has become quite clear that to understand how animals have evolved, we must understand how orthologous genes are used in different ways to achieve the diversity of developmental plans.

Before considering how gene function evolves, it is useful to think about types or categories of genes and how their

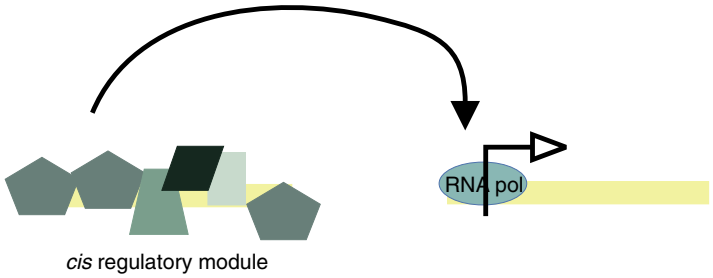

Figure 1 Enhanceosome on a *cis*-regulatory module (CRM) regulates gene transcription. Transcription factors proteins (depicted as green polygons) bound to a CRM. When bound these proteins will cause transcription of the target gene (arrow). Transcription factors can also act as repressors to block transcription of the target gene.

evolution might affect development. This has been discussed very elegantly by Carroll *et al.* (2004). Many genes in the genome function to control a variety of universal cellular processes and metabolism. All animals, and in many cases all life, will use the same gene orthologs for these critical processes. These genes therefore tend to be highly conserved and hence uninformative about the mechanisms of animal diversity evolution. There are also those genes that are expressed in particular cell types, for example, myosin in muscle cells, various neurotransmitters in neurons, hemoglobin in red blood cells. These genes also tend to be highly conserved among animals. Although as more taxa are sampled, and especially those at the base of the metazoa, there are variations in gene sequence and uses, which provide insight into how these genes evolved their function (e.g., Bridgham *et al.*, 2010). Finally, there are the subset of genes that are regulatory in nature, i.e., their function primarily is to direct the expression of other genes. These are mostly genes encoding transcription factors and signaling pathway components. There are other classes of regulatory genes, particularly microRNAs and other noncoding RNAs, but as yet very little is understood about how these might contribute to the evolution of development. Regulatory genes are expressed in different cells types and at different times during development. Most animals start life as a fertilized egg, which will repeatedly divide to produce many cells, each specified to the correct type. These cell types are the product of the sets of genes expressed in each cell, thus, for example, a neuron expresses a very different sets of genes than does a red blood cell. It is the job of regulatory genes to regulate the expression of other genes and thereby to determine cell type specific gene expression. Regulatory genes have therefore been very aptly termed the genetic toolkit for development (Carroll *et al.*, 2004), as these are the genes that are used to make the cell types and hence to construct the form of the embryo.

Before we can understand how development evolves, we must understand how new cell types evolve and how these cell types are positioned in the correct place in time and three-dimensional space in the embryo. A great deal of EvoDevo has therefore focused on the evolution of the function of regulatory genes (e.g., Wray, 2007). Before considering how these genes evolve, it is helpful to understood more clearly how they function during development. The functional role of a transcription factor is to bind DNA with some sequence specificity. Thus each transcription factor has a stretch of often only 6–13 base pairs of sequence to which the protein will bind. These sequences are often degenerate so that there are many variants within this sequence. Therefore within the genome there could be many thousands of loci where each protein could bind. Other transcription factors may bind nearby, to their own preferred binding site, and multiple copies of the same protein could also bind to preferred sites nearby. Thus, there forms a collection of proteins bound to a 300–800 base pairs stretch of DNA called the *cis*-regulatory module (CRM) (**Figure 1**); the collective binding of each of these proteins form a stable complex termed the enhanceosome (reviewed, (Arnosti, 2002). The transcription factors bound to the CRM activate the transcription of genes by helping to stabilize the complement of proteins that will recruit polymerase to the transcription start site or by influencing the chromatin state. Transcription factors may also act as repressors of gene expression. In these cases the bound protein will disrupt the recruitment of RNA polymerase or promote closed chromatin. In this way transcription factors can be conceived of as a binary switch; when bound in the right combination with other proteins they will work to either turn on or turn off transcription of a single gene. Signaling pathways initiate with a ligand, which are either membrane bound or diffusible. The ligand will bind a receptor to establish a signaling cascade, the outcome of which is to activate or repress the transcription of a target gene. Therefore signaling pathways regulate gene expression in neighboring cells, while transcription factors act cell autonomously.

Given the importance of these regulatory genes, they constitute a surprisingly small fraction of the total genes in the genome. For instance, in an extensive analysis of transcripts from the sea urchin, less than 10% are predicted to be transcription factors (Tu *et al.*, 2012). The genes therefore must be used multiple times, often in multiple cell types and at many different times during development. Additionally, in each context, each factor also regulates the expression of many other genes. New technologies permit an unbiased probing to reveal where transcription factors are bound to the DNA at any one time (Johnson *et al.*, 2007). These indicate that a given transcription factor may have thousands of target genes (e.g., Zeitlinger *et al.*, 2007). Transcription factors are therefore highly pleiotropic. Changing the function, for example, the binding properties of any one transcription factor, will potentially affect the expression of many thousands of other genes. Such large scale changes are presumed to most often be extremely deleterious and therefore unlikely to occur with great frequency. Therefore, the biochemical functions of transcription factors are likely to be highly conserved. For these

reasons it has been argued that a more likely common source of variation is of the *cis*-regulatory targets of these factors (Wray, 2007). This allows one target gene to change, and can also lead to more subtle effects that can pass the filter of natural selection. Increasingly, however, it is being discovered that transcription factors can also evolve. Critical to this type of evolution is the ability to evolve in ways that reduce pleiotropic effects, i.e., that only subsets of their target genes will change (Cheatle Jarvela *et al.*, 2014; Lynch and Wagner, 2008; Pick and Heffer, 2012). As yet, however, very little is known about how such protein level evolution changes the structure of GRNs but this is likely to be an important future direction in the field.

From Gene Regulation to Gene Regulatory Networks

A gene regulatory network (GRN) is a model that seeks to describe the entire set of regulatory interactions that occur in any given cell lineage or territory during development (Davidson, 2006; Davidson and Erwin, 2006). Instead of considering just one or even several regulatory factors at a time, GRNs include all of the gene regulatory events together into a network of interactions. Each node in the GRN is the CRM that regulates each gene at that time and place. The edges, or interactions, are the transcription factors that regulate the target gene at this regulatory module. GRNs, therefore, provide a systems-level explanation of development. As discussed above, changes in these regulatory interactions are a significant source of evolutionary change in development. The goal of GRN evolutionary studies is to understand how these changes alter the topology of the GRN and the effect that this has on development.

Ideally a GRN will start with regulatory molecules in the egg and end with a description of the genes expressed in the differentiated cell. In the example of **Figure 2**, a maternal factor may be inherited asymmetrically into cell lineage 'A' and will specifically activate zygotic transcription of the transcription factors A and B. Once these initial factors are expressed, they now coordinately activate yet more factors, in this example, transcription factors C, D, and E. This regulatory hierarchy will continue as combinations of factors expressed in any cell activate yet more transcription factors. Eventually, in this example, the factors expressed in cell type 'A' are sufficient to activate the expression of differentiation genes, i.e., those classes of genes that execute the final function of the cell. The set of expressed genes is termed the regulatory state of this cell, which is changing over developmental time. The other class of regulatory genes shown in this figure is the signaling pathway genes; in this example a signaling ligand is activated by transcription factors D and E. The ligand will bind its receptor in cell 'B.' The activated receptor will activate a transcription factor W through a signaling cascade. W in this example is a repressor and thus represses the expression of factor C. Consequently the factors downstream of C are also extinguished. W additionally represses V, which is also a repressor, and therefore W functions indirectly to activate the expression of factors Y and Z. The function of signaling here therefore is twofold, to repress the expression of genes in common with type 'A' and to also direct expression of specific factors that will direct it to cell type B. The regulatory state of cell 'B' therefore become W, Y, and Z which will activate expression of a distinct set of differentiation genes, R and S.

Figure 2 represents a basic, simplified version of the types of GRNs that have been determined experimentally (e.g., Aguilar-Hidalgo *et al.*, 2013; Chan *et al.*, 2009; Davidson, 2006; Davidson *et al.*, 2002; Kueh and Rothenberg, 2012; Morley *et al.*, 2009). Advances in technologies are making it increasingly possible to generate expansive data sets of all of the interactions that comprise a developmental GRN. RNA-Seq technologies associated with various cell type sorting approaches permit rapid assessment of the regulatory states in a particular cell type over time (Pepke *et al.*, 2009). These can be

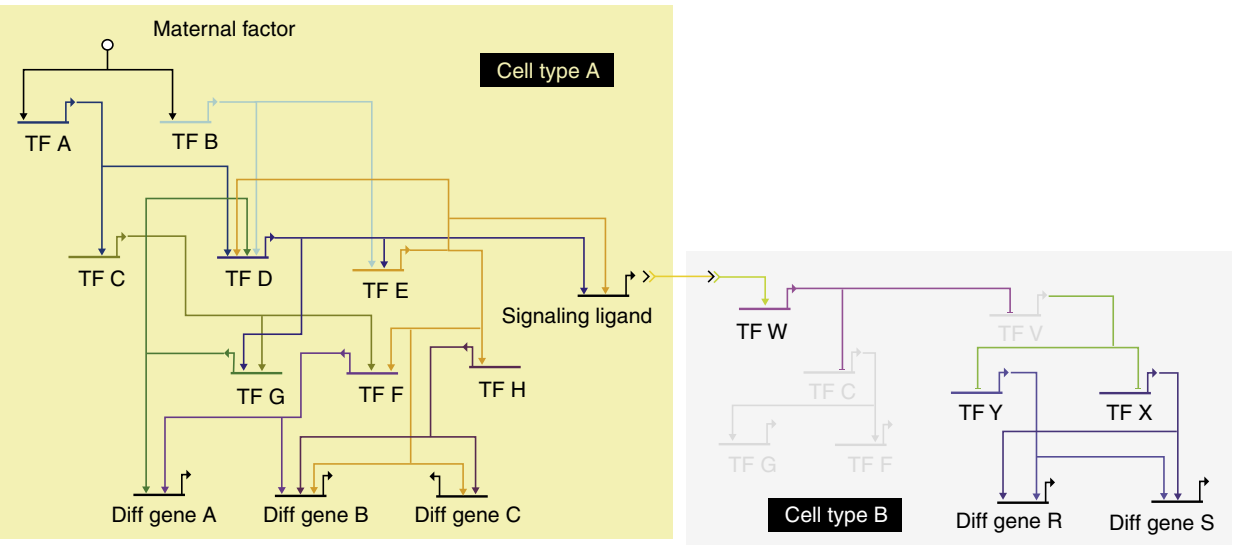

Figure 2 An stylized example of GRN. Each horizontal line represents the CRM for the regulated gene. Lines emanating from a gene represents transcription, with arrows indicating a positive regulation on the target gene and bars a repression event. TF- transcription factor, Diff Gene – terminal differentiation gene. GRN was drawn using drawn in Biotapestry (Longabaugh, 2012).

coupled to knockdown or other perturbation strategies to assay the change in expression profiles under perturbed conditions. These data can be used to fairly rapidly build a picture of the epistatic interactions between genes. Ideally the GRN should include the direct regulatory connections, i.e., that each interaction shown should be the binding of the factor to the CRM of the target gene. Here again new technologies are making this increasingly feasible. ChIP-sequencing, for example, is a high throughput method for identifying the regions of chromatin bound by a factor of interest (Johnson *et al.*, 2007; Pepke *et al.*, 2009). These types of technologies are expanding the number of taxa for which GRNs can be determined and therefore comparative analyses on GRN topologies will become a more accessible approach for studying evolution (Fischer and Smith, 2012).

When considering an entire GRN, as in **Figure 2**, types of subcircuits of several interacting nodes stand out. For example, **Figure 3** highlights a subcircuit of a group of three genes from **Figure 2** that are interconnected by positive feedback. Thus, in this example transcription factor D regulates E and G, and in turn D is regulated by G and E. Another type of commonly observed subcircuit is a feedforward loop. For example, again highlighted from **Figure 2**, factor E regulates H and the differentiation genes B and C. H also regulates differentiation genes B and C. These subcircuit topologies are thought to confer very particular dynamic functions. (Alon, 2007b), which are simply the result of the kinetics that occur naturally as genes are transcribed, translated, and bind to regulatory DNA (e.g., Ben-Tabou de-Leon and Davidson, 2009). Therefore, developmental GRN function can depend on the topology of the subcircuits of interacting factors. For instance, in the example of positive feedback, as one gene in the subcircuit is expressed, all genes will be transcribed and remain on due to this feedback. Thus a function of such a positive feedback loop in development is thought to be to establish a maintained memory of a transient input (Shoval and Alon, 2010; Alon, 2007a). A feedforward subcircuit is thought to function as a filter for transient inputs; the differentiation genes in this example will not be expressed until transcription factor E has driven the expression of transcription factor H, which in turn must be translated and processed before differentiation gene expression is permitted.

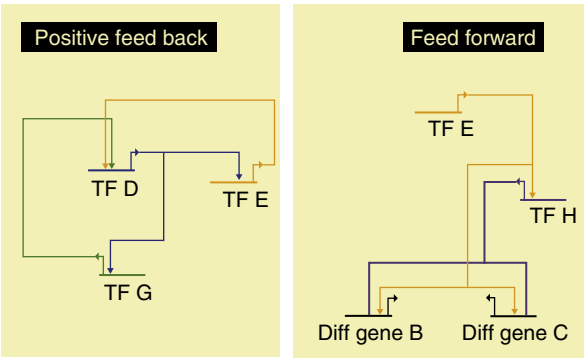

Figure 3 Two types of subcircuit commonly observed in GRNs, (a) Feedback loop and (b) Feedforward loop. Both subcircuits are found in **Figure 2** and highlighted here to show concept of modular subcircuit.

The developmental function of feed forward is therefore to ensure that a state is stably present in a cell before activating target genes. Therefore, the function of a GRN can be dictated from the types of subcircuits and their relative placement within the network. This idea, as will be expanded on below, has very important consequences for how GRNs might evolve.

Evolution of GRNs

Much of the great body of literature in the field of EvoDevo examines the evolutionary and developmental consequences of changes in gene regulation. Comparisons of GRNs provide a powerful extension to this approach as these analyses permit an understanding of how these evolutionary changes alter development. One especially important goal in this research is to use the framework of the GRN to understand whether all types of changes are equally likely, i.e., whether some changes modify GRNs in less disruptive ways that therefore are more likely to pass the filter of selection. The notion that there are constraints on developmental possibilities has been widely discussed and debated (e.g., Raff, 1996), but it remains unclear whether this occurs, and if so, what mechanisms might underlie constraint. Identifying the types of GRN topologies that are more or less likely to evolve and linking this to development provides a solution to this problem.

There are still relatively few comparison of detailed GRNs, but some of the best known comparison of GRNs have been performed between groups of echinoderms (Hinman and Cheatle Jarvela, 2014; Hinman *et al.*, 2009). This is because the best example of a detailed developmental GRN is for the sea urchin, a member of one of the classes of echinoderms (Davidson *et al.*, 2002; McClay, 2011; Peter and Davidson, 2011; Sethi *et al.*, 2012). The sea star, a representative of another class of echinoderm, was selected as an ideal comparative model as it has an overall fairly similar developmental plans but with several distinct differences. One of the most remarkable observations from these comparative analyses was the finding that certain types of GRN subcircuitry may have different capacity for evolutionary change (Davidson and Erwin, 2006). The best described example of this is with positive feedback circuitry. A comparison between early development in sea urchin and sea stars showed that among the earliest regulatory events is the activation of a feedback subcircuit (Hinman *et al.*, 2003; McCauley *et al.*, 2010). Remarkably this feedback circuitry is maintained in common, i.e., the same gene ortholog are engaged in positive autoregulation to form a feedback loop. Not all regulatory connections are identical, but the overall positive feedback function of the subcircuit is conserved. In both the sea urchin and sea star this subcircuitry occurs downstream of early signaling processes during early cleavage and thus the function of these circuits may be to simply provide a 'lock down' of specification state to one germ layer cell type. While these subcircuits are conserved, there are significant differences in the GRN acting earlier and later in development. (Hinman and Davidson, 2007; McCauley *et al.*, 2010). Most significantly in the mesoderm, the sea urchin GRN downstream of this conserved subcircuit leads to the development of biomineralization genes required for the formation of the larval skeleton. The orthologous GRN

in sea stars forms other types of mesoderm. This demonstrates that conserved circuitry in early development does not constrain the later evolutionary capacity for development.

The evolution of novel features that underlie the diversity of animal forms must arise from changes to GRNs (e.g., Erwin and Davidson, 2009). There are a variety of well-understood mechanisms through which gene regulation can evolve. The consequences of changes in gene regulation can be explored in the context of how such changes will generate changes in GRN topologies. The loss and gain of individual nodes are likely to be fairly frequent events, and as discussed above (e.g., Wray, 2007) are most likely to be due to a change to CRMs. As shown in the example above, for individual interaction changes within otherwise conserved feedback loops, this may not affect an obvious change in function (Hinman *et al.*, 2007). Another well studied evolutionary mechanism are duplications, either of coding regions or CRMs (Kimura and Ohta, 1974). Duplicated genes allow for rewiring of circuits. Initially, the duplicated gene will continue to regulate its original subcircuit but over time this additional gene will lose and gain targets genes and presumably this will change development (e.g., **Figure 4(a)**). This has been implicated in the developmental a several vertebrate specific novelties, for example, neural crest (Green and Bronner, 2013), and biomineralization (Fisher and Franz-Odendaal, 2012). The two duplicates may also simply split their ancestral function. When this happens the associated changes to development are expected to be relatively minor. Alternatively, a CRM may duplicate during evolution. This duplicated CRM can acquire or lose binding sites that will allow the regulated gene to be expressed in a new context (e.g., **Figure 4(b)**). Potentially the subcircuit driven by the new domain of gene expression may then 'bring along' or co-opt the downstream target genes. This circuitry is now therefore also expressed in a new developmental context. This is an attractive solution to making novel structures during development and this mechanism for

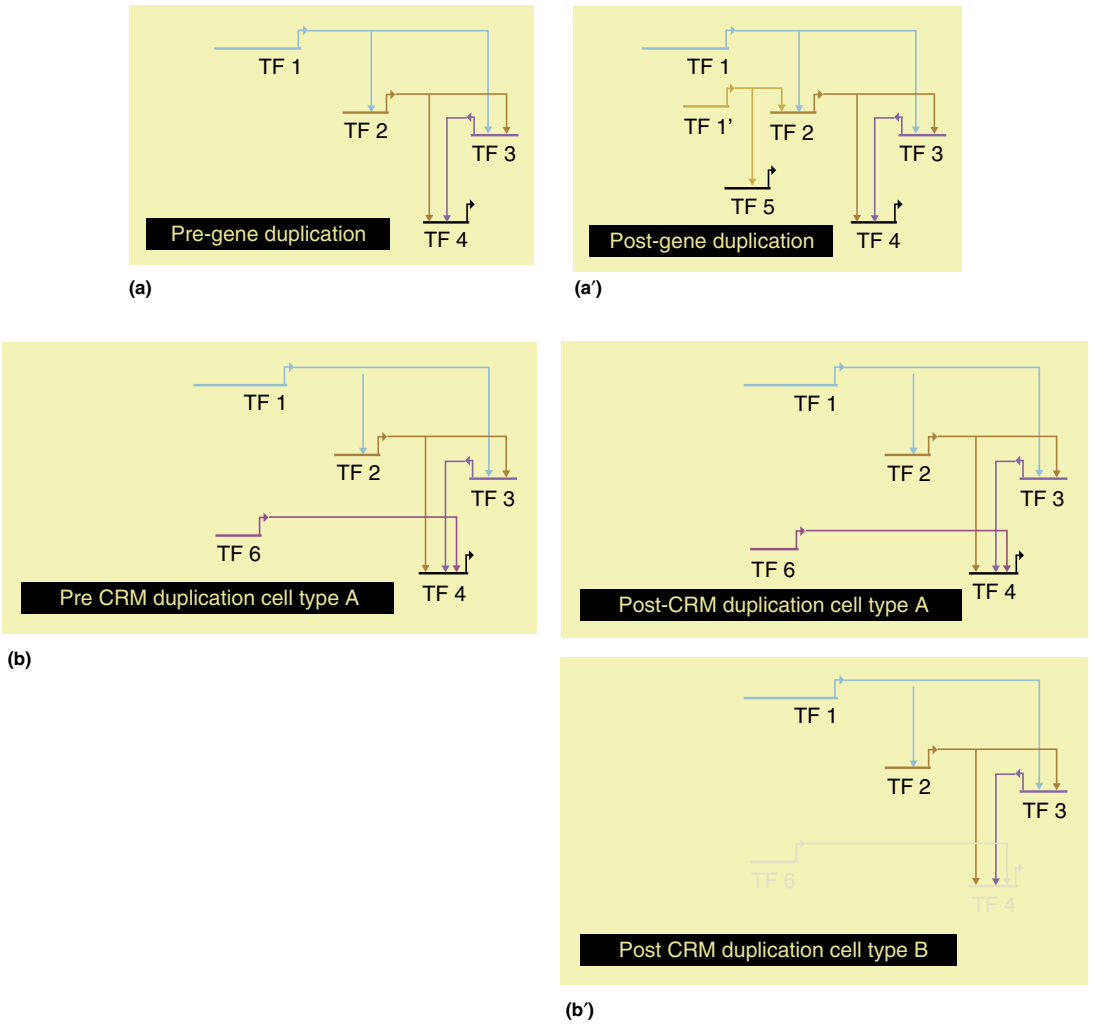

Figure 4 Evolution of GRNs. (a), (a′) Gene (coding) duplication. TF 1 is duplicated to TF1 and TF1′ in (a′). TF1′ continues to regulate some of its original target genes (TF2), losses its ability to regulate some target genes (TF3,4) and gains new target gene regulation (TF 5). (b), (b′). *Cis*-regulatory duplication. In this case TF1 duplicates its CRM (in (b′)) which leads to TF 1 being expressed in a different cell type "B." TF1 continues to regulate its targets in this new context if the other TFs needed for their expression are also present. Thus as TF 6 is not also expressed in Cell Type B, then TF4 is not co-opted.

quickly generating rapid changes may be pervasive in biology. Many examples have recently been suggested as indications of co-option. These almost entirely rely on finding many of the same (i.e., orthologous) genes expressed in two different structures. Thus for example, co-option has been suggested as a model for butterfly wing patterns from eye GRNs (Monteiro *et al.*, 2006); limb patterning (Bowsher and Nijhout, 2009; Lemons *et al.*, 2010) and beetle horns may have been co-opted from other axial patterning systems (Moczek and Rose, 2009); the turtle carapace may have been co-opted from limb patterning (Kuraku *et al.*, 2005); and sea urchin larval skeleton co-opted from the adult skeleton (Gao and Davidson, 2008). To be strictly defined as subcircuit co-option, however, requires that a cluster of pre-wired genes is brought along together (Monteiro and Podlaha, 2009). This means, therefore, that the downstream co-opted genes must be regulated by single CRMs that can function in both the original and new situation (e.g., TFs 2 and 3 are regulated using the identical CRM in both contexts rather than have also evolved new modules). As any CRM is regulated by many factors to ensure the fidelity and specificity of expression needed during development, this must influence the type of CRMs or GRN structure that can co-opt. Once co-opted these enhancers are pleiotropic and so in addition must be under selective pressure in both contexts (Monteiro and Podlaha, 2009). Any changes in the CRM would affect both the old and co-opted gene and associated circuit. These types of restrictions may have largely unexplored consequences on both how CRMs evolve and also on the structure of GRNs that permit this.

Conclusions

Comparisons of GRNs is a new approach for understanding how development can evolve. New technologies, which allow high throughput probing of genes and their interactions, will enable a rapid expansion of this approach as GRNs from more taxa become increasingly available. Such comparisons should reveal how subcircuits of genes evolve and how their placement within the GRN affects both their evolutionary potential for change and the consequence that this change has on the evolution of development.

Glossary

Dosage compensation It is a process by which gene expression between males and females is equalized.
Heteromorphic chromosomes Homologous chromosome pair that is not morphologically identical: differing in features such as size, shape, and staining properties, for example, sex chromosomes.
Meiotic sex chromosome inactivation (MSCI) It is a process in which sex chromosome expression is inactivated or down-regulated through a global process of chromatin structure change during meiotic phase of the heteromorphic sex gametogenesis.
Sexual antagonistic selection The case of opposing selection pressure on the two different sexes.

Introduction

Gene evolution is revealed by the study of genes that recently emerged in the evolutionary history of a taxon, so-called new genes. The interest in study gene evolution differs from conventional molecular evolution that has been focused on small-scale changes such as nucleotide substitutions, insertions, and deletions (Long *et al.*, 2003; Kaessmann, 2010; Chen *et al.*, 2013; Long *et al.*, 2013). Gene evolution is concerned with the changes at gene level, typically with gain of a new gene, loss of an old one, the change in gene structure, and their consequence on the function and evolution of genomes. Because a gene is a basic genetic unit that code for a specific function, gene evolution is often associated with evolution of gene functions and phenotypes (Long *et al.*, 2003; Kaessmann, 2010; Chen *et al.*, 2013). Sex chromosomes provide a unique environment in the genome for the evolution of new functions and phenotypes, as they are intrinsically related to the distinct evolution of males and females (Ellegren and Parsch, 2007; Parsch and Ellegren, 2013). Indeed, as the genomic era advance, evolutionary studies with independently originated sex chromosomes from several different taxa reveal that genes evolved as a major process (e.g., Ellegren and Parsch, 2007; Bachtrog, 2013). In this review, we not only describe sex chromosomes gene content with examples of well-studied organisms, but also discuss evolutionary processes and forces related to their roles on the origination of new genes and death of old ones.

Molecular Processes that Generate New Genes

New genes can form through no less than a dozen of mutation mechanisms (**Figure 1**), for example: recombination of exon, lateral gene transfer, *de novo* origination, and duplication of preexisting genes, which are more frequently investigated (more can be found in summary in Long *et al.*, 2013 and Chen *et al.*, 2013). The most common mechanism, duplication by retrotransposition or at the DNA level, generates genes with similar sequence and function to the parental genes and therefore are prone to accumulate detrimental mutations and become functionless, i.e., a pseudogene (Ohno, 1970; Kimura, 1983). Alternatively, these duplications over an evolutionary period can undergo neofunctionalization, a process of diversification where a gene acquires a new function that might be maintained in a population, spread and become fixed in the species population (Ohno, 1970).

Potential Impact of Sex Chromosomes on New Gene Evolution

Different from the autosomes, sex chromosomes are those that males and females do not share. In some sexual systems, one of the sex chromosomes carries a sex-determining gene, e.g., the human Y chromosome carries a male determining gene (Goodfellow and Lovell-Badge, 1994). In other cases, the sex is determined by the ratio of one chromosome over the others, e.g., *Drosophila* (Bull, 1983). Sex chromosomes are often different from each other in terms of size, shape, and gene content (Bachtrog, 2013). It has been found that sex chromosomes originated independently many times in nature, generally by a similar process in which one member of an autosomal pair acquire one or more sex-determining genes giving rise to a proto X-Y or Z-W chromosomes. Suppression of recombination between those chromosomes is favored by natural selection, which together with genetic drift leads to a progressive degeneration of the Y or the W chromosome, by accumulation of repetitive sequences and massive loss of genes (Charlesworth and Charlesworth, 2000). The chromosome that continues to recombine in one sex, including X in females and Z in males, does not degenerate and is hemizygous (haploid) in the opposite sex. Therefore, mechanisms that compensate their dosage such as somatic X inactivation in females may be favored by natural selection (Charlesworth, 1978).

Although not all sex-determining systems bear a heteromorphic-conserved sex chromosome like in human and other genetic model organisms, in most of those systems, sex chromosomes evolve under different selective and mutational environment than the autosomes (Viçoso and Charlesworth, 2006). Mutational processes and genetic drift have huge impact over the evolution of sex chromosomes, however, gene content differences between them is not solely a result of

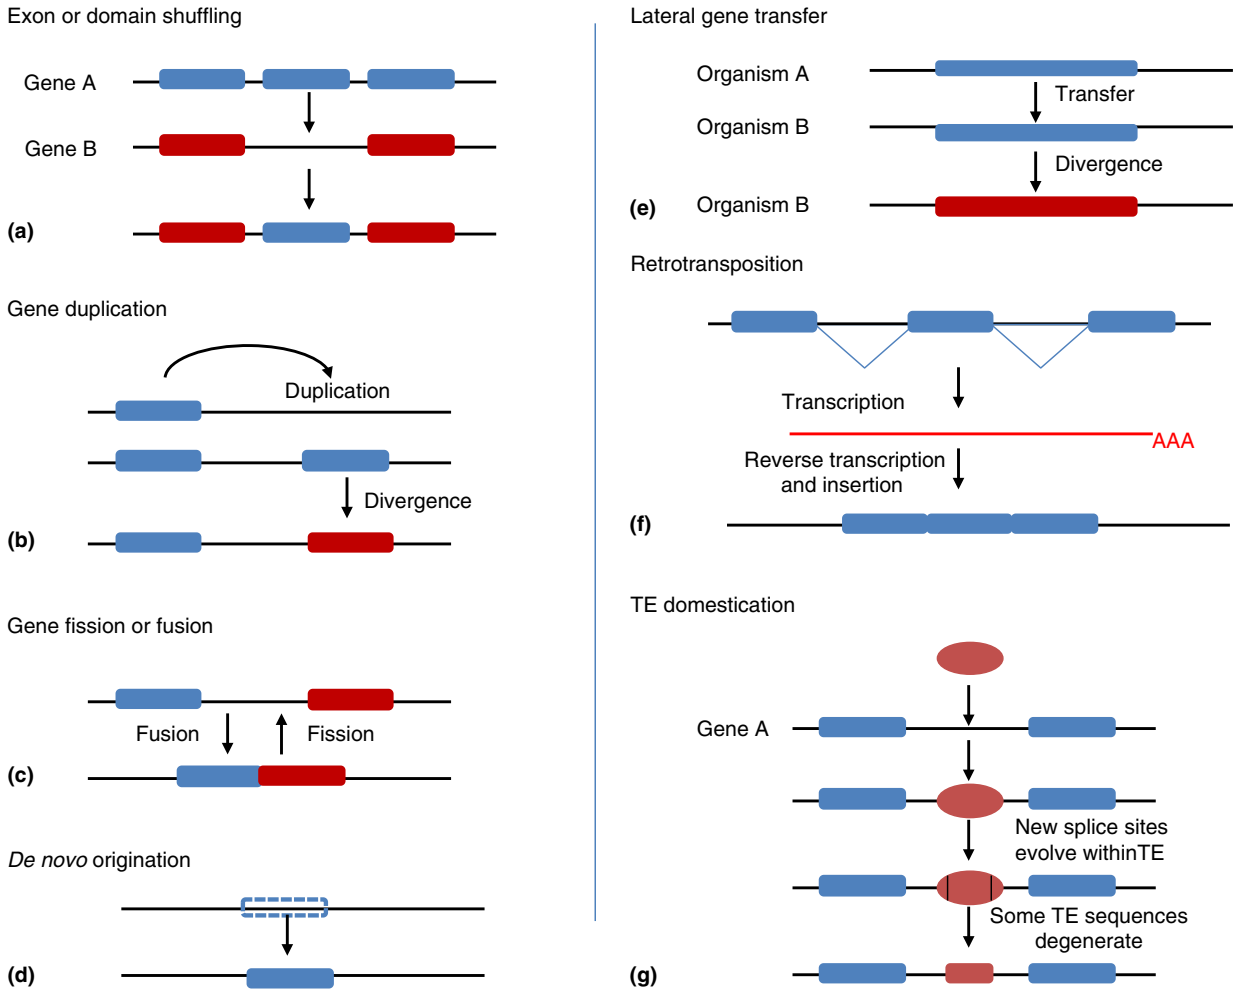

Figure 1 Molecular mechanisms for creating new genes. Major molecular processes that can generate new protein-coding genes. For more descriptions, discussion, and other mechanisms, see references Long *et al.* (2003), Chen *et al.* (2013), and Long *et al.* (2013). (a) Chimeric genes can be formed by recombination of exons or domains from different genes; (b) gene duplication; (c) gene fission divides one gene into different genes while gene fusion combines together neighboring genes; (d) *de novo* origination refers to the generation of a completely novel protein from the accumulation of mutations in noncoding genomic sequences; (e) genes can be transferred between organisms, specially found in bacteria; (f) genes can be generated by the transcription of a parental copy in mRNA and posterior reverse transcription and insertion of this sequence into a new position in the genome. The result will be an intronless new gene that can diverge acquiring new function; (g) transposable element (TE) can be domesticated forming new genes.

degeneration and gene loss of the Y or W chromosomes (Viçoso and Charlesworth, 2006). Even the X and the Z chromosome usually do not carry the same genes as the ancient proto-sex-chromosomes and gene content continues to evolve with both loss and gain of genes. Evolutionary forces applied differently in females and males over time have great differential consequences on the sex chromosomes.

A sexual antagonistic gene has beneficial fitness effect on males but detrimental effects on females or vice-versa (Arnqvist and Rowe, 2005). The detrimental effect in one sex can decrease if the expression in this sex is reduced. Therefore, sexually antagonistic forces can drive sex-biased genes, i.e., genes more expressed in one sex than the other. The sexual antagonistic hypothesis proposes that sexual antagonistic and possible sex-biased genes have different probability to be fixed in the X/Z chromosome compared to the autosomes (**Figure 2**) (Charlesworth *et al.*, 1987; Rice, 1984). The early theoretical prediction by Rice (1984) is that the polymorphic antagonistic recessive alleles that favor males and disfavor females would prefer the X-linkage, as shown in recent observations in *Drosophila* populations (Innocenti and Morrow, 2010). However, the fixation of sexual antagonistic genes often shows opposite distribution. For example, considering a long evolutionary process, the X chromosome would have less opportunity to accumulate male-biased genes, as they are present in a single copy in males and in two copies in females (Wu and Xu, 2003). For the same logic, the X chromosome is more prone to accumulate female-biased genes. This prediction depends on the dominant or recessive character of the sexual antagonistic mutation but expectation for differential accumulation of sex-biased genes between X/Z chromosomes and autosomes is general for the evolution of

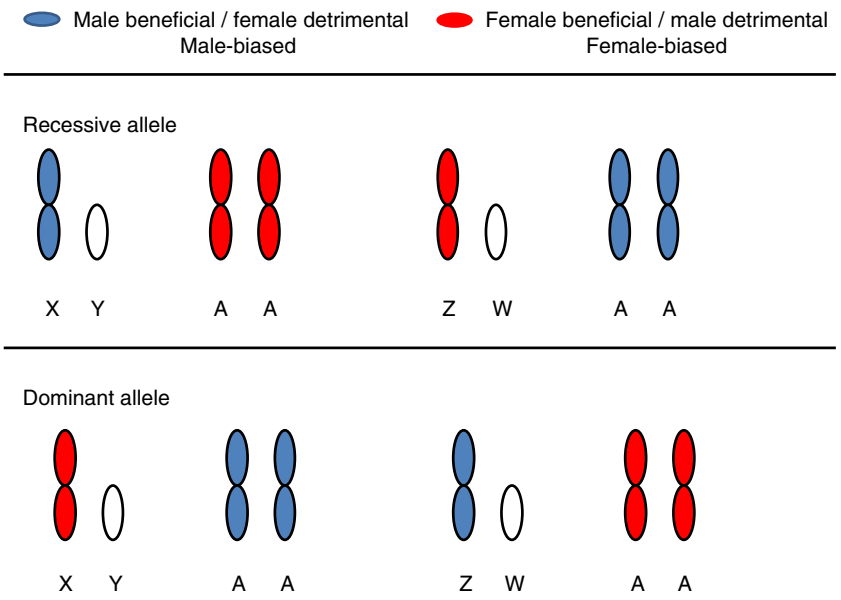

Figure 2 Chromosomal distribution of sexual antagonistic mutations/sex-biased genes. In a male heterogametic system (XY), it is unlikely that an X-linked recessive mutation beneficial to females and detrimental to males will be spread in the population. Those mutations will be exposed to negative selection in single copy in males and will not be visible to positive selection at first in heterozygous females (Rice, 1984). Alternatively, a dominant X-linked mutation will be present in females more often (two-thirds of the time) and will have more chance to be positive selective if beneficial to females. Alternatively, X-linked male-beneficial/female detrimental recessive mutation will be positively selected right away in males. However, if those mutations are dominant, negative selection will occur more frequently in females (Rice, 1984). Following the same principles, the reverse chromosomal patterns are expected for female heterogametic systems (ZW) (Ellegren and Parsch, 2007). These dynamics and the assumption that sexual antagonistic mutations will present ultimately sex-biased expression predict that sex chromosomes and autosomes will have distinct distribution of sex-biased genes.

sex chromosomes (see **Figure 2** for details) (Charlesworth *et al.*, 1987; Rice, 1984). In female heterogametic systems, similar rules but with sex roles reversed are assumed to be more likely to occur (Ellegren and Parsch, 2007).

Dosage compensation usually evolves with sex chromosomes as a balance of the expression levels between autosomal and X/Z-linked genes (Ohno, 1967; Charlesworth, 1978). Different mechanisms evolve in different organisms such as the inactivation of the X chromosome in female somatic cells of some mammals (Julien *et al.*, 2012). In *Drosophila*, however, there is a global change of chromatin structure of the X chromosome leading to the hypertranscription of its genes in males (Baket *et al.*, 1994). It has been proposed that the mechanism of dosage compensation in *Drosophila* would inhibit the presence of male-biased genes in the X chromosome, as further up-regulation of X-linked genes in males would be more difficult to be achieved (Bachtrog *et al.*, 2010; Viçoso and Charlesworth, 2009). Therefore, this hypothesis expected a paucity of male-biased genes in the X chromosome content (Bachtrog *et al.*, 2010; Viçoso and Charlesworth, 2009).

Meiotic sex chromosome inactivation (MSCI) may also have effects on the gene composition of the X/Z chromosomes (Lifschytz and Lindsley, 1972; Betran *et al.*, 2002). During male meiosis, the X chromosome is down-regulated through a global process of chromatin structure change (McKee and Handel, 1993; Turner, 2007). In mammals, where MSCI is well documented, inactivation in male germline would prevent the deleterious products from the recombination of nonhomologous sequences especially those from heteromorphic sex chromosomes (Lee 2005; Turner *et al.*, 2005). Nonetheless, there is experimental evidence for the existence of MSCI in other taxonomic groups such as *Drosophila*, nematodes, and grasshoppers (Vibranovski *et al.*, 2009a, 2009b; Cabrero *et al.*, 2007; Deng *et al.*, 2011; Hense *et al.*, 2007; Kelly *et al.*, 2002). If the X chromosome is inactive during male meiosis, X-linked testis-biased genes cannot be expressed (Betran *et al.*, 2002; Vibranovski *et al.*, 2009a, 2009b). Therefore, evolution of MSCI associated with sex chromosomes would broadly favor the origination of male-biased genes out of the X chromosome (**Figure 3**) (Lifschytz and Lindsley, 1972; Betran *et al.*, 2002). The opposite pattern should be expected for Z chromosome inactivation in female meiosis.

Meiotic drive is a phenomenon where a mutation in one allele distorts meiotic transmission in its own favor and result in the distortion of the normally 1:1 offspring sex-ratio (Gershenson, 1928; Hamilton, 1967). Usually meiotic drive alleles located on the X chromosome lead to the extinction of a population with excess of females due to the lack of males. Alternatively, suppressors in the Y chromosome and in the autosomes could be favored (Fisher, 1930; Thomsom and Feldman, 1975). Normally those autosomal suppressors are expected to function during male meiosis and therefore are male-biased expressed (Tao *et al.*, 2007). The evolution of such suppressors could lead to the accumulation of male-biased genes out of the X chromosome (Tao *et al.*, 2007).

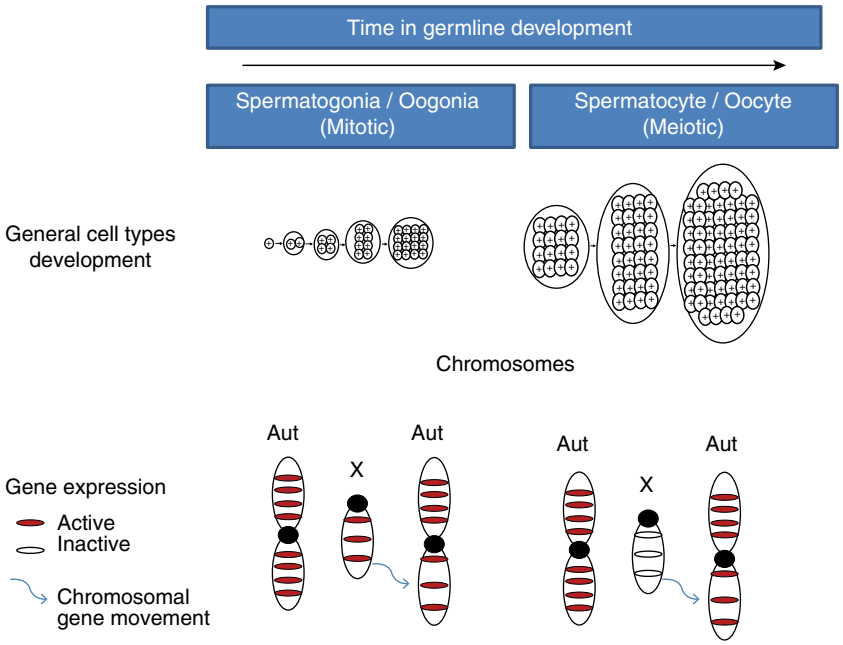

Figure 3 Meiotic sex chromosome inactivation (MSCI) and the movement out of the X chromosome. MSCI is the inactivation or down-regulation of the X- or Z-linked genes during male or female meiosis, respectively (Turner, 2007; Schoenmakers *et al.*, 2009). Duplicated genes from the X or Z to the autosomes will have more chance to be expressed in testis or ovaries, respectively (Lifschytz and Lindsley, 1972; Betran *et al.*, 2002).

Gene Evolution with the XY Systems

X Chromosomes

Several organisms with XY chromosome system of sex determination have been extensively studied: *Drosophila*, mammals, worms, mosquitos, and other insects (Betran *et al.*, 2002; Dorus *et al.*, 2006; Parisi *et al.*, 2003; Ranz *et al.*, 2003; Khil *et al.*, 2004; Reinke *et al.*, 2004; Wang *et al.*, 2005; Baker *et al.*, 2011; Baker and Wilkinson, 2010). In most of them, the general predictions regarding the demasculinization of the X chromosome in the overall evolutionary history have been confirmed, but each system shows peculiarities of specific evolutionary driving forces. In the *Drosophila* X chromosome, there is a paucity of male-biased protein coding and noncoding genes and an excess of female-biased ones revealed by several studies comparing transcriptomes of males and females (Parisi *et al.*, 2003; Ranz *et al.*, 2003, Sturgill *et al.*, 2007; Gao *et al.*, 2014). X chromosome demasculinization was found not only in testis and ovaries comparisons but also, though in lower levels, in studies of male and female carcasses (Parisi *et al.*, 2003). Those studies uncovered the role of sexual antagonistic dominant mutations as MSCI is expected to drive gene evolution only in male gonad tissue (Parisi *et al.*, 2003).

In addition, early genomic studies in *Drosophila* showed that retrogenes, new genes originated by retroposition from a parental gene, preferentially move out of the X chromosomes to the autosomes, so-called X→A gene movement (Betran *et al.*, 2002; Bai *et al.*, 2007; Dai *et al.*, 2006). Interestingly, this movement contributed to the X desmasculinization, as those new genes are frequently testis expressed as opposed to their broadly expressed parental genes (Betran *et al.*, 2002; Bai *et al.*, 2007; Dai *et al.*, 2006). Also, new genes generated by other mechanism involving DNA duplication also show X→A pattern indicating that natural selection instead of an intrinsic retrotransposition mutational bias drives the nonrandom movement (Vibranovski *et al.*, 2009b; Meisel *et al.*, 2009). The evidence in support of natural selection was detected also from population genomic analyses of copy number variation of retrogenes in *Drosophila* (Schrider *et al.*, 2011) and humans (Schrider *et al.*, 2013). MSCI was shown to be one of those selective forces driving the gene movement out of the X as autosomal retrogenes present specific higher male meiotic expression than their inactivated X-linked parental genes (Vibranovski *et al.*, 2009a). Dosage compensation also seems to play a role on the demasculinization of the *Drosophila* X chromosome by limiting further increase of male-biased gene expression close to the compensated regions (Bachtrog *et al.*, 2010).

In mammals, studies with mouse spermatogenic transcriptome have shown that the paucity of X-linked male-biased genes is more restricted to meiotic and some level of post-meiotic cells consistent with the action of MSCI (Khil *et al.*, 2004). Genes specifically expressed in spermatogonia and sertoli cells, MSCI-free tissues, are overrepresented on the X chromosome (Wang *et al.*, 2001; Soumillon *et al.*, 2013). Interestingly, brain-specific genes are also enriched in the X chromosomes, indicating that recessive sexual antagonistic mutations beneficial to males might be prevailing in the evolution of genes expressed in spermatogonia, sertoli cells, and brain (Zhang *et al.*, 2010b; Soumillon *et al.*, 2013). Recently, X chromosome enrichment of male-biased genes expressed in the brain was found in *Drosophila*, but the study also suggests association with dosage compensation (Huylmans Parsch, 2015).

Retrogene movement out of and into the X chromosome has been also found in excess in humans and mouse genomic

studies (Emerson *et al.*, 2004). However, only X-derived autosomal genes present association with testis expression (Emerson *et al.*, 2004). Actually, the movement is most likely to be driven by MSCI as, similar to in *Drosophila*, those retrogenes compensate the expressions of their inactive X-linked parental genes during meiosis (Potrzebowski *et al.*, 2008; Vibranovski *et al.*, 2009a, 2009b; Dai *et al.*, 2006).

Recently, the genome sequencing of *Drosophila* species and other vertebrates allowed the use of phylogenetic relationships to date the origin of *D. melanogaster*, human, and mouse new genes (Zhang *et al.*, 2010a,b). This approach revealed that paucity of male-biased genes in both *Drosophila* and mammals X chromosomes is only observed for genes older than a few million years. Recently originated male-biased genes are found to be overrepresented on the X chromosome consistent with fixation of recessive male-beneficial alleles by sexual antagonism. In both cases, the proportion of X-linked genes decreases gradually with time leading to an excess of male-biased genes on the autosomes, suggesting that X demasculinization is an evolutionary process (Wu and Xu, 2003; Zhang *et al.*, 2010a,b; Gao *et al.*, 2014). In *Drosophila*, the switch from X-linked to autosomal enrichment of male-biased genes occurs before the split of the *melanogaster* subgroup (<3–6 million years ago) (Russo *et al.*, 1995; Zhang *et al.*, 2010a), whereas in mammals there were two bursts of gene gain on the X chromosome (Zhang *et al.*, 2010b). It is evident in mammals that, however, the MSCI contributed to the switch dynamics in addition to sexual antagonistic forces (Zhang *et al.*, 2010b; Mueller *et al.*, 2008). Inactivation does not affect young genes in meiotic cells, only old ones suggesting that new genes are immune at first to the chromosomal-wide mechanism of silencing (Zhang *et al.*, 2010b). Also, feminization of the X chromosome is associated with the process of demasculinization in both mammals and *Drosophila* as most of the genes expressed in ovaries are relatively old (Zhang *et al.*, 2010a,b).

In *Anopheles gambiae*, the malaria vector mosquito, the X chromosome is also depleted with male-biased genes and enriched with female-biased ones (Baker and Russell, 2011; Baker *et al.*, 2011). Only testis and ovaries transcriptomes were able to detect the biased chromosomal distribution emphasizing the importance of using of gonad tissues to study sex-biased genes (Baker and Russell, 2011; Baker *et al.*, 2011; VanKuren and Vibranovski, 2014). The mosquito testis is several times smaller than its ovary and their differential rate of dilution in whole-body transcriptome turns the detection imprecise (Baker and Russell, 2011; Baker *et al.*, 2011). It is interesting that excess of retrogene moving off the X chromosome has been also detected in *A. gambiae* (Toups and Hahn, 2010). The movement associated with male-biased expression (Baker and Russell, 2011) is only detected after the split from this species and *Aedes aegypt* – a homomorphic sex chromosome species – from their common ancestor. This indicates that X→A pattern is probably a property of organisms with heteromorphic sex chromosome (Toups and Hahn, 2010).

In another model organism, the worm *Caenorhabditis elegans*, the X chromosome desmasculinization and feminization are also observed (Reinke *et al.*, 2004). The X chromosome is depleted with sperm-enriched genes (Reinke *et al.*, 2000, 2004). Transcriptome analyses together with histone modification studies provide evidence for X inactivation both in *C. elegans* spermatogenesis and in the hermaphrodite germline, suggesting the role of MSCI with other forces on the evolution of demasculinization (Kelly *et al.*, 2002; Reuben and Lin, 2002; Bean *et al.*, 2004; Bessler *et al.*, 2010; Reinke *et al.*, 2004).

Y Chromosomes

Sex chromosomes in placental mammals and marsupials have a common origin about 200 million years ago after the split from monotremes which carry independently originated five Y chromosomes (Lahn and Page, 1999; Potrzebowski *et al.*, 2008; Grützner *et al.*, 2004). The sex-determining gene SRY probably triggered the differentiation of all therians sex chromosomes, including humans (Goodfellow and Lovell-Badge, 1994; Lahn and Page, 1999). Suppression of crossing-over between proto X and Y should be advantageous as no proto-Y-linked new allele that confers a selective advantage to males, but neutral or detrimental to females would be able to recombine to the proto-X (Charlesworth and Charlesworth, 2000; Bachtrog, 2013). Although human Y chromosome still bears a cluster of X-Y paralogues with active recombination, discrete clusters of genes with different degree of divergence – called 'evolutionary strata' – provide evidence that progressive reduction in recombination have taken place along the therian sex chromosome evolution (Lahn and Page, 1999). The human Y chromosome, therefore, became enriched with repetitive sequences, very heterochromatic and containing genes with male-specific functions due to gene retention and amplification (Bellot *et al.*, 2010; Skaletsky *et al.*, 2003; Lahn and Page, 1999). Two recent studies (Bellott *et al.*, 2014; Cortez *et al.*, 2014), however, reconstructed the evolutionary function of the Y chromosome along several mammals revealing that gene content in the Y chromosome is not only a reflection of the male reproduction and spermatogenesis function. Gene retention and survival in the Y chromosome in those mammals are enriched with regulatory function and most probably are very sensitive to dosage constraints caused by deterioration on the proto-Y.

The *D. melanogaster* Y chromosome is completely heterochromatic and contains just a small number of protein coding genes in comparison to the X chromosome (Gepner and Hays, 1993; Carvalho *et al.*, 2000; Carvalho *et al.*, 2001; Vibranovski *et al.*, 2008; Carvalho *et al.*, 2003). The Y chromosome does not determine sex; therefore flies without it are viable but sterile due to the presence of fertility factors (Bridges, 1916; Brosseau, 1960; Kennison, 1981; Gatti and Pimpinelli, 1983; Hazelrigg *et al.*, 1982). *Drosophila* genomic and functional studies have shown that Y-linked genes are expressed and/or have a role in spermatogenesis such as *kl-2*, *kl-3*, and *kl-5* genes that encode for proteins involved in the sperm flagella motor (Hardy *et al.*, 1981; Gepner and Hays, 1993; Carvalho *et al.*, 2000; Carvalho *et al.*, 2001; Vibranovski *et al.*, 2008; Carvalho and Clark, 2013).

Interestingly, there is not a single-copy gene in the Y chromosome of *D. melanogaster* with a homologue in the X chromosome (Carvalho *et al.*, 2000; Carvalho *et al.*, 2001; Vibranovski *et al.*, 2008). The majority of the genes, however, are recent acquisitions of the autosomes (Carvalho *et al.*, 2000; Carvalho *et al.*, 2001; Vibranovski *et al.*, 2008). Comparative

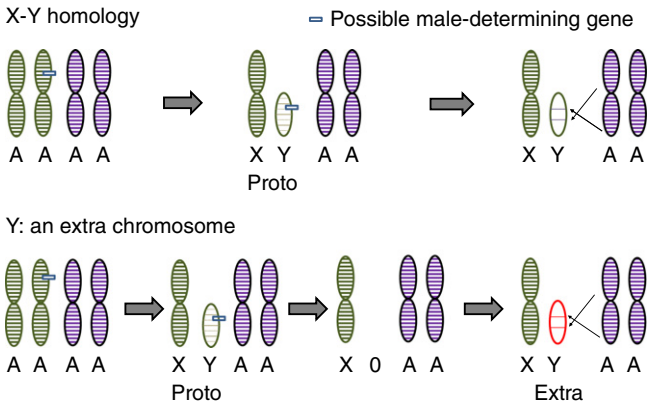

Figure 4 Scenarios for the Y chromosome origin in *Drosophila*. Two possible scenarios for the Y chromosome origin and evolution resulting in the current observation that single-copy Y-linked genes are homologous to autosomal ones (Bernardo Carvalho *et al.*, 2009). Only male karyotypes are shown. X–Y homology – one member of one autosome pair acquires a male determining gene; the process of degeneration and evolution of dosage compensation lead to the formation of a proto X-Y; the degeneration is complete while Y chromosome acquired new genes duplicated from the autosomes. Y: extra chromosome – the homologous Y chromosome has been completely degenerated and lost. An extra chromosome (shown in red) acquires the capacity to pair with the X and new genes duplicated from the autosomes. Note that for both scenarios, the male determining gene has been lost during evolution or never existed. Therefore, the Y chromosome does not determine sex. Rather, as observed in *Drosophila*, sex is determined by the relative dosage of X chromosome in comparison to the autosomes.

genomic studies with other *Drosophila* species have shown that the Y chromosome gene content is not very conserved due to gene gain being more frequent than gene loss (Koerich *et al.*, 2008). For example, the *Drosophila pseudoobscura* Y chromosome is not homolog to the Y of other *Drosophila* species and the genes present in the ancestral *Drosophila* Y chromosome are found in the *D. pseudoobscura* dot autosomal chromosome (Carvalho and Clark, 2005). The general lack of homology of Y-linked coding protein genes with the X chromosome and the high rate of gene turnover suggest that *Drosophila* Y is not a degenerated autosome like in mammals but might has been originated by the acquisition of an extra chromosome instead (**Figure 4**; Bernardo Carvalho *et al.*, 2009).

Regardless the origin, *Drosophila* Y-linked genes show some sign of natural selection efficacy reduction (Singh *et al.*, 2014). However, it seems that there is purifying selection on strong deleterious mutations despite its smaller effective size and lack of recombination (Singh *et al.*, 2014). Moreover, several of those genes already show sign of positive selection along the *Drosophila* genus evolution (Singh *et al.*, 2014). This, together with the recent evidence on the important role of the *Drosophila* Y chromosome in regulating the expression of other autosomal and X-linked genes emphasizes the significant phenotypic impact that the Y chromosome has evolved (Lemos *et al.*, 2008; Singh *et al.*, 2014).

Neo-Sex Chromosomes

New sex chromosomes can be also formed in nature by chromosomal fusion between autosomes and ancestral sex chromosomes. At the time of their formation, those new chromosomes – named neo-X and neo-Y – have the same gene content as the original autosome. However, as neo-sex chromosomes segregate in the same manner as the X and Y chromosomes, changes in many aspects occurs with time making them gradually resembling genuine sex chromosomes (Bachtrog, 2013). The studies of independently formed neo-sex chromosomes with different age of origins have revealed rich information about how heteromorphic pair of sex chromosomes usually differentiates (Bachtrog, 2013), for example, the general evolutionary forces and molecular mechanisms driving such differentiation and the order of evolutionary events (Bachtrog, 2013).

Neo-sex chromosomes were independently formed by the fusion of autosomes with the same ancestral sex chromosome in several *Drosophila* species and lineages, for instance, in *D. willistoni*, *D. pseudoobscura*, *D. miranda*, *D. albomicans* (Lucchesi, 1978). With the advance of comparative genomics, the studies of the last three species provide a powerful framework to compare evolutionary events in an old, an intermediate and a young sex chromosome, as their origin were respectively approximately 15, 1, and 0.1 million years ago (Lucchesi, 1978; Bachtrog, 2013). The analysis of *D. pseudoobscura* neo-sex chromosomes has shown that it took only15 million years for a *Drosophila* autosome to evolve completely into a sex chromosome (Bachtrog, 2013). Neo-X chromosome is fully dosage compensated and already shows significant paucity of male-biased genes and excess of female ones (Marin *et al.*, 1996; Sturgill *et al.*, 2007; Assis *et al.*, 2012). In addition, selective forces have already started to drive the relocation of genes out of the X chromosome to the autosomes (Vibranovski *et al.*, 2009b; Meisel *et al.*, 2009). An old neo-Y chromosome, due to degeneration, is mostly heterochromatic and bears only a few active genes (Carvalho and Clark, 2005). Alternatively, a young neo-Y chromosome like the one present in *D. albomicans* almost does not show signs of DNA degeneration and pseudogenization (Zhou *et al.*, 2012). However, several neo-Y linked genes are lower expressed in comparison to their neo-X-linked homologues, suggesting transcription down-regulation as the first step in sex chromosome differentiation (Zhou and Bachtrog, 2012b). The *D. miranda* neo-Y chromosome shows intermediate features: partially heterochromatic, accumulation of repetitive DNA such as

transposable elements, approximately half of the genes with homologues in the neo-X already show signs of loss of function (Zhou and Bachtrog, 2012a). Active genes in the neo-Y are not a random small subset of the ancestral autosome. Masculinization of the neo-Y chromosomes is noted by the retention of genes with male-beneficial effects and evolution of male-biased expression for genes involved in reproductive functions (Zhou and Bachtrog, 2012a,b). In addition, as in mammals, the retained genes tend to enrich with regulatory functions, suggesting that dosage sensitive genes have more chances to be maintained on the neo-Y (Zhou and Bachtrog, 2012a,b). On the other hand, the intermediate neo-X chromosome of *D. miranda* already shows signs of demasculinization as male-specific genes are more prone to be lost or down-regulated in a considerably short evolutionary time (Kaiser and Bachtrog, 2014).

Another example of neo-sex chromosomes that have been reported is the one found in stalked-eye flies (Baker and Wilkinson, 2010). Those species present a sexual dimorphism in eyespan that is linked to the success of male reproduction (see review in Baker *et al.*, 2012). Recently, studies with comparative genomic hybridization – an efficient approach for non-model organism – revealed a neo-X chromosome formed in several species of the *Teleopsis* genus (Baker and Wilkinson, 2010). Interestingly, chromosomal gene movement between sex chromosomes and autosomes was also observed confirming that gene evolution is a major process on the formation of sex chromosomes.

Gene Evolution with the ZW Systems

ZW systems, in which the female is heterogamety, have been found in several organisms, e.g., birds, reptiles, and some species in fishes and insects, but only recently more extensively studied. There are several reasons for the increase of interest in species with ZW chromosomes. First, the genomic era made the genetic studies with non-model organism more feasible. Second, as we expanded our taxonomic view about the sex chromosomes, it is realized that ZW are more commonly found than previously thought (Bachtrog *et al.*, 2014). Third, the comparison between XY and ZW systems have shown to be very useful to separate the sex chromosome effects from sex effects (Ellegren, 2011). Individuals harboring different chromosomes (heterogamety) present different sexes in ZW and XY: female and male, respectively. Therefore, patterns and processes associated with harboring the heterochromatic, differentiated W or Y chromosome can be disentangled from sexual selection and evolution of sex (Ellegren, 2011).

We focus our review on gene evolution and origination in ZW systems with differentiated chromosomes such as avian and some Lepidoptera species. ZW chromosomes in birds seem to share largely homology and have started to differentiate around 130 million years ago or even older (Shetty. *et al.*, 1999; Nam and Ellegren, 2008; Cortez *et al.*, 2014). The same Z chromosome found in Lepidoptera, including moths, butterflies, and silkworm seems to be already present in the common ancestor shared with Trichoptera more than 190 million years ago (Traut *et al.*, 2007).

W Chromosomes

In birds, there is still a debate regarding the sex determination mechanism. It is not known if sex determination depends on the Z chromosome dosage relative to autosomes or if there is one or several female-determining genes or factors on the W chromosome (e.g., Cortez *et al.*, 2014; Smith *et al.*, 2009). The knockdown of the gene *DMRT1*, located on the Z chromosome in all birds, directs the gonad feminization, suggesting this gene as the sex determining one in birds (Smith *et al.*, 2009). However, there is still the possibility that *DMRT1* is a downstream gene on the sex-determining pathway lead by other Z-linked and/or W-linked genes (Ellegren, 2011). Alternatively, sex in birds could be determined by Z chromosome dosage suggested by the fact that, in chicken, there is no full chromosome-wide dosage compensation of Z-linked genes (Ellegren *et al.*, 2007; Itoh *et al.*, 2007). Nonetheless, there is one feature of W chromosome in birds that is known for sure: the formation of different evolutionary strata consistent with the model that the loss of recombination may occur in steps caused by distinct successive inversion events (Nam and Ellegren, 2008; Cortez *et al.*, 2014).

Studies with chicken have shown that the W chromosome share similar features with the Y chromosome, such as large portion of repetitive heterochromatin and small size as well as decrease of genetic diversity (Berlin and Ellegren, 2004; International Chicken Genome Sequencing Consortium, 2004). Therefore, those features are probably not a result of selective sweeps due to sexual selection in sperm competition. Rather, the reduced diversity seems to be independent of the type of heterogamety (Ellegren, 2011). The W chromosome in chicken, however, shows a distinct pattern in comparison to therian Y chromosomes: expression levels and spatial patterns are preserved in comparison to the proto-sex chromosome (Cortez *et al.*, 2014) that could be related to the lack of global dosage compensation (Ellegren *et al.*, 2007; Itoh *et al.*, 2007).

In Lepidoptera, the majority of basal clades lack a W chromosome (Z0 females), suggesting that W chromosome arose later and it is not homologue to the Z chromosome as proposed for the Y chromosome in *Drosophila* (Traut *et al.*, 2007; Bernardo Carvalho *et al.*, 2009). However, there is still a possibility that the W chromosome has been lost in those basal clades. In *Bombyx mori*, the model organism for Lepidoptera, domesticated more than 5000 years ago and economically important for the production of silk, there is a genetic factor on the W chromosome that determines the female sex (Traut *et al.*, 2007; Goldsmith *et al.*, 2005). Although no precise localization has been defined, sex is not determined by the ratio of Z chromosomes relative to autosomes (Traut *et al.*, 2007; Goldsmith and Marec, 2010).

Z Chromosomes

Both chicken and silkworm present a deficit of female-biased genes and an excess of male-biased genes on the Z chromosome (Wang *et al.*, 2012; Xia *et al.*, 2007; Arunkumar *et al.* 2009; Kaiser and Ellegren, 2006; Storchová and Divina, 2006; Mořkovský *et al.*, 2009; Mank and Ellegren, 2009). These observations are in agreement with the model of partly dominant mutations with sexual antagonistic effects (**Figure 2**; Rice, 1984). However, the genes that are biased expressed in

somatic cells of chicken female germline are overrepresented on the Z chromosome, raising the possibility that recessive mutations beneficial to females but harmful to males have their role in the avian evolution (Mořkovský *et al.*, 2009). Nonetheless, oocytes do not show such pattern (Mořkovský *et al.*, 2009) and therefore the MSCI, even if brief (Schoenmakers *et al.*, 2009), could also contribute to the overall picture of the chromosomal distribution of sex-biased genes in birds.

Another possible explanation for the excess of male-biased genes in the chicken Z chromosome is the lack of dosage compensation (Ellegren *et al.*, 2007; Itoh *et al.*, 2007). Two copies of the Z-linked genes in males as opposed to just one in females would result in a general male-biased expression of the Z chromosome. However, recent works analyzing different strata showed that the Z chromosome gene expression might be more influenced by masculinizing selection, rather than by selection for dosage compensation (Wright *et al.*, 2012).

Gene trafficking between sex chromosomes and autosomes also revealed the dynamics of gene origination in ZW systems. In chicken, little movement of retroposition events, including the formation of retrogenes (International Chicken Genome Sequencing Consortium, 2004; Toups *et al.*, 2011), were detected, probably due to some mechanisms including inefficiency of the reverse transcriptase in recognizing polyadenylated mRNAs (Haas *et al.*, 2001). One study failed to find excess of gene movement in or off the avian Z chromosomes analyzing duplications mediated at DNA level (Toups *et al.*, 2011). However, other study observed that genes that have been repeatedly relocated to the Z chromosome during avian evolution show testis-specific expression (Bellott *et al.*, 2010). In silkworm, the excess of female-biased gene movement out of the Z was detected (Wang *et al.*, 2012).

Final Remarks

The multiple independent originations of sex chromosomes had profound impact on the evolution of organisms. The impact can be on the processes of sex chromosome formation including chromosome degeneration and dosage compensation mechanism or on the underlying mechanisms such as sexual antagonistic conflicts, sexual selection, meiotic sex chromosome inactivation, meiotic drive etc. Independently of the types of heterogametic system (XY or ZW), the achieved scientific advances have shown that sex chromosomes are an assured source in nature to trigger the evolution of new genes to novel functions and phenotypes.

Genetic Architecture

JM Álvarez-Castro, University of Santiago de Compostela, Lugo, Galiza, Spain

Nomenclature

E Vector of genetic effects
G=(G$_{ij}$) Vector of genotypic values; $G_{ij}=\mu+\alpha_{ij}+\delta_{ij}$
R Reference point of an individual-referenced model of genetic effects
S Genetic-effects design matrix
a Individual-referenced additive genetic effect
d Individual-referenced dominance genetic effect
p$_i$ Allele frequencies; $p_i=p_{ii}+\frac{1}{2}\Sigma p_{ij}$
p$_{ij}$ Genotype frequencies; Indicator variables at individual-referenced formulations
α Population-referenced additive genetic effect
α$_i$ Average additive effect; $\alpha=\alpha_2-\alpha_1$ (with multiple alleles, $\alpha^{ij}=\alpha_j-\alpha_i$)
α$_{ij}$ Breeding value; $\alpha_{ij}=\alpha_i+\alpha_j$
δ Population-referenced dominance genetic effect
δ$_{ij}$ Dominance deviation
μ Population phenotype mean

Glossary

Additive genetic effect Genetic effect that retains properties of the alleles that add up, whether in a population context or not and regardless of whether there are also interaction effects present or not. In the population context, this is the genetic effect directly related with phenotype resemblance due to sharing alleles – rather than genotypes – and thus with selection response (conditioned by resemblance between parents and offspring).
Average additive effect of allele A_i Expectation over a population of the effect on phenotype of a substitution of one allele at locus A by allele A_i.
Breeding value Expectation of the phenotype of the offspring of an individual in a random mating population, in relation to the population mean.
Dominance genetic effect Genetic effect that accounts for evolutionary properties of a one-locus genotype, particularly due to interaction effects (departures from additive expectations) of alleles within that locus.
Epistatic genetic effect Genetic effect that accounts for evolutionary properties of multilocus genotypes, particularly due to interaction effects (departures from additive expectations) of alleles across loci.
Genetic architecture Set of loci underpinning phenotypic variation of a trait in a population, including the sets of alleles present at each locus and the genetic (additive and interaction) effects involved.
Genetic effect Parameter that accounts for effects of allele substitutions and thus has a direct genetic and evolutionary meaning. It comes from the reparameterization of a genotype-to-phenotype (GP) map using a specific model of genetic effects.
Genotype-to-phenotype map Function assigning genotypes to phenotypes, often provided as a vector of genotypic values.
Genotypic value Expected phenotype of a particular genotype.
Imprinting genetic effect Genetic effect that reflects properties of one-locus genotypes in which allele properties depend upon the sex of their parent-of-origin, particularly accounting for interaction effects of alleles due to that dependence.
Individual-referenced genetic effects Genetic effects coming from the reparameterization of a GP map in terms of allele substitutions performed from the reference of an individual genotype.
Model of genetic effects Mathematical expressions reparameterizing a GP map into (additive and interaction) effects of allele substitutions with reference to a defined (individual or population) context.
Population-referenced genetic effects Genetic effects coming from the reparameterization of a GP map in terms of allele substitutions averaged across a population with particular genotype frequencies.
Reaction norm Expected phenotypes displayed by a genotype under a range of values of an environmental variable.

Genetic Source of Phenotypic Variation

Gregor Mendel inferred the existence and key properties of inheritance factors related to several binary phenotypes of pea plants (*Pisum sativum* L.). The foundations of genetics as a scientific field were established on his finding at the beginning of the twentieth century. Toward one and a half centuries after Mendel, we keep on trying to disclose loci with genetic variants underpinning phenotypic variation of traits in populations. The desired information is the relation between genotypes and phenotypes, the genotype-to-phenotype (GP) map, which can be expressed as a vector of genotypic values, **G** – gathering the expected phenotypes of each of the genotypes considered.

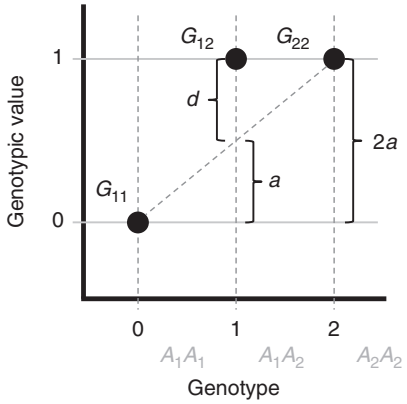

Figure 1 Graphical representation of the individual-referenced genetic effects in **Table 1**. The genotypes are in the horizontal axis represented as content of allele A_2, and the genotypic values (G_{ij}) are in the vertical axis. The difference between the genotypic values of the two homozygotes determines the additive effect (of substituting allele A_1 by allele A_2) and the dominance effect is the departure of the heterozygote from its additive expectation (due to the presence of interaction between the two alleles).

Table 1 Individual-referenced genetic effects derived from a phenotype studied by Mendel, pea color

Phenotype	*Genotype*	G_{ij}	*Genetic effects*
Green	A_1A_1	0	$R=0$
Yellow	A_2A_2	1	$R+2a=1=>a=½$
Yellow	A_1A_2	1	$R+a+d=1=>d=½$

Notes: Mendel inferred that genetic factors (genotypes) determined the phenotypes. A GP map consists in just assigning numerical (genotypic) values (G_{ij}) are to the phenotypes – in this case 'yellowness' is measured so that green peas are assigned to 0 and yellow ones to 1. Choosing the green pea as reference, the additive effects of allele substitutions come directly from comparison against A_2A_2 (involving two-allele substitutions). Finally, the dominance effect can be derived by accounting for the genotypic value of the heterozygote, where the two different alleles coincide and may interact. A graphical interpretation is given in Figure 1.

Genetic Effects

However, the GP map is seldom directly informative about evolutionary properties. In the simplest case – a genetic architecture of one locus with two alleles, A_1 and A_2 (and assuming also for simplicity that phenotype is fitness) – the outcome of selection depends on the genotypic value of the heterozygote (G_{12}) relative to the midpoint of those of the homozygotes (G_{11}, G_{22}). Such dependence is easier to express in terms of additive, a, and dominant, d, effects (as defined in Figure 1): fixation of the allele in the highest homozygote occurs whenever $-|a|<d<|a|$, *becoming* asymptotic as d approaches $|a|$, a polymorphic equilibrium is attained when $d>|a|$, and fixation of any of the two alleles is possible (depending on the initial frequencies) when $d<-|a|$. Thus, it is in general compulsory to reparameterize the genotypic values of a genetic architecture into genetic effects. This can be done in two different ways, using two different kinds of mathematical formulations that fit to two different genetic meanings.

Individual-referenced formulations

Genetic architectures of traits vary across populations since, on the one hand, one locus may bear different (from a single one to many) variants in different populations and, on the other hand, the effects on phenotype of variation at that locus may also differ depending upon the (genetic and/or environmental) background. Nevertheless, it is possible and actually sensible to initially express a genetic architecture regardless of the frequencies of the considered alleles at any population, through individual-referenced formulations. A toy example of such approach using Mendel's experiments is given in Table 1.

In order to reflect how genetic variation underpins phenotypes, genetic effects account for the effects of allele substitutions, which implies the choice of a particular starting point, or reference. Individual-referenced formulations use an individual genotype as reference point. As shown in Figure 1 and Table 1, comparing homozygotes allows us to extract effects that add up whilst interactions appear in the parameterization due to deviations from the additive expectations. Interactions between alleles within a locus are called dominance, whereas those affecting alleles at different loci shall be called epistasis.

Although not absolutely necessary for understanding that the models of genetic effects reparameterize the GP map into additive and interaction effects, it is very illustrative to have a look at how such reparameterizations can be conveniently condensed with matrix notation as $\mathbf{G}=\mathbf{SE}$:

$$\begin{pmatrix} G_{11} \\ G_{12} \\ G_{22} \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 1 \\ 1 & 2 & 0 \end{pmatrix} \begin{pmatrix} R \\ a \\ d \end{pmatrix} \qquad [1]$$

In the previous expression it is easy to track that the genotypic values are decomposed into additive and interaction (dominance) effects of allele substitutions from the reference of A_1A_1. In detail, the first row of the genetic-effects design matrix, $\mathbf{S}$, indicates that the genotypic value of A_1A_1, G_{11}, is the reference point ($G_{11}=R$). The second row indicates that the genotypic value of A_1A_2, G_{12}, differs from the reference in one additive effect and one dominance effect ($G_{12}=R+a+d$), and the third row indicates that the genotypic value of A_2A_2, G_{22}, differs from the reference in two additive effects ($G_{22}=R+2a$). Thus, expression [1] exactly fits Figure 1 and Table 1.

The matrix notation enormously facilitates computations. For instance, we can check how the genetic effects are defined in terms of the genotypic values by just inverting the genetic-effects design matrix, $\mathbf{S}$, leading to:

$$\begin{pmatrix} R \\ a \\ d \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ -1/2 & 0 & 1/2 \\ -1/2 & 1 & -1/2 \end{pmatrix} \begin{pmatrix} G_{11} \\ G_{12} \\ G_{22} \end{pmatrix} \qquad [2]$$

The first row of $\mathbf{S}^{-1}$ designates which is the reference point, whilst the other two rows provide the definitions of the genetic effects in terms of the genotypic values, $a=(G_{22}-G_{11})/2$ and $d=G_{12}-((G_{22}+G_{11})/2)$. A general expression for any reference point can be obtained by just replacing that row by p_{11}, p_{12}, p_{22} (which would here work just as indicator variables, taking values 0 or 1, instead of as frequencies). Inverting again, after that replacement, we obtain a general expression of the

genotypic values from any reference point:

$$\begin{pmatrix} G_{11} \\ G_{12} \\ G_{22} \end{pmatrix} = \begin{pmatrix} 1 & -(p_{12}+2p_{22}) & -p_{12} \\ 1 & 2(p_{11}-p_{22}) & 1-p_{12} \\ 1 & p_{12}+2p_{11} & -p_{12} \end{pmatrix} \begin{pmatrix} R \\ a \\ d \end{pmatrix} \quad [3]$$

Population-referenced formulations

We also need formulations appropriate to reflect the properties of populations with particular genotype frequencies. Such formulations stem from the seminal work of Fisher (1918), and can be obtained through a linear regression of the genotypic values on the allele content (**Figure 2**). These formulations keep on decomposing the genotypic values into additive and interaction effects, although with a different meaning – fitting the population context. The reference point becomes the population mean phenotype. The additive component of each genotypic value, G_{ij}, is its breeding value, α_{ij}, reflecting whether the offspring of individuals with that genotype are expected to score below or above the population mean phenotype. Its dominance component, δ_{ij}, is the deviation of the breeding value from the genotypic value.

The breeding value of genotype A_iA_j is the sum of the average effects of the alleles it bears, $\alpha_{ij}=\alpha_i+\alpha_j$. The average effect of allele A_i is the expected phenotype change that would be caused by substituting an allele of an individual of the population by that allele (see, e.g., Falconer and MacKay, 1996, p. 113). Therefore, population-referenced formulations are still parameterized by effects of allele substitutions, which, in contrast with the individual-referenced formulations, are averaged over the whole population considered.

It is also possible to express population-referenced formulations in matrix notation, as (Zeng *et al.*, 2005; Álvarez-Castro and Carlborg, 2007):

$$\begin{pmatrix} G_{11} \\ G_{12} \\ G_{22} \end{pmatrix} = \begin{pmatrix} 1 & -2p_2 & -2p_2^2 \\ 1 & p_1-p_2 & 2p_1p_2 \\ 1 & 2p_1 & -2p_1^2 \end{pmatrix} \begin{pmatrix} \mu \\ \alpha \\ \delta \end{pmatrix} \quad [4]$$

which is a general formulation for any allele frequencies, with p_1, p_2 as frequencies of A_1, A_2, respectively, and Greek letters (μ, α, δ) instead of Latin ones for stressing the different meaning of the genetic effects relative to the individual-referenced formulations – expressions [1–3]. Expression [4] decomposes the genotypic values into additive and interaction components from the reference of a population, as $G_{ij}=\mu+\alpha_{ij}+\delta_{ij}$. Additionally, it holds $\alpha(=\alpha^{12})=\alpha_2-\alpha_1$ and in general (with multiple alleles) $\alpha^{ij}=\alpha_j-\alpha_i$, $i<j$; hence $\alpha^{ik}=\alpha^{ij}+\alpha^{jk}$, $i<j<k$ (i.e., they actually are additive parameters).

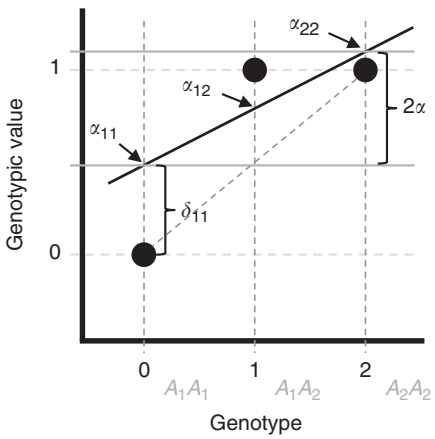

Figure 2 Population-referenced genetic effects for the same simple genetic architecture of **Table 1** and **Figure 1**. The frequency of A_2 is 0.7 and Hardy–Weinberg proportions hold. The departures (δ_{ij}, only δ_{11} marked) of the genotypic values from the values predicted by the weighted (by the genotypic frequencies) linear approximation (which are the breeding values, α_{ij}) are due to dominance (i.e., to the three genotypic values not laying in the same line). The slope of the approximation, α, is given by the difference between the breeding values of the homozygotes and reflects the average effects of allele substitutions.

Genetic variance decomposition

Population-referenced formulations of genetic effects are directly related to genetic variance decomposition – the variances of the (additive and interaction) components of the genotypic values. The most important component is the additive variance, V_A, which is the variance of the aforementioned breeding values, α_{ij}. With **Figure 2** in mind, it is easy to appreciate that the values population-referenced genetic effects take may vary remarkably for different population frequencies. Hence, so will the genetic variance components, which makes complete sense since they are built to keep a consistent biological meaning in different population contexts. The additive variance, for instance, is an index of the potential of a population to change the mean phenotype under directional selection in a one-generation step. Indeed, populations with different genotype frequencies may respond differently to selection and therefore have different additive variances (coming from different population-referenced genetic effects) for the trait under study.

What is true for different populations becomes even more remarkable when comparing different (individual- and population-referenced) formulations. Formalizing the decomposition of the genetic variance enabled Fisher (1918) to found the theoretical basis of quantitative genetics on Mendelian inheritance, but he would not at that juncture (when genes were not even known to lay in the DNA) bother to develop in detail additional formulations representing specific effects of substitutions of particular alleles from the reference of a given genotype. Such a task makes much more sense in the gene-mapping era, when it consequently becomes sensible also to beware the differences in meaning between the new individual- and the classical population-referenced genetic effects.

Indeed, comparing **Figures 1** and **2** it becomes clear that individual- and population-referenced genetic effects of the same genetic system are expected to be different. More to the point, it is noteworthy that, on the one hand, large additive variances are consistent with absence of individual-referenced additive genetic effects, since all individual-referenced genetic effects may contribute to the additive genetic variance (see, e.g., **Figure 1** in Álvarez-Castro, 2014; Álvarez-Castro and Le Rouzic, 2015), whereas on the other hand, nil additive variance may occur in the face of significant individual-referenced additive effects – particularly at polymorphic equilibria (see, e.g., Álvarez-Castro and Yang, 2011).

Genetic Architecture

The previous examples illustrate that sustaining a concept of genetic architecture on population-referenced genetic effects would be tricky to handle. Indeed, genetic architecture would that way become a property of a population with specific genotypic frequencies. Although little or no population-referenced interaction effects and variances do not warrant little or no individual-referenced interaction effects, the opposite is in point of fact true. Individual-referenced genetic effects are thus better candidates for grounding a definition of genetic architecture, as a number of loci underpinning phenotypic variation on a trait and their evolutionary properties, expressed as additive and interaction effects.

It is noteworthy, though, that the concept of genetic architecture is in any case not completely unaware of the population context. Evolutionary genetics is all about variation and different populations bear different genetic variation. In the extreme, one locus may bear a number of alleles underlying phenotypic variation at one population whilst being monomorphic – and therefore inconsequential to genetic architecture – at another one. It may also be useful to recall at this point that population-referenced genetic effects are necessary for properly making use of a genetic architecture, since they enable us to analyze its evolutionary implications at the particular context of a population with specific genotype frequencies. Transforming any kind of (e.g., individual-referenced) genetic effects, $\mathbf{E}_1$, into the ones fitting a particular population, $\mathbf{E}_2$, can easily be done using simple matrix algebra (Álvarez-Castro and Carlborg, 2007):

$$\mathbf{E}_2 = \mathbf{S}_2^{-1}\mathbf{S}_1\mathbf{E}_1 \qquad [5]$$

For being able to perform this transformation it is necessary to know, on top of the initial vector of genetic effects, $\mathbf{E}_1$, the genetic-effect design matrices of the two cases considered, $\mathbf{S}_1$ and $\mathbf{S}_2$. It is therefore necessary to develop such matrices for any putative genetic architecture to be considered, both concerning individual- and population-referenced formulations and from any reference point (Álvarez-Castro, 2012; Álvarez-Castro *et al.*, 2012a). Albeit we have initially considered, for simplicity, the population-referenced case of Hardy–Weinberg proportions (expression 4), it is also possible to provide a more general expression also accounting for departures from those proportions (Álvarez-Castro and Carlborg, 2007):

$$\begin{pmatrix} G_{11} \\ G_{12} \\ G_{22} \end{pmatrix} = \begin{pmatrix} 1 & -2p_2 & -\dfrac{p_{12}p_{22}}{2p_1p_2 - 1/2p_{12}} \\ 1 & p_1 - p_2 & \dfrac{p_{11}p_{22}}{p_1p_2 - 1/4p_{12}} \\ 1 & 2p_1 & -\dfrac{p_{11}p_{12}}{2p_1p_2 - 1/2p_{12}} \end{pmatrix} \begin{pmatrix} \mu \\ \alpha \\ \delta \end{pmatrix} \qquad [6]$$

Here, p_{ij} stands for the frequency of A_iA_j in the population considered. The only interaction effect we have addressed so far is dominance, the one already discovered by Mendel. Other important facts of genetic architecture follow.

Multiple alleles

As a first step beyond the one-locus two-allele case, we address in this section the case of a multiallelic locus. The multiallelic individual-referenced formulation can easily be obtained as a natural extension of expression [1] or, even more easily, of expression [2] (Yang and Álvarez-Castro, 2008). Kempthorne (1954) pioneered multiallelic population-referenced developments, providing expressions that determined the multiallelic genetic effects implicitly under Hardy–Weinberg proportions. In the same year, a PhD student of his published two-allele formulations accounting for departures from the Hardy–Weinberg proportions (Cockerham, 1954). Both approaches were more recently generalized with developments by Álvarez-Castro and Yang (2011) leading to expressions of the type $\mathbf{G} = \mathbf{SE}$, providing explicit population-referenced formulations with multiple alleles and accounting for departures from the Hardy–Weinberg proportions.

Epistasis

The classical works by Kempthorne (1954) and Cockerham (1954) had in common a motivation for implementing epistasis on Fisher's (1918, 1930) foundational developments. Toward the end of the twentieth century, a group of scientists felt encouraged enough to address the complexity of these interactions, which already justified a first compendium at the turn of the century (Wolf *et al.*, 2000) and a second installment 15 years later (Moore and Williams, 2015). Epistasis is a kind of interaction between or among alleles that, in contrast with dominance, occurs across loci. A simple instance of epistasis is shown in **Figure 3**.

Concerning models of genetic effects, the matrix notation used above enormously facilitates implementations of epistasis, by computing multilocus genetic-effects design matrices as Kronecker products of single-locus ones (Tiwari and Elston, 1997), which holds for multiallelic loci and for both (individual- and population-referenced) formulations. This way, epistasis genetic effects naturally emerge as interactions between the marginal ones (for the two-locus case, additive-by-additive, additive-by-dominance, dominance-by-additive, and

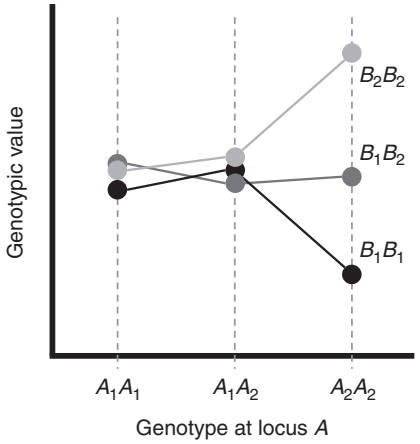

Figure 3 Representation of a two-locus two-allele GP map with epistasis. In this case, locus B is canalized (allele substitutions within it have little effect) when allele A_1 is present. In general, epistasis occurs as long as the solid lines in the figure are not parallel.

dominance-by-dominance) or among them (for higher order interactions that may occur when more than two loci are involved). Despite some work done in this direction, developing epistatic population-referenced formulations fully accounting for linkage disequilibrium remains a challenge (Yang, 2004; Mao *et al.*, 2006).

On the other hand, directionality of the genetic architecture of a trait has proven to be a relevant index since it is informative about the mid- to long-term evolutionary properties of a trait (Hansen, 2006, 2015). Very briefly, directionality has been designed to measure whether, and how much (on average), allele substitutions increasing trait value in the direction of selection have synergistic effects. When the directional epistasis index is significantly positive (positive epistasis), the response will eventually become significantly higher than expected under additivity, whereas if it is negative, canalization (low population-referenced additive genetic effects and response to selection) is prone to occur. When the index is virtually zero (nondirectional epistasis), the response to selection does not depart significantly from its additive expectation.

Imprinting and epigenetics

Also, attention on non-Mendelian inheritance has increased since the late twentieth century (see, e.g., Halgrímsson and Hall, 2011). Particularly, imprinting – a mechanism by which the inherited alleles are different depending on their parent-of-origin – has deserved special focus. In the simplest case (one two-allele locus), the GP map just has to include an additional term, G_{21}, since two different heterozygotes are possible – depending on which of the two alleles has maternal origin. This in its turn implies accounting for an extra genetic effect, which can be done either with two dominance effects (e.g., Santure and Spencer, 2011; Álvarez-Castro, 2014) or with an extra imprinting effect (e.g., Wolf *et al.*, 2008; Xiao *et al.*, 2013; Álvarez-Castro, 2014).

Gene-by-environment interactions

Since an individual may experience different environments during its life history, classical evolutionary genetics acknowledged the reaction norm as the target unit of selection (see, e.g., Sarkar, 2004). We may be more interested in considering that different individuals may experience significantly different environments. In both cases, gene-by-environment interactions may be a key factor to consider in the analysis of the genetic implications of phenotype variation (see **Figure 4**). Since these interactions appear when the effects of allele substitutions do not just sum up with the effects of changing environmental backgrounds, the way they can be modeled is similar to that of epistasis (see, e.g., Ma *et al.*, 2012). However, as opposed to genotypes, environment may be a continuous parameter and, to the increase of complexity, the reaction norms of the genotypes may not be linear functions (Yang, 2014).

Mapping Genetic Architectures

Gene-mapping experiments became widespread at the end of the latest century as molecular techniques enabled the inspection of a sufficient number of markers at a reasonable cost.

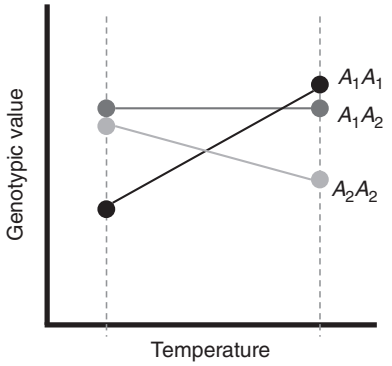

Figure 4 Representation of gene-by-environment interactions. Substitutions at the two-allele locus, *A*, have different effects depending on the environment as long as the solid lines (reaction norms) in the figure are not parallel. In this case, temperature does not affect the phenotype of the heterozygote, while each homozygote has higher values at opposite temperatures.

The initial quantitative trait loci (QTL) experiments (see **Figure 5**) consisted in performing selection for a trait in opposed directions to obtain a large trait mean difference in the two resulting populations, which would then be inbred. Molecular markers with different alleles at the two populations would then be identified and the populations themselves would be intercrossed – and allowed to recombine. Genotyping (at the chosen markers) and phenotyping the resulting individuals, would make it possible to map regions of the genome with genetic variability responsible for the trait mean difference between the two selected lines (for a more detailed description, see, e.g., Lynch and Walsh, 1998).

The key point of this experimental design is to generate linkage between each region of the genome of each of the lines and one allele of at least one molecular marker. As molecular techniques enabled sufficiently denser marker maps, the chance of a marker falling close to (and thus to retain linkage with) a responsible mutation increases. This is the principle behind genome-wide association (GWA) studies, which can be applied without the need of any previous design of selection and intercross – and thus enable mapping experiments at non-model species, particularly including humans.

In any case, gene-mapping methodologies aim for the location (as precise as possible) of loci with genetic variation responsible for trait variation at the population under study, and the genotype (or at least genotype probability) of each individual of the study at each of those loci. That is the information required for building up a GP map and to obtain estimates of genetic effects.

Obtaining the Genotype-to-Phenotype Map

Let us start by considering how we could estimate a GP map from the aforementioned information – the phenotypes of the individuals of our sample, P_i, and their genotypes for a set of mapped responsible loci. The parameters we would like to obtain are the expected phenotypic value of each genotype, G_i. The classical expression $P = G + E$ (e.g., Falconer and MacKay, 1996) accounts for the genetic and environmental influence

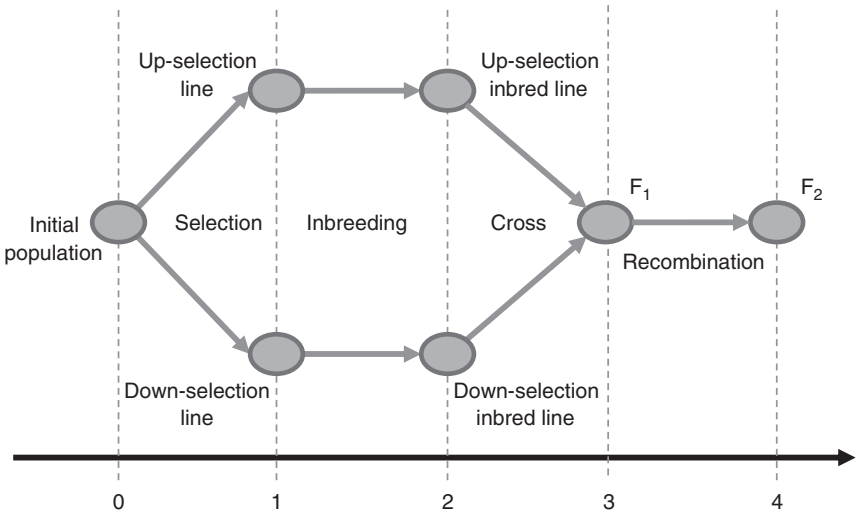

Figure 5 Schematic view of a QTL experimental design for a model species. The starting point (0) is a population with variation for the trait of interest, which is selected upwards and downwards to obtain two populations with sufficiently different mean trait values (1). Those are inbred, for example, through sib-mating for a number of generations. At the resulting inbred populations (2), molecular markers are obtained having different alleles for each of the lines – the individuals at the up-selection inbred line would have genotypes $M_1M_1/M_2M_2/M_3M_3/...$, whereas the ones at the down selection inbred line are $m_1m_1/m_2m_2/m_3m_3/...$ The two lines are then intercrossed to obtain an F_1 population (3), whose individuals are all $M_1m_1/M_2m_2/M_3m_3/...$ At this point there are several options to allow recombination. An F_2 population is represented in the last step (4), with recombining individuals of the kind $M_1M_1/M_2m_2/m_3m_3/...$ Other options are backcrosses and F_n populations.

on phenotype at the individual level (here E stands for environment, not to be confused with the vector of genetic effects, **E**, in the expressions above). For each of the individuals of our study, it can be rewritten as $P_i = G_i + E_i$. If individuals i and j in our sample have the same genotype, then $G_i = G_j$, and hence in general $P_i = G_k + E_i$, where k stands for the genotype of individual i.

In other words, the column vector gathering the phenotypes of the individuals in our sample, $\mathbf{P} = (P_1, P_2, P_3, \ldots)^T$, is larger than the column vector of the genotypic values, **G** – which for the one-locus (A) two-allele (A_1 and A_2) case is just $\mathbf{G} = (G_{11}, G_{12}, G_{22})^T$ as in the expressions above. Each individual can be assigned to its genotypic value as long as its genotype is known. In practice, this is done using a matrix called incidence matrix, **Z**. If the first three individuals of our sample have genotypes A_1A_1, A_1A_2, and A_2A_2, respectively, then the first three rows of the incidence matrix shall be (1, 0, 0), (0, 1, 0), and (0, 0, 1), respectively. The vector of genotypic values can now be estimated by solving the regression (see, e.g., Nettelblad *et al.*, 2012):

$$\mathbf{P} = \mathbf{ZG} + \varepsilon \qquad [7]$$

In this expression, the environmental values of each of the individuals are the residuals of the regression. Indeed, for each individual this expression reads $P_i = G_k + \varepsilon_i$ – note the analogy of expression [7] with the aforementioned P = G + E. For considering gene-by-environment interactions, an extra term needs to be added.

Estimating Genetic Effects

As stated above, it is preferable to estimate genetic effects directly from the data, rather than the raw GP map. The split of the genetic influence into additive and interaction components is traditionally represented as G = A + D, where A stands for additive and D for dominance (an extra term may be included to account for epistatic interactions). That split has been performed above using genetic-effects design matrices, **S**, which makes it straightforward to substitute **G** in expression [7] and turn it into a regression to directly estimate genetic effects from data as:

$$\mathbf{P} = \mathbf{XE} + \varepsilon \qquad [8]$$

In this expression, $\mathbf{X} = \mathbf{ZS}$ and for each individual it reads $P_i = \mu + \alpha_{kl} + \delta_{kl} + \varepsilon_i$, where $\alpha_{kl} = \alpha_k + \alpha_l$. Greek letters are used here instead of Latin ones (R, a, d) because the best choice of genetic-effects design matrix for performing the regression in expression [8] is the population-referenced one fitting the frequencies of the genotypes of the individuals represented in the vector **P**, which conveniently enables an orthogonal estimation of genetic effects.

Hitherto, it has been assumed that the loci underlying variation on the trait under study are known, but that is precisely the information often pursued, which increases complexity in two important senses. First, it shall often be the case of feeding the incidence matrix, **Z**, with genotype probabilities rather than certainties, since we want to test the hypothesis that loci underlying trait variation (QTL) lay at locations whose genotype probabilities may be inferred from flanking markers. Opportunely, it is possible to preserve orthogonality in expression [8] (and therefore also the genetic meaning of the estimates obtained) under these circumstances (Nettelblad *et al.*, 2012).

Second, even when putative QTLs have been located, it will be necessary to choose among several possible genetic architectures, by comparing several submodels resulted from discarding either certain genetic (or gene-by-environment) effects

within a locus or even one to several complete loci. Orthogonality is highly desirable at this point, since it implies that subtracting effects form a model (from a genetic architecture under evaluation) does not alter the estimates of the ones remaining. There exist quite interesting literature on the specificities of model selection (e.g., McKinney *et al.*, 2006; Zou *et al.*, 2010; Steen, 2012) and in general on methodologies related to QTL analysis (see Rifkin, 2012 for a compendium).

Genetic Architectures Discovered

Beyond single QTLs, very many interesting facts of genetic architectures have already been discovered. Epistasis has been found widespread especially by studying model species (e.g., Mackay, 2014). More specifically, it has been shown that mapped interactions (particularly, epistasis) improve prediction of evolutionary properties as compared with information of marginal loci alone (Álvarez-Castro *et al.*, 2012b) and that directional epistasis is consistent with real data (Le Rouzic, 2014). It is crucial to consider the implications of epistasis also for the study modularity of genetic networks (Wagner *et al.*, 2007), loci affecting expression (eQTL; Chen, 2012; Li *et al.*, 2012), loci affecting the pleiotropic relationships of different traits (rQTL; Pavlicev *et al.*, 2013), and variance-controlling QTL (Rönnegård and Valdar, 2011; Shen *et al.*, 2012).

The increase of molecular data opened the possibility of mapping genetic architectures using GWA studies, also with particular progress made in the direction of detecting epistatic interactions (see, e.g., Wei *et al.*, 2014; Wang and Biernacka, 2015). In data for which dense marker maps are available, blocks of alleles of molecular markers (haplotypes) occur, so that even when there are only two versions of each marker, the haplotypes are multiallelic. Multiallelic systems may also be detected through QTL mapping experiments (Rönnegård *et al.*, 2008) – although the mapping populations come from the cross of two lines, those may not be fully inbred as the original experimental design advises (see, e.g., Lynch and Walsh, 1998). **Figure 6** shows a three-allele genetic architecture found for human *ACP1* in European populations. There already exist sound evidences for imprinting effects as well (e.g., Wolf *et al.*, 2008; Xiao *et al.*, 2013) and a promising method for systematically searching for signals of general epigenetic inheritance has been developed (Varona *et al.*, 2015).

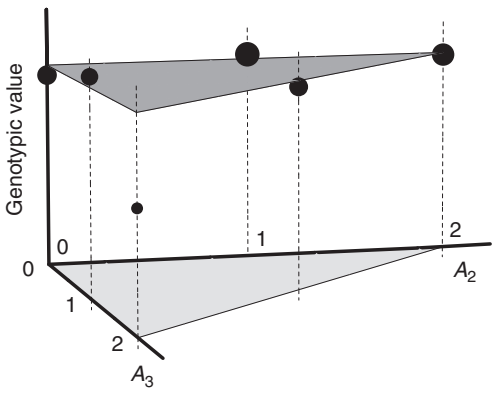

Figure 6 One-locus three-allele GP (in particular, genotype-to-fitness) map deduced using a population-referenced formulation. The model of genetic effects was fed with the frequencies of the genotypes at a population (represented by the size of the dots of the genotypic values) and minimized for the variance of population-referenced additive effects. The minimum was zero, indicating that the population may be at equilibrium, with the fitnesses found at the minimum. Note that indeed the plane of the linear approximation weighted by the genotype frequencies is parallel to the horizontal plane of the coordinates of the genotypes (for details see Álvarez-Castro and Yang, 2011; Álvarez-Castro and Le Rouzic, 2015).

Evolutionary Quantitative Genetics

The basic conceptual ground of genetics gained soundness as compatibility between Mendel's laws and inheritance of continuous traits was shown (Provine, 1971; Kim, 1994). More to the point, Fisher's (1918) work enabled Mendelian reinterpretation of the results of biometry – particularly, the regression toward mediocrity (Galton, 1886) – and kicked off new paradigms for the study of (gradual) evolution. Albeit quantitative genetics cannot elude the population dimension, and a population genetics of strictly discrete traits would not bring the brightest light, these instantly became two distinct lines of work. On the one hand, quantitative geneticists pursued (and achieved) to prompt the development of practical tools to aid plant and animal breeding, in which context, a model "does not have to be true to be useful" (Hill, 2014). On the other hand, population geneticists started a slower-paced hike toward a comprehensive understanding of mechanisms of natural selection and evolution, an endeavor in which (paraphrasing Hedrick and Murray, 1983) "we do not want to be right for the wrong reason".

Thus, the divide between population and quantitative genetics is of epistemological nature. Albeit this conditions differences in methodology, ultimately the two disciplines address mostly the same phenomena and thus it means no surprise that there has occurred profuse feedback between them, seeding a common ground for a merge into evolutionary quantitative genetics (see, e.g., Roff, 1997). To close this article, new opportunities blossoming in this common ground, watered by the advent of mapping experiments, are briefly commented (see **Figure 7**).

The traditional strategy of quantitative genetics used the data available (basically, phenotypes and relatedness) for improvement on production traits with a statistical machinery that enables handling phenotype (and genetic) variance decomposition whilst being parsimonious about the genetic architecture of the underlying Mendelian factors. This can be labeled as a top–down approach, in contrast with a bottom–up one consisting in predicting the outcome of selection based on the knowledge of the loci involved in trait variation and their genetic properties (additive genetic effects, interactions, etc.) at the population under study (see, e.g., Zuk *et al.*, 2012). Models of genetic effects were initially developed, at the beginning of the twentieth century, under the top–down paradigm, the only way possible at that time. Only at the turn of the century – as mapping experiments started to become

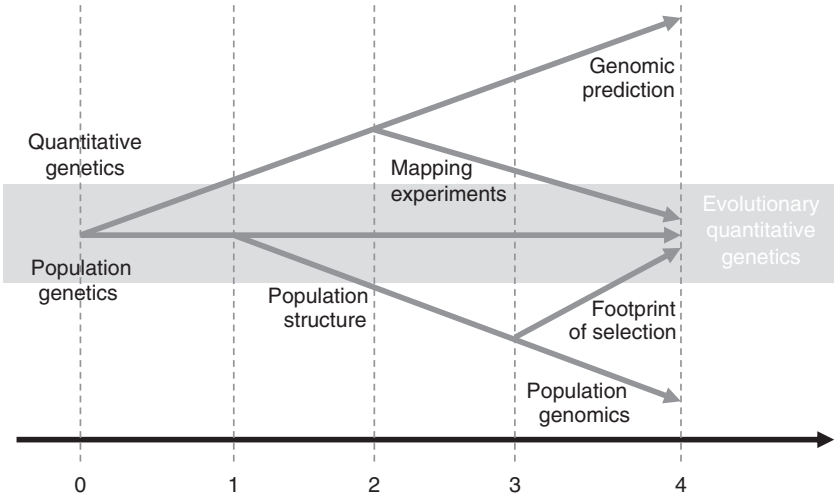

Figure 7 Diagram representing directions taken along history within population and quantitative genetics relative to their focus on the GP map (shadowed area). Initially (0), only population genetics addressed the GP map explicitly. The availability of the first molecular markers enabled population genetics to branch out with the analysis of neutral variation (applied to, e.g., population structure and phylogeny studies), thus also diverging from the GP map (1). The exponential development of molecular techniques eventually made gene-mapping experiments possible, which entailed a convergence with population genetics through the study of GP maps (2). Finally, advanced studies of neutral variation tracked the footprint of selection and, together with candidate-gene approaches, triggered a re-convergence of this line of work toward the study of the GP map (3). Currently, there keep on existing population and quantitative genetics directions both within and outside the GP map (4).

feasible and eventually widespread – it became apparent that models of genetic effects had to be updated for bottom–up applications (see Álvarez-Castro and Yang, 2015 for a compendium).

One of the initial worries consisted in being able to express genetic architectures in ways independent from the (experimental) population under study. Cheverud and Routman (1995) brought this issue to the table with their physiological model, which prompted Hansen and Wagner (2001) to develop their multilinear model with individual-referenced (which they called functional) genetic effects and to introduce the concept of change of reference. A second worry was about being able to express complex models (particularly, with epistasis) within an operational mathematical framework, which was attained by means of a practical matrix notation (Tiwari and Elston, 1997). Third, it was necessary to make an effort in generalizing approaches made in different directions, which required addressing several levels of action.

Álvarez-Castro and Carlborg (2007) used the matrix notation to unify individual- and population-referenced (statistical) formulations of genetic effects, with the expressions shown above (1–6). Le Rouzic and Álvarez-Castro (2008) provided a first software package for the use of that framework – the NOIA (natural and orthogonal interactions) model. Yang and Álvarez-Castro (2008) and Álvarez-Castro and Yang (2011) extended NOIA to multiple alleles, thus generalizing the aforementioned classical implementations of epistasis by Kempthorne (1954) and Cockerham (1954), with multiple alleles and departures from the Hardy–Weinberg proportions, respectively. Further facts of genetic architectures keep on being implemented in NOIA (e.g., Ma *et al.*, 2012; Xiao *et al.*, 2013; Álvarez-Castro, 2014).

Overall, the inspection of GP maps with the advent of mapping experiments opened new thrilling opportunities not only to integrate population and quantitative genetics, but also both into a systems biology perspective (Álvarez-Castro and Yang, 2014). Such a shift has already proven to be productive and would rather be accompanied by a certain dose of patience, for major achievements within a new and complex scientific paradigm are expected to come with work and time rather than instantly (Álvarez-Castro, 2012). Incidentally, this shall not preclude rewarding work to keep on being done also outside the domains of the GP map, both in population and quantitative genetics (see **Figure 7**).

Genetic Drift, Models of Random

CA Muirhead, Ronin Institute, Montclair, NJ, USA

Glossary

Allele vs. allele copy In this article, an 'allele copy' refers to one (of $2N$) physical instance of an allele at a locus; it does not imply a copying process such as gene duplication or replication from parent to offspring generation.

Binomial distribution A probability distribution describing the following process: an activity with two possible outcomes (e.g., a coin flip) is done repeatedly. The number of times that an outcome having constant probability p of occurring in one attempt happens in n attempts is said to be binomially distributed with key parameters n and p.

Coalescent theory A backwards-time method of analyzing population genetic data, focusing on the mathematical properties of the genealogy of a sample of allele copies.

Diffusion theory An approximate method of analyzing complex stochastic processes.

Effective population size (N_e) For a population that may violate one or more assumptions of an idealized Wright–Fisher population, the size of an equivalent idealized Wright–Fisher population. 'Equivalent' here means matching in some aspects of their population genetic characteristics (e.g., variance in allele frequencies or degree of inbreeding).

Fixation An allele is 'fixed' or 'goes to fixation' when its frequency in the population equals 1.

Geometric distribution A probability distribution describing the following process: an activity with two possible outcomes (e.g., did it rain today or not?) are repeated until the first time one of the outcomes occurs (a day with no rain). The number of unsuccessful trials (number of rainy days) before the first success is said to have a geometric distribution.

Markov chain A type of stochastic (random) process. The key feature of this type of process is that it is 'memoryless' – none of the history of the process, other than the current state, matters to the future prospects.

Multinomial distribution A probability distribution, very similar to the binomial distribution, but with more than two possible outcomes.

Poisson distribution A probability distribution describing the following process: an event has a constant (but low) probability of happening (e.g., getting a flat tire on a well-maintained car under normal driving conditions). Given some set time interval (10 years worth of driving), the total number of events (flat tires) is said to have a Poisson distribution.

Time reversible A property of some stochastic processes. The process looks the same (probabilistically) whether looking forward in time or backwards.

Overview

From the earliest days of population genetics, evolutionary biologists have used a variety of mathematical models to describe and understand the dynamics of random genetic drift. By far the most common model analyzed is the Wright–Fisher model, although in recent years an alternative, the Moran model, has proved to be a useful complementary tool. Although these two main models were first proposed well before widespread DNA sequencing and the development of the field of molecular evolution, it is in the service of molecular evolutionary studies that they have seen their utility expand. This article outlines the basic mathematical structures, results, and applications of the two main models of random genetic drift used by evolutionary biologists: the Wright–Fisher model and the Moran model. A third category of random genetic drift models, the Cannings models, is referenced briefly.

Core Assumptions of Genetic Drift Models

All of the models considered here assume a simple population structure (a single population of constant size) and an idealized view of how individuals in the population interact to form a new generation (individuals are monoecious – no separate sexes – and mate at random). Because the core descriptions of genetic drift models focus on random sampling as the only factor affecting allele frequencies, they often assert many of the Hardy–Weinberg assumptions in order to remove other factors from consideration: random mating of parents, no mutation, migration, or natural selection. Once the basic structure of the stochastic model is established, these other evolutionary forces can be reintroduced and incorporated into more complex models of evolution in a finite population (see Ewens (2004) for several examples of these more complex models, and Gale (1990) for an exploration of some of the approximation methods used for their analyses).

Two Different Genetic Drift Models

The random genetic drift models considered here have a critical structural difference in how they view the transmission of alleles and genetic information from parent to offspring. The Wright–Fisher model is a particular type of Cannings model (Cannings, 1974). This category of models focuses on the population-scale transmission of information from the parental generation to the offspring generation; all parents reproduce (and then die) simultaneously in such models, so that generations are non-overlapping. The Cannings-type models

 doi:10.1016/B978-0-12-800049-6.00024-X

(including the Wright–Fisher model) have an appealingly direct intuitive connection to the behavior of some species (such as annual plants) with non-overlapping generations in nature.

The Moran model is quite different in structure. Here, the focus is on the birth and death of individual allele copies, and only one or two members of the population are involved in reproduction and/or death at a particular time. Thus, generations are overlapping. This makes the Moran model initially appear to be more appropriate for the majority of species (including humans) that have continuous reproduction and overlapping generations. Historically, however, it has received much less attention than the Wright–Fisher model, perhaps because the specific structure is harder to connect directly to a familiar natural system. For example, the Moran model, with its focus on birth and death of single allele copies, is strictly speaking a haploid model, and, although in practice it can be applied approximately to diploids, this apparent limitation may hinder making intuitive connections to the natural world. The barriers to adoption for the Moran model may be receding in recent years, as its advantages in mathematical tractability have become more widely recognized and the model itself has become more familiar. Additionally, its inherent time-reversibility makes it an attractive starting point for modern 'retrospective' population genetics analyses such as coalescent theory. Nevertheless, the main mathematical framework for evolution in a finite population remains the Wright–Fisher model.

Wright–Fisher Model

Over several decades in the middle of the twentieth century, Sewall Wright and R.A. Fisher (along with J. B. S. Haldane) set the theoretical foundations for much of what became the field of population genetics (Provine, 1971). Both Wright (1931) and Fisher (1922, 1958) recognized that it was necessary to have a mathematical description of the random fluctuations of allele frequency due to sampling in a finite population. We refer to the model that they developed as the Wright–Fisher model.

Mathematical Framework of the Wright–Fisher Model

The Wright–Fisher model is structured in the following way (Figure 1):

- generations are non-overlapping: all individuals reproduce and die simultaneously;
- the population is characterized by the current numbers of each allelic type;

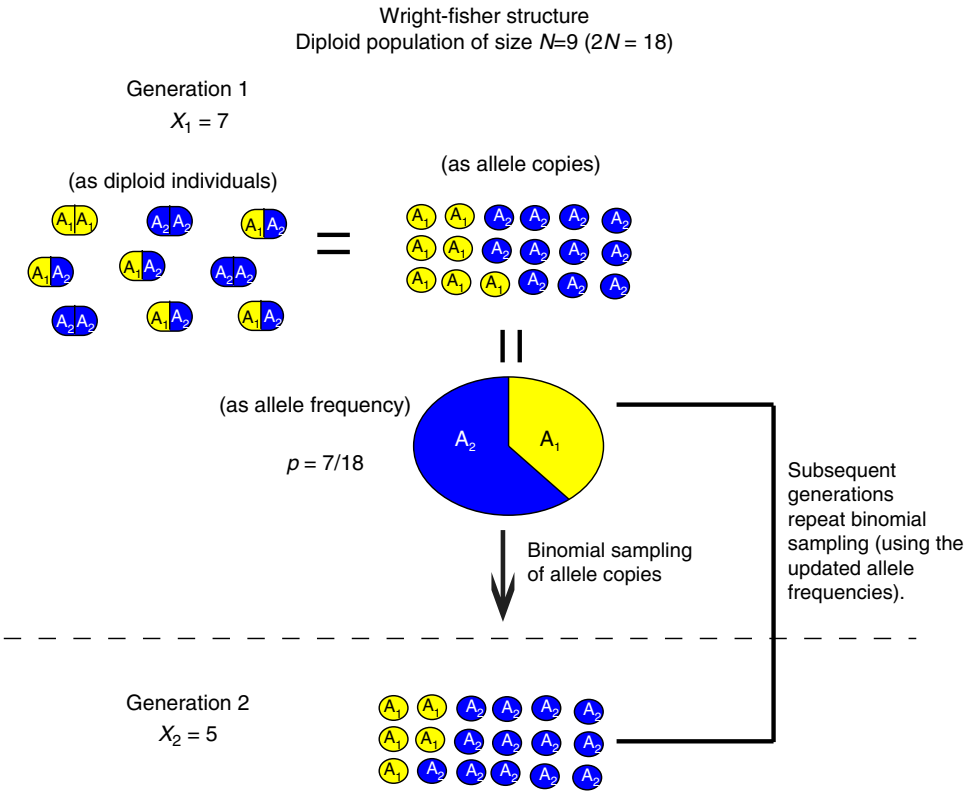

Figure 1 Structure of the Wright–Fisher model. The population is characterized by the number (X_t) of a focal type of allele, which are converted to fractions ($p = X_t/2N$) to represent an infinite pool of gametes. An entire new generation of $2N$ allele copies (shown: one of several possibilities) is produced through binomial sampling of the old generation's gamete pool. At this point, the sampled offspring alleles may be assembled into a new set of diploids, or else simply used to calculate a new p for a new generation of binomial sampling.

- new generations are formed by binomial sampling of allelic types from the parental generation when there are two allelic types, and multinomial sampling when there are more than two alleles.

The Wright–Fisher model is a specific type of Cannings (1974) model. All Cannings models share the features of non-overlapping generations and stochastic sampling of alleles (from an infinite parental 'gamete pool') from one generation to the next; particular Cannings models are distinguished by their method of generational sampling and their characteristic amount of variation in offspring number. For the Wright–Fisher model, a new generation of alleles is generated by binomial (or, in the case of more than two alleles, multinomial) sampling of the current generation's gamete pool. Much of the analytical power of the Wright–Fisher model comes from our knowledge of binomial and multinomial sampling.

Mathematically, this model is straightforward to describe: given a single locus with two alleles, A_1 and A_2, let X_t be a random variable describing the number of A_1 alleles in a diploid population of size N. If, in the present generation t, $X_t = i$, then the probability that the next generation contains $X_{t+1} = j$ copies of A_1 is given by the binomial sampling formula:

$$P_{ij} = \binom{2N}{j} \left(\frac{i}{2N}\right)^j \left(\frac{2N-i}{2N}\right)^{2N-j}$$

where $\binom{2N}{j} = \frac{2N!}{j!(2N-j)!}$ gives the binomial coefficient.

As might be expected with a model of random genetic drift, the trajectory or outcome for any particular population cannot be predicted absolutely – the next generation described by P_{ij} is described only in terms of the probabilities of many possible outcomes (**Figures 2** and **3**). Many interesting results can, however, be derived about the long-term or expected behavior of the process by using mathematical methods designed to study stochastic processes.

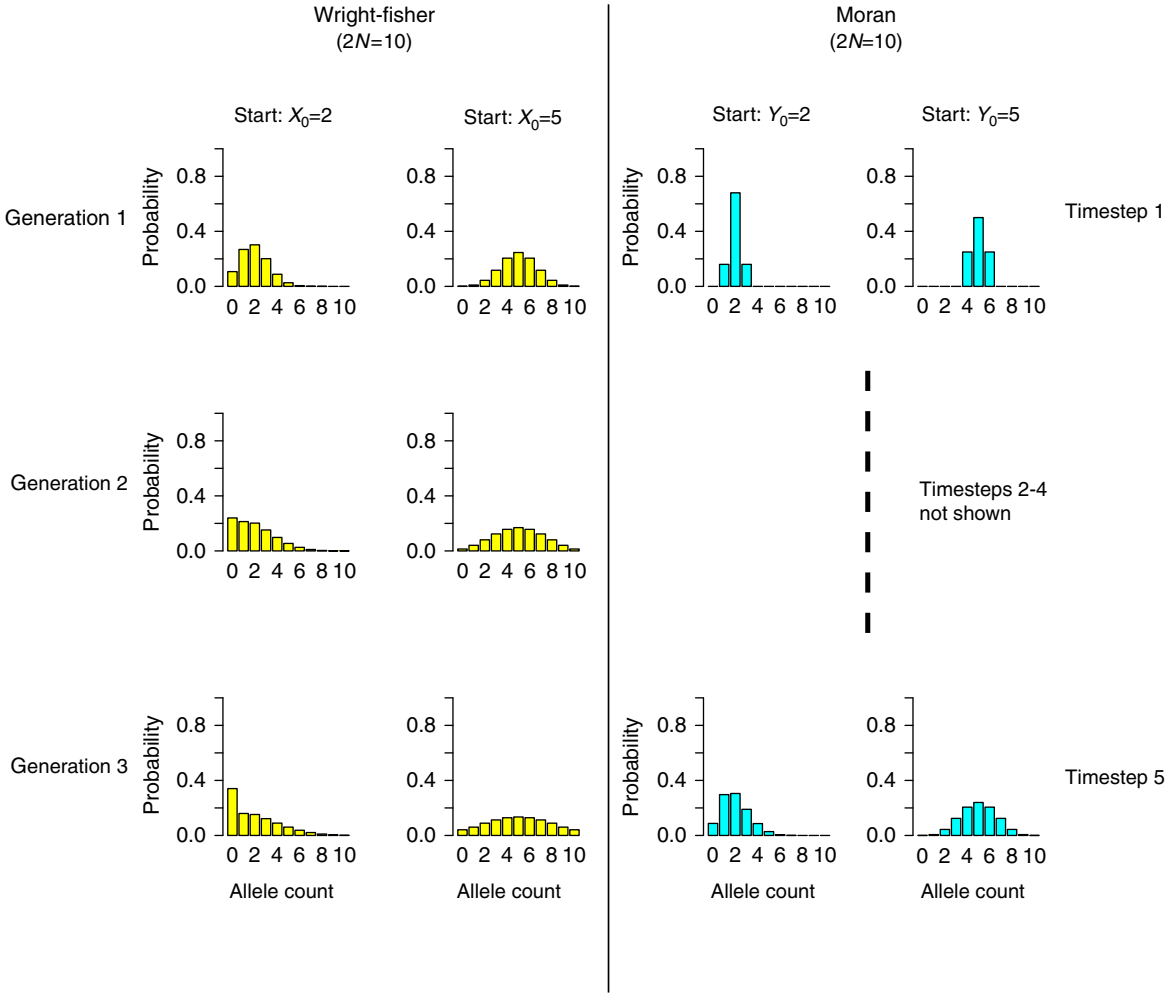

Figure 2 Probability distributions over time for both the Wright–Fisher and Moran models. Each graph shows the probability that a population which began with either 2 or 5 copies of the focal allele (out of a total $2N=10$ copies) has, in subsequent generations, 0, 1, 2, etc. of that allele. The Wright–Fisher results on the left show the predictions under three consecutive generations of random genetic drift, while the Moran model on the left shows 1 and 5 timesteps. In this case, the 5-timestep Moran result approximates one generation of Wright–Fisher evolution.

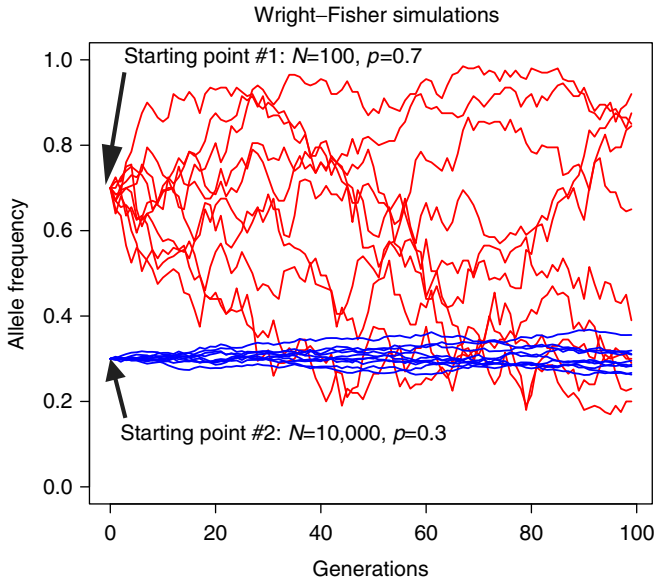

Figure 3 Simulations of random genetic drift under a Wright–Fisher model. Two different population sizes and starting conditions are shown. Red lines: $N=100$, $p_0=0.7$. Blue lines: $N=10\,000$, $p_0=0.3$. Each line is a separate simulation, and uses the binomial sampling scheme of the Wright–Fisher model to follow the frequency of the focal alleles remaining in the population over time.

Over multiple generations, the repeated application of the Wright–Fisher sampling strategy forms a particular type of stochastic process, a Markov chain, with transition matrix $\boldsymbol{P}$ composed of elements P_{ij}. The Markov chain can be written

$$x(t+1) = P \cdot x(t)$$

where $\boldsymbol{P}$ has been transposed and the (column) vector

$$x(t) = [x_0(t), x_1(t), \cdots, x_{2N}(t)]$$

is composed of probabilities, with each $x_i(t)$ representing the probability that the population has i copies of the allele at time t, $x_i(t) = \text{Prob}[X_t = i]$. Figure 2 (left side) shows these probabilities for a diploid population of size $N=5$ over three generations of the Wright–Fisher Markov chain, with the two columns giving two different starting conditions.

Direct Results from the Wright–Fisher Model

Unfortunately, while we can readily write down the form of the transition matrix of the Wright–Fisher Markov chain and can iterate it by hand for any particular population (Figure 2), a full exact analysis of this Markov chain appears to be largely intractable. Nevertheless, substantial insights into the long-term consequences of random genetic drift under the Wright–Fisher model can be gained using methods that draw only upon the basic structure of the model and a thorough understanding of the single generation transitions and binomial sampling.

Probability of fixation

Under one generation of binomial sampling, the expected value of the allele frequency in generation $t+1$ is just its frequency in generation t. In fact, this will remain the case in all subsequent generations. Thus, if the current allele frequency is p, p must also be the long-term expected value for the allele frequency. In the very distant future, the allele must either be fixed ($X_\infty = 1$) or lost ($X_\infty = 0$), and so, allowing $\text{E}[X]$ to indicate the expectation of X,

$$\begin{aligned} p &= E[X_\infty] \\ &= 0 \cdot \text{Prob}[X_\infty = 0] + 1 \cdot \text{Prob}[X_\infty = 1] \\ &= \text{Prob}[X_\infty = 1] \\ &= \text{fixation probability} \end{aligned}$$

which gives the familiar result that the eventual fixation probability of a neutral allele is equal to its current frequency.

Variance in allele frequencies over time

In order to understand a stochastic process such as random genetic drift it is essential to characterize the variability in the process as well as the average behavior. It is clear in Figure 2 that many possible fates are possible for a population undergoing random genetic drift, and Figure 3 shows several possible trajectories for allele frequency in simulated populations. Using the Wright–Fisher model, it is possible to quantify the variation in allele frequencies expected over time, and thus obtain a rough measure of the magnitude of the effects of random genetic drift.

If x is the current count of the focal allele and thus $p = x/2N$ the current allele frequency, then from the properties of the binomial distribution, after one generation the allele count will have variance $2Np(1-p)$. The variance in allele frequencies becomes

$$\begin{aligned} \text{Var}[\text{frequency}] &= \text{Var}\left[\frac{\text{count}}{2N}\right] \\ &= \frac{\text{Var}[\text{count}]}{(2N)^2} \\ &= \frac{p(1-p)}{2N} \end{aligned}$$

Over time, allele frequency trajectories in replicate populations diverge from each other, and the variance in allele frequency between them increases (**Figure 3**). The above equation quantifies the variance produced in a single generation, given the population size and the current frequency. Quantifying the variance provides a measure of not only the expected impact of genetic drift on individual trajectories, but also, importantly, the timescale upon which drift operates and the speed at which alleles are fixed or lost from the population. Smaller population sizes lead to higher generation-to-generation variances (**Figure 3**; red lines, $N=100$; blue lines, $N=10\,000$), corresponding to our intuition that smaller population sizes should experience more pronounced effects of random genetic drift than do larger populations.

Reproductive output of individual alleles

With binomial sampling, as the $2N$ allele copies in the offspring population are generated, at every 'pick' of an allele copy for the new generation an allele copy in the parent population has a $1/2N$ chance of being chosen to leave a descendant. If N is very large, $1/2N$ is very small and the number of 'picks' is very large. The total number of descendants left by an allele copy will then be approximately Poisson distributed with mean 1, or

$$D_{WF} \sim \mathrm{Po}(1)$$

Approximate Results from the Wright–Fisher Model

Many other interesting results from this model, notably those involving time, are only obtainable through approximate methods, many of which were first developed by Fisher and Wright in their initial analyses of the model and then elaborated on by later workers, chiefly Motoo Kimura (1955).

Time to fixation or loss of a neutral allele

Given initial allele frequency p, the expected time before a neutral allele is either fixed or lost from the population is:

$$\text{Expected time to fixation or loss} \approx -4N\{p\ \log p + (1-p)\log(1-p)\}$$

Time to fixation (conditional on fixation)

If only fixation events are considered, the expected time until fixation occurs, given current allele frequency p is:

$$\text{Expected fixation time; given fixation} \approx -4N\left\{\frac{1-p}{p}\log(1-p)\right\}$$

This time is of particular interest when the allele is a new mutant, $p=1/2N$:

$$\text{Expected fixation time for a new mutant given fixation} \approx (4N-2)\ \text{generations}$$

Approximation Methods

The above quantities can be derived using the common approximation method of Taylor expansions (Ewens, 2004). Many additional important results, however, are available through diffusion methods, which have been widely applied in population genetics (Feller (1951) and Hartl and Clark (2007) gives a good overview of the basic method as used in population genetics; see also Crow and Kimura (1970) and Ewens (2004) for more mathematically involved discussions and several applications). These mathematical tools were developed essentially in parallel in the fields of physics and biology, with the biological development driven by Wright and Fisher in the service of their genetic drift model. The techniques involve approximating discrete-time stochastic processes such as the Wright–Fisher Markov chain by similar continuous-time processes that are more amenable to analysis.

One useful consequence of a successful diffusion analyses is that it converts the basic Wright–Fisher model into a 'time-reversible' process, so that the process looks identical probabilistically whether one is looking forward or backward in time. This is not only convenient mathematically, it gives the familiar forward-time Wright–Fisher model added authority in the context of modern analysis methods which rely heavily on backward-time coalescent models. Meanwhile, the main alternative to the Wright–Fisher model of random genetic drift, the Moran model, uses an inherently time-reversible stochastic process.

Moran Model

P.A.P. Moran (1958, 1962) developed an alternative stochastic model of allele frequency evolution over time. Moran's model both differs strikingly from and complements the Wright–Fisher model: where the Wright–Fisher model uses discrete non-overlapping generations, in the Moran model generations overlap. Strictly speaking, the Moran model is a haploid model (although it can, with some cost in complexity, be modified to accommodate diploids), while the Wright–Fisher model has more inherent flexibility regarding ploidy. Lastly, while the Wright–Fisher model has an intuitively straightforward structure that is mathematically difficult to analyze, the Moran model has a much more mathematically tractable framework that comes perhaps at some cost to intuition.

Mathematical Framework of the Moran Model

The Moran model does not specify discrete generations for the population as a whole; instead, it follows the fate of individual allele copies in 'timesteps.' Each timestep involves the death of an allele copy and the reproduction (exact duplication) of an allele copy to replace the one that died (**Figure 4**). This simple structure ensures that the population size remains constant. The mathematical description of the process is further simplified by assuming that the two events (death and reproduction) are simultaneous, so that an allele copy's probability of being chosen for reproduction does not depend upon whether or not it was chosen for death.

We again begin with a single locus with two alleles, B_1 and B_2. Let Y_t be a random variable describing the number of B_1 alleles in a haploid population of size M. If, in the present generation t, $Y_t=i$, by the rules of the Moran model the only possible fates for Y_t in a single timestep (one death, one birth) are to increase by 1, to decrease by 1, or to stay the same.

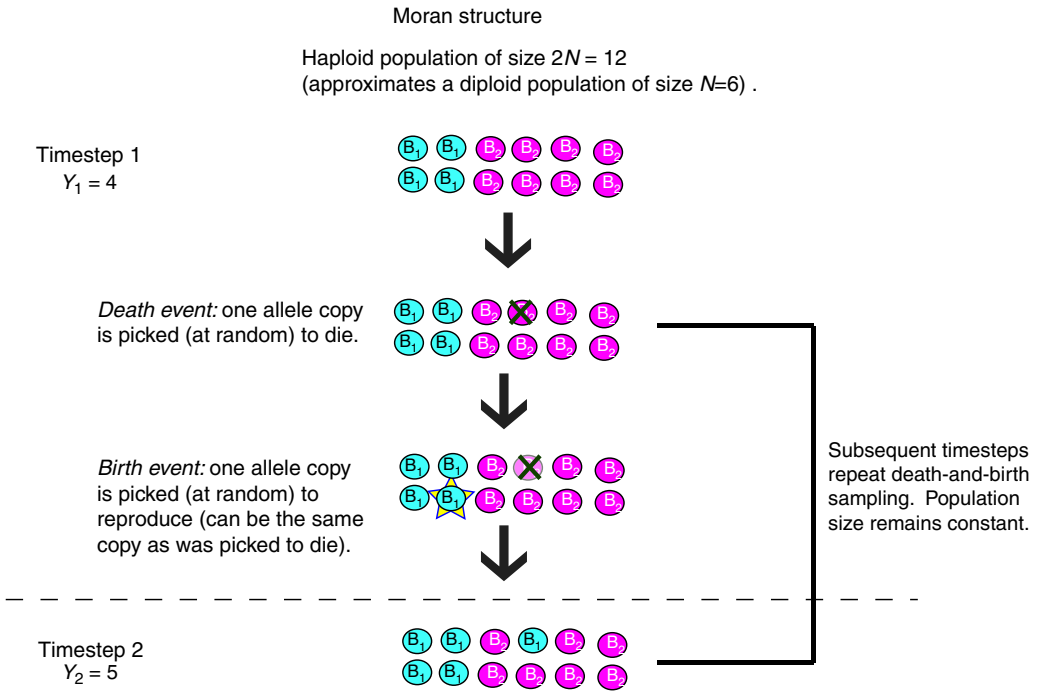

Figure 4 Structure of the Moran model. The population begins in a haploid representation, and is characterized by the number (Y_t) of a focal type of allele. Only (at most) two allele copies are affected in each timestep, and Y can only increase or decrease by (at most) one in any timestep. Each timestep consists of one birth and one death (possibly the same individual) of an allele copy. 'Birth' results in a replicate of the chosen allele copy replacing the allele copy chosen for death.

The probabilities of each type of outcome are:

$$P_{i,i-1} = \left(\frac{i}{M}\right)\left(\frac{M-i}{M}\right) \quad \text{for } i>0$$

$$P_{i,i+1} = \left(\frac{M-i}{M}\right)\left(\frac{i}{M}\right) \quad \text{for } i<M$$

$$P_{i,i} = \left(\frac{i}{M}\right)\left(\frac{i}{M}\right) + \left(\frac{M-i}{M}\right)\left(\frac{M-i}{M}\right)$$

In each case, the overall probability is obtained by multiplying probabilities of two independent events: an allele is picked to die, and an allele (possibly the same) is picked to reproduce. No other transitions are possible ($P_{i,j}=0$ if $|i-j|>1$), and so the Markov chain describing the timestep-by-timestep changes in the population has a relatively simple transition matrix compared to that of the Wright–Fisher model, with only the diagonal and immediately adjacent elements non-zero. This simple structure yields a model that is considerably more mathematically tractable than the Wright–Fisher model, particularly when extensions incorporating additional evolutionary forces (e.g., mutation, natural selection) are added. In addition, continuous-time diffusion approximations can still be applied to the Moran model, allowing for direct comparisons between the two models.

Direct Results from the Moran Model

Many of the basic results outlined for the Wright–Fisher model above have analogs in the Moran model. In particular:

Fixation probability of an allele

We can use the same intuitive argument given for the Wright–Fisher model and find again that the fixation probability of a neutral allele is equal to its initial frequency:

Probability of fixation = p0

Variance in allele frequencies over time

The variance in allele count from timestep to timestep is no longer the binomial variance of the Wright–Fisher model. It can be calculated from the general variance formula:

$$\mathrm{Var}[Y] = E\left[Y^2\right] - (E[Y])^2$$

where the capital E again indicates an expected value. Beginning with i B_1 alleles and letting $M=2N$ (so that the frequency of B_1 is $p=i/2N$, facilitating comparison with the Wright–Fisher results), after one timestep the expectation for Y is:

$$E[Y] = i$$

and

$$\begin{aligned} E\left[Y^2\right] &= (i-1)^2 P_{i,i-1} + (i+1)^2 P_{i,i+1} + (i)^2 P_{i,i} \\ &= (i^2-2i+1)P_{i,i-1} + (i^2+2i+1)P_{i,i+1} \\ &\quad + (i)^2 P_{i,i} \\ &= (i^2-2i+1)p(1-p) + (i^2+2i+1)p(1-p) \\ &\quad + i^2\left\{p^2 + (1-p)^2\right\} \\ &= 2p(1-p) + i^2 \end{aligned}$$

After one timestep of the Moran model, the variances in allele count and frequencies are:

$$\text{Var}[\text{count}] = 2p(1-p)$$

and

$$\text{Var}[\text{frequency}] = \frac{2p(1-p)}{(2N)^2}$$

There are two important mathematical differences between these results and the Wright–Fisher results. First, there is an extra $2N$ in the denominator of the variance in allele frequency. This is related to the difference between a Wright–Fisher generation (in which all $2N$ allele copies turn over at once) and a Moran timestep (which turns over allele copies one at a time). It might be expected a priori that $2N$ timesteps of the Moran model would be equivalent to 1 generation of the Wright–Fisher model. However, there is also an additional factor of two in the numerator of the Moran variance, meaning that drift in the Moran model proceeds roughly twice as fast as might be expected using this simple correspondence. Thus, in Figure 2 the Moran model prediction looks very similar to the 1-generation Wright–Fisher prediction after only five (rather than $2N=10$) timesteps have elapsed. In this case, the intensification of the drift process is due to an increased variance in offspring number, or reproductive output.

Reproductive output of individual alleles

In the Wright–Fisher model, the number of offspring of an allele copy was distributed as a Poisson random variable. The Moran model, by contrast, leads to a geometric distribution of offspring number. In every timestep in which a particular allele copy experiences an event, that event can either be reproduction (adding to the count of offspring) or death (the waited-for event that ends the series), with equal probability. The total number of offspring (reproductive events before the series-ending death) thus follows a geometric distribution with $p=1/2$:

$$D_{Mor} \sim \text{Geo}\left(\frac{1}{2}\right)$$

which has a mean of 1 and variance of 2 (contrast with the Wright–Fisher model's Poisson distribution of reproductive output, which has mean and variance of 1). The increased variance in offspring number increases the variability of outcomes and thus makes the population behave, with respect to random genetic drift, as if it is a much smaller population – the 'effective population size' (N_e) is half the census size.

Time-Based Results for the Moran Model

In the analysis of the Wright–Fisher model, approximate methods were required to obtain the expected time to fixation and other similar results. By contrast, all of the results below can be obtained in exact form from the Moran model Markov chain (see Ewens (2004) for an overview).

Given initial allele count i, we have:
Expected time to fixation or loss

$$= 2N(2N-i)\sum_{j=1}^{i}\frac{1}{2N-j} + 2Ni\sum_{j=i+1}^{2N-1}\frac{1}{j}$$

Expected fixation time, given fixation

$$= 2N\left(\frac{2N-i}{i}\right)\sum_{j=1}^{i}\frac{j}{2N-j} + 2N(2N-i-1)$$

and, for a new mutant:

$$\text{Expected fixation time for a new mutant, given fixation} = 2N(2N-1) \text{ time steps}$$

As predicted from our examination of the variance in allele frequencies from generation to generation, the timescale of random genetic drift (in the form of fixation of new mutants) in the Moran model differs from the timescale of the Wright–Fisher model by a factor of $2N/2$. The similar behavior of each model (once population size and time have been rescaled appropriately), despite very different structures (Figures 1 and 4), is encouraging. No population in nature has ever followed either model exactly in its mode of reproduction, but the convergence in results seen here suggests that it will very often be entirely appropriate to approximate a wide variety of naturally complex systems by one of these simple models.

Genetic Variation in Populations

H Hollocher, University of Notre Dame, Notre Dame, IN, USA

Glossary

Allele A variant form of a gene.
Amplified (or anonymous) fragment length polymorphism (AFLP) Polymerase chain reaction-based molecular tool that uses restriction enzymes to cut genomic DNA into fragments and adaptors to select a subset of the fragments for visualization on an electrophoretic gel.
Cytogenetics Microscopic analysis of chromosomes in individual cells.
Haplotype Alternative forms for a multisite genotype in a defined DNA region.
Identity by descent Identical alleles in two or more individuals in a population due to shared ancestry.
Identity by state Identical alleles or phenotypes in two or more individuals in a population derived from separate mutations, not shared ancestry.
Insertions and deletions (indels) Class of DNA changes that involves the addition (insertion) and/or the removal (deletion) of small numbers of base pairs in the sequence.
Karyotype The number and appearance of chromosomes in the nucleus of a eukaryotic cell.
Microsatellite sequences Tract of repetitive DNA comprised of two to four base pairs repeats occurring at a high number of different locations throughout the genome
Minisatellite sequences Tract of repetitive DNA comprised of 10–60 base pair repeats occurring at a high number of different locations throughout the genome.
Mitochondrial DNA (mtDNA) DNA located in the mitochondria, which are cellular organelles responsible for energy production within eukaryotic cells.
Phylogenomics Analysis that involves genome data and the reconstruction of evolutionary relationships between taxa.
Polymerase chain reaction (PCR) Molecular technology that is used to amplify single copies of DNA regions several orders of magnitude for analyses.
Polymorphism The condition of occurring in many different forms.
Population genetics The field of study of the distributions and changes in allele frequencies within and between populations over time.
Population genomics Population genetics extended to include analyses involving whole genome data.
Restriction fragment length polymorphism (RFLP) analysis Molecular tool that uses restriction enzymes to cut genomic DNA into fragments for visualization of genetic variation on an electrophoretic gel.
Single-copy nuclear DNA (scnDNA) DNA regions that occur only once in the nuclear genome.
Single nucleotide polymorphism (SNP) Class of DNA variation that involves changes in nucleotide identity of individual base pairs in the sequence.
Y DNA Molecular markers mapping to the Y sex chromosome of an organism.

Introduction

Nothing is as fundamental to evolutionary biology than genetic variation. That is because genetic variation is the engine of all evolutionary change. Genetic variation can be defined as hereditary differences within or between populations and species. Without these hereditary differences, there is nothing on which natural selection can act. Going beyond natural selection alone, without genetic variation, there can be no change of any sort over time. In short, without genetic variation, there can be no evolution.

Population genetics is the study of the distributions and changes in the genetic compositions of populations and species over time. Population geneticists have developed numerous abstract mathematical models that allow them to predict how genetic variation will change in the future under the influence of different evolutionary processes, such as mutation, natural selection, nonrandom mating and sexual selection, random genetic drift, and gene flow between populations. In practice, population geneticists examine patterns of extant genetic variation and use abstract theory to infer how each of these evolutionary processes may have played a role in shaping this variation in the recent and more distant past. With this approach, population geneticists are able to identify specific loci under the influence of natural selection, deduce the relationships of different populations and species across both space and time, and infer historical changes in population sizes and dispersal events that are important for facilitating or constraining divergence and the emergence of new species.

Types of Genetic Variation

Population geneticists are interested in all types of genetic variation and have been throughout history. The types of variation that have been utilized by evolutionary biologists have ranged widely from morphological variation to chromosomal variation to assessing variation at individual loci to whole genome scans today. As molecular genetic techniques have advanced, so has the ability of population geneticists to detect patterns of genetic variation at higher and higher levels of resolution.

Morphological Variation

Biodiversity in the world is manifested most obviously by morphological variation. Morphological differences between

 doi:10.1016/B978-0-12-800049-6.00021-4

species are the most apparent. However, almost all natural populations also show some form of variation in morphological traits between individuals. Before an actual mechanism of inheritance was established, it was still understood that a good portion of this morphological variation was heritable, and therefore, represented what we now know to be genetic differences between individuals. The desire to explain the generation and maintenance of morphological variation at all levels (from individuals through species) has been a driving force throughout the history of the development of evolutionary thought (Young, 2007).

Morphological traits are often classified as being either Mendelian or quantitative. Variation in both types of morphological traits represents genetic variation, albeit with different underlying genetic bases. For Mendelian traits, generally only a few loci with relatively large effects on phenotype are involved (referred to as Mendelian Genetics; see Griffiths *et al.*, 2015). For quantitative traits, many more loci are involved each with smaller individual effects on phenotype in addition to environmental influences on their expression (referred to as Quantitative Genetics; see Falconer and Mckay, 1996). The foundation of our understanding of genetics was formulated through the analyses of the transmission of phenotypic traits across generations, whether looking at Mendelian or quantitative traits. Although different mathematical formulations are used to analyze these different classes of traits, both follow the same basic underlying principles of inheritance.

With respect to evolutionary genetics, perhaps there is no model organism that has been as influential on advancing our understanding of genetic variation as *Drosophila* has been. Developed as a model organism by Thomas Hunt Morgan and his colleagues in the early 1900s, *Drosophila* has continued to have profound impacts on population, developmental and molecular genetics for 100 years (Kohler, 1994; Powell, 1997). One particular colleague of Morgan's who changed the face of evolutionary genetic studies was Theodosius Dobzhansky, who took the rigors of genetics being developed in the laboratory and applied them to natural populations. While most variation associated with fitness in natural populations does not have a simple genetic basis, Dobzhansky was able to use technological tools developed in *Drosophila* (such as Balancer chromosomes, which can be used to isolate whole chromosomes without recombination) to assess the rate and accumulation of lethal mutations in natural populations. This research proved very important for empirically testing theoretical models describing the action of natural selection operating on lethal mutations and the evolutionary dynamics involved in maintaining genetic variation underlying fitness (Dobzhansky and Wright, 1941).

Chromosomal Variation

A major breakthrough in assessing genetic variation in natural populations came about with the advent of cytogenetics and the ability to visualize the karyotype of individuals. Here population geneticists were able to look directly at genetic traits rather than only assessing genetic variation based on the expression of different phenotypes. A peculiar property of *Drosophila* is the polytene chromosomes in their salivary glands where hundreds of rounds of DNA replication occur without cell division. The result is visible chromosomes with distinctive banding patterns that can be used as unique identifying genetic markers. The banding patterns could be compared between individuals and stretches where the banding patterns were inverted relative to each other (termed inversions), were very useful for looking at genetic variation in populations. A major advantage was that one could observe genetic variation in the microscope directly. Examining inversion polymorphisms became the cornerstone of early population genetics and allowed researchers to look at natural selection operating on large blocks of linked loci in wild populations of *Drosophila* (Dobzhansky, 1937). Inversion polymorphisms were also used to construct some of the first phylogenetic relationships based on genetic information and were informative both for looking at relationships within species (*Drosophila pseudoobscura*: Dobzhansky, 1938) as well as between species (Hawaiian Picture-winged *Drosophila*: Carson, 1983) for over half a century.

Although polytene chromosomes are unique to a subset of organisms, karyotype analyses can be performed on any eukaryotic organism. The variation revealed in chromosome shape and number opened up the door for cytogenetics to be useful for evolutionary studies beyond *Drosophila*. Many organisms were found to have supernumerary chromosomes (also sometimes referred to as B chromosomes), which would vary in number and provide material for assessing genetic variation in species for which crosses are not possible (Palestis *et al.*, 2004; Jones *et al.*, 2008).

Protein Variation

The application of protein electrophoresis in the 1960s to the study of genetic variation in natural populations marks a critical turning point in the development of population genetics. Protein electrophoresis allowed for the separation of soluble proteins based on size and charge. Differences in amino acid composition could shift a protein's electrophoretic properties allowing for the detection of genetic differences between individuals. A substantial advantage to utilizing protein electrophoresis is that no breeding of the study organism was necessary. This opened the door for the population genetic analysis of any natural population of organisms and allowed for generalizations to be made beyond what could be gleaned from the handful of model organisms available at the time.

Population geneticists could look at how variable proteins were across multiple loci simultaneously (i.e., average polymorphism) and how often individuals carried different alleles at a particular locus (i.e., average heterozygosity) (Hartl and Clark, 2007). These measures gave a better metric for determining how variable populations were across a vast spectrum of organisms and revealed that although generally speaking increases in heterozygosity went hand in hand with increases in polymorphism, there was quite a bit of variability across populations as governed by differences in population size, mating, natural selection, and gene flow.

More variation than was previously imaginable was revealed (Hubby and Lewontin, 1966; Harris, 1966), leading

researchers to propose alternative explanations for the maintenance of variation beyond directional natural selection (e.g., balancing selection with heterozygotes having highest fitness and background purifying selection acting on recessive deleterious mutations). Another explanation proposed at that time that gained traction was that not all the genetic variation we see is subject to natural selection, because not all of the genetic variation revealed leads to differences in fitness, supporting the neutral theory of evolution proposed by Kimura and Crow (1964).

DNA Variation

If protein electrophoresis represented a renaissance in population genetics, the advent of direct deoxyribonucleic acid (DNA) analyses represented a revolution and led to a new branch of population genetics referred to as molecular evolution (Graur and Li, 2000). DNA analysis remains the principle approach used to describe genetic variation to this day. An advantage is that genetic variation can be assessed in any stretch of DNA, and is no longer confined to soluble proteins or even coding regions of the genome. Additionally, DNA studies no longer rely on gross mobility shifts as in protein electrophoresis, but can obtain a much higher level of resolution of the genetic changes. Most importantly, DNA analysis allows for the determination of *identity by descent*, the ability to trace multiple copies of a DNA segment in a population back to a single common ancestor in the past. Theoretical population genetics relies on identity by descent as a central organizing principle for describing evolutionary change. This is in contrast with *identity by state*, where two proteins may appear identical but actually represent proteins with different evolutionary histories because of changes that cannot be revealed by protein electrophoresis (i.e., showing convergence in phenotypic state). This is not to say that convergence cannot occur with DNA markers as well, but the resolution is often high enough to be able to distinguish between identity by state and identity by descent. Previously identified protein electrophoretic types were revealed to harbor an abundance of genetic variability in the noncoding and flanking regions of the locus not detectable from protein electrophoresis alone. This increased molecular resolution was very important for determining the evolutionary relationships between different alleles and inferring the mode of selection operating on the protein level that was most important for maintaining the genetic variation (Aquadro *et al.*, 1986; McDonald and Kreitman, 1991).

To assess genetic variation, Restriction Fragment Length Polymorphism (RFLP) analysis was commonly used. RFLP analysis involves cutting a target segment of DNA with restriction enzymes and looking at variation in lengths of the fragments that result. RFLPs reveal differences in the sequences underlying the restriction enzyme cut sites. A more direct assessment of changes occurring on the DNA level is to sequence the DNA segment of interest to reveal single nucleotide polymorphisms (SNPs) or small insertions and deletions (indels). In this manner, a direct read of the bases along a stretch of DNA can be made. Direct sequencing was technically more demanding than RFLP analyses, but as technological advances were made using polymerase chain reactions (PCR) to amplify specific DNA regions of interest that required very little amounts of starting material, direct sequencing became the popular standard for assessing genetic variation that remains to this day. The generation of sequence data has led to new measures of genetic diversity based on polymorphic nucleotides segregating in a population (θ, theta) and average proportion of nucleotide differences between all possible pairwise comparisons of sequences in a population sample (π, pi) (Graur and Li, 2000; Hartl and Clark, 2007). RFLPs also use similar measures, albeit with lower resolution, if it is assumed that there is only one nucleotide site change per restriction site difference. These are now the standard measures of genetic variation that are used today, similarly to how polymorphism and heterozygosity measures were used for protein electrophoresis in the past.

Highly Polymorphic Molecular Markers

While DNA sequencing was still relatively expensive for large population surveys, other methods for detecting DNA variation were developed in parallel, taking advantage of repeated genetic elements that are highly variable and very abundant across the genome in most eukaryotes. Higher levels of variability often translate into greater power in detecting population level processes operating during evolution, which makes these genetic markers valuable tools still used to this day (Avise, 2004; DeYoung and Honeycutt, 2005). These techniques also allow for the assessment of multiple loci in comparison to sequencing which normally relied on single-locus evaluations.

Repeated genetic elements fall into different categories based on the length of the repeat and the number of times it is repeated in the genome. Minisatellite DNA refers to sequences of approximately 10–60 base pairs in length that show a variable number of tandem repeats throughout the genome. Microsatellite DNA is comprised of even shorter repeated units (di-, tri-, or tetra-base pair repeats) that occur in higher numbers of tandem arrays throughout the genome. Both of these molecular markers have been very useful for DNA fingerprinting of individuals in populations and for assessing variability on short time scales. Multi-locus analyses of these markers can be very complex, because of the number of fragments being analyzed and overlap in size classes that cannot be easily attributed to a specific locus. However, composite single-locus approaches have helped.

A combination of PCR-based and RFLP-based approaches is Amplified (or Anonymous) Fragment Length Polymorphism (AFLP) analysis. In this case, total genomic DNA is digested with restriction enzymes. The cut sites serve as anchors for adding adaptor sequences which are then used as primer sites for PCR amplification, resulting in a range of amplified fragments that vary in size. Although the specific loci being surveyed in this case are unknown, these approaches are very good for surveying large numbers of loci simultaneously which has proven to be very useful in mapping studies. There are some problems with amplification in AFLP studies, however, where amplification of one allele in a heterozygote maybe favored over the other allele as well as other issues with

reproducibility, indicating that the results would need to be interpreted with caution.

All of these molecular markers have the advantage of revealing high variability, which is very important for certain applications in population genetics; however, these approaches also lose the ability to infer identity by descent directly. Additional assumptions are needed for the evolution of these markers in order to place them in a population genetics framework. Without accurate estimates of actual identity by descent, direct use in population genetic models of these highly variable markers becomes less powerful. Combining microsatellite analyses with sequence information from the flanking regions has been useful for understanding the evolutionary dynamics of these markers and recovering more direct identity by descent information in population studies (Schlotterer, 2000; Chatrou *et al.*, 2009). In any event, by using highly variable markers over very short generational time scales, researchers can be pretty confident about assuming identity by descent. The much higher levels of variability and relatively low costs, outweigh the loss of direct descent in certain applications.

Applications of Different Tools

Different measures of genetic variation capture different temporal scales of relatedness between individuals, populations, and species. Therefore, different classes of molecular data (e.g., RFLP, DNA sequence, microsatellites, etc.) will be more effective at answering different types of evolutionary questions than others. There are advantages to using the highly variable markers (such as minisatellite or microsatellite markers) across several loci as compared to using sequencing approaches with fewer loci. Even with the same type of molecular tool being employed, different parts of the genome experience different evolutionary histories because of their mode of inheritance and mutational constraints. As a result, the genome is actually a mosaic of evolutionary information with different parts of the genome representing different depths of evolutionary time (Graur and Li, 2000; Avise, 2004; Templeton, 2006).

For example, animal mitochondrial DNA (mtDNA) is haploid and maternally inherited in most species. These characteristics leave mtDNA more subject to drift than other parts of the genome and can reveal population dynamics that have occurred over relatively recent time scales. Similarly, animal Y DNA is also haploid (there is very little homologous DNA in comparisons of the X and Y chromosomes) and is paternally inherited making this molecular marker also more subject to genetic drift effects. In addition, high variance in male reproductive success further reduces the effective population size for Y DNA causing it to evolve even more rapidly than mtDNA. As a result, Y DNA is a very good marker for differentiating populations and looking for episodes of recent gene flow. Single-copy nuclear DNA (scnDNA) is associated with autosomes, which are diploid and biparentally inherited. These markers evolve more slowly than mtDNA and Y DNA markers because they are less subject to drift and experience lower rates of mutation due to more efficient DNA repair mechanisms. As a result, scnDNA markers typically exhibit more standing genetic variation in populations than mtDNA and *Y* DNA and can reveal population histories dating further back than the haploid, unisexually inherited markers. Molecular markers on sex chromosome (X or Z, depending on species) show temporal patterns of evolution on average that are intermediate between mtDNA and Y (or W) DNA markers and autosomal markers because of sex chromosomes being diploid in one sex, but hemizygous in the other (i.e., being paired with a nonhomologous sex chromosome with which it does not freely recombine).

Plants also have mtDNA, yet this haploid genome exhibits unusual patterns of variation and tends to be highly variable with respect to gene order, but very conserved with respect to sequence changes, making it more difficult to use as a molecular marker for evolutionary analyses. Plant chloroplast DNA (cpDNA), on the other hand, follows more standard models of evolutionary change similar to mtDNA in animals, albeit with rates of mutation that are much slower, making it a better molecular marker for questions involving more distantly related taxa (Avise, 2004).

The types of molecular markers used in a given study depends on the questions being addressed, the availability of molecular markers in the study system, the amount of variation present for those markers, and costs (DeYoung and Honeycutt, 2005). The best approach is to use multiple markers from more than one genome region. Different regions of the genome are expected to respond differently to the same underlying population processes, allowing for independent estimates of events that have occurred at different temporal scales (Templeton, 2005). Researchers can also tailor their molecular markers to suit different rates of evolutionary change by choosing particular loci experiencing different selection constraints or even confine their analyses to different parts of the DNA region (e.g., DNA changes that do not alter the protein amino acid sequence, such as synonymous change, versus DNA changes that do alter the resulting amino acid sequence, such as nonsynonymous changes, which are expected to evolve at different rates with synonymous changes following more neutral expectations of change).

Which molecular marker is chosen depends on the evolutionary time scale that the question being addressed encompasses. For questions that rely on identification of unique individuals in the population, such as parentage analyses, the markers that evolve more quickly and provide higher levels of variation across multiple loci will be more informative than more slowly evolving markers. Conversely, for questions that aim to relate evolutionary taxa across deeper time scales, markers that evolve more slowly would necessarily need to be employed. **Table 1** provides an approximation for which markers would be most useful for which applications.

Future Directions: Whole Genome Approaches

With technological advances allowing for increased automation of sequencing, more studies of natural populations are aiming to assess genome-wide patterns of genetic variation, opening up new areas of inquiry in population genomics (Ellegren, 2014) and phylogenomics (Lemmon and Lemmon,

Table 1 Applicability of Different Molecular Markers to Different Questions in Evolutionary Biology

2013). Although these whole genome approaches do not necessarily provide greater resolution of variability on the molecular level, they do provide greater statistical power resulting from the shear magnitude of the number of genetic elements that can be analyzed, which has led to new insights and approaches to studying evolutionary processes.

Up to this point, traits that had been identified as being important in adaptation were first identified phenotypically and then used to map the underlying loci to analyze the evolutionary processes involved. Through the application of whole genome approaches, adaptive traits no longer need to be defined a priori and whole genome scans looking for patterns of variation relative to neutral expectations allow for the direct identification of DNA regions that have been under different types of selection (e.g., positive selection versus purifying selection). Different types of selection will leave specific genetic footprints of increased or decreased genetic variation in the genome that can then be studied further.

The same type of whole genome scan approach can be used to look at which parts of the genome may be more subject to gene flow between populations or newly evolving species. Identifying regions that are more or less permeable to gene flow between diverging populations can reveal DNA regions that may be important for providing reproductive barriers (either because of reproductive incompatibilities in the genome or strong selective difference of traits in different ecological contexts) in the early stages of species divergence (Feder *et al.*, 2012; Sousa and Hey, 2013). These types of considerations have also been very important for using whole genome information for phylogenetic reconstruction, where careful data selection of DNA regions to include in the analyses is critical for obtaining accurate taxa relationships (Lemmon and Lemmon, 2013). Once relationships have been established, they can be used to test hypotheses about the origins of adaptive genetic variation leading to phenotypic divergence (Feder, *et al.*, 2012; Ellegren, 2014).

Other Considerations and Controversies for Future Research

Just as the historical trend has been to move closer and closer to the genetic elements over time, there is a more recent reversing trend to try to move back to analyzing the adaptive traits themselves. This has taken different forms, but one large-scale approach has been evolutionary proteomics, which looks at the whole genome dynamics of protein expression, regulation, and interactions within an evolutionary context (Diz *et al.*, 2012). Although these types of studies are moving back to identity by state rather than identity by descent, the argument is that we are ultimately getting closer to studying the actual traits that matter (i.e., protein phenotypes involved in adaptation, as opposed to only the DNA sequences that underlie them). Another emerging large-scale approach has been the analyses of whole genome gene expression (termed the transcriptome). Researchers are combining whole genome sequencing with gene expression analyses to directly connect changes in DNA sequences to changes in expression and the ultimate development of morphological differences within and between species (e.g., humans and chimpanzees: Prescott *et al.*, 2015), coming back full circle to the detailed analysis of the type of variation that was originally of interest to population and evolutionary geneticists.

Although these studies investigating changes in gene regulation and the role of development in evolution have been exciting, they have also reignited controversies centered around determining whether structural changes in proteins or changes in gene regulation have been more important in adaptation (Hoekstra and Coyne, 2007; Wray, 2007). Part of this controversy stems from lumping morphological change with all types of adaptive change, which may not always be morphological in nature. In any event, the relative importance of regulatory versus non-regulatory genetic variation underlying adaptation is yet to be determined.

The controversy surrounding the nature of genetic variation underlying adaptive traits may also lie in differences in scale that have often been used to provide evidence of the relative importance of regulatory and non-regulatory change in evolution. A relevant, yet still controversial, insight stemming from studies of evolution and development centers on the nature of genetic variation at different scales of divergence (Stern, 2011; Hollocher *et al.*, 2013). The assumption has been that within-species genetic variability and genetic differences between species are similar and follow the same basic assumptions of evolutionary change. In that respect, the assumption has been that the study of evolutionary dynamics occurring within species can be used to extrapolate

to the processes underlying speciation. However, patterns are beginning to emerge that suggest that changes underlying long-term evolution may be regulatory in nature, while the vast majority of mutations underlying short-term evolution are not regulatory. Therefore, short-term, within-species variation is quite different from the long-term changes that move to fixation in entire species. If this generalization proves to be true, then this insight could fundamentally change our understanding of the evolution of morphology and our concepts of the genetic variation underlying species divergence.

Additional complexity is presented by changes that involve epigenetics. Up to this point, all discussion of genetic variation have been concerned with changes in DNA sequence, which then can be inherited across generations to serve as the engine of evolutionary change. However, with the discussion of gene expression and development, comes an enhanced appreciation of the role epigenetic changes may play in evolutionary processes. Epigenetic changes are those genetic modifications that control gene expression that give rise to variable phenotypes even when the underlying genetic sequences are identical (West-Eberhard, 2003; Jablonka, 2013). The relevance and evolutionary significance of epigenetics is not completely understood and highly controversial with several researchers claiming that the evolutionary consequences of epigenetic variation have not been adequately accommodated in standard models of evolution (Laland, *et al.*, 2014), while others say that they have (Wray *et al.*, 2014). These ideas have been extended to include other processes beyond the interplay of epigenetics and development, looking at the role of behavior and learning on the subsequent evolution of populations (termed niche construction; Bateson and Gluckman, 2011; Jablonka and Lamb, 2014), revealing the potential for these processes to shape evolutionary trajectories and influence rates of change. Whether one sides with one camp or the other (and there is some evidence that both camps are talking about similar phenomena, but with different emphases; Scott-Phillips, *et al.*, 2014), the impact of epigenetics and other nongenetic modes of inheritance is an area of investigation that complements ongoing studies of changes in DNA sequence to help advance our collective understanding of the roles all different types of variation play in evolution.

Genetic Variation, Maintenance of

HG Spencer, University of Otago, Dunedin, New Zealand

Glossary

Balancing selection Any form of natural selection that balances or actively maintains genetic variation in a population.

Effective population size (N_e) An idealized population size in which the effects of genetic drift are the same as in the population under study. This concept allows us to compare populations with geographical or age structures, different number of males and females, etc. In most cases, the effective size is less (sometimes considerably less) than the actual size.

Equilibrium (in the context of allele frequencies) Values that do not change from one generation to the next. An equilibrium can be stable, unstable, or neutral. A stable equilibrium is one to which the population returns if, for some reason (e.g., random changes due to genetic drift), the values are disturbed by some small amount. Heterozygote advantage in a two-allele model gives a stable polymorphic equilibrium. An unstable equilibrium is one from which a population moves further if the allele frequencies are perturbed (e.g., the polymorphic equilibrium for heterozygote disadvantage with two alleles). Allele frequencies neither return to nor move further away from a neutral equilibrium.

Genetic load The reduction in the mean fitness of a population compared to the fitness of the optimal individual.

Heterozygote advantage A model of selection (especially one with just two alleles) in which heterozygotes have higher fitnesses than homozygotes.

Heterozygote disadvantage A model of selection (especially one with just two alleles) in which heterozygotes have lower fitnesses than homozygotes.

Polymorphic Consisting of two or more variants (usually alleles).

Segregational load A form of genetic load arising from segregating variation maintained by balancing selection.

Introduction

Natural populations of most diploid organisms are characterized by genetic differences among individuals. This variation is vital to the adaptation and long-term survival of each species: genetic variation is often described as the 'fuel' for natural selection. Just why this genetic variation is present, however, is unclear. The two most prominent population-genetic theories (selectionism and neutralism) appear to predict patterns of variation inconsistent with those observed in nature. This mismatch between theory and observation has been dubbed 'the paradox of variation' and held to be the central problem in population genetics. On the one hand, selectionist explanations emphasize the current adaptive value of genetic variation: different genotypes have different viability or fertility and their frequencies are actively maintained by selection. On the other hand, neutralists argue that variation is selectively equivalent and that genetic drift is the primary process governing allele frequencies, which change randomly over time. Of course, different explanations may be correct for different genes and some combination of the two theories may apply. In this article we outline these theories, discussing their various strengths and weaknesses.

The Evidence

Many debates in population genetics in the 1950s centered around the levels of genetic variation that were present in natural populations. The technology of the time, however, was not able to provide a definitive estimate; it was not until the advent of gel electrophoresis in the 1960s that the question was apparently settled. In short, electrophoretic data were interpreted as showing that genetic variation was at high levels in nearly all populations, a conclusion that was reinforced when the results of direct DNA sequencing became available. Today it is clear that genetic variation is ubiquitous in populations of nearly all diploid species (and many haploid taxa, too) for almost all genes. Just why this variation is present, however, is not immediately clear.

Hypothesis 1: Natural Selection

One possible explanation is that this variation is actively maintained – balanced – by natural selection, a view sometimes described as the 'selectionist paradigm' or the 'balance school.' This view derives from the argument that individuals harboring genetic variation have a selective advantage: variation is intrinsically beneficial to its bearers (Lerner, 1953). Certainly, it is clear that highly inbred (and hence largely homozygous) individuals have generally lower fitnesses. Heterozygotes may also have an advantage in being more phenotypically flexible, being able to present two versions of the gene product being coded at the locus in question. For example, the allelic differences may result in proteins that have their optimal catalytic functions at slightly different temperatures and so heterozygotes can function better over a wider range of physiological or environmental conditions than either homozygote.

Hypothesis 2: Genetic Drift and Mutation

A second possible explanation is that the observed variation, rather than being actively maintained, is in constant flux, with

the overall level of variation being at some steady state even though its constituents are continually being turned over. The 'neutral hypothesis' or 'neutralist school' argues that standing variation is equivalent with respect to selection, a consequence of its generation by (neutral) mutation and its elimination by genetic drift (Kimura, 1968). The role of selection is confined to the purging of deleterious mutations (which constitute the vast majority of novel mutations). This view derived, in part, from considerations of the molecular biology of genes and proteins, where it was difficult to envisage a genuine selective difference for much of the variation observed (e.g., differences in codons' 3rd positions that made no difference to the protein being encoded).

Problems with the Selectionist Hypothesis

Both hypotheses have theoretical and empirical weaknesses. For example, the intuition underlying the balance school suggests that selection in the form of heterozygote advantage underlies the observed levels of genetic variation. Interestingly, this model is unique among the classical, one-locus, two-allele models of constant viability selection in maintaining both alleles at a stable equilibrium: heterozygote advantage is both necessary and sufficient to ensure that any population with allele frequencies close to those at this equilibrium will evolve toward that equilibrium. All other classical models with constant viabilities (e.g., deleterious recessive) predict that genetic variation should eventually be depleted. (Compare Figures 1 and 2.)

Unfortunately, when this basic model is extended to more than two alleles, the situation is less clear. For a start, the very meaning of 'heterozygote advantage' becomes ambiguous. We could mean simply that each heterozygote is fitter than its two corresponding homozygotes, or we could require the stronger condition that all heterozygotes are fitter than the fittest homozygote. Ironically, whatever our definition, it turns out that heterozygote advantage is neither necessary nor sufficient to maintain all the alleles at a stable equilibrium. In other words, it is possible to find fitness parameters that do not fit our definition that afford a stable fully polymorphic equilibrium, as well as other fitnesses that do meet our definition that nevertheless lead to the elimination of one or more alleles. Lewontin *et al.* (1978) exhibit counterexamples to both the necessity and sufficiency of 'heterozygote advantage' in maintaining even 3 alleles at equilibrium.

A related issue is that the sorts of fitnesses that are able to maintain larger number of alleles at an equilibrium are highly unusual. In a simulation study, Lewontin *et al.* (1978) generated random sets of $n(n+1)/2$ viabilities for a population with n alleles (and hence $n(n+1)/2$ different genotypes) for $n=2$, 3, 4, 5, and 6 in different simulations, and asked what proportion of these sets allowed a stable equilibrium with all n alleles present. For $n=2$, heterozygote advantage is both necessary and sufficient and thus we know the answer is 1/3, since there are 3 viabilities needed (for the two homozygotes and one heterozygote) and the chance that the heterozygote fitness in the largest of the 3 viabilities is 1/3. For $n>2$, however, there is no intuitive explanation. Simulations showed that the proportion rapidly becomes minute: for $n=3$, the proportion was ~ 0.042, for $n=5$, it was 6×10^{-5}, and for $n=6$, not one in 100 000 sets yielded a stable 6-allele polymorphism. Note that the viability sets that did maintain all n alleles did not necessarily display heterozygote advantage, however defined (except for $n=2$). Clearly, being able to maintain n alleles for larger values of n is a very unusual property of fitness sets.

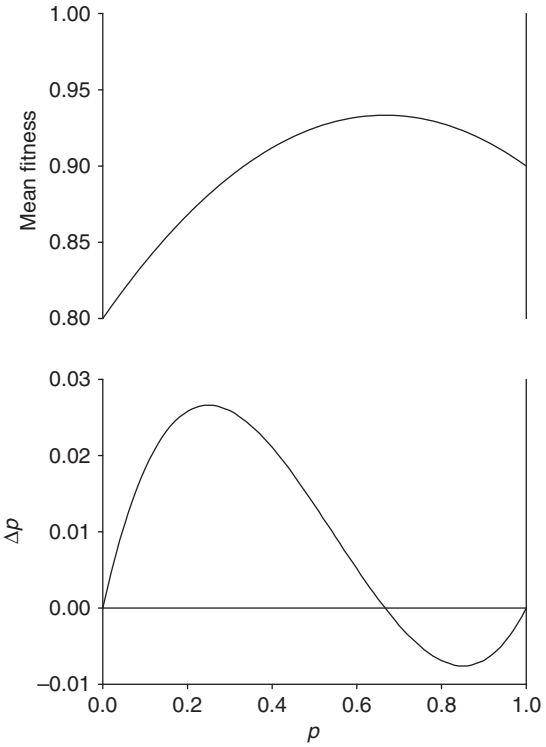

Figure 1 Mean fitness of the population (above) and change in frequency of allele A_1 (below) under an example of heterozygote advantage with 2 alleles. The fitness of A_1A_1 homozygotes is 0.9, that of A_2A_2 homozygotes 0.8, compared to A_1A_2 heterozygotes with a fitness of 1.0. Note that for frequencies of A_1 below $^2/_3$, the change in frequency of A_1 is positive (i.e., it increases); above this value the change is negative (i.e., A_1 becomes rarer). Hence, A_1 moves closer to the stable equilibrium frequency of $^2/_3$ every generation. At the same time A_2 moves toward a stable equilibrium frequency of $^1/_3$. Since both alleles are present at this equilibrium, it is polymorphic. Its stability means that this form of selection maintains variation in the population. This equilibrium frequency also maximizes the population's mean fitness.

These findings were interpreted as showing that the likelihood of such sets occurring in nature was minute. But such a conclusion is a logical fallacy: the size of parameter space is not a measure of likelihood, especially in a system that evolves over time. In another simulation study, Spencer and Marks (1988) showed that recurrent mutation at a locus could lead to the occasional successful invasion of a population by a new allele and the building up of polymorphism over time. Indeed, after 10 000 generations, with just one mutation per generation, the simulated populations possessed an average of more than 5 alleles (Marks and Spencer, 1991). These ideas have been applied to various other forms of selection (e.g., frequency-dependent selection, spatially variable selection,

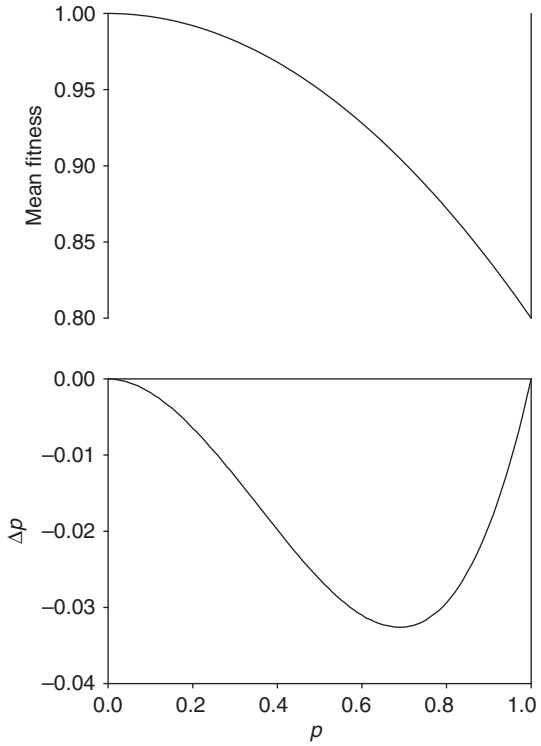

Figure 2 Mean fitness of the population (above) and change in frequency of allele A_1 (below) under an example of deleterious recessive with 2 alleles. The fitness of A_1A_1 homozygotes is 0.8, compared to A_1A_2 heterozygotes and A_2A_2 homozyotes with fitnesses of 1.0. Note that for all non-trivial frequencies of A_1, the change in frequency of A_1 is negative (i.e., A_1 becomes rarer). Hence, A_1 moves closer to the stable equilibrium frequency of 0 every generation. At the same time A_2 moves toward a stable equilibrium frequency of 1. Since only A_2 is present, this equilibrium is monomorphic, not polymorphic. Its stability means that this form of selection does not maintain variation in the population. Nevertheless, this equilibrium frequency also maximizes the population's mean fitness.

differential selection on males and females) and the overall conclusion is similar: variation is constructed over time under simple combinations of mutation and selection. Nevertheless, it is not clear if these models are sufficiently realistic. For example, one possible disconnect is that many of the simulations generated some form of heterozygote advantage and yet convincing cases of this form of selection acting in natural populations are extremely rare.

A different theoretical problem arises when variation at many loci is considered. Under simple models of selection such as heterozygote advantage at a single locus, the mean fitness of the population is lower than that of the ideal (heterozygous) genotype. This reduction in fitness is called the 'segregational load,' a form of 'genetic load.' When multiple loci are considered, it seems reasonable to assume that effects of each locus are independent and so fitnesses combine multiplicatively. Doing so, however, leads to an absurdity if large numbers of loci have variation maintained by these forms of selection: the mean fitness becomes ridiculously small compared to that of the ideal, multiply-heterozygous types (see Lewontin (1974) and Kimura (1983) for the details of this criticism). Different forms of selection, such as frequency-dependent selection, are less subject to this problem, but it has not been satisfactorily answered.

Finally, as mentioned above, convincing cases of genetic variation in natural populations that are actively maintained by selection are rare. In part, this absence of evidence reflects the difficulty of measuring selection in the wild, but if it is due to a real dearth of examples, then the selectionist hypothesis needs significant modification.

Problems with the Neutralist Hypothesis

One of the attractive features of neutralism is that it leads to clear, mathematically derived predictions (Kimura, 1983). For example, the rate of molecular evolution (i.e., the rate at which neutral alleles are replaced by others) should be equal to the neutral mutation rate, independent of population size. Evidence from numerous studies, however, suggests that population size may have an effect and that over short time scales, this prediction is not borne out.

The neutral theory also makes predictions about the levels of variation to be expected in populations. For instance, the expected level of heterozygosity, H, in a population of effective size N_e subject to neutral mutation at a rate μ is given by

$$H = \frac{4N_e\mu}{1 + 4N_e\mu}$$

Thus, larger populations (everything else being equal) should harbor more variation (whether measured using H or other measures), but this prediction is only weakly supported, with most species' levels of variation falling in a rather narrow range. Similarly, the amount of variation within a species should be positively correlated, as one moves across the genome, with the amount of divergence from a closely related species, and yet in a number of cases, this correlation turns out to be negative. Finally, again as one moves across the genome, the neutral theory predicts no correlation between recombination rates and polymorphism, but numerous observations show a positive relationship. Hahn (2008) and Wagner (2008) expand on these and other problems with neutralist predictions. Unfortunately, many of these predictions require the study system to be in a 'steady state,' which in practice requires a very long period of constant conditions (e.g., mutation rate, population size, absence of selection at nearby loci).

Possible Solutions

More complex forms of selection, such as frequency-dependent selection, density-dependent selection, spatially and temporally variable selection, and differential selection on males and females can also maintain variation. For example, 'negative frequency-dependent selection' in which rare types are favored can often preserve allelic variation. Such selection pressures naturally arise when the alleles concerned confer resistance to parasites (or disease). Hosts carrying common alleles are likely to have been encountered by the parasite, which may then have developed resistance to the effects of

these common alleles. Hosts bearing rare alleles, however, are less vulnerable to the parasite and so have higher fitness. The evidence for frequency-dependent selection acting in natural populations is much stronger, and it does not lead to the same segregational-load issues as heterozygote advantage. Similarly, density-dependent selection, in which selection coefficients depend on the population size can also maintain genetic variation without the same load issues. Spatially variable selection, reflecting the different selection pressures arising from environmental heterogeneity, and variation in selection pressures over time (at different stages of an organism's life cycle or from one generation to the next) would also seem to be more realistic than uniform selection. Nevertheless, depending on the form of selection in the different habitats or time periods, segregational load may still occur. Differential selection on males and females has been relatively neglected by theorists, but it too appears to occur reasonably often in natural populations. The assumption about independence of fitnesses at different loci could also be relaxed to allow epistasis (fitness interactions between loci), although how to do so for many loci is not immediately obvious. The algebraic complexity of many of these models has meant they are relatively poorly understood, especially when more than 2 alleles at more than one or two loci are involved.

A modified version of the neutral theory, the 'nearly-neutral theory' avoids several of the problems of the original proposal. In the original modification (Ohta, 1973) much standing variation is mildly deleterious, but a more expanded view also included mildly advantageous variation (Ohta and Gillespie, 1996). As in the neutral theory, genetic drift is the predominant process affecting allele frequencies, but the nearly-neutral theory predicts that in larger populations, molecular evolution is slower because drift has less effect in larger populations. Interestingly, nearly-neutral alleles also appear to constitute the standing variation in some models purely of selection. Marks and Spencer (1991) found that in their simulated populations, in which there was no genetic drift, many of the resulting polymorphisms were not detectable as different from those expected under neutrality, according to a standard statistical test. Effectively, many of the alleles surviving the selective filter had fairly small selective differences, and could be described as nearly neutral.

This convergence between explanations is, perhaps, no accident. One longstanding suggestion is that both the selectionist and neutral hypotheses apply, but to different aspects of the genome. For example, alleles at a highly polymorphic locus that differ in DNA sequence may fall into a small number of classes within which there are no selective differences; such differences only apply among classes. So the neutral hypothesis applies within classes and the selectionist hypothesis among them.

More fundamentally, perhaps, the two explanations may apply at different loci. Moreover, theoretical predictions may be confounded, especially if those loci are linked: genetic linkage between loci has fundamental consequences for levels of variation. For instance, if, at one locus, selection has driven a favorable newly arisen mutation to fixation, levels of variation at nearby linked loci will be reduced because only a few of the variants will have been present on haplotypes carrying the favored mutation. Such 'selective sweeps' (as these fixations are dubbed) can explain the correlations often observed between recombination rates and levels of genetic variation. Thus, even if the assumptions of the neutral hypothesis are satisfied, its predictions might be awry because a steady state at the locus of interest has yet to be reached: more time might be needed for neutral mutation to restore the predicted levels of variation at loci to which it applies. In an intriguing recent study, Corbett-Detig *et al.* (2015) showed that selective sweeps had a greater effect on levels of linked neutral variation in species with larger populations. Thus, the neutralist expectation of a strong correlation between population size and genetic variation is severely constrained by natural selection acting at linked loci, and the observed correlation is unexpectedly weak.

In summary, some combination of genetic drift, mutation (both neutral and non-neutral), and selection is responsible for maintaining the variation observed in natural populations; the arguments revolve around the relative importance of these population-genetic processes.

Genome Evolution's Role in Developmental Evolution

N Rohner, Stowers Institute for Medical Research, Kansas City, MO, USA

Glossary

Cis-regulatory mutations Mutations in the DNA affecting the regulation of a nearby gene.
Coding mutations Mutations in the DNA affecting the amino acid sequence of a protein.
Comparative genomics New field of biological research in which the genome sequences of different species are compared.
Copy number variant (CNV) A gene which varies in the number of copies from one individual to the next.
Horizontal gene transfer Transfer of genetic material between organisms without mating.
Phyla Taxonomic rank below kingdom and above class.
Pleiotropy One gene that influences multiple traits.
Pseudogene Nonfunctional relative of gene is called pseudogene.
Transposons DNA sequence that can change its position within the genome.

"Curiously the improved understanding of the nature of gene and mutation has not added, so far, to the understanding of evolutionary phenomena"
Ernst Mayr, 1963

Half a decade after Ernst Mayr expressed his frustrations in this famous statement, its significance has not entirely faded. Despite ongoing interest and a steady rise in knowledge about the genetic basis of evolution, we are still far from its comprehensive understanding. Recent technical developments, especially in increasingly cheaper and high-volume sequencing technologies, have improved the feasibility of whole genome comparisons and have raised our hope that we will be closer to a new level of understanding in the near future. The emerging field of comparative genomics has indeed provided us with a wealth of sequenced, annotated, and published genomes of species from almost all extant phyla over the last decade. Such a heavy focus on the genome is turning the field of evolutionary genetics more and more into the field of evolutionary genomics. But this wealth of genomic data does not immediately translate into insight. Genomes are big and diverse, and genome evolution is driven by various forces, hence the crucial question remains: what exactly in these genomes is responsible for the vast phenotypic diversity in the tree of life? Fortunately, previous work in classic evolutionary genetics can give important clues into where in the genome to look and what types of changes are likely to be important in evolution. This article will provide a glimpse into some of the ongoing areas of study in genome evolution and discuss some examples that have shaped our understanding of developmental evolution. The end of the article will address some recent trends in genome evolution and make a case of how important it is to continue these sequencing efforts, as even some of the simplest questions have yet to be resolved.

Transposons

Transposons are pieces of DNA that can change their position in the genome. Most transposons, however, have become inactive and do not 'jump' anymore. They were first discovered by Barbara McClintock as the cause of the irregular color pattern in some strains of maize, *Zea mays* (**Figure 1**). Her discovery at first earned her a lot of skepticism but was eventually accepted and led to a Nobel prize (McClintock, 1950). Transposons come in many flavors (for a review see Muñoz-López and García-Pérez (2010)) and make up a surprisingly large percentage of most genomes that have been studied so far (Chalopin *et al.*, 2015; Lisch, 2013). In our species, for example, almost half of our genome is comprised of transposable elements, although only less than one-tenth of a percent are still potentially active (Mills *et al.*, 2007). Active

Figure 1 Ears of corn, which formed the subject of Barbara McClintock's research on transposons as seen on display at the Nobel Museum in Stockholm. One can almost see the transposons hopping.

transposons can have far-reaching consequences. When transposons jump, they can mutate their host genomes by interfering with a gene or changing a regulatory region. Due to their repetitive nature, even when they remain inactive they can facilitate chromosomal rearrangements (such as deletions or duplications) through homologous recombination (Burns and Boeke, 2012). When transposons disrupt the function of genes, they can induce phenotypic changes. One such example comes from plant domestication and has been studied by generations of students of genetics. The famous wrinkled peas, which inspired Mendel to formulate his second law of inheritance, owe their shape to a transposon interruption of a starch-branching enzyme (Bhattacharyya *et al.*, 1990). Another example, one the wine drinker amongst us might appreciate, is a transposon integration in the Vvmby1A gene (not present in the red wine Cabernet grape) which caused the loss of color in the white wine producing Chardonnay variety (Kobayashi *et al.*, 2004). In addition to disrupting function, transposons can also modulate where or how much a gene is expressed. One study, Barbara McClintock surely would have appreciated, showed that one of the main loci responsible for the gross morphological differences between maize and its wild relative teosinte is a retrotransposon roughly 60 kb upstream of the tb1 gene, a gene that represses branching. The retrotransposon enhanced expression of this gene resulted in a dramatic reduction in the number of branches in modern maize, which in turn contributed to the success of corn as one of the most popular crops in the world (Studer *et al.*, 2011). Transposons are not only important in plants. Their role in shaping genome evolution extends to animals as well, including most likely our own. It is intriguing to note, that since the split between humans and chimpanzees, roughly 6 Mio years ago, over 10 000 transposons have changed their location (Mills *et al.*, 2006). It would be hard to believe that none of them had an effect on the evolution of either of the two species. If not adaptive, at the very least they have had a clear role in many human diseases (Ayarpadikannan and Kim, 2014).

Given their importance in genome evolution, it is clear that research on transposons will continue to provide important new findings in the future. Indeed in almost every new genome project one of the first things people focus on are the number and structure of transposable elements.

Coding Mutations

Coding mutations have been at the forefront of evolutionary genetics for a long time, simply because the genetic code makes it easy to identify mutations that alter proteins by solely looking at the DNA sequence. There are generally three types of mutations that change protein sequences: nonsynonymous substitutions, premature stop codons, and frameshifts, which ultimately lead to the former. Although their importance in evolution has come under attack recently (Carroll, 2008), their contribution to genome and developmental evolution remains undeniable. Case studies of coding mutations in developmental evolution come mainly from work on coloration. Examples range from changes in pigmentation in cavefish, to the coat pigmentation in beach mice (*Peromyscus polionotus*), and the black fur in some cat species, all due to single amino acid substitutions in pigmentation genes (Protas *et al.*, 2006; Hoekstra *et al.*, 2006; Schneider *et al.*, 2015). In human populations coding mutations have also changed the way we look. The paler skin of Europeans is at least partly due to such structural mutations (Lamason *et al.*, 2005). The occurrence of coding changes in the evolution of pigmentation is most likely attributable to the fact that the affected genes seem to have very specific functions and hence the mutations do not have pleiotropic effects. Nevertheless there are many examples for coding mutations driving evolution besides the ones affecting coloration. For instance, the reason that Andean geese can tolerate such high altitudes is, in part, due to a single amino acid change in their hemoglobin protein, which leads to increased O2 binding (Perutz, 1983). Visual acuity can come from coding changes as well. The opsins of the canary, for example, have shifted their sensitivity due to a single amino acid change, which transformed their violet pigment into a UV pigment (Yokoyama and Shi, 2000). Last but not least, for most known cases, where the genetic basis of hybrid sterility is known, there seems to be evidence for selection on mutations in coding regions (Orr *et al.*, 2004; Brideau *et al.*, 2006) suggesting an important role for structural mutations in speciation.

Regulatory Mutations

Coding mutations can also affect regulation of genes, especially if they occur in transcription factors (Lynch *et al.*, 2011), or if they affect mRNA stability (Schiavi *et al.*, 1994). However, most of the time when regulatory mutations are invoked, it is implied that they affect either the promoters of genes or cis-regulatory elements such as enhancers or repressors. Regulatory elements were first discovered by Jacob and Monod in their ground-breaking paper describing the lac-operon in 1961 (Jacob and Monod, 1961). Their work was so paradigm shifting that it earned them the Nobel prize in Medicine four years later. From this seminal finding it took only a few years until some influential papers speculated about the role of cis-regulatory elements in evolution (Britten and Davidson, 1971; King and Wilson, 1975; Bryson and Vogel, 1965; Jacob, 1977). Such arguments have not ceased since then, though there has been a recent surge of advocacy for the role of cis-regulatory evolution over the last decade (e.g., Stern, 2000; Stern and Orgogozo, 2008; Carroll, 2000, 2008; Wray, 2007). Arguments for why evolution would favor regulatory mutations over coding mutations usually converge around the assumption that cis-regulatory mutations are less pleiotropic than coding mutations. Due to the modularity of cis-regulatory elements it is expected that mutation of individual enhancers would allow for time or tissue-specific effects, rather than systemic effects associated with coding mutation (Carroll, 2008; Stern and Orgogozo, 2008). Also, mutations in enhancers are believed to frequently be dominant as each allele in a diploid organism is transcribed largely independently. A dominant effect of a mutation would in principle allow for selection in heterozygotes (Wray, 2007). While there is evidence for the role of promoter mutations in genomic evolution (Haygood *et al.*, 2007), promoter sequences often bind to a core set of widely used transcriptional regulators and are

therefore not believed to be the primary driver of regulatory variation. Since enhancers tend to be more variable, most work is focused on enhancer elements as a source of evolutionary divergence. Examples for cases of developmental evolution caused by changing regulatory elements include the bristle pattern on *Drosophila* larvae (Sucena and Stern, 2000), armor plate reduction in stickleback (O'Brown *et al.*, 2015), and the ability of digesting lactose in adult humans (at least in some of us) (Tishkoff *et al.*, 2007) and many more. For a more comprehensive list see Stern and Orgogozo (2008). The types of mutations that underlie cis-regulatory divergence can vary from a single nucleotide substitution (Shirangi *et al.*, 2009) to deletions of the entire regulatory element (Chan *et al.*, 2010). Recent studies using multiple stickleback populations allowed for some estimates about the contributions of coding and regulatory changes to evolution. Using a genome-wide set of loci, used repeatedly in parallel marine to freshwater stickleback adaptation, the authors estimated the contributions of coding changes to be roughly 20%, while regulatory changes could contribute up to 80% (Jones *et al.*, 2012). Another study focusing on cichlid genomes found that coding changes are more likely to be involved in the divergence of physiological or terminally differentiated traits like color, while regulatory changes seem to be more important in morphological changes especially when genes with pleiotropic effects are involved (Brawand *et al.*, 2014). There has been a long debate about whether there are differences in the types of mutations affecting morphology, physiology, or behavior (Hoekstra and Coyne, 2007). Current studies have been biased toward mutations affecting anatomical traits, in part because the latter two are much harder to study in the fossil record. Future work will help in addressing this question. The development and affordability of high-throughput RNA sequencing protocols and the growing use of eQTL studies have already started to open the door to unprecedented cross-species transcriptome analyses and comparisons (Necsulea and Kaessmann, 2014; Albert and Kruglyak, 2015). Such cross-species analyses will shed further light into the genetic basis of regulatory variation in genome evolution and ultimately link it to phenotypic, developmental, and adaptive evolution.

Gene/Genome Duplications

In principle, there are alternative ways to avoid the negative consequences of pleiotropy, besides changing the regulation of genes. One possibility is gene duplication followed by divergence of one of the duplicated copies. The idea that gene or genome duplication can be important in evolution and speciation can be found throughout the scientific literature of the last century (e.g., Tischler, 1915; Haldane, 1932; Müntzing, 1936; Bridges, 1936; Goldschmit, 1940) but gained the most popularity after Ohno's well formulated theory of duplication in evolution (Ohno, 1967, 1970). His argument circled around the notion that when a gene is duplicated, its duplicated copy is free to act as a 'play' copy potentially acquiring new functions while the ancestral role is preserved by the original gene-copy. However, the role of gene and genome duplication in developmental evolution has been somewhat neglected since Ohno. This is probably due to the technical challenge of assembling overly repetitive sequences. Therefore recently duplicated genes remain often undetected. However, despite the limited number of examples, there is no doubt that gene duplication is a fundamentally important mechanism in genomic evolution. For instance, most crop plants are polyploid, which contribute to an increase in robustness and crop yield (Renny-Byfield and Wendel, 2014). There are also plenty of other examples in domestication, one of them being the loss of scales in the common carp, a trait that makes it such an easy-to-prepare fish in the kitchen, which is a result of a duplicated gene selected for by breeders (Rohner *et al.*, 2009) (**Figure 2**). In addition to domestication, gene duplications have generated entire gene families such as olfactory receptors (Kratz *et al.*, 2002), opsins enabling color vision (Dulai *et al.*, 1999), or Hox genes (Brooke *et al.*, 1998) as only some prominent examples. After all, vertebrates have undergone two, and in the case of most bony fishes even three, whole genome duplications with far-reaching consequences (Taylor *et al.*, 2003). It is still a theory, but one which is gaining popularity, that the diversity in fishes, which are the most diverse vertebrate group, is linked to the fish-specific whole genome duplication (Glasauer and Neuhauss, 2014). In at least Cichlids there is evidence that the species richness of this family is partly due to duplicated genes (Brawand *et al.*, 2014). Another argument for duplications being important in evolution comes from studies that found frequent positive selection for amino acid changes within duplicated genes (Heger and Ponting, 2007; Birtle *et al.*, 2005). In human populations many genes are observed to be present in varying number of copies in different individuals, the so-called CNV (copy number variants). A recent study found that up to 15% of human genes vary in their copy number (Redon *et al.*, 2006). Over a broader time frame, nearly every gene can be considered to be a duplicate of earlier genes or some parts of the genome, so it is fair to say that the emergence of new genes plays an integral role in genome and developmental evolution.

Figure 2 *Cyprinus carpio*, the common carp has been bred as a food fish for millennia in China and Europe, mainly due to its robustness and relatively fast growth. One domesticated trait which makes it particularly popular in modern times is its reduction in scalation. The almost complete absence of body scales allows for an easy preparation in the kitchen as depicted in this franconian specialty version, the so-called mirror carp.

Origins of New Genes, Pseudogenes

Duplication and divergence is a major source of new genes. However, gene duplication is not the only way of generating new genes. They can emerge through a variety of different mechanisms from gene fusion over retrotransposition to originating *de novo* from noncoding regions of the genome (for a more exhaustive overview see Chen *et al.*, 2013; Kaessmann, 2010; Long *et al.*, 2003). There is no doubt that new genes have to be important in evolution. However, the extent to which this is the case may not be fully appreciated; for example, 21% of human protein coding genes have no known homologs in mice (Hoekstra and Coyne, 2007). Even compared to our closest living relative, the chimpanzee, 6% of the genes in one species have no known homologue in the other (Demuth *et al.*, 2006). One problem is that the functions of lineage-specific genes will often remain mysterious because no orthologues are available for study in experimentally tractable organisms. Fortunately there are some notable examples where novel genes were studied and were shown to play an important role in helping animals adapt to new environments. In Antarctic fish, antifreeze proteins have emerged *de novo* from ancestral noncoding DNA (Chen, 1997a) enabling survival in frozen environments. Remarkably, almost identical proteins have evolved independently in Artic fish as well, interestingly from entirely different genomic regions (Chen, 1997b) providing a striking case of convergent evolution. Another example, not completely *de novo*, but due to a transposition of an existing gene (fgf4) generated a variant of the gene in the dog genome. This variant, which was selected for by breeders, is the underlying genetic cause of the cute stubby legs of the dachshund and probably other short legged dog breeds as well (Parker *et al.*, 2009). These are just some of many other examples where recent evidence suggests that new genes have contributed to phenotypic diversity (for a more comprehensive list see Chen *et al.* (2013), Kaessmann (2010), and Long *et al.* (2003)). Even relics of genes, originally thought to be nonfunctional and therefore named pseudogenes, can still have effects on the regulation of other genes (Sasidharan and Gerstein, 2008). For example, in mouse oocytes several small RNAs controlling gene expression (so-called siRNAs) are derived from pseudogenes (Tam *et al.*, 2008).

Genome Reduction, Gene Loss (Compact Genomes), Deletions

However, not only is the gain of genes or genomic regions important, sometimes their loss can be as well. One famous example of gene loss in mammalian evolution is the loss of ancient egg-yolk genes in non-egg laying mammals (Brawand *et al.*, 2008). In terrestrial animals many odorant or pheromone genes are particularly transient (Ponting, 2008). Immunity genes are another case of frequently gained or lost genes (Goodstadt *et al.*, 2007). Overall, sequence deletion rates in mammals are high; in fact a quarter of the human genome has been lost since its split from the common ancestor with rodents (Mouse Genome Sequencing Consortium, 2002). But even within shorter evolutionary distances, deletions seem to have had an important impact on human evolution; a recent study found the genetic basis for the human-specific loss of penile spines (keratinized structures on the male sexual organ) compared to great apes and other mammals to be the consequence of a genomic deletion near the gene for the androgen receptor (McLean *et al.*, 2011). Evidently, genomic deletions can even make us more gentle lovers.

Horizontal Gene Transfer

Horizontal gene transfer also known as lateral gene transfer is the process by which an organism incorporates genetic material from another organism without mating. Horizontal gene transfer is traditionally believed to be restricted to bacteria and unicellular eukaryotes; however, recent work challenges this dogma and argues for a potentially broader significance of lateral gene transfer in animal evolution and development, including humans (Ivancevic *et al.*, 2013; Schönknecht *et al.*, 2014; Crisp *et al.*, 2015). For example, it has been argued that our ABO blood group gene has been horizontally transferred from bacteria (Crisp *et al.*, 2015).

Evolution of Sex Chromosomes

Sex chromosomes underlie strong selective pressures in evolution and as a consequence exhibit many unusual patterns in sequence and gene expression relative to autosomes (Vicoso and Charlesworth, 2006). Sex determining mechanisms have evolved independently several times and differ drastically between different clades, families, and even species (for a review on sex determination see Bachtrog *et al.*, 2014). In species with heterogametic sex chromosomes, such as mammals or birds, the lack of recombination between the two nonidentical chromosomes can lead to substantial genomic and structural changes. This is particular bad news for all men on this planet as it has been argued that the male determining human Y chromosome will vanish from the earth surface in the future (Wilson and Makova, 2009).

Open Questions

Despite substantial interest in genome evolution and a rising number of available genome sequences many substantial questions remain. This last paragraph will briefly mention some open questions in genome evolution and shortly reference the areas addressing them. Such brevity does not make the immense investigation justified and each of these topics could have easily filled a chapter of their own.

A still controversial question in the field is the extent in which genome size is contributing to organismal complexity. As the numbers of genes do not correlate well with organismal complexity in animals and lie only within a relatively narrow range from 13 100 genes in the mosquito to 23 300 genes in the sea urchin (Ponting, 2008), other factors must be more important. Evidently related to this observation is the question about the potential role of so-called 'junk' DNA, areas in the genome where we have not been able to attribute any obvious meaning. Another important area of inquiry deals with the

question of the role of population sizes and associated random genetic drift (Lynch and Conery, 2003) on genomic evolution. Further topics of rising interest are the role of micro RNAs (Berezikov, 2011) and long-noncoding RNAs in developmental evolution. Equally interesting are questions probing the importance of epigenetic effects, epistasis, and gene networks. Last but perhaps most fundamental is the question of how genomes evolved from RNA precursors in the first place (Goldman and Landweber, 2012). These are a few of many open questions and plethora of opportunities for future generations of genome and evolutionary studies.

Finally it is important to put forth the claim that genome-wide studies are fundamentally important and it is hoped the interest in whole genome sequencing will not cease. Fortunately, support for sequencing genomes remains high. As evidence, a particularly ambitious and valuable approach currently underway is the genome 10K project with the aim of sequencing 10 000 vertebrate genomes (Koepfli and Paten, 2015). However, one caveat of many genome-wide studies, which is hoped to be resolved soon, is that most genome-wide studies are conducted in the absence of phenotypic information. This deficiency limits their informative value about mutations and alterations in the genome which truly affect developmental evolution.

Genome Organization, Evolution of

SW Schaeffer, The Pennsylvania State University, University Park, PA, USA

Glossary

Conserved linkage Genes that are on the same chromosome and in the same order in two or more species.
Deletion The loss of <10 kb of DNA from a chromosomal location.
Duplication The gain of <10 kb DNA at a chromosomal location either from DNA duplication or through reverse transcription of mRNA sequences.
Inversion A chromosomal rearrangement that reverses the order of genes through the introduction of two double-stranded breaks.
Karyotype Organization of the genome into chromosomes.
Neofunctionalization Result of a gene duplication where one copy retains the original function and the second copy has gained a new function.
Nonfunctionalization Result of a gene duplication where one copy retains the original function and the second copy becomes nonfunctional.
Ploidy The haploid number of chromosomes in the genome.
Polyploid A species with more than the haploid number of chromosomes.
Pseudogene A copy of a duplicate gene that has lost function.
Segmental duplication The gain of >10 kb of DNA at a chromosomal location that is 95% similar in sequence to other regions in the genome.
Specialization Result of a gene duplication where both copies acquire new functions that are distinct from the original gene.
Subfunctionalization Two genes that resulted from a gene duplication where each duplicate has acquired a unique part of the original single gene's function such that both genes are indispensable.
Synteny Refers to genes found on the same chromosome in two or more species.
Translocation Reorganization of genes that moves one or more genes from one location to another location on the same chromosome or different chromosomes.

Introduction

The genomics era has opened the door to detailed studies of how genes are organized in the genome and will allow tests of hypotheses about the mechanisms that generate and maintain karyotypic variation within and between species. A naïve view might be that genes are clustered according to shared function or how they are regulated (Hurst *et al.*, 2004). The HOX clusters are a well-documented example of a nonrandomly arrayed set of genes. Without detailed knowledge of what genes are in a species' genome and what the functions of the genes are, it is difficult to evaluate whether nonrandom clusters of functionally related genes are the rule or the exception. Adjacent genes that are divergently transcribed can have similar expression profiles given shared *cis* regulatory sequences unless insulator elements are recruited into the intergene region to prevent coordinate regulation (Yang *et al.*, 2012). Rearrangements may provide a second mechanism to prevent maladaptive expression of adjacent genes.

Genomic rearrangements can restructure the genome through deletions, duplications, inversions, or translocations (Coghlan *et al.*, 2005). A species karyotype can be modified by the fission and fusion of chromosome arms. Species can also duplicate all of the genetic information in their genomes either through hybridization with different species or spontaneous duplications of their own genomes. Not only can these changes be observed in natural populations of many organisms, but in humans, they are often associated with genetic diseases (Pettenati *et al.*, 1995; Shaffer and Lupski, 2000). A study of a million human conceptions found that 7% of spontaneous abortions result from some form of genome rearrangement or ploidy change (Sankaranarayanan, 1979). Until recent advances in genomics, it has been unclear how often rearrangements occur in human populations, but do not cause disease (Stefansson *et al.*, 2005).

Until recently, the study of genome structure was largely descriptive, but with the availability of complete genomes we are now beginning to be able to test evolutionary hypotheses about how these rearrangements originate and how they are established in populations. The effect that rearrangements have on chromosomes is that they act as modifiers of recombination either in a positive or negative way. It has long been known that genome rearrangements can have profound effects on the transmission of chromosomal variants in heterozygotes (Sturtevant and Beadle, 1936). For instance, crossing over between homologous chromosomes heterozygotes for chromosomal inversions or translocations leads to the formation of recombinant gametes with deletions and duplications that will produce inviable offspring. This reduction in the transmission of recombinant gametes can lock particular combinations of genes together. Processes that lead to increases in chromosome numbers may lead to a species better able to adapt to a heterogeneous environment because the population is better able shuffle the contents of their genomes via independent assortment of chromosomes (Otto and Barton, 2001). This article will discuss the structure of genomes, the types of chromosomal rearrangements, and how chromosomal rearrangements may influence the evolutionary process.

Structural Organization of Genomes

Genomes of viruses to eukaryotes are organized or packaged to facilitate transmission of genomes from one generation to the next. The length of most organismal genomes is larger than the particle or cell that contains it. Viral genomes are quite diverse based on the type of nucleic acid-based genome and the proteins that generate the virus particle (Abrescia *et al.*, 2012; Baltimore, 1971). Viruses can have either DNA or RNA genomes that are either linear or circular. The sizes of viral genomes can be constrained by the protein particle that houses the genome (Feiss *et al.*, 1977). In many cases, genes that comprise viral genomes overlap reducing the amount of nucleic acid necessary to encode essential functions. Some viral genomes are segmented into independent pieces of nucleic acids, which can allow for diversification as is seen in the influenza viruses (Pleschka, 2013).

Bacterial genomes are circular DNA-based genomes. The genomes are packaged through supercoiling of DNA and short single-stranded RNA molecules (Pettijohn and Hecht, 1974). Factors such as DNA replication, nucleoid structure, and gene function play a role in how genes are nonrandomly organized in bacterial genomes (Rocha, 2008). Bacterial genomes are replicated from a single origin of replication and genes are encoded on both strands of DNA, but highly expressed genes tend to be near the origin of replication (Rocha, 2008). Genes are arrayed in operons with one or more genes being expressed from a single promoter. Operons lead to the coordinate expression of genes with related functions.

Eukaryotic genomes are organized into linear chromosomes (**Figure 1**). Chromosomes are units of segregation insuring that the genetic material is transmitted accurately each generation. Each chromosome has three fundamental parts a telomere, a centromere, and one or more origins of replication (Tyler-Smith and Willard, 1993). The telomere is the end or cap of the chromosome. Because DNA replicates in 5′ to 3′ direction, the ends of chromosomes would tend to get shorter with each cell division because DNA synthesis on the lagging strand is initiated away from the chromosome end. Telomerase is an enzyme that creates a special sequences at the ends of chromosomes that prevents the loss of DNA from the ends of chromosomes (Zakian, 1996). Centromeres are the regions where the spindle apparatus attaches to chromosomes during cell division and positions the chromosomes at the middle of the cell prior to segregation (Nicklas and Koch, 1969). Two types of chromosomes are found in the plant and animals, monocentric and holocentric. Monocentric chromosomes have a single centralized region that attaches to the spindle fibers while holocentric chromosomes have attachment points for spindle fibers along the entire length of the chromosome. The consequences of genome rearrangements in monocentric and holocentric species are quite different. In monocentric species, crossing over in an inversion heterozygote leads to the formation of acentric and dicentric chromosomes and the formation of unbalanced gametes (Sturtevant and Beadle, 1936). In holocentric species, segregation of chromosomes is unaffected by rearrangements because the entire length of the chromosome is engaged with the spindle apparatus (Dernburg, 2001; Maddox *et al.*, 2004; Melters *et al.*, 2012).

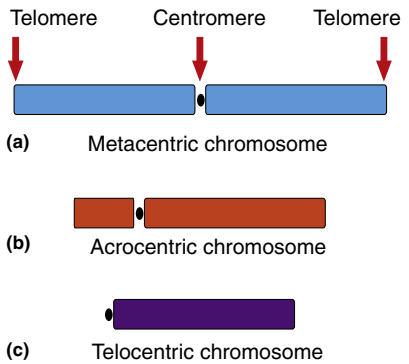

Figure 1 Basic chromosome structures showing the centromere and telomere. The types of chromosome are defined by the location of the centromere. (a) Metacentric chromosome with the centromere in the middle of the chromosome. (b) Acrocentric chromosome with the centromere offset from the middle of the chromosome. (c) Telocentric chromosome with the centromere at the end of the chromosome.

DNA in eukaryotic chromosomes is packaged by the histone proteins that make up the nucleosome particles (Hayes and Hansen, 2001). The DNA associated with the nucleosomes is known as chromatin, which can be found in three different states. Euchromatin occurs in DNA that is always transcriptionally active. Facultative heterochromatin goes between a transcriptionally active and inactive state. Constitutive heterochromatin is always in the transcriptionally inactive state. Giesma stain when applied to chromatin stains heterochromatic regions of DNA allowing one to map transcriptionally inactive state particularly in *Drosophila* polytene chromosomes (Sorsa, 1988a,b). Chromosomes are arranged nonrandomly in the nucleus based on recent data from chromatin conformation mapping, which determine what sequences are in close proximity to one another (Lieberman-Aiden *et al.*, 2009).

Genome Rearrangements

Deletions

Deletions result from the loss of DNA from a chromosome (**Figure 2**). The fitness cost of deletion mutations is not clear. The rapid deletion of DNA associated with recent transposable element insertions suggests that the loss of DNA is not deleterious (Petrov *et al.*, 1996; Petrov and Hartl, 1998). This could suggest that the initial DNA insertion was deleterious such that deletion mutations are favored. On the other hand, analysis of deletions in homologous sequences of DNA suggests that deletions may be deleterious relative to insertions (Pritchard and Schaeffer, 1997; Schaeffer, 2002). It is thought that interstitial deletions from the central regions of chromosomes are more likely to occur than terminal deletions because of the deleterious consequences of shortening the telomeric sequences (Armanios, 2009; Swanson *et al.*, 1981).

Duplications

Duplications result from the gain of DNA in a chromosome resulting from unequal crossing over during meiosis (Takahashi *et al.*, 1982; **Figure 3**). Population differences in

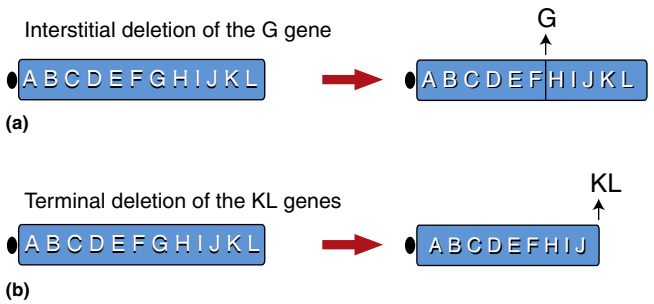

Figure 2 Chromosomal deletions. (a) Interstitial deletion that loses the G gene from the central part of the chromosome. (b) Terminal deletion that removes the KL genes from the telomere of the chromosome.

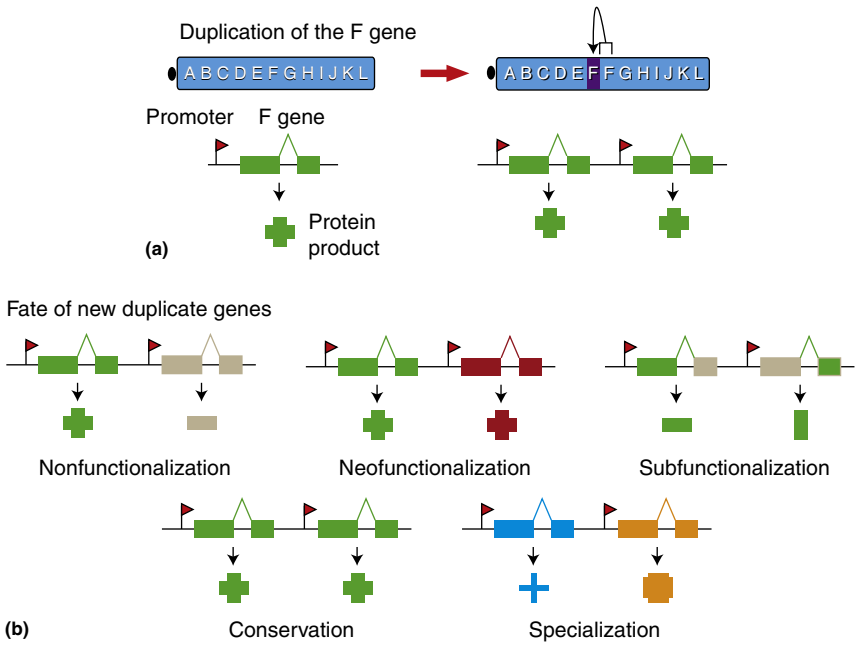

Figure 3 Chromosomal duplication. (a) The chromosome gains a second copy of the F gene. Below the chromosome is a depiction of the F gene duplication at the DNA level including its encoded product where the shape and color symbolizes the confirmation of the protein. (b) The five possible fates of the duplicate genes showing nonfunctionalization, neofunctionalization, subfunctionalization, conservation, and specialization, which are explained in the text.

deletions and duplications are also called copy number variants or CNVs that are of interest because of their potential effects on gene expression, phenotype, and disease (Girirajan *et al.*, 2011; Iskow *et al.*, 2012; Paudel *et al.*, 2013; Völker *et al.*, 2010). The duplication of genetic information especially that of complete protein coding genes has been proposed as a mechanism to generate genes of new functions (Ohno, 1970). There are five possible fates for recently duplicated genes (Assis and Bachtrog, 2013; Lynch and Conery, 2000; **Figure 3**). Nonfunctionalization occurs when one of the copies retains the original function and the second copy loses its function becoming a pseudogene. In this case, selection may favor the loss of one gene if the extra gene dosage is deleterious. Neofunctionalization occurs when one copy retains its original function and the second copy evolves a new function. Subfunctionalization occurs when each gene copy loses a different part of the original gene's function such that both genes are retained for the ancestral gene function. Conservation occurs when both copies of the duplication maintain the original protein function. Selection may favor this type of duplication because the additional gene may provide increased dosage of the protein. Specialization occurs when both copies of the duplication each evolve new functions. Good examples of gene families that resulted from gene duplications are the globin genes in vertebrates and the immunoglobulins of the vertebrate immune system (Efstratiadis *et al.*, 1980; Takahashi *et al.*, 1982).

Gene duplications can also be generated through reverse transcription of messenger RNAs and integration of the complimentary copy of the mRNA back into the genome (Meisel, 2009a,b). For the gene to be functional, the integrated gene must insert near a *cis* regulatory sequence that is capable of transcribing the inserted DNA. Recent data from ribosomal profiling suggests that much of the genome is transcribed at a

low level, which may provide a starting point for selection to act on a newly inserted gene if it is transcribed and translated at a modest level (Carvunis *et al.*, 2012). The integration of reverse transcribed messenger RNAs near preexisting genes can create chimeric genes that can quickly create gene transcripts with new functions for selection to act upon (Long and Langley, 1993; Ponce and Hartl, 2006; Rogers and Hartl, 2012).

Segmental duplications are larger increases of DNA in the genome that are 95% similar to its ancestral copy and comprise 5% of the genome (Eichler, 2001; Girirajan *et al.*, 2011). Segmental duplications were discovered as genomes were assembled from larger cloned sequences such as BAC clones. The use of next-generation short-read technologies has made the detection of segmental duplications difficult because the smaller reads do not assemble well through duplications that are larger than the size of the sequence reads (Alkan *et al.*, 2011; Salzberg *et al.*, 2012). Segmental duplications in mammals are distributed throughout the genome, but tend to be located near centromeres and telomeres (Eichler, 2001). Within chromosomes, these duplications result from unequal crossing over between repeated sequences that flank large segments of unique sequence. Duplications can also occur between chromosomes occur via duplicative transposition. Segmental duplications may have played a role in adaptive evolution in some species (Joshi and Nayak, 2013; Samonte and Eichler, 2002).

Finally, the whole genome can be duplicated. Whole genome duplication is common in plant species and has accompanied the domestication of many crop plants (Coghlan *et al.*, 2005; Renny-Byfield and Wendel, 2014). Evidence for whole genome duplications in animals and fungi is increasing as more complete genomes become available (Albertin and Marullo, 2012; Sémon and Wolfe, 2007).

Inversions

Inversions are generated when two double-stranded breaks are introduced into the chromosome and are rejoined such that the gene order of sequence between the breakpoints is reversed (**Figure 4**). Chromosomal inversions were discovered in *Drosophila melanogaster* when a strain had no cross overs between two loosely linked loci in mapping crosses (Sturtevant, 1917). Sturtevant suggested that this strain carried a 'C-factor' that reduced crossing over. Comparisons of gene order between *D. melanogaster* and *Drosophila simulans* suggested that the C-factors resulted from an inversion that flipped the order of genes (Sturtevant, 1921). Comparison of genetic maps within species suggested that 'C-factors' result from inverted gene orders (Sturtevant, 1926). The examination of polytene chromosomes from larval salivary glands (Painter, 1934) cytologically confirmed that C-factors were due to the reversal of gene order. Cytogenetic examination of a variety of insects has shown a wealth of inversion polymorphism within species (Dobzhansky and Sturtevant, 1938; Krzywinski and Besansky, 2003; Sperlich and Pfriem, 1986).

Two models have been suggested for how inversions are generated in populations based on the study of pairs of inversion breakpoints, nonallelic homologous recombination and staggered cut model (Cáceres *et al.*, 1999; Mathiopoulos and Lanzaro, 1995; Mathiopoulos *et al.*, 1998, 1999; Matzkin *et al.*, 2005; Ranz *et al.*, 2007; Richards *et al.*, 2005).

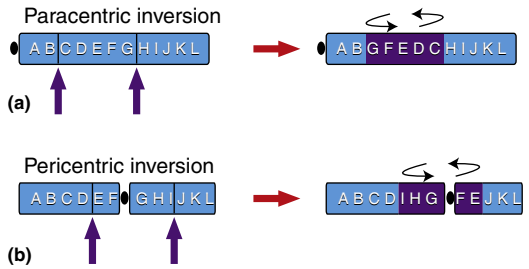

Figure 4 Chromosomal inversions. (a) Paracentric inversion that reverses the order of the CDEFG genes between the two double-stranded DNA breaks (purple arrows). A paracentric inversion does not include the centromere. (b) Pericentric inversion that reverses the order of the EFGHI genes between the two double-stranded DNA breaks (purple arrows). A pericentric inversion includes the centromere.

Several lines of indirect evidence suggest that inversions are selected in natural populations. First, gene arrangements form clines or gradients in frequency in natural populations that in some cases form in parallel in the northern and southern hemispheres (Cheng *et al.*, 2012; Dobzhansky, 1944; Hoffmann *et al.*, 2004; Hoffmann and Weeks, 2007; Kennington and Hoffmann, 2013; Kennington *et al.*, 2006, 2007). Second, arrangements cycle seasonally and form altitudinal clines (Dobzhansky, 1943, 1948). Third, gene arrangement frequencies reach stable equilibria when reared in population cages (Wright and Dobzhansky, 1946).

There are two types of inversion, paracentric and pericentric, with the difference being whether the centromere is involved in the rearrangement. A pericentric inversion includes the centromere in the inverted segment, while a paracentric inversion does not. Paracentric inversions are common in Dipterans, while pericentric inversions are rare typically being observed between species (Lemeunier and Ashburner, 1976; Sperlich and Pfriem, 1986). The situation in mammals is the opposite where paracentric inversions are rare and pericentric inversions are more common (for a review see Dobigny *et al.*, 2015).

Translocations

Translocations involve the movement of genes to new locations within a chromosome or to different chromosomes (**Figure 5**). Robertsonian translocations are a special case where two acrocentric chromosomes recombine to form a metacentric chromosome (Slijepcevic, 1998; **Figure 5(c)**). Polymorphic translocations are not as frequent as chromosomal inversions in natural populations (Dobigny *et al.*, 2015), but have played an important role in the restructuring of chromosomes. Chimpanzees and gorillas have 24 pairs of chromosomes while humans have 23 pairs. Evidence suggests that the reduction in the number of human chromosomes was the result of a Robertsonian translocation caused by a telomeric fusion (IJdo *et al.*, 1991). In *Drosophila*, one tends to observe translocations as fixed differences between species, but there are some cases of polymorphic translocations (McAllister and Charlesworth,

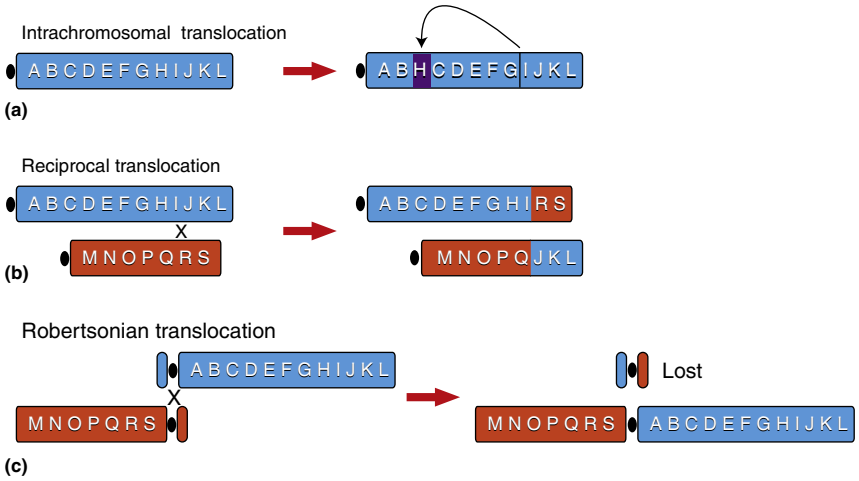

Figure 5 Chromosomal translocations. (a) Intrachromosomal translocation where the H gene moves to a new location within the chromosome. (b) Reciprocal translocation where the ends of two chromosomes are swapped. (c) Robertsonian translocation where exchange between the centromeres of two chromosomes generates a fusion product between two different chromosome arm.

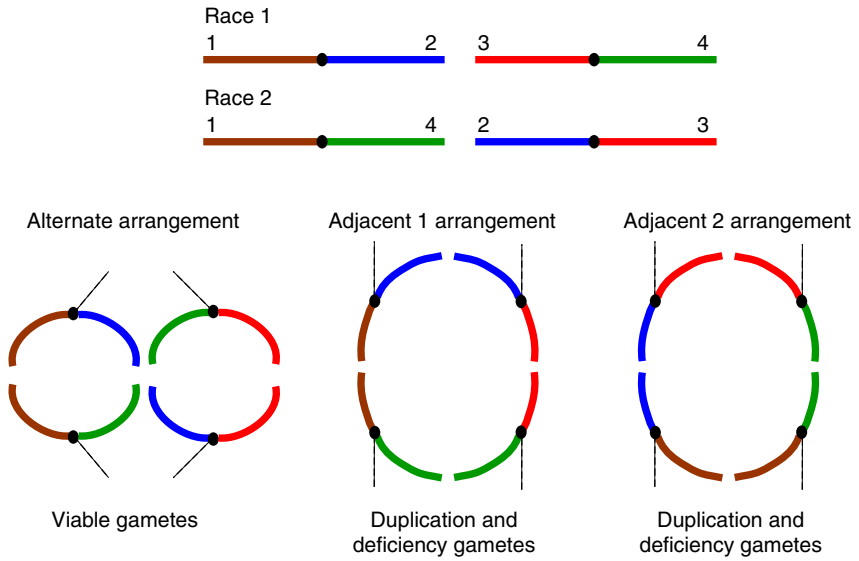

Figure 6 Segregation of chromosomes in a species hybrid that carries different chromosomal fusions.

1999; McAllister, 2002, 2003; McAllister and Evans, 2006; McAllister *et al.*, 2008). The plant genus *Oenothera* has a variety of species that differ in the chromosomal translocations that they carry. Homologous chromosomes in hybrids between *Oenothera* species form rings during meiosis based on the pairing of the translocated chromosomal arms (Darlington, 1929; Golczyk *et al.*, 2014; **Figure 6**). The rate of karyotypic evolution driven by translocation mutations can vary widely among closely related species (Carbone *et al.*, 2014).

Establishment of Rearrangements in Populations

There is no overall consensus for the evolutionary mechanisms responsible for the establishment of inversions in populations and this is an open area for research. Theoretical studies have established conditions for the invasion of new inversions into a population (Charlesworth and Charlesworth, 1973). Kirkpatrick and Barton (2006) summarized four major classes of hypotheses that can allow a new inversion to invade in a population. In the first class of models, the inversion mutation at either site of chromosomal breakpoints creates variation for selection to act on so called position effects. This could result from changes in the structure genes (Calvete *et al.*, 2012) or the alteration of gene expression of adjacent genes (Puig *et al.*, 2004). The second type of model involves the indirect effect due to recombination suppression. Reduced recombination within the inverted region can hold large combinations of alleles together in different chromosomal backgrounds either because the inversion captures epistatically interacting genes (Dobzhansky, 1950; Wallace, 1968), captures a chromosome relatively free of deleterious recessive alleles (Nei *et al.*, 1967;

Ohta and Kojima, 1968), or captures a set of genes involved in local adaptation (Guerrero and Kirkpatrick, 2014; Kirkpatrick and Barton, 2006). The pattern of linkage disequilibrium within inverted regions supports the indirect effect of recombination hypothesis because one sees long-range LD and short-range linkage equilibrium (Schaeffer *et al.*, 2003; Wallace *et al.*, 2013). The local adaptation model is supported in a numerical analysis of selection–migration balance is used to explain the differences in inversion frequencies among *Drosophila pseudoobscura* populations (Schaeffer, 2008). The third class of model assumes that the inversion captures a single positively selected gene that carries the gene arrangement to high frequency (Schaeffer and Aguadé, 2000). The final type of model is genetic drift, which suggests that the gene arrangement increases in frequency by neutral processes (Lande, 1984).

Rearrangements Effect on Nucleotide Variation in Populations

Once established in populations, rearrangements can shape the pattern and organization of nucleotide diversity along the chromosome (Navarro *et al.*, 1997, 2000). Chromosomal rearrangements lead to the suppression of recombination in heterozygotes, which acts as an isolating mechanism to restrict genetic exchange between chromosomes (Hasson and Eanes, 1996). Theoretical studies on how inversions restrict genetic exchange in heterozygotes has shown that the size of the paracentric inversion and its position relative to the centromere dictates divergence between inverted chromosomes (Navarro *et al.*, 1997). Divergence is expected to be greatest near inversion breakpoints (Navarro *et al.*, 2000). Data from inversions within and between species of *Drosophila* are largely consistent with these predictions (Andolfatto *et al.*, 1999; Andolfatto and Kreitman, 2000; Hasson and Eanes, 1996; Noor *et al.*, 2007; Wallace *et al.*, 2013).

Rearrangements as Contributors to the Speciation Process

Once established in populations, genome rearrangements can promote the formation of new species especially in cases where the dominant arrangement is fixed in different environments. White (1973) proposed that underdominance in rearrangement heterozygotes in species hybrids might serve as a reproductive barrier between species. The problem with this model is that experimental estimates of fitness sets do not show underdominance for inversion heterozygotes (Coyne *et al.*, 1991). The discovery of reproductive incompatibility genes in inverted regions of chromosomes led to a reevaluation of the role that rearrangements play in the speciation process (Noor *et al.*, 2001). Navarro and Barton (2003) suggested that rearrangements could isolate genomes through reduced genetic exchange rather than the traditional geographic isolation model. The emergence of a rearrangement frequency cline driven by local adaptation could provide fertile ground for the formation of new species. Different allelic combinations can be fixed within different rearrangement backgrounds, but are less likely to spread among the different chromosomal backgrounds because of suppressed recombination. If any of these fixed allelic differences include incompatibility genes that limit viability or fertility, then this process can lead to the initial phases of the formation of new biological species. *Drosophila* species have been identified based on differences in their karyotypes, which suggests that chromosomal rearrangements may have helped to drive the formation of new species throughout the genus *Drosophila* (Carson, 1992; Lemeunier and Ashburner, 1976; Wasserman, 1992).

Rearrangements and Sex Chromosome Evolution

Chromosomal rearrangements have played a role in the evolution of sex chromosomes (Charlesworth *et al.*, 2005). Sex chromosomes are thought to evolve from autosomal progenitors where one homologue acquires a sex determination gene. Later, the chromosome picks up a negative recombination modifiers in the form of DNA rearrangements that limit genetic exchange between the pair of homologues (Lahn and Page, 1999). In humans, reduced recombination prevents the movement of the sex determination factor between the two sex chromosomes limiting sex reversal mutations, i.e., XX males or XY females (Ferguson-Smith, 1966; Page *et al.*, 1987). In *Drosophila*, new sex chromosomes have evolved multiple times via chromosomal fusions (Bachtrog, 2013).

Computational Methods to Infer Phylogenies from Genome Rearrangements

Muller, Sturtevant, and their colleagues used comparative genetic mapping in *Drosophila* to show that genes tended to be conserved on the same chromosomal arms between different species, yet the gene order was different presumably because of chromosomal rearrangements (Muller, 1940; Sturtevant and Tan, 1937; Sturtevant and Novitski, 1941). Genes on the same chromosomal arm in different species are defined as being in synteny, while syntenic genes also found in the same order on the chromosome among different species are defined as being in conserved linkage or syntenic blocks (Ehrlich *et al.*, 1997; **Figure 7**). Comparisons of complete genomes among different species has confirmed that there is extensive synteny among species and that there has been extensive shuffling of gene order as well (Bhutkar *et al.*, 2008; Hillier *et al.*, 2007; Pevzner and Tesler, 2003a,b). The availability of complete genomes among different species has led to the development of computational approaches to infer the number of rearrangements between two genomes (Bergeron *et al.*, 2006; Durrett *et al.*, 2004; Moret *et al.*, 2001; Sankoff, 2003; Tang and Moret, 2003).

Summary and Future Prospects

Chromosomal rearrangements are just beginning to be appreciated as an important source of genetic diversity that can shape the evolution of genomes. Prior to the use of genomic technologies, the best systems for the study of chromosomal rearrangements were limited to species where cytogenetic techniques were sufficient to detect large-scale changes such as in *Drosophila* (Painter, 1934) and some mammalian systems

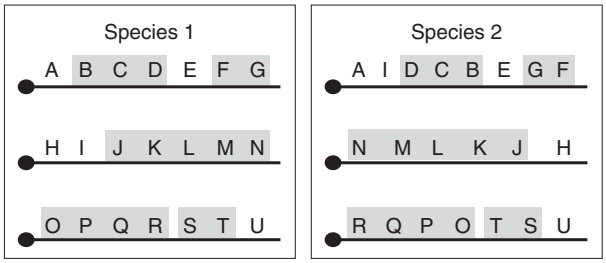

Figure 7 Synteny of genes in chromosomes between two different species. Two related species have genes found on three chromosomes. Each chromosome is indicated with a dot for the centromere and a line. The letters indicate genes for each chromosome. Genes A, B, C, D, E, F, and G are syntenic on the top chromosomes in the two species with two conserved linkage blocks (BCD and FG). Genes H, J, K, L, M, and N are syntenic on the middle chromosomes in the two species with the one conserved linkage block (JKLMN). Genes O, P, Q, R, S, and T are syntenic on the bottom chromosomes in the two species with the two conserved linkage blocks (OPQR and ST).

(for a review see Dobigny *et al.*, 2015). With the aid of genomic approaches, the extent of naturally occurring chromosomal rearrangements is becoming apparent raising new questions about how chromosomes evolve. Of particular interest is taxon specific differences in the rate of one type of rearrangement versus another. For instance, why are paracentric inversion so prevalent in *Drosophila* (Sperlich and Pfriem, 1986), while pericentric inversion more prevalent in mammals (Dobigny *et al.*, 2015). Perhaps the answer lies in differences in population structure. *Drosophila* populations tend to be large with extensive migration between multiple climatic niches which may favor inversions to prevent exchange between chromosomes that have been selected for a particular local environment (Kirkpatrick and Barton, 2006; Schaeffer, 2008). On the other hand, mammalian populations tend to be small, which may lead to the fixation of chromosomal rearrangements due to genetic drift (Dobigny *et al.*, 2015; Lande, 1984). Next-generation sequencing technologies offer the hope that chromosomal rearrangements can be detected in more diverse set of taxa that will help to generate a more general picture of how chromosomes evolve in natural populations.

Glossary

Conjugation Transfer of plasmid DNA from a donor to a recipient cell by direct cell-to-cell contact.
Genetic recombination A process by which a DNA molecule is broken and the fragments are rejoined in a different combination. By homologous recombination different DNA molecules with highly similar (homologous) nucleotide sequence are combined. In case of site-specific recombination, extensive nucleotide sequence homology is not required for recombination.
Horizontal gene transfer Transfer of genetic information between distinct members of a species and beyond species barriers that is independent of sexual reproduction.
Indels A class of mutation that includes insertions, deletions, or the combination of both.
Nucleoid The region within a bacterial cell comprising all or most of the cell's genetic material and DNA-binding proteins.
Pan-genome The pan-genome comprises all genes present in a species. The pan-genome includes (1) the core genome containing the genes, which are shared by all the species members and (2) the flexible genome containing genes present only in some strains.
Synteny Physical co-localization (linkage) of genes and gene clusters on the chromosome of different individuals.
Transduction Virus-mediated transfer of bacterial DNA from a bacterial donor to a bacterial recipient cell.
Transformation Uptake/transfer of free DNA into competent recipient cells.

Mechanisms and Constraints of Bacterial Genome Plasticity

There is large variation in size and content of bacterial genomes between different genera and species, but also among strains of the same species. Bacterial versatility can be directly correlated with genome size. For example, intracellular parasites, which live in constant and rich environments, have rather small genomes compared to environmental bacteria, which are often exposed to variable and changing growth conditions. The Darwinian theory of evolution (Darwin, 1859) relies on the generation of genetic diversity and natural selection. This holds also true for bacteria, and bacterial genome plasticity mirrors the mechanisms and constraints, which shape bacterial genomes and are thus involved in bacterial evolution.

When the chromosomes of related bacterial species are compared, it can be seen that the overall synteny is stable. A typical bacterial genome consists of a core gene pool containing the genes that encode essential cellular functions, and a flexible gene pool encompassing genes that are advantageous under certain environmental conditions. The core genome represents the stable genomic backbone and defines the basic metabolic capacities of a species. In related species it is largely co-linear with only few rearrangements detectable. In contrast, the flexible genome is responsible for the phenotypic diversity within a bacterial species and for its adaptability (Medini *et al.*, 2005; Segerman, 2012). Components of the flexible genome often exhibit marked nucleotide sequence variability and are frequently located on mobile genetic elements (MGEs) or in variable chromosomal regions. They can be horizontally transferred by transformation, transduction, or conjugation (see **Table 1**; for review see Darmon and Leach (2014)).

Table 1 Properties of mobile genetic elements

Type of element	*Example*	*Autonomous replication*	*Autonomous transfer*	*Mobilization*	*Integration*	*Excision*
Large plasmid	RP4	+	+	+	+/−	+/−
Small plasmid	RSF1010	+	−	+/−	(−)	(−)
Prophage	λ	−[a]	(+)	+	+	+
Conjugative transposon[b]	SXT	−	+	+	+	+
Integron, super-integron	In1	−	−	−	+	+
PAIs/GEIs	PAI II_{536}	−	−	(+)	(+)	+
Transposon	Tn*10*	−	−	−	+	+
Insertion sequence element	IS*1*	−	−	−	+	+

[a]Most prophages are integrated into the chromosome with the exception of few phages (e.g., P1) that are maintained as extrachromosomal replicons.
[b]including elements designated as integrative and conjugative elements or conjugative genomic islands.

 doi:10.1016/B978-0-12-800049-6.00236-5

Successful horizontal gene transfer (HGT) is characterized by the transfer of genetic material from a donor to a recipient by the stable incorporation into the recipient's genome and its successful expression by the recipient. The acquisition and exchange of mobile and accessory genetic elements by HGT is one of the driving forces of bacterial genome plasticity and evolution (**Figure 1;** Ochman and Jones (2000)).

Acquisition of foreign genetic information is, of course, not unlimited. There are several limitations, which affect the uptake and successful incorporation of MGEs (see **Table 2**). Obviously, strategies exist, which distinguish 'foreign' from 'own' DNA or which recognize closely related MGEs. One well-known defense mechanism of incoming foreign DNA is restriction-modification (R–M). By degrading incoming foreign genetic information, R–M systems help to limit the integration of invasive DNA elements (Vasu and Nagaraja, 2013). Similarly, the 'clustered regularly interspaced short palindromic repeats' (CRISPRs) help the host cell to identify previously encountered bacteriophage or plasmids and mediate their degradation (Sorek *et al.*, 2013; Westra *et al.*, 2014). Also the coexistence of closely related plasmids within a host cell is controlled on the basis of their incompatibility (*inc*) systems, which affect plasmid replication. The stability of MGEs can be controlled by MGE-encoded R–M systems and so-called toxin–antitoxin (TA) systems. R–M as well as TA systems prevent the loss of extrachromosomal plasmids and in case of R–M systems also of some chromosomally inserted MGEs due to postsegregational killing of daughter cells, which lost these

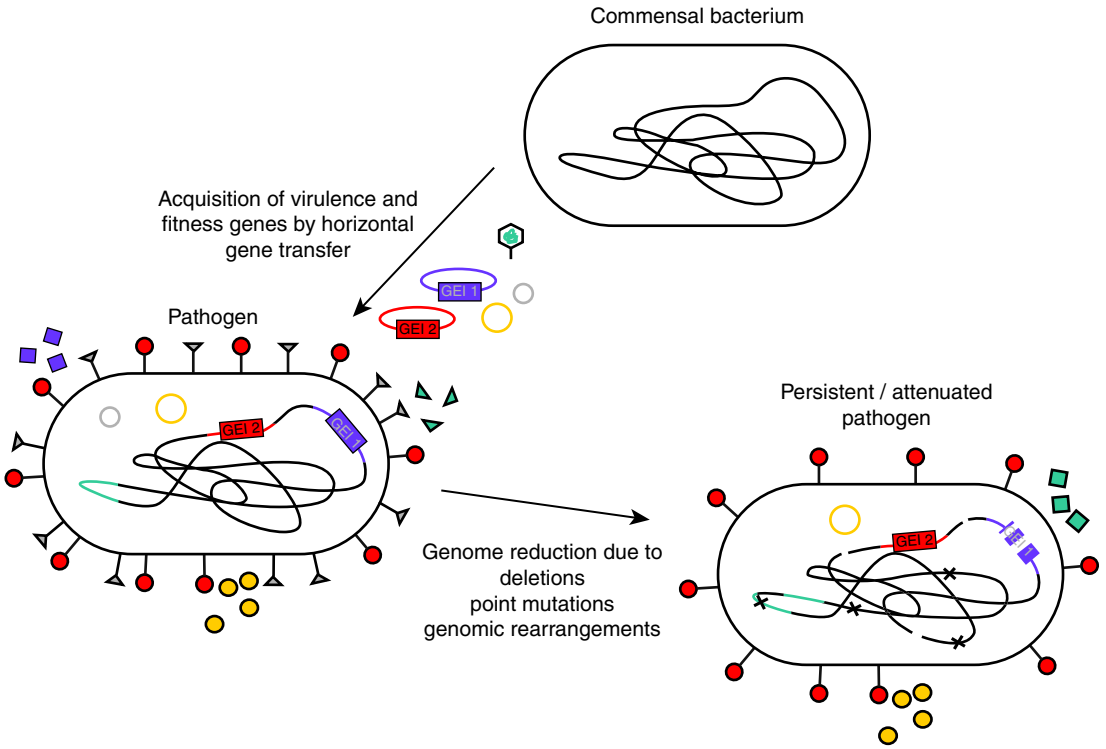

Figure 1 Influence of genome plasticity on bacterial evolution. Horizontal gene transfer by means of transformation, transduction, and conjugation plays an important role during bacterial evolution, for example for the evolution from a commensal to a pathogenic or attenuated bacterium. Commensal bacteria acquire mobile genetic elements such as plasmids, bacteriophages, and genomic islands that can encode fitness and virulence factors and render the strain pathogenic. During further adaptation to the host, gene deletions, point mutations, and genetic rearrangements might occur resulting in altered gene expression and possible loss of certain virulence traits. Those pathogens can evolve into attenuated strains that are able to persist in the host. GEI: genomic island.

Table 2 Limitations of genome plasticity

Trait	*Effect*
Niche restrictions	Availability of foreign DNA or interaction partners for HGT
Availability of phage receptors	Exclusion/limitation of bacteriophage infection
Restriction/modification (R–M) systems	Exclusion/limitation of DNA uptake, genome stability, improved recombination efficiency
CRISPR	Exclusion/limitation of DNA uptake
Plasmid incompatibility	Exclusion/limitation of plasmid uptake
Toxin/antitoxin (TA) systems	Genome stability, maintenance of plasmids
Nucleotide sequence homology	Recombination efficiency
Toxic or lethal mutations	Genome fidelity, gene functionality

elements (for reviews see Unterholzner *et al.* (2013) and Vasu and Nagaraja (2013)). Furthermore, the acquisition and exchange of foreign DNA can be limited by the presence/absence of surface receptors required for bacteriophage infection, by the general availability of foreign DNA (e.g., microorganisms in isolated niches have rarely access to foreign DNA), and by missing nucleotide sequence homology required for recombination and MGE integration into the host genome.

Besides HGT, point mutations and DNA rearrangements contribute to constant evolution of bacterial genomes (**Figure 1**). The accumulation of point mutations and indels can result in gene diversification as well as in gene inactivation. DNA rearrangements may cause relocation or deletion of genomic regions as well as gene duplication. Duplicated genes can then be further shaped by divergent evolution. Also the loss of genetic information contributes to genome plasticity. Non-functional or deleterious genes are frequently lost from bacterial genomes. The inactivation or deletion of genes, which are no longer required, has been observed especially during adaptation to physiologically stable environments (Lawrence, 1999; Maurelli *et al.*, 1998), or as one important aspect of within-host evolution and attenuation of bacterial pathogens causing persistent or chronic infection. *Escherichia coli* (*E. coli*) isolates from asymptomatic bacteriuria often exhibit smaller genome sizes than closely related commensals or uropathogens, because many virulence genes have been inactivated or lost due to the above-mentioned mechanisms (Lawrence, 1999; Maurelli *et al.*, 1998; Roos *et al.*, 2006; Zdziarski *et al.*, 2010; Zdziarski *et al.*, 2008). Another example of such within-host evolution of uropathogenic *E. coli* has been reported for consecutive *E. coli* isolates from recurrent bacteraemia cases (Olesen *et al.*, 1998). Similarly, attenuation and inactivation of virulence-associated genes during persistent asymptomatic infection occurred in *Burkholderia pseudomallei* as well as in *Pseudomonas aeruginosa* isolates from cystic fibrosis patients (Marvig *et al.*, 2015; Price *et al.*, 2013). It is tempting to speculate that *in vivo* growth may be accompanied with increased genome plasticity as a result of increased mutation rates and/or efficient selection for attenuated or best adapted variants.

The variable bacterial genome organization and content mainly originates from transposition and homologous recombination events. For this, repeated and redundant DNA sequences play an important role, because they allow for homologous recombination. Most of the genomic variation can be attributed to insertions or deletions in so-called chromosomal hotspots (Tenaillon *et al.*, 2010). However, the organization and the function of bacterial chromosomes are strongly interconnected with cellular processes such as replication, segregation, transcription, and translation. Furthermore, the insertion or deletion of DNA sequences can disrupt operon structures or regulatory networks and should therefore only be favorable at genomic sites, which are not restricted by such structural or organizational constraints. It has been suggested that chromosomal integration hotspots may result from the insertion of larger DNA stretches into permissive chromosomal regions, thereby supporting future recombination events and additional HGT in this less perfectly adapted region (Touchon *et al.*, 2009b). Whereas point mutations, genome rearrangements and deletions are stochastic processes contributing to relatively slowly occurring evolutionary processes (Ahmed *et al.*, 2008; Dobrindt *et al.*, 2004) (**Figure 2**), HGT allows for faster changes of the genomic content, thus contributing to significantly accelerated evolution, the so-called microevolution.

The Mosaic Continuum of Mobile and Accessory Genetic Elements as a Toolbox of Genome Plasticity
