EDITOR IN CHIEF

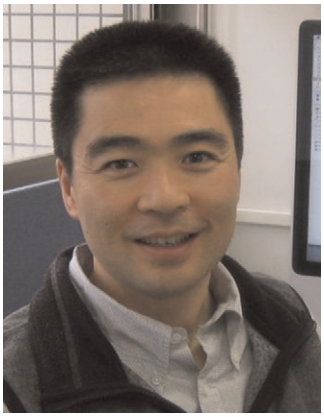
Richard M. Kliman, PhD, is Professor of Biological Sciences at Cedar Crest College in Allentown, Pennsylvania. He received his BA from Colby College in biology and music. His graduate work at Wesleyan University focused on quantitative genetics of circadian rhythms and photoperiodism in the Djungarian hamster, *Phodopus sungorus*. As a postdoctoral fellow at Rutgers University and Harvard University, he studied molecular evolution and population genetics. Prior to Cedar Crest College, he taught at Radford University in Virginia and Kean University in New Jersey. He has also served as a program director in the Division of Environmental Biology at the US National Science Foundation (NSF).

Kliman's research interests center on questions in molecular evolution, including the evolution of codon usage bias in a variety of organisms; speciation and natural history; and ecology and conservation. Much of this work has relied on population genetics/genomics and bioinformatics approaches. He has also collaborated with Cedar Crest colleague John Cigliano on an Earthwatch-supported "before-after-control-impact" study on the effects of a new marine reserve in Belize on queen conch populations. His research in evolutionary and ecological genetics has been supported by the US National Institutes of Health and by Conservation International.

Kliman has served on the editorial boards of *Genetica* and *The Journal of Molecular Evolution*. He has been deeply involved in evolution education, helping to coordinate "Undergraduate Diversity at SSE/SSB," an NSF-supported program to bring a diverse group of undergraduates to the annual Evolution research conference. He was a lead editor of population/quantitative genetics and evolutionary genetics for *Nature Education/Scitable* at its inception. He is a member of the Education and Outreach Committee of the Society for the Study of Evolution, and editor of the society's peer-reviewed educational resource, the *EvoEd Digital Library*.

SECTION EDITORS



Hiroshi Akashi is a Professor of Evolutionary Genetics at the National Institute of Genetics, Japan. He worked with Marty Kreitman for his PhD in Ecology & Evolutionary Biology from the University of Chicago (1996) and with John Gillespie as a postdoctoral fellow at UC Davis. He has been a faculty member at the University of Kansas (1998–2000), Penn State University (2000–2008), and NIG (2009–present). Akashi's research focuses on inferring causes of genome evolution, especially weak selection, from within and between species sequence variation. His studies of codon usage employed population genetic methods to detect natural selection acting at its limit of efficacy and identified a phenotypic basis of natural selection (translational accuracy) from sequence comparisons in *Drosophila*. Extensions of this work revealed constraints related to biosynthesis that act globally on compositional properties of microbial proteins. The interplay of weak evolutionary forces appears to shift frequently among closely-related species and current interests include tests of adaptive changes in protein/DNA composition.

Tim Coulson's primary interest is in creating better links between the fields of ecology and evolution. He does this by developing theory, parameterising models for field and laboratory systems, making predictions from these models, and, where possible, testing these predictions with experiments. He works on a range of systems, from bulb mites within the laboratory, to guppies living in streams in Trinidad, to wolves in Yellowstone. His motivation to do this comes from observations that ecological and evolutionary change can be observed occurring on similar time scales, yet ecological theory typically ignores evolutionary processes and vice versa.

Tim was awarded his PhD in plant ecology from Imperial College, London, in 1994. He moved on to research genotype-by-environment interactions as Natural Environment Research Council (NERC)-funded post-doc at the Institute of Zoology in London. He remained at the Institute on a fellowship where he developed models to investigate the economic and life history consequences of a range of population management strategies. In 2000 he moved to the University of Cambridge, where he briefly lecturered in the Zoology department. In 2004 he moved back to Imperial College London as a senior lecturer where he started developing models that allow the simultaneous investigation of the dynamics of life history, populations, and quantitative characters. In 2007 he became Professor of Population Biology at Imperial College London. He left Imperial in 2013 to take up his current position as Professor of Zoology at the University of Oxford. He is also a Professorial fellow of Jesus College, Oxford.

Andrew Forbes

Rosemary Gillespie is a Professor at the University of California, Berkeley, where she also holds the Schlinger Chair in Systematics. She is Past President of the *International Biogeography Society* and Trustee and Fellow of the *California Academy of Sciences*, and serves as Associate Editor for *Molecular Ecology*. Gillespie was born and educated in Scotland, receiving her BSc in Zoology from Edinburgh University in 1980. She came to the US to conduct graduate work on the behavioral ecology of spiders at the University of Tennessee. After her PhD she spent several months at the University of South in Tennessee, and then started work at the University of Hawaii in 1987, initially as a postdoc, and then in 1992 as Assistant Professor in Zoology and Researcher in the Hawaiian Evolutionary Biology Program. It was during her first year in Hawaii that she discovered an adaptive radiation of *Tetragnatha* spiders. She left Hawaii in 1999 to join the faculty at the University of California in Berkeley, where she continues her research focus on the islands of the Pacific, Hawaii in particular, using islands of known age and isolation to assess the combined temporal and spatial dimension of biogeography and determine patterns of diversification, adaptive radiation, and associated community assembly.

David Guttman received his PhD from Stony Brook University in 1994 working with Daniel Dykhuizen on questions related to the role and importance of recombination in structuring genetic diversity in bacterial populations. He followed this with a postdoc in molecular evolution with Brian and Deborah Charlesworth at the University of Chicago, and a second postdoc at the University of Chicago with Jean Greenberg to gain experience in the fields of molecular plant pathology and plant-microbe interactions. He started his faculty position at the University of Toronto in 2000, and is currently a Professor in the Department of Cell & Systems Biology (CSB). He is also the Associate Chair for Research in CSB, founder and Director of the University of Toronto Centre for the Analysis of Genome Evolution & Function, and Canada Research Chair in Comparative Genomics. He has served as the Chair of the American Society for Microbiology, Division R (Evolutionary and Genomic Microbiology), and was the *PLoS Pathogens* Section Editor for Bacterial Evolution & Genomics.

Dr. Guttman runs a highly diverse research program generally focused on bacterial evolutionary genomics, with three major foci: (1) the evolution of host specificity and virulence in plant pathogenic bacteria; (2) microbial comparative genomics; and (3) studies of the human and plant-associated microbiome. He is best known for elucidating and linking evolutionary and mechanistic processes that determine the course and fate of bacterial infections, and characterizing the impact of genetic variation on the balance between disease and immunity.

Norman A. Johnson, the section editor for Applied Evolution, is an evolutionary geneticist and author. He received his PhD from the University of Rochester in 1992 and did postdoctoral research at the University of Chicago. His research interests have generally focused on aspects of speciation, specifically those related to the genetics and evolution of hybrid incompatibility: sterility, inviability, or other reduction of fitness in hybrids between species. Dr. Johnson, an adjunct professor in the Biology Department at the University of Massachusetts at Amherst, has taught classes there, as well as at Hampshire College, the University of Texas at Arlington, and the University of Chicago.

Dr. Johnson also has a long-standing commitment toward improving the communication of science in general and evolutionary biology in particular to other scientists, educators, and the public at large. He is the author of *Darwinian Detectives: Revealing the Natural History of Genes and Genomes* (Oxford University Press: 2007), a book geared to general audiences that shows how biologists use DNA sequence data to make inferences about evolutionary processes. He also was the lead organizer for a working group on communicating human evolution at the National Evolutionary Synthesis Center (NESCent).

Laura Kubatko received a PhD in Biostatistics from The Ohio State University (OSU) in 1999. After seven years on the faculty at the University of New Mexico, she returned to OSU in the Fall of 2006, and is now Professor of Statistics and of Evolution, Ecology, and Organismal Biology at OSU. Laura served as an Associate Director of the Mathematical Biosciences Institute at OSU from 2013–2015. At OSU, she is a Faculty Affiliate of the Initiative in Population Research, and a Faculty Affiliate in Translational Data Analytics (TDA@OSU). She holds appointments as an Affiliate Faculty Member at the Battelle Center for Mathematical Medicine at Nationwide Children's Hospital in Columbus and as an Adjunct Research Scientist at Lovelace Respiratory Research Institute in Albuquerque, NM. Laura's research interests are in statistical genetics, with a focus on the development of statistical methods for inferring phylogenies from molecular data. Her recent work in this area concentrates on bridging the gap between traditional phylogenetic techniques and methodology used in population genetics analyses, primarily through the application of coalescent theory to species-level phylogenetic inference. She develops and distributes several software packages for phylogenetic inference, and has been an active member of the *Society of Systematic Biologists*. She has served as an Associate Editor for the journal *Systematic Biology* since 2007.

Amy Litt has been studying plant evolution and diversity since her PhD on floral structure and evolution in the neotropical plant family Vochysiaceae, known for its beautiful but unusual flowers many of which have only one petal and one stamen. While completing her PhD in plant systematics and morphology in the joint City University of New York/New York Botanical Garden Plant Sciences program under Scott Mori and Dennis Stevenson, she became interested in the molecular basis of plant diversity. She did her post-doc in the developmental genetics lab of Vivian Irish at Yale University on the evolution of a family of transcription factors involved in flower development, and she continues to study the functional evolution of this gene family currently. After one year on the faculty of University of Alabama, she moved back to The New York Botanical Garden as Director of Plant Genomics, where she developed her research program studying the evolution of plant form along two paths: studying evolutionary changes in genes to see how those changes affected flower and fruit form; and identifying the genes that underlie differences in form among closely related species. Dr. Litt also served as a program director in Plant, Fungal, and Microbial Development and Evolutionary Development at the National Science Foundation. She recently moved to the University of California at Riverside, where she continues to study the genetic basis of plant diversity.

Maria E. Orive is a professor of evolutionary genetics in the Department of Ecology and Evolutionary Biology at the University of Kansas. Her research in theoretical population genetics aims to develop mathematical models that provide a conceptual framework for exploring important questions in evolutionary biology and analytical tools for demographic and genetic data. Her work has considered levels of selection and mutation in organisms that reproduce both sexually and asexually, the relationship of population structure and life-history attributes to gene flow and genetic diversity, and models of within- and between-host pathogen and symbiont population dynamics. Orive received her BS from Stanford University and her PhD from the University of California at Berkeley. After spending two years as a postdoctoral researcher in genetics at the University of Georgia, she was an NSF-NATO Postdoctoral Fellow at the University of Edinburgh. Her research has been funded by multiple grants from NSF and NIH. In 2007–2008, she was the Carl and Lily Pforzheimer Foundation Fellow at the Radcliffe Institute for Advanced Study (Harvard University), and has served as the University Faculty Ombudsman for the University of Kansas since 2007.

Daniel Ortiz-Barrientos is an Associate Professor in evolutionary genetics in the School of Biological Sciences at The University of Queensland, Brisbane, Australia. During his scientific career he has investigated the ecological and genetic basis of speciation both in plants and animals. His current research program explores the early stages of speciation, the molecular basis of parallel speciation, and the interplay between recombination and natural selection during the origin of new species. His research funds come from The Australian Research Council. He is married to Antonia Posada, and is the father of three energetic and beautiful kids.

Claudia Russo was born in Leeds, England, but has lived in Rio de Janeiro, Brazil since she was two years old.

Claudia has an academic major in Ecology from Universidade Federal do Rio de Janeiro completed in 1989, and finished her Master's thesis in 1991 on population genetics of two actiniid species of sea anemones with different reproductive strategies, under the supervision of Associate Professor Antonio Mateo Sole-Cava. Her PhD dissertation was on the diversification of drosophilids and on the use of a known phylogenetic tree to estimate the reliability of tree building methods. The dissertation was completed in 1995 under the supervision of the Evan Pugh Professor Masatoshi Nei who recently received the prestigious Thomas Hunt Morgan Medal. Her graduate degrees were obtained as a student at the Genetics Program from the Universidade Federal do Rio de Janeiro and as a visiting scholar at the Pennsylvania State University (1992–1995).

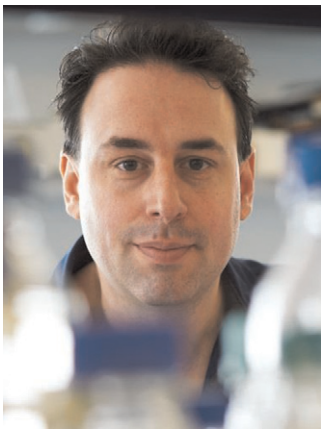
Claudia is currently the Head of the Genetics Department at the Federal University of Rio de Janeiro, having been a member since 1997. Claudia has supervised 13 Master's dissertations, eight PhD theses and seven post-docs, of which eight are now Assistant Professors at universities in Brazil and abroad. She has published 42 academic papers that have been cited over 1,200 times. Her *h-index* is 14. Since 2012, Claudia has been a member of the editorial board, and an associate editor of the *Molecular Biology and Evolution* journal. Since 2012 she has been a council member for the Pan American Association of Computational Interdisciplinary Sciences and since 2009 for the Brazilian Association for the Advancement of Science.

Claudia's general academic interests are on key aspects of animal phylogenetics, including their diversification patterns in time and space. She has worked with various metazoans groups but more prominently on marine sponges, sea anemones, arthropods, passerine birds, and mammals. Claudia has also published on the use of known phylogenetic trees to estimate the efficiency of phylogenetic methods in recovering and rooting those trees. More recently, she has developed some interesting *hands-on* educational tools for evolutionary biology practices in the classroom.

Karen E. Sears is an evolutionary developmental biologist whose primary research goal is to determine how developmental variation within a species produces congenital malformations in humans, and among species generates new evolutionary forms in mammals. Dr. Sears earned her PhD from the University of Chicago, did postdoctoral research at in the Howard Hughes Medical Institute (HHMI) lab of Dr. Lee Niswander, and joined the faculty of the University of Illinois at Urbana-Champaign. At Illinois she holds positions as an Associate Professor in the Department of Animal Biology, a Faculty Member in the Institute of Genomic Biology, and an Affiliate of the Program in Ecology, Evolution and Conservation Biology and the Department of Cell and Developmental Biology. She is also the President of the Pan American Society for Evolutionary Developmental Biology. She has authored or co-authored over 35 publications including first-authored publications in *Nature*, *Proceedings of the National Academy of Sciences*, and *Evolution*. She has served as a principal investigator on multiple, nationally-funded research projects, and presented invited seminars at more than 30 institutions and symposia. She is routinely ranked among the top 10% of Illinois professors for her teaching, and was a featured scientist in the PBS/HHMI documentary "*Your Inner Fish*."

Vassiliki "Betty" Smocovitis is Professor of the History of Science in the Department of Biology and in the Department of History at the University of Florida. Her areas of expertise include the history of evolutionary biology, genetics and systematics and the history of botany. She is best known for her contributions to understanding the historical event known as the "evolutionary synthesis" and in gaining greater understanding of the origins of the discipline of evolutionary biology. She has published extensively on both the intellectual and social aspects of the history of evolutionary biology including a history of the Society for the Study of Evolution, a history of the Darwin Centennial of 1959, and the integration of botany, genetics, and anthropology into the evolutionary synthesis. She was the contributor to the *Oxford Bibliographies* entry on Charles Darwin at over 25,000 words and the entry on the modern synthesis. She is the author of *Unifying Biology: The Evolutionary Synthesis and Evolutionary Biology* (Princeton: Princeton University Press, 1996).

Nina Wedell is a professor of evolutionary biology with research interests focused on the evolutionary ecology of sex. She has worked extensively on various aspects of sexual selection and sexual conflict, in particular on the role of selfish genetic elements in reproductive biology. Nina is the Academic lead for the Behaviour research group at the University of Exeter.



Jason Wolf is Professor of Evolutionary Genetics in the Department of Biology & Biochemistry and The Milner Centre for Evolution at the University of Bath. His research is unified with a special focus given to understanding the influence that frequently ignored or under-appreciated sources of genetic variation have on the genotype-phenotype relationship and how this, in turn, influences evolutionary processes. He integrates theoretical, computational and empirical quantitative and population genetic techniques to achieve this goal. He is particularly interested in understanding the evolutionary consequences of various types of interactions, including gene interactions (epistasis), parent-offspring interactions and social interactions. He received a PhD from the University of Kentucky, after which he was a postdoctoral researcher at Indiana University and a US National Science Foundation Postdoctoral Fellow at Washington University School of Medicine. Prior to moving to the University of Bath he held positions at the University of Tennessee and the University of Manchester. He won the Dobzhansky Prize from the Society for the Study of Evolution, a Young Investigator's Prize from the American Society of Naturalists and the Scientific Medal from the Zoological Society of London.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged alphabetically as a series of entries.

1. Alphabetical Contents List

Your first point of reference will likely be the contents. The complete contents list appears at the front of each volume providing volume and page numbers of the entry. We also display the article title in the running headers on each page so you are able to identify your location and browse the work in this manner.

2. Cross-references

All articles within the encyclopedia have an extensive list of cross-references which appear at the end of each article, for example:

Adaptive Mutation Controversy

> *See also*: Directional Selection and Adaptation. Microbial Experimental Evolution. Mutation, Population Genetic Models of. Natural Selection, Introduction to. Recombination in Bacterial Populations

3. Subject Classification List

A subject classification list has been developed by the editors to group articles under broad topics. This index is useful for making broad connections between articles and locating the relevant article for a topic that is covered in more than one article.

4. Index

The index provides the volume and page number for where the material is located, and the index entries differentiate between material that is a whole article; is part of an article, part of a table, or in a figure.

5. Contributors

A full list of contributors appears in the front mater of each volume.

Subject Classification List

PREFACE

The *Encyclopedia of Evolutionary Biology* was developed to provide an authoritative overview of the current state of evolutionary biology. It was an ambitious goal, especially given that the field did not pause for the two and a half years needed to complete the project. The encyclopedia's 15 section editors collaborated to ensure that content gaps were kept to a minimum, and their efforts show. When the project was completed, we had compiled 256 entries, covering a broad range of topics selected by the editors to ensure a comprehensive resource. It was a privilege to read every one of these entries, and I was truly humbled by the collective efforts of hundreds of authors to communicate the excitement and sophistication of a field of study that touches on every conceivable topic in biology today.

There are many ways to envision an encyclopedia of evolution, and we had to choose an approach that would lead to a cohesive resource. Readers will note that, in the more organismal-focused entries (edited by David Guttman, Amy Litt, and Claudia Russo), there is an emphasis on *diversification* of life. We did not set out to provide an overview of the diversity of life, as such a goal would be untenable; rather, we focused on the evolutionary processes and key events responsible for diversity. Numerous entries deal with speciation, life history evolution, evolutionary biogeography, and coevolution. These entries (edited by Daniel Ortiz-Barrientos, Tim Coulson, Rosemary Gillespie, and Andrew Forbes) bring to light how the evolution and diversification of life is intimately entwined with ecology. Of course, there is extensive coverage of population genetics, quantitative genetics, evolutionary developmental biology, the evolution of sex and mating systems, molecular/genome evolution, and phylogenetic analysis (edited by Maria Orive, Jason Wolf, Karen Sears, Nina Wedell, Hiroshi Akashi, and Laura Kubatko), all fundamental to our understanding of evolutionary processes. And as thematic bookends, several entries (edited by Betty Smocovitis and Norman Johnson) cover the history of evolutionary biology and applications of evolutionary biology.

Readers of the encyclopedia will find that entries are generally pitched at a somewhat advanced level, although with great effort by authors to make entries as accessible as possible to a broad audience. Encyclopedias, like living organisms, are compromises. If all entries could be readily understood in their entirety by first-year university students, this encyclopedia would be of limited value to experts. At the other extreme, if entries were extremely technical – and our authors were undoubtedly capable of producing such entries – the encyclopedia might be inaccessible to students. While there is, by necessity, variation among entries in this regard, we settled on a general target: the majority of an entry should be accessible to a motivated, advanced undergraduate. Readers are, of course, directed to additional resources, with authors providing bibliographies and lists of further reading.

As with any undertaking of this scale, there are many individuals who should be recognized for their roles in the development of this encyclopedia. Special thanks go to Norman Johnson for early discussions that helped us develop the general structure of the encyclopedia. The dedicated and distinguished team of section editors deserves the credit for drafting the table of contents, recruiting authors, and working extensively with authors to ensure the highest quality product. It should go without saying that the high quality of this encyclopedia ultimately reflects the efforts of the editors and authors. Finally, the project management and development teams at Academic Press were always ready to assist, and while it is not possible to name everyone who contributed to the effort, I am particularly indebted to Simon Holt, Will Bowden-Green, Paula Davies, and Justin Taylor.

Richard Kliman
Editor in Chief

FOREWORD

What is life, how did it originate, and what accounts for its great diversity? These are fundamental scientific questions that have and will always be the source of endless fascination and wonderment. Charles Darwin and Alfred Russel Wallace provided an answer to the latter question through the grand idea of evolution and the process of natural selection. Darwin also speculated on the where question of the origin of life by hypothesizing it originated long ago in a warm lagoon. Most importantly, however, Darwin shattered the notion that the natural world is static and replaced it with a biology that is dynamic and continually changing. Species are not fixed, typological entities. Rather, they are related by common descent in a great tree of life. Analogous to tracing one's ancestors back in time in a pedigree, one can climb down the tree along its branches and boughs that connect species in a hierarchy of phylogenic relationships until reaching the base of its trunk and the common ancestor of us all. One can also climb up the tree and quickly realize that evolution produces a seemingly endless array of new forms (and sometimes extinction). Thus, as the tree of life grows, populations are continuously evolving and diverging from one another, creating novel varieties and races (showing slight differences) that eventually evolve into new species (separated by distinct gaps). And natural selection – the differential survival of individuals in populations possessing heritable traits favorable for their survival and reproduction – is the primary materialistic process causing evolutionary change and the origin of new species.

The *Encyclopedia of Evolutionary Biology* chronicles our current state of understanding of the dynamics of evolution and its product, Darwin's great tree of life. A diversity of seminal topics are covered including overviews of the history of the field, the origin of life, the history of life (including the phylogentic methods used to reconstruct life's history), the myriad ways and means (including mechanisms other than natural selection) that evolution is affected, and the important roles that conflict versus cooperation, and mergers and acquisitions, occurring within across varying levels of biological organization, play in the narrative of life. In so doing, the *Encyclopedia* highlights the grandeur in Darwin's view of life. We are not separate, but rather a twig along a branch of life, a twig that has evolved the ability to comprehend the existence of and our connectedness to the tree, and climb around its branches to see what has been and think about what may come. It is a wonder of life that it can look at and understand the meaning of itself.

But Darwin's grand view has even larger ramifications, going beyond providing a materialist basis for organismal change and putting us in our place. The reality of evolution also answers the question of what life is. If pressed to define life, most of us would reply with a list of the things that living organisms do. For example, living organisms metabolize, grow, develop, move, behave, mutate (are variable), and reproduce with inheritance. One can investigate these different characteristics of life separately and discern the mechanistic basis for the different processes that constitute life – the "how" of life. And such studies represent the basis for many fields of the life sciences. However, these are only the components of life and, in isolation, produce a static view of the natural world. Rather, the seminal insight is that populations of living beings possessing these characteristics have the emergent property that they evolve. Darwin's "*On the Origin of Species*" therefore not only describes how populations evolve, and as a logical extension how new species form, but also conveys the essence of what life itself is – evolution. Thus, as Theodosius Dobzhansky famously stated "nothing makes sense except in the light of evolution." The Encyclopedia wonderfully brings this view of life to light, providing the reader with the breadth of knowledge and overview of the current state of the field of evolution needed to appreciate and participate in the next major ongoing synthesis in our understanding of life, the so-called "Omics Revolution."

The study of evolution is in an accelerated phase of discovery brought about by major technical advances in our ability to DNA sequence whole genomes (genomics), and to generate profiles of mRNA transcription (transcriptomics), protein levels and enzymatic activity (proteomics), and metabolic products (metabolomics) at varying stages in the life cycle and development of organisms. This "Omics Revolution" may not change foundational evolutionary principals, per se. Our understanding of evolution has been heightened by a series of such advances in the past, including the "Modern Synthesis" when Mendelian genetics was wedded to Darwinian thinking and the "Molecular Revolution" in which genetic technology increasingly allowed allele frequencies in natural populations to be analyzed. The Omics Revolution is an extension of these pervious advances, but one in which the workings of whole organismal systems and the composition of entire communities can be gleaned at once.

Perhaps, the most important discoveries in Omics will come from linking an understanding of the process occurring at the cellular and microevolutionary level with large scale patterns and trends at the macroevolutionary scale. Previously, processes occurring within and interactions occurring among cells could be studied in at least some detail. Omics is providing an opportunity to fully understand how all of these processes interact simultaneously to result in the development and functioning of integrated, multicellular systems of life. At the other end of the spectrum, fossils attest to the evolution of new life forms through time and the creation of great and observable morphological diversity. Genomic sequencing is providing a powerful means to help accurately place these fossils within the framework of a fully resolved molecular phylogenic tree to better understand the history of life, including major trends, themes, and variation in the tempo and mode of evolutionary change. But it is the middle of the micro and macro at the branching points in the tree of life that Omics may prove most insightful. Now it is possible to not only DNA sequence large numbers of individuals within populations, but to equate these genetic differences within and between populations to morphological, physiological, and behavioral phenotypes, and discern the developmental

and physiological mechanisms by which these genetic changes produce organismal variation, diversity, and reproductive isolation – the stuff of evolution and speciation itself. Thus, we will be able to not only understand the everyday processes responsible for how the tree of life grows, but be able to translate this into a mechanistic appreciation of how these processes result in new branches on the tree forming and others dying out, giving shape to the history of being on our planet.

The field of evolution is currently inundated with a mass of Omics data and the bottleneck is the development of bioinformatic analytical tools to edit, analyze, and interpret the results. However, it is clear that many new insights are on the horizon, and even if they do not affect the root principles of evolution, soon a deep connection of the how and why of life will emerge to help forge a truly integrative evolutionary biology: The *Encyclopedia of Evolutionary Biology* is an excellent guide to prepare readers to assimilate these new findings, keeping bioinformatics grounded in the bio and providing a valuable source for seeing the tree through the forest to understanding the grand synthesis of life that is flowering.

Adaptation, History of

A Larson, Washington University, Saint Louis, MO, USA

Glossary

Acquired characteristics Traits obtained by an organism during its lifetime, such as hypertrophy of muscles through exercise. Lamarck's hypothesis that such traits could be passed to offspring by altering heredity underlay his evolutionary mechanism for adaptation.

Adaptation (as a character) An organismal trait that evolved gradually by natural selection for a biological role retained by its possessors, and superior to contrasting traits present in the evolutionary history of the population.

Adaptation (as a process) In Darwinian and neo-Darwinian theory, evolution by natural selection causes a population to accumulate favorable characters that arise among its members and to discard less favorable alternatives.

Adaptationist program Term used by Stephen Jay Gould and Richard Lewontin to criticize an idealistic research program prevalent in the late 1960s and 1970s that uncritically assumed widespread adaptation of characteristics that had simpler historical explanations. An analogistic approach equating, for example, behavioral variation in a bird species to family conflicts in humans, was a widespread methodology criticized as having no basis in testable historical hypotheses.

Additive variance in fitness In Ronald Fisher's genetic theory of natural selection, the critical condition for evolution by natural selection and the condition ultimately destroyed by the resulting evolutionary change. It constitutes populational variation in traits influencing the expected numbers of offspring produced by individuals of a given genotype relative to those of contrasting genotypes.

Aptation A trait that provides a useful biological role to its possessors not present in contrasting traits present in the evolutionary history of the population.

Behavioral drive Allan Wilson's term for a learned behavior that changes evolutionary adaptation in a population; for example, discovery of a novel food source could lead to evolution by natural selection to adapt the population to use the novel food.

Burden Rupert Riedl's term for a trait that becomes indispensable to a population following its evolutionary origin; for example, presence of a notochord early in development is indispensable for viability in chordates despite absence of this characteristic in other animals.

Developmental constraint An evolved bias in the phenotypes or morphologies capable of being produced by a developmental process; disturbance of development by mutation or an environmental stimulus typically produces a small set of possible outcomes. Although perceived as a contrast to adaptation, it was later recognized as important for evolution by natural selection of complex traits.

Developmental module A semiautonomous pattern of development of interrelated subparts of an organismal structure. For example, mutations as well as environmental stimuli can cause the metathorax of a fruit fly to develop the typical appendage, a bulb-like balancer, or an alternative developmental sequence producing a wing. Switching of development between contrasting developmental modules can be tied to genetic or developmental switches.

Exaptation A trait that performs a biological role other than one for which it evolved by natural selection and contributes greater utility than contrasting traits present in the evolutionary history of the population. Presence of feathers in birds, for example, is an exaptation for flight because feathers preceded flight in avian evolution, yet feathers contribute utility in flight not possible from the scales from which feathers evolved.

Function A biological role through which a character evolved by natural selection. For example, the hypothetical role for feathers in avian evolution was as insulation for a homeothermic animal.

Genetic assimilation A developmental process or phenotype initially induced by an environmental stimulus reveals additive variance in the population capable of being selected to stabilize expression of the novel phenotype. The concept was proposed by Conrad Waddington to explain experimental evolution in fruit flies.

Genetic drift Random change in the frequency of a genetic trait caused by sampling error in a finite population. By chance alone, the gene pool of a population is not identical to the gene pool of the same population in earlier generations.

Gradualism Darwin's theory that only small, quantitative changes in organismal form would be potentially favored

by natural selection, and that large changes in form could evolve only through a succession of small steps across generations. Gradual evolution by natural selection is critical for selection to be judged the creative force underlying adaptation rather than just a sieve that retains adaptations produced by mutation or development.

Homology Equivalence relationship among characters that descend from an equivalent characteristic of a common ancestor. Hypotheses of homology are critical for testing hypotheses that a trait constitutes an adaptation evolved by natural selection.

Idealism In science, a pejorative term used for explanations that fail to provide potential falsification through testing of hypotheses. Lewontin criticized the adaptationist program for arbitrarily constructing organismal traits and perceived utilities that could not withstand historical testing.

Lamarckism General term for an evolutionary theory that postulates hereditary transmission of acquired characters as the basis of evolution. The term 'neo-Lamarckism' is often used for theories from the late 1800s onward that purged Lamarck's original notion that organismal volition played a major role in evolution of adaptation.

Modern Evolutionary Synthesis Progression of evolutionary theory from the 1920s through 1940s toward favoring neo-Darwinian explanations of gradual evolution of adaptation through natural selection, generally discrediting alternative theories based on Lamarckian inheritance, saltation, or orthogenesis.

Mutation Term proposed by de Vries around 1900 for large genetic changes that can produce new species and adaptations by saltation rather than by gradual evolution. Mutation is now used more broadly to denote any genetic change regardless of its consequences for organismal phenotype.

Natural Selection Darwin's primary mechanism for evolution of adaptation, in which organisms possessing the traits most favorable for using environmental resources have higher rates of survival and reproduction than individuals with contrasting traits. The population thus accumulates the most favorable characteristics across generations and discards less favorable characteristics.

Neo-Darwinism Darwin's evolutionary theory as modified by August Weismann's purging of its Lamarckian elements in the late 1800s. Mendelian genetics and the chromosomal theory of inheritance would become the genetic basis of neo-Darwinism in the 1900s.

Neutral evolution Evolutionary change explained by the interaction of mutation and genetic drift and not requiring a selective explanation. Most evolutionary change measured in genes and proteins is likely neutral. Neutral evolution is nonetheless a useful null hypothesis whose rejection leads investigators to discover adaptive evolutionary change at the molecular level.

Orthogenesis General term for disparate theories popular in the decades around 1900 that considered evolutionary change directed by biases in the production of new variation rather than by Darwinian natural selection. Although the hypothesis of a 'momentum' in production of variation would be discredited by Mendelian genetics, orthogenetic theories often used arguments similar to those of 'developmental constraint' that would become established in the 1980s by evolutionary developmental biology.

Phenocopy Environmentally induced change in development that produces a phenotype characteristic of a known genetic mutation in the species. For example, Waddington's treatment of fly eggs with ether caused some genetically wild type individuals to express the phenotype characteristic of the Bithorax mutation.

Phenotypic accommodation West-Eberhard's observation that an organism's altered use of body parts often causes those parts to undergo atypical development that enhances the new use. For example, a goat with paralyzed forelimbs used the hind limbs for bipedal locomotion and caused non-characteristic development of the associated skeletal and muscular structures. This could expose additive variance in the population for evolutionarily stabilizing the new phenotype.

Phylogeny Empirical reconstruction of the history of common descent of species.

Saltation Occurrence of a discontinuous phenotype suddenly within a single generation. Darwin argued that such variants would be too harmful to contribute to evolution by natural selection.

Selfish DNA An intragenomic process analogous to natural selection in which particular DNA sequences use the cellular processes of gene replication and expression to make extra copies of themselves to be inserted into the genome. This process has no inherent advantage to the organism, but it can produce populational variation that leads to evolution of adaptation by natural selection.

Volition A notion that an organism's choices, sometimes but not necessarily conscious ones, influence its adaptive evolution. Lamarck's evolutionary theory put strong emphasis on organismal volition. In Darwinian theory, an organism's choice of a favored habitat among various alternatives can influence how natural selection acts on the population to produce adaptation.

Pre-Darwinian Concepts and Lamarck's Theory

Perhaps the greatest challenge to evolutionary theory from its beginnings was to explain the origins of organismal characteristics that appeared structured to fit their possessor's needs. The implied teleological argument that an organism's needs were somehow assessed prior to its formation, and its characteristics constructed to meet preconceived needs, was at odds with a materialistic explanation of life. The problem of 'adaptation' in organismal form has long dominated the study of evolution.

In the most noteworthy pre-Darwinian theory of evolution, Jean-Baptiste de Lamarck (1809) credited animals with volition that could direct acquisition of useful characteristics, which would then be transmitted by heredity to their offspring.

Differential use versus disuse of body parts, for example, would influence corresponding hereditary changes in body form and thus direct adaptive evolution. Lewontin (1983) applies the term 'transformational' to evolutionary theories like Lamarck's in which organismal change during development is the hypothesized mechanism of evolutionary change. Allen (2014) makes a critical distinction between Lamarck's notions of organismal volition versus inheritance of characteristics 'acquired' during an organism's lifetime. Although a role for volition was widely discredited in early criticism of Lamarck's theory, Lamarck's notion of inheritance of acquired characters persisted at least as a minor component of evolutionary theory from Darwin (1859) to contemporary evolutionary genetics (Jablonka and Raz, 2009). The Darwinian tradition following Weismann (1886) nonetheless largely discredited Lamarckian transformational arguments entirely as being inconsistent with hereditary mechanisms and thus unable to explain adaptation. Evolution by natural selection is indispensable to neo-Darwinian explanations of adaptation, although evolution by natural selection does not guarantee adaptation.

Darwin's Theory of Evolution by Natural Selection

Darwin's insight in explaining adaptation is that variation among individuals within populations is the material from which adaptive characteristics arise. This theory is thus 'variational' in its evolutionary mechanism in contrast to Lamarck's 'transformational' mechanism (Lewontin, 1983). Darwin (1859) had no concepts of genes or gene mutations, both of which emerged following rediscovery of Mendel's work in 1900 (Allen, 2014). Darwin's selection theory required that variation be produced at random with respect to an organism's needs, and that the variation be 'heritable' in the sense that organisms resemble their parents or grandparents more closely than they do individuals sampled randomly from the population. Darwin considered saltations, large changes in organismal form arising within a generation, inevitably harmful to their possessors. Only changes of small effect could include new forms potentially beneficial and thus potentially leading to adaptation. Adaptation as a process thus required gradual change in organismal form. Accumulation of small, gradual changes over hundreds or thousands of generations could construct new adaptations. Such adaptations would have no reasonable chances of occurrence except by natural selection increasing the frequency in a population of many small, individually favorable subparts, and thus combining them to construct a novel organismal form.

Mayr (1985) separates the observations and logical inferences underlying Darwin's theory of natural selection. The first major inference is a struggle for existence among organisms within populations, resulting from what would later be called 'superfecundity': populations produce large numbers of offspring each generation, with a biological potential for exponential growth in population size, but most individuals perish prior to adulthood because resources are insufficient to support them. Combined with the observations of heredity and variation as described in the preceding paragraph, Darwin argued that organisms whose characteristics are most favorable for survival and reproduction contribute disproportionately large numbers of offspring to the next generation. The favorable characteristics that permit an organism to survive and to reproduce thus increase in frequency in the population. Favorable characteristics that arose in different individuals in different generations have a high probability of being combined in the same organism when those characteristics are common in the population. Such combinations of favorable characteristics gradually construct new adaptations. Dennett (1995) characterizes evolution by natural selection as an algorithm that operates by chance (random variation) to produce order (adaptations). Adaptations of greater complexity become possible using previously evolved adaptations as modular subunits.

Criticism of Natural Selection as the Mechanism of Adaptation

Critics of natural selection as the source of adaptation focus on the ability of randomly produced, gradually accumulated changes to construct new features. 'Mivart's dilemma' argues that the incipient stages of an adaptation would provide insufficient utility for natural selection to accumulate them. Darwin (1859) anticipated this challenge in arguing that the initial stages of a structure often served biological roles different from ones acquired later following evolution of a minimum level of complexity. Feathers in birds clearly have utility for flight, although feathers preceded flight in avian evolution. The initial evolutionary stages of feathers likely provided insulation for a homeothermic animal, with some feathers being modified to form flight structures much later by co-opting a thermoregulatory device for a new role. The concept of exaptation, as formalized by Gould and Vrba (1982), is clearly expressed but not distinguished from adaptation in Darwin's *On the Origin of Species*.

The integrity of natural selection as a means for creating highly improbable new structures lay in its coupling with gradualism. Only by bringing together many variant forms, each one arising in a different individual in a different generation, could natural selection actually construct something new. If a new form occurred abruptly in a single individual and natural selection served merely to increase its frequency to become the prevalent form, natural selection would fail to explain how the new form was constructed. That explanation would be sought either in the process that generated the saltational variation (mutation) or by developmental properties of the organism that governed how a new genetic mutation would alter organismal form. The mutation theory of de Vries (1901–03) would emphasize the former explanation; theories of orthogenesis (reviewed by Bowler, 1983) would emphasize the latter, coupled with a notion that 'momentum in variation' would direct evolution in linear trends, sometimes but not always adaptive ones. The saltational theories of Goldschmidt (1948) would include both of these criticisms of natural selection, judging it incapable of explaining evolution of the characteristics that distinguish higher taxa of animals.

As in many biological controversies, both sides contributed critical parts to our current understanding of adaptation. Pharyngeal jaws of many cichlid fishes show hypertrophied skeletal and muscular elements considered useful in crushing hard prey, such as snails. This 'molariform' morphology differs

from the contrasting and presumably ancestral form, the 'papilliform morph,' in which the homologous skeletal and muscular components are much smaller. There is no obvious reason why the hypertrophied molariform structures could not have evolved gradually from the papilliform structures; nonetheless, these contrasting morphs are expressed as discrete alternatives within species (Liem and Kaufman, 1984). Switching of development between these discrete developmental pathways might be genetic in some cases, although it occurs facultatively in some species depending on the dietary environments of young fishes. The contrasting molariform and papilliform morphs are sufficiently different to qualify as saltational change should the change arise within a generation, as it appears to do. Perhaps the simplest explanation is that the molariform morph and its associated developmental processes evolved gradually by natural selection for an ability to process hard food, such as snails, and became tied to a developmental 'switch' that could activate this module or the contrasting papilliform one depending on genetic and environmental cues at a critical stage of development. A population that normally does not express the molariform morph might retain an ability to do so under the critical conditions. Gradual evolution in the past would make possible later saltational evolution by activating a latent developmental pathway whose result is potentially beneficial.

Saltational change mediated by developmental modularity also can occur by expressing a module that evolved gradually in one part of the body at a new location in which the module is potentially useful. A major characteristic of geckos is presence of adhesive toepads, modified scales on the ventral tips of the digits. Some members of genus *Lygodactylus* exhibit such toepads also at the tip of the tail (reviewed by West-Eberhard, 2003, p. 257), conceivably evolved by a saltational change that substituted toepad development for the ventral scales at the tip of the tail.

Evolution of developmental modularity fits Dennett's (1995) analogy of evolution by natural selection to construction of buildings by cranes; construction of smaller cranes makes possible construction of larger cranes, which make possible construction of large buildings. Construction of developmental modules that are semiautonomous of their surroundings, such as developmental of a lizard scale in the form of an adhesive toepad, can form the building blocks of new characters that would be unlikely without such modularity.

Historical Development of the 'Adaptationist Program'

Much of what now constitutes evolutionary developmental biology (West-Eberhard, 2003; Wagner, 2014) was largely missing from evolutionary theory in the 1950s–70s. Also absent was a precise means for constructing phylogenetic relationships among species or even patterns of gene flow among populations within species. Molecular genetic data provided the critical means for measuring the past history of populations and estimating the historic origins of characteristics considered adaptations. One cannot overstate the increased precision of hypotheses of adaptation made possible by robust hypotheses of homology and phylogenetic relatedness of species (Baum and Larson, 1991; Larson, 2009).

Adaptation and Natural Selection by George C. Williams (1966) was perhaps the most influential work of its time on adaptation. It formalized the meaning of adaptation as a structure or behavior that evolved by natural selection for a particular biological role. Williams was instrumental in discrediting group selection as a source of either adaptation, or of characteristics that would favor other organisms at the expense of their possessor. Apparently, altruistic behaviors received special focus because Darwin claimed that natural selection could not evolve a trait primarily for the benefit of others rather than its possessor. Explanations that such traits arose as group-level adaptations rather than as organismal-level adaptations declined following Williams (1966). Williams simultaneously introduced a reductionist principle that adaptive explanations should focus on the lowest biological level of complexity capable of explaining the data, specifically the genic level. From this precedent, Dawkins (1976) popularized the notion that organisms are merely vehicles for the propagation of selfish genes. Williams (1989) would extend this argument to claim that human genomes are a blueprint for selfish behavior, an evil force that human society must combat. This genic-level determinism of organismal characters and adaptations was widely criticized as unfounded and inconsistent with the very fluid relationship between genotype and phenotype on an evolutionary timescale. Waddington's genetic-assimilation experiments (summarized in Waddington, 1975) already had revealed the complexity of mapping genotype onto phenotype. Williams dismissed Waddington's genetic-assimilation theory because the experiments used saltational traits that were clearly nonadaptive. Waddington's process nonetheless later emerged as a general one from later discoveries in evolutionary developmental genetics, whereas the selfish-gene model yielded no comparable insights on the developmental relationship between genotype and phenotype.

A naïve mixing of gradualism and natural selection in the absence of precise tests of phylogeny produced what Gould and Lewontin (1979) criticized as the 'adaptationist program' (see also Lewontin, 1985). Extant characteristics were often considered adaptive by default, perhaps optimally so, using an argument that the population otherwise would be extinct. Natural selection would act each generation to eliminate structural deviations from the optimal form. Adaptationism thus became an idealism in which organismal form was arbitrarily partitioned into characters with no precise tests of character homology, and each such character was assumed optimally adaptive for reasons to be revealed by adaptationist study (see critique by Lewontin, 1985). Perhaps the most extreme version of adaptationism and the one that stimulated the criticisms of the 'adaptationist program' was sociobiology (Wilson, 1975). Lewontin (1985) used Wilson's claim that indoctrinability was a characteristic of human populations evolved by natural selection and encoded by our genes to illustrate the idealism of apaptationist arguments. How could such conjectures be tested and potentially refuted by data?

Idealism of the adaptationist program is perhaps most evident in analogistic approaches to studying human behavioral evolution by finding 'unrelated' species having behaviors judged equivalent to human ones; studies of selective consequences of those behaviors then would explain human evolution (Alcock, 2001). For example, Alcock (2001:196–200)

interprets behaviors of individuals in 'durable and sometimes less than harmonious families' of white-fronted bee-eaters (*Merops bullockoides*) as sharing selective explanations with analogous behaviors in humans, both driven by the ultimate goal of contributing as many surviving copies of their genes as possible to their respective populations. The author doubts that the avian study has any relevance for understanding human social behavior, or even that the human behaviors being addressed demand a biological explanation as adaptation.

Fortunately, advances in molecular phylogenetics and population genetics combined with evolutionary developmental biology provided a precise means for testing hypotheses of adaptation by reconstructing the historical sequence of events antecedent to the population being studied. Lineage-specific developmental constraints on variation reveal the contrasting morphological and behavioral character states most likely to arise and thus to be discriminated by natural selection.

Developmental Constraints and Adaptation

Central to Gould and Lewontin's (1979) criticisms of the adaptationist program is the claim that any characteristic sufficiently explained by physico-chemical causes or the inherent limitations of organismal development need not be burdened by the less parsimonious claim that it evolved by natural selection. In such cases, no contrasting traits could reasonably be expected to have occurred in the past evolutionary history of the population being studied, thus precluding a selective explanation. Ellstrand (1983) makes this argument effectively and humorously in a parody of adaptationism called "Why are juveniles smaller than their parents?" The parody considers a number of different but not mutually exclusive explanations for the ubiquitous occurrence among living forms of juveniles at birth being smaller than their parents. The parody makes passing reference to a possibility that juvenile small size (JSS) is a historical or physical constraint. A phylogenetic approach to this question would reveal in its first step that JSS arose with the origin of life, and remained a fundamental physical constraint within which all subsequent life evolved. There would thus be no need to investigate separate but analogous selective explanations of JSS in all species.

Newman and Müller (2000) present what is probably the most expansive argument that inherent physical properties and dynamics of cellular matter provide the building blocks of and constraints on organismal form. Genetic evolution consists largely in placing control constraints on which among alternative possible forms becomes stabilized and produced with fidelity at a particular developmental stage in a particular population lineage. Evolution by natural selection thus increases the frequency of particular forms over counterparts by ensuring that evolved genic functions make the favored form much more likely to occur than contrasting ones within the environmental conditions experienced by a population. In some cases, a particular developmental event becomes evolutionarily 'burdened' (Riedl, 1978); its occurrence becomes critical for later developmental events and viability of the organism following subsequent evolution. Group-specific developmental constraints thus evolve from the more basic physical constraints shared by living matter.

An extreme case of a burdened structure is the notochord of chordate animals, including all vertebrates. Only chordates have a notochord in their development, and most chordates do not retain this structure intact into their adult morphology. The notochord most likely evolved by natural selection as a cartilaginous and cellular rod serving to support attachment of muscles, a simple skeleton. This condition characterizes *Branchiostoma*, but most chordates depart from it. Most animals never had a notochord in their evolutionary history and never will, but chordates are incapable of survival without development of a notochord at gastrulation, because developmental induction of the central nervous system, and of vertebrae in vertebrates, depends upon the notochord. The notochord is thus a developmental constraint of chordates; separate adaptive explanations for a notochord in the diverse species of chordates in the manner of the adaptationist program would be superfluous and misleading. Such explanations would imply incorrectly that presence versus absence of a notochord is a polymorphism subject to evolution by natural selection within chordate populations.

Developmental constraints, unlike simple physical ones, are thus group-specific evolved features. These features usually would have adaptive origins, but their role in extant species may bear little relationship to the role for which the character evolved by natural selection. The notochord in adult vertebrates is reduced to a series of intervertebral discs located on the ventral side of the spinal column; the inferred adaptive role of the notochord as a skeletal rod enabling movement no longer pertains.

The notion of developmental constraints initially met hostility from many evolutionists who perceived it to diminish the role of adaptation in evolution. This conclusion would hold only in a nonhierarchical theory of evolution. Wagner (1988) used corridor models to examine evolution by natural selection of complex morphological structures, ones in which constraints on variation in some interactions among the component parts are required for adaptive condition of the composite structure. Mathematically, developmental constraints on evolution perpendicular to an adaptive corridor enhance evolution by natural selection along the corridor. The corridor models could be applied, for example, to evolution of molar dentition in mammals. Mammalian molars have large, modulated grinding surfaces that make contact with corresponding molars of the other jaw. The molar structure likely evolved from an ancestral condition in which the teeth contacted at pointed tips, similar to those of canine teeth. Evolution by natural selection likely expanded the surface of contact between upper and lower teeth in the molar region, producing an undulating surface useful for grinding food. It is unlikely that such a surface could have evolved if genetic variation in the area and ridges of the contacting surfaces were accompanied by extensive variation in alignment of upper and lower teeth, heights of upper and lower teeth, anchoring of the teeth in their respective jaws, hardness of the teeth, strength of the enamel, and presumably many other characteristics that remained largely stable as the grinding surface became elaborated. A larger or more nuanced grinding surface would have no consistent selective advantage if it were associated, for example, with decreased tooth height such that the upper and lower teeth did not contact

with the mouth closed, or if the alignment were off, or the teeth subject to being crushed or displaced from the jaw. Directional selection on the nuances of the molar surface would require developmental constraints evolved by stabilizing selection on other dimensions of tooth shape and interaction. Developmental constraints then become the basis for evolution by natural selection of higher-order structures that would be unlikely to evolve without those constraints.

Non-Darwinian Evolution and Selective Neutrality as a Null Hypothesis for Studying Adaptation

Criticism of the adaptationist program in evolutionary morphology and behavior accompanied discoveries in molecular genetics that much of the content and structure of the nuclear genomes of animals and plants could not be explained as adaptations evolved by natural selection for organismal functions.

King and Jukes (1969) used 'non-Darwinian evolution' for their hypothesis that most evolutionary change in proteins occurs without natural selection. It is thus not adaptive. Because population sizes are finite, statistical sampling alone ensures evolutionary change across generations in a polymorphic population. This 'random genetic drift' was important to Sewall Wright's shifting-balance theory but served mainly to influence natural selection (Wright, 1932). The notion that most evolutionary change could be explained by mutation and genetic drift alone, without natural selection, was a new theory, elaborated mathematically by Motoo Kimura in the 1960s and summarized in *The Neutral Theory of Molecular Evolution* (Kimura, 1983). Neutral theory postulates that natural selection mainly discards harmful mutations. Most non-detrimental mutations are selectively equivalent to their predecessors, contributing no populational variance in fitness. Such mutations might increase in frequency by chance alone. Very few mutations would have sufficient benefit for natural selection to drive them to fixation. Neutrality theory predicts that the long-term rate of genic evolution approximately equals the rate of neutral mutation. Adaptively important parts of a gene or protein typically evolve slowly, because new mutations likely impair a highly evolved function.

Following much controversy, neutral evolution became a useful null hypothesis for molecular evolution. Mathematical models of neutral evolution serve to identify cases where data reject neutrality, thus highlighting specific molecular structures that demand an adaptive explanation by natural selection. Because neutral evolution requires only mutation and genetic drift, and because these evolutionary forces occur in all populations regardless of whether selection acts, neutrality is the simplest explanation of evolutionary phenomena that fail to reject its predictions (see review by Templeton, 2006).

In an impressive example, Walter Messier and Caro-Beth Stewart in 1997 demonstrated adaptive evolution of mammalian lysozyme c proteins by statistically rejecting the null hypothesis of neutrality. Foregut-fermenting ungulates and primates evolved stomach expression of lysozyme c to enable them to digest bacteria as a food source. The ancestral role of lysozyme c is to destroy infectious bacteria consumed by white blood cells. Recruitment of lysozyme c as a stomach enzyme is enhanced by amino acid substitutions that enable lysozyme c to operate in the stomach's highly acidic and caustic conditions. Lysozyme c evolved more rapidly than predicted by neutrality on ancestral lineages that evolved foregut fermentation, followed by evolutionary rates much lower than neutral ones, representing selective conservation of adaptations for stomach conditions.

Selfish DNA as a Challenge to and Source of Adaptation

Ford Doolittle and Carmen Sapienza (1980) and Leslie Orgel and Francis Crick (1980) introduced a new theory to explain the paradox that organisms contain more nuclear DNA than needed to guide protein synthesis, and that similar species often differ greatly in the DNA content of their cell nuclei. They postulated that some DNA sequences manipulate cellular processes of gene replication and expression to insert extra copies of themselves in a genome, without any advantage to the host organism. This 'selfish DNA' is essentially a genomic parasite. Because transposable elements are primarily detrimental or neutral to the host organism, their origin is not by natural selection but by an intragenomic analogue of natural selection. Vrba and Gould (1986) provide a detailed explanation of selfish DNA as a lower-level analogue of natural selection. Burt and Trivers (2008) present an encyclopedia of selfish genomic elements in their *Genes in Conflict*.

Retroviruses are the most elaborate selfish DNA elements. Their RNA genome encodes reverse transcriptase (makes a DNA copy of the RNA genome), a capsid protein (encloses the viral genome and reverse transcriptase in a particle), and an envelope protein (recognizes receptor molecules on a host cell, permitting infection). A retrovirus inserts copies of itself into the nuclear genomes of host cells, sometimes including the germ line. Latent retroviruses, capable of evolutionary activation by later infection or recombination, can remain in the genome of a species for many millions of years. Nuclear genomes also typically contain many transposable elements that encode reverse transcriptase but not the capsid or envelope proteins of a retrovirus. Transposable elements multiply within a genome but do not produce infective particles; they spread from one cell to another only through the hereditary process of cell division. Some small selfish DNA elements called SINES encode no proteins, but they have signals that utilize the transcriptases (RNA polymerase III) and reverse transcriptases (encoded by longer transposable elements) to replicate themselves in nuclear genomes.

Because occurrence and movement of selfish DNA elements can impair organismal survival and reproduction, an important class of organismal adaptations consists of mechanisms for suppressing activity of transposable elements (reviewed by Burt and Trivers, 2008).

Genetic changes caused by activity of transposable elements occasionally produce traits favorable to an organism, leading them to be co-opted by natural selection for organismal advantage. Roy Britten (2010) reviews evidence that transposable elements were recruited for adaptive evolution of

gene expression in human evolution. The immune system of vertebrates includes evidence of co-option of transposon activity for the kinds of gene rearrangement that are needed for an organism to develop immunity to unanticipated infectious agents.

Adaptation survives as a critical aspect of evolutionary biology whose operation requires a hierarchical perspective. All of the biological phenomena that were perceived initially as replacing evolution by natural selection (genetic drift, developmental constraint, selfish DNA) provide new opportunities for evolution of adaptation by natural selection.

A Role for Volition in Darwinian Evolution of Adaptation?

Darwinian theory of evolution by natural selection has been criticized, even by some of its advocates, for overlooking a role for organismal volition in evolution of adaptation (Lewontin, 1983). The mathematical theory of neo-Darwinism often treats an organism as a passive object of genetically determined traits and the environmentally determined differences in fitness conferred by those contrasting traits (Alberch, 1989). Notions that an organism's choices of habitat or that characters acquired, perhaps by learning, can influence adaptation are often resisted as inevitably introducing discredited Lamarckian inheritance. Nonetheless, most organisms have at least some means of evaluating and often selecting environmental conditions most appropriate for them from the available alternatives. A monarch butterfly seeks plants of the genus *Asclepias* for depositing its eggs. Seeds of *Ceanothus* bushes remain dormant for many years until a sporadic fire stimulates their germination. Clearly, many organisms have at least some ability to discriminate the habitats most suitable for them from an array of environmental conditions encountered. Three related concepts, genetic assimilation (Waddington, 1975), behavioral drive (Larson *et al.*, 1984), and phenotypic accommodation (West-Eberhard, 2005) provide means by which an organism's choice of environment could influence its population's evolution of adaptation by natural selection.

Genetic assimilation arose from experiments by Waddington (1975) on the relationship between genetic variation and susceptibility of development to environmentally induced changes. He exposed eggs of the fly *Drosophila melanogaster* to ether at a critical stage of development, causing the posterior segment of the thorax to develop the physical appearance of the middle thoracic segment, including a pair of hind wings absent in normal fly development. This environmentally induced phenotype closely resembles one produced by mutations at the *Bithorax* locus and is called a *Bithorax* phenocopy. By selecting flies having the greatest propensity to respond to ether treatment by producing a *Bithorax* phenocopy, Waddington demonstrated that the population contained genetic variance capable of being selected to 'canalize' development toward the Bithorax phenotype. The canalization was strong enough after many generations of selection that the *Bithorax* phenotype became common even in the absence of the ether treatment. In terms of population-genetic theory, the environmental stimulus (ether present at a critical stage) revealed additive variance in fitness in the selection experiment. The genetic variation underlying the additive variance in fitness was part of the *D. melanogaster* population even prior to the experiment, but it did not express itself as additive variance in fitness mediated through contrasting modes of thoracic development prior to the experimental conditions.

West-Eberhard's (2005) model of evolution by phenotypic accommodation has many similarities to genetic assimilation. It differs largely by noting that homeostasis during organismal development can cause an organism to develop favorable responses to environmental challenges through developmental plasticity. She illustrates her claims by citing Slijper's observations on development of a goat whose forelimbs were paralyzed at birth. The goat balanced on its hind limbs only, and by doing so directed its muscular and skeletal development toward a novel form conducive to bipedal walking. In a hypothetical case where environmental conditions favored bipedal gait in a goat population following a stimulus that caused some goats to adopt this posture, preexisting genetic variation contributing additive variance in stabilizing the bipedal habit and associated morphological changes could lead to adaptation. The initial usage of bipedal locomotion and developmental changes induced by the altered musculoskeletal development need not be genetic in origin; the evolutionary process is nonetheless a Darwinian one because stabilization of the new condition is achieved by natural selection on genetic variance in fitness.

Allan C. Wilson proposed the hypothesis of behavioral drive to explain what he perceived as disproportionately higher rates of anatomical evolution in mammals and birds than in other vertebrates. He argued that the greater influence of learned behaviors in these groups would lead them more often to explore new environments and in doing so to subject the population to selection for novel utilities and forms of structures. Among his favored examples was learning by a population of *Cyanistes caeruleus* birds to obtain milk from bottles delivered outside homes in the United Kingdom. The novel source of nutrition undoubtedly would have revealed additive variance in fitness with respect to digesting lactose had this become a primary food for the population. Mammals whose diets contain large numbers of bacteria, such as those that inhabit the rumen of foregut-fermenting ungulates and leaf-eating monkeys, show a series of adaptations to this food source, especially high levels of stomach expression of the bacteriolytic enzyme lysozyme and evolutionary changes in the lysozyme protein structure for optimal functioning in the stomach (Messier and Stewart, 1997).

It is likely that evolution of feeding preferences and other instincts begin as behavioral changes not initially under strong genetic control, but that the new context leads to selection for genotypes most conducive to stabilizing expression of a behavior beneficial under new environmental circumstances. As genetic mechanisms are constructed by natural selection, a particular behavior, such as hygienic behavior in bees (Lapidge *et al.*, 2002), acquires a strong genetic association. Evolution of genetic canalization of a behavior initially not under strong genetic control seems more parsimonious than the contrasting interpretation that genetic mutations initiated the details of the behavioral expression. Bonner (1996) used the term 'gene accumulation' to denote the increasing genetic control of

a particular developmental pathway, and 'gene silencing' to denote evolutionary diminishing of such control. Phenotypic accommodation, behavioral drive, and genetic assimilation provide a stronger mechanism for evolution of new adaptations than do models postulating strong genetic control of particular developmental or behavioral pathways as the initial condition rather than as the product of adaptive evolution.

Adaptive Landscapes

Ehl Svensson, Lund University, Lund, Sweden

Glossary

Adaptive landscape The relationship between fitness (dependent variable) and genotype (at one or several loci) or phenotype. Different definitions of adaptive landscapes exist; the two most common being either fitness depicted against individual genotypes or fitness depicted against allele frequencies in the population.

Adaptive peak A gene or trait combination in the adaptive landscape that is connected with high fitness, and tends to drive populations to evolve by natural or sexual selection.

Brownian motion (BM) A popular and widely used model of phenotypic evolution that is often used as a null model or point of departure in phylogenetic comparative studies of adaptation. In BM models, interspecific variance increases linearly over time, due to stochastic processes such as mutation accumulation, and variance is thus unbounded.

Correlational selection Selection for optimal trait (or gene) combinations, typically expected to operate around a fitness peak in a multidimensional adaptive landscape.

Epistasis Interactions between alleles at different loci in shaping phenotypes. A special case, of particular relevance to adaptive landscape theory is fitness epistasis, where the phenotype is fitness which is interactively affected by two or more loci, resulting in adaptive peaks or valleys. Fitness epistasis is conceptually closely related to correlational selection.

Fitness valley Combinations of genes or traits in between adaptive peaks that result in low fitness.

Holey adaptive landscape A special case of adaptive landscapes initially modeled and suggested by theoretical evolutionary biologist Sergey Gavrilets, where large regions of genotype space form selectively neutral 'ridges' of high fitness, separated by low-fitness genotypes. Genotypes are assumed to only take two fitness-values in this model (1 = 'viable' and 0 = 'unviable'). This model of adaptive landscape has inspired researchers interested in the dynamics of molecular evolution.

Ornstein–Uhlenbeck (OU) model An alternative model of phenotypic evolution to Brownian motion in phylogenetic comparative studies of adaptations. In contrast to BM models, in OU models the accumulation of interspecific variance is not unbounded, but constrained. This reflects the effects of a 'pullback' force in BM models, which are usually interpreted as the effects of stabilizing selection as populations and species climb alternate adaptive peaks.

Peak shift The process by which a population moves from one adaptive peak to another in the adaptive landscape, and was traditionally thought to be difficult or impossible, as the population would have to cross a fitness valley in between the peaks.

Shifting Balance Theory (SBT) A controversial model of evolution and the problem of peak shift that was initially suggested by population geneticist Sewall Wright in 1932. It invokes a delicate balance between different evolutionary forces in subdivided populations such as genetic drift, local selection, and gene flow.

Stabilizing selection A conservative form of selection that favors intermediate trait values or heterozygotes (as in overdominant selection). Stabilizing selection is thought to be a common mode of selection when populations are at their evolutionary equilibria, such as when they are close to their adaptive peaks.

Historical Introduction

A Central Position in Evolutionary Theory and Population Genetics

Adaptive landscapes hold a central and special position in evolutionary theory, particularly in population and quantitative genetics, but also in some models of macroevolution. The adaptive landscape concept was originally formulated by the population geneticist Sewall Wright in his now classical paper from 1932 entitled 'The roles of mutation, inbreeding and crossbreeding in evolution' (Wright, 1932; **Figure 1**). An adaptive landscape shows the relationship between fitness (vertical axis) and one or several traits or genes (horizontal axes). An adaptive landscape is therefore a form of response surface, describing how dependent variable (fitness) is causally influenced by one or several predictor variables (traits or genes). Evolution by natural selection in the context of adaptive landscapes can be viewed as a hill climbing process, in which populations climb upwards to the trait or gene combination with the highest fitness ('adaptive peaks'). In between the adaptive peaks, there are regions in phenotype or genotype space of low fitness ('fitness valleys'). Adaptive landscapes have appeared in the popular science literature on evolutionary biology, perhaps most explicitly in Richard Dawkin's book 'Climbing Mount Improbable,' published in 1996 (Dawkins, 1996). Here, Dawkins, like many others, likened evolution by natural selection to a hill climbing process, in which populations and species evolved by climbing the closest adaptive peak, even though it is not always the peak with the highest overall fitness.

In the precomputer era, adaptive landscapes were often visualized as three-dimensional surface plots with only two traits (or genes) as independent variables. Adaptive landscapes then mainly served a heuristic function for qualitative reasoning, rather than quantitative analysis. With the rapid

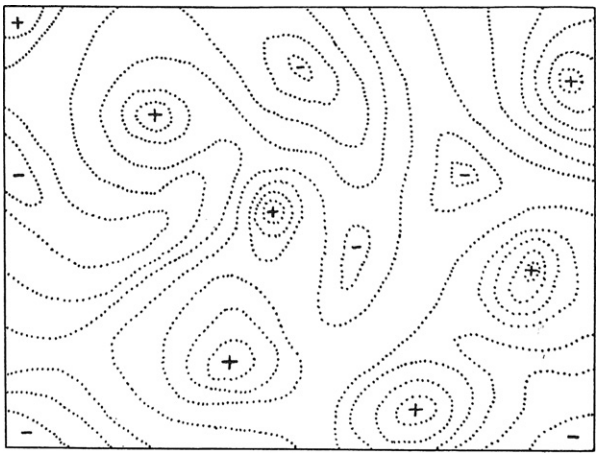

Figure 1 Sewall Wright's classical adaptive landscape figure. The contour plots show various genetic combinations of high fitness ('+' in figure), separated by fitness valleys ('−' in figure). Sewall Wright introduced the concept of the adaptive landscape in his 1932-publication (Wright, 1932). Reproduced from Skipper, R.A., Dietrich, D., 2012. Sewall Wright's Adaptive Landscape: Philosophical reflections on heuristic value. In: Svensson, E.I., Calsbeek, R., (Eds.), The Adaptive Landscape in Evolutionary Biology, Oxford: Oxford University Press, pp. 16–25, with permission from original publisher.

development of evolutionary quantitative genetic theory and increasing computer power, adaptive landscapes are now one of several analytical tools for modern evolutionary biologists. However, the adaptive landscape concept has also generated many criticisms from both philosophers and evolutionary biologists (Kaplan, 2008; Svensson and Calsbeek, 2012).

Influence on Various Fields of Evolutionary Biology

Sewall Wright's main scientific rival at the time when he formulated the adaptive landscape concept was the British mathematical population geneticist Ronald Fisher, who had a different view of the evolutionary process (Provine, 1986; Frank and Slatkin, 1992). Frank and Slatkin (1992) discussed the different views of Sewall Wright and Ronald Fisher, and they argued that whereas Wright's goal was to establish a dynamical theory of evolution, Fisher was more interested in evolutionary equilibria, as reflected in his formulation of the 'Fundamental Theorem of Natural Selection', rather than being interested in adaptive landscapes.

The paleontologist George Gaylord Simpson took the adaptive landscape concept of Sewall Wright into the field of macroevolution of phenotypes, and also discussed so-called quantum evolution – the rapid appearance of novel traits and lineages often seen in fossil record (Simpson, 1944; Kirkpatrick, 1982). The adaptive landscape does still influence paleontological research, particularly those who try to interpret stratigraphic time series in the fossil record (Hunt, 2007; Hunt *et al.*, 2008; Bell, 2012). Unlike Sewall Wright, Simpson thus focused on quantitative phenotypic traits, regardless of their genetic basis, which later influenced evolutionary quantitative genetic theory (Hansen, 1997; Arnold *et al.*, 2001). A major step forward in evolutionary quantitative genetics was achieved by modeling the temporal dynamics of Gaussian phenotype distributions and how these distributions change over time due to natural selection and genetic drift (Lande, 1976). Arnold *et al.* (2001) argued that the adaptive landscape provides a natural conceptual bridge between micro- and macro-evolution. In ecology, the adaptive landscape metaphor has perhaps been most influential in the fields of adaptive radiation and ecological speciation (Schluter, 2000) and in analyses of the evolutionary consequences of competition (Fear and Price, 1998). The adaptive landscape has also been a major influence in experimental evolution studies, particularly in studies on microbes such as *Escherichia coli* (Lenski and Travisano, 1994; Cooper, 2012).

Another field where adaptive landscape theory has been strongly influential are phylogenetic comparative methods, where models are now being developed to test various scenarios of phenotypic evolution and adaptive landscape dynamics, including models for evolutionary stasis, peak shifts, random bursts, and directional selection (Uyeda and Harmon, 2014). An important conceptual insight has been that dynamics of phenotypic traits over evolutionary time might sometimes better be described by an Ornstein–Uhlenbeck (OU) process rather than by the traditional stochastic Brownian motion (BM) model (Hansen, 1997). OU models are thought to capture stabilizing selection around adaptive peaks better than BM models, as there is often a signature of a significant 'pullback force' that is usually interpreted as the signature of stabilizing selection (Hansen, 1997).

There has recently been increasing interest in applying adaptive landscape theory to problems in molecular evolution, such as metabolic networks. One key insight that has stimulated this interest is that multiple genotypes can give rise to the same phenotype(s), implying that they can be more or less neutral with respect to fitness. Thus, there might be multiple genetic solutions to the same ecological problem facing organisms surviving in complex environments. In multidimensional genotypes, there can often be a series of mutational steps connecting genotypes to each other, and populations can therefore traverse extensively in genotype space on nearly-neutral ridges (Gavrilets, 2004; Wagner, 2012). With the rapid development of molecular biology and related fields, the adaptive landscape has also recently emerged at the intersection between evolutionary biology and systems biology (Kogenaru *et al.*, 2009) and has caught the attention of researchers interested in protein evolution (Carneiro and Hartl, 2010).

Analytical Approaches and Methods of Study

There are five traditional major empirical approaches to study adaptive landscapes:

1. Measuring and quantifying the mode of selection in natural populations
2. Experimental manipulations of individual genotypes, phenotypic traits or agents of selection
3. Experimental evolution
4. Phylogenetic comparative methods
5. Inferences from time series in the fossil record.

All these methods have their pros and cons, and in-depth reviews and discussions of each of the approaches can be

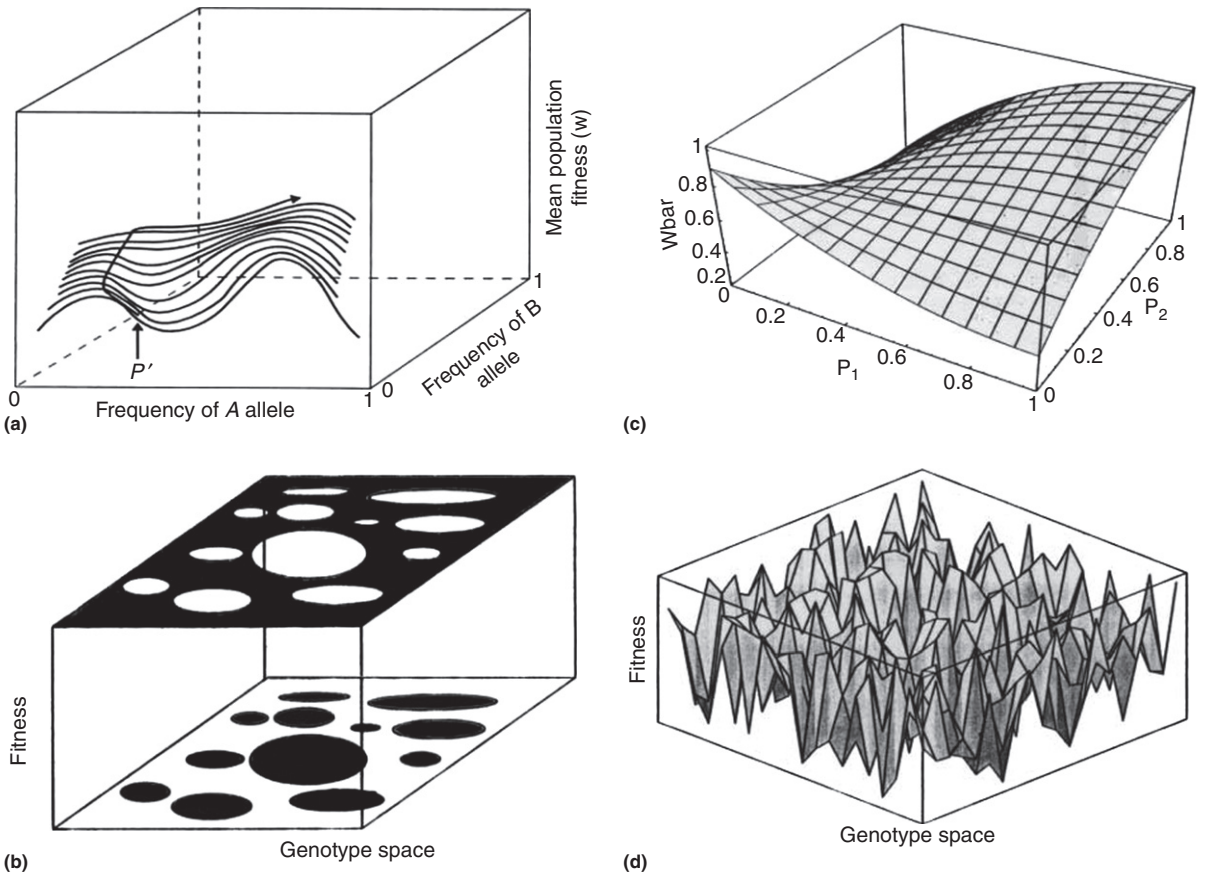

Figure 2 Four different adaptive landscape versions that have grown out from various critiques of Sewall Wright's original adaptive landscape. (a) 'Fisherian' adaptive landscape with a single fitness peak. (b) 'Holey adaptive landscape', where genotypes can either have high or low fitness, as formulated by Gavrilets (2004). (c) 'Wrightian' adaptive landscape with two fitness peaks. (d) 'Rugged adaptive landscape.' Reproduced Skipper, R. A., Dietrich, D., 2012. Sewall Wright's Adaptive Landscape: Philosophical reflections on heuristic value. In: Svensson, E.I., Calsbeek, R., (Eds.), The Adaptive Landscape in Evolutionary Biology, Oxford: Oxford University Press, pp. 16–25, with permission from original publisher.

found elsewhere (Endler, 1986; Harvey and Pagel, 1991; Rose and Lauder, 1996). Methods 1, 4, and 5 are correlative approaches and are inferential, whereas methods 2 and 3 manipulate either phenotypes, selective environments, or both.

The analysis and visualization of adaptive landscapes and fitness surfaces have become increasingly sophisticated with the development of multivariate statistical techniques. Today, evolutionary biologists can describe fitness surfaces both in terms of elevation and curvature and have developed a rigorous formal mathematical framework to quantify adaptive peaks and fitness valleys as well as interactions between traits ('correlational selection') and how they affect fitness (Arnold *et al.*, 2001; Sinervo and Svensson, 2002; Blows, 2007). The development of multivariate statistical methods to analyze fitness surfaces now means that evolutionary biologists are no longer constrained about thinking about adaptive landscapes in only three dimensions, which has been a frequent criticism of adaptive landscapes (Kaplan, 2008). The parameters that are used to quantify fitness surfaces include directional selection gradients (β), curvilinear, and correlational selection gradients (Phillips and Arnold, 1989). Fitness is then modeled as response surface, which is depicted against one or several underlying phenotypic traits (predictor variables).

Different Versions of Adaptive Landscapes

Landscape Structure

Several different types of adaptive landscapes have been developed since Wright (1932), and evolution on these will follow very different dynamics (Skipper and Dietrich, 2012; Figure 2). 'Wrightian adaptive landscapes' are characterized by multiple adaptive peaks, and fitness valleys in between them, reflecting the fitness epistasis that is expected from strong gene interactions. 'Fisherian adaptive landscapes' are smoother than their Wrightian counterparts, and are characterized by a single adaptive peak toward which the population moves through the action of mass selection in large and panmictic populations. In contrast, in the 'rugged adaptive landscapes' envisioned by Wright, populations get stuck on local adaptive peaks for a very long time, being unable to move across fitness valleys. In 'holey adaptive landscapes,' evolution can easily proceed along neutral or semi-neutral ridges that connect genotypes of approximately equal fitness to each other throughout genotype space.

The target model of adaptation is an application of adaptive landscape theory that was initially proposed by Fisher (1930), and formally modeled by Orr (1998) to understand

the genetic architecture of the process of adaptation by natural selection toward a fixed optimum. The target model predicts an exponential size distribution of the fixed factors involved in adaptation, with genes of large effects typically fixed first, followed by genes of smaller effects as the population approaches the optimum (Orr, 1998). The underlying reason for this sequence of events leading to the fixation of factors of differing size is that early on in the population history, genes of major effect are more likely to push the population closer to the fitness optimum, but as the optimum is approached, large-effect mutations are more likely to lead to 'overshoot' of the optimum and hence decrease fitness (Fisher, 1930; Orr, 1998).

Landscape Dynamics

Natural and sexual selection often fluctuate strongly in natural populations when measured across different years or generations. These fluctuating selection pressures strongly suggest that adaptive peaks and valleys are not stable on microevolutionary timescales (Calsbeek *et al.*, 2012). Moreover, adaptive peaks and fitness valleys are expected to be even less stable on macroevolutionary timescales, due to major climatic and biotic changes (Hansen, 2012). The ecological causes and evolutionary consequences of such landscape dynamics are largely unknown and are subject to much discussion among evolutionary biologists. A distinction can thus be made between 'static' and 'dynamic' adaptive landscapes. Major changes in the environment, such as the movement into new 'adaptive zones' are generally considered to be the major explanation for peak movements on macroevolutionary timescales, as envisioned by Simpson (Simpson, 1944; Hansen, 1997; Arnold *et al.*, 2001).

On microevolutionary timescales, density- and frequency-dependent selection have attracted special interest as mechanisms causing landscape dynamics and the movement of adaptive peaks. For instance, under negative frequency-dependent selection (NFDS), a rare morph or genotype will experience high fitness because of its low frequency, but this fitness advantage will disappear as it increases in frequency and climbs the closest adaptive peak. Therefore, a fitness peak will become a fitness trough, over time and a fitness trough will turn into a fitness peak across generations, as the genetic composition of the population changes. The adaptive landscape will therefore be more similar to an 'ocean' with moving waves than a static mountain range. Other ecological interactions and processes such as coevolutionary arms races and 'Red Queen'-dynamics can generate similar effects, and Fisher emphasized this aspect of the evolutionary process in his 'Fundamental Theorem of Natural Selection' (Frank and Slatkin, 1992). Therefore, under NFDS and in similar ecological scenarios, population mean fitness will not necessarily increase, even though the fitness of some genotypes do increase, which points to the crucial distinction between the fitness surface of individuals and the mean fitness of the population (Fear and Price, 1998).

Controversies and Criticisms

The Problem of Dimensionality

One misunderstanding by less mathematically inclined philosophers and historians of science is the frequently repeated claim that adaptive landscapes are only meaningful in three dimensions and that they cease to exist or are meaningless in higher dimensions (Provine, 1986). This early criticism against the adaptive landscape essentially states that since organisms and genotypes are multidimensional, and cannot be restricted to two traits, the adaptive landscape should be abandoned and be replaced with 'formal modeling' (Kaplan, 2008). However, this criticism misses the fact that the phenotypic adaptive landscape in the tradition of evolutionary quantitative genetics does have a rigorous mathematical framework in the form of the visualization of both fitness surfaces through the estimation of parameters quantifying the steepness and curvature of adaptive peaks and valleys (Arnold *et al.*, 2001). This statistical framework is not restricted to only two traits and constitutes exactly the kind of formal modeling that has been requested by critics of the adaptive landscape. With the development of multivariate statistical tools from matrix algebra, such as canonical analysis (CA) and diagonalization techniques, it is now possible to model fitness surfaces in more than three dimensions and to investigate multiple traits simultaneously (Blows and Brooks, 2003). The frequently reiterated criticisms against the simplified three-dimensional fitness surfaces by Sewall Wright (Kaplan, 2008) are therefore no longer valid as modern mathematical, statistical, and computational tools are now regularly used to explore surfaces of increasing dimensionality, both at the phenotypic and genotypic levels (Gavrilets, 2004; Blows, 2007).

Fitness of Individual Genotypes or Allele Frequencies of the Population?

Provine, who published an early and influential in-depth biography of Sewall Wright (Provine, 1986), criticized the adaptive landscape metaphor and pointed to inconsistencies of the two different versions of the adaptive landscape: the genotypic version versus the one showing population allele frequencies. Provine argued these two versions of the adaptive landscape suggested by Wright were 'wholly incompatible,' and that it was only the adaptive landscape of the population allele frequencies that was meaningful. Provine further argued that the adaptive landscape of individual genotypes should be abandoned, as there was no natural way of arranging the discrete genotypes on the axes and essentially this version was meaningless. However, Gavrilets (2004) criticized Provine's view and showed that information about the fitnesses of individual genotypes could be used to deduce fitness landscapes at the population level (but not the other way around). Gavrilets therefore questioned the claim by Provine that these two types of adaptive landscapes were wholly incompatible as they instead are quite naturally connected through each other, as the population mean fitness is obviously influenced by individual fitnesses, but it is not necessarily the other way around (Fear and Price, 1998; Svensson and Calsbeek, 2012).

The adaptive landscape of individual genotypes and the adaptive landscape of allele frequencies of the population have influenced different subfields of evolutionary biology. The adaptive landscape of gene combinations has been particularly important in evolutionary genetics and the understanding of fitness epistasis (Wolf *et al.*, 2000; Phillips, 2008) and in speciation theory, particularly postzygotic speciation

and the development of hybrid incompatibility. In contrast, the adaptive landscape of allele frequencies has played a more prominent role in quantitative genetics and the evolution of phenotypic traits.

The Debate Over the Shifting Balance Theory

Considerable controversy and debate has been focused on the problem of peak shifts and the crossing of fitness valleys in the adaptive landscape. Sewall Wright's suggested solution to the problem of peak shifts and the dilemma for a population that has to traverse through a valley of low fitness was outlined in his Shifting Balance Theory (SBT) of evolution (Wright, 1932; **Figure 1**). Wright argued that in large panmictic populations, peak shifts were unlikely to happen, as mass selection would predominate and the role of genetic drift would be negligible. At the other extreme, in very small populations, genetic drift is stronger and such small populations would potentially go extinct at a high rate. However, in populations of intermediate size that are connected through moderate gene flow, genetic drift could interact with local selection and shape evolutionary outcomes in a different way than would selection operating alone (Wade and Goodnight, 1998). Wright envisioned this ecological setting to be most favorable for peak shifts. SBT, since it was first suggested, has been subject to considerable controversy. For a critical perspective on SBT, where the authors argue it is unlikely to be important in adaptive evolution, see Coyne *et al.* (1997, 2000). For a defense of SBT and Wright's view of peak shifts, see Wade and Goodnight (1998) and Goodnight and Wade (2000). The different views expressed by these different authors illustrate a still existing and strong division between different branches of population genetics, relying either on Sewall Wright's or Fisher's modeling traditions (Provine, 1986; Frank and Slatkin, 1992).

Mathematical Models of Peak Shifts

Several other mathematical models of how peak shifts could happen have been developed. Among these models is the insight that peak shifts could more easily happen when environments fluctuate, so that fitness valleys may temporarily disappear (Whitlock, 1997). Peak shifts can also happen for purely intrinsic reasons, without any environmental change, through increased genetic variance from inbreeding or developmental noise (Kirkpatrick, 1982; Whitlock, 1995). Phenotypic plasticity and subsequent genetic accommodation have also been shown to be able to bring population closer to the domain of attraction of a new adaptive peak (Price *et al.*, 2003).

Peak shifts could also result from correlated responses to selection, if phenotypic traits are genetically correlated with each other, as they typically are (Price *et al.*, 1993). Genetic drift alone has also been shown to be able to cause peak shifts, although the effective population size (N_e) has to become extremely low for this to plausibly happen (Lande, 1985). Finally, the adaptive landscape of the population is influenced by both the relative fitness of different phenotypes and their relative frequency (Kirkpatrick, 1982). As a consequence, the adaptive landscape will 'flatten out' compared to the individual fitness surface, making fitness valleys shallower and potentially easier to cross than one would get the impression of if one only looks at individual fitness surfaces (Fear and Price, 1998). Taken together, these different models have shown that the problem of peak shifts might not be as severe as originally thought, and peak shifts can happen through several different mechanisms. The plausibility of each of these different scenarios is mainly a remaining empirical issue.

Adaptive Ridges and the Non-Existing Problem of Peak Shifts

An alternative perspective on the peak shift debate is that peaks might not exist in real (multidimensional) adaptive landscapes, because all such real adaptive landscapes are likely to have at least one ridge of high fitness between different peaks (Gavrilets, 2004). The increasing number of ridges with increasing dimensionality of the adaptive landscape leads to something which has been coined the 'extradimensional bypass,' relative to the situation for three-dimensional adaptive landscapes (Gavrilets, 2004). This view, therefore, does not deny the existence of the adaptive landscape, as did some early critics of adaptive landscapes, but, according to this view, there will exist large selectively neutral or nearly neutral regions in genotype space that can connect genotypes of approximately equal fitness to each other through networks. Thus, it is therefore the structure of the adaptive landscape, rather than its existence, that is the focus of this and other models of 'holey adaptive landscapes' (Gavrilets, 2004). In these models, the problem of peak shifts therefore disappears, as populations are expected to easily traverse on these adaptive ridges throughout more or less the entire genotype space.

Conclusions and Future Outlook

The adaptive landscape has stimulated a lot of empirical and theoretical research in various subfields of evolutionary biology, including evolutionary and population genetics, quantitative genetics, evolutionary ecology, macroevolution, paleontology, and speciation, to only mention a few such areas. The adaptive landscape has therefore been a very useful concept to evolutionary biologists, judged by the number of investigations and articles that has been published and which are anchored in the adaptive landscape tradition. It is even questionable if certain research fields would have existed at all if the adaptive landscape concept had not been formulated by Wright. These fields include experimental evolution, evolutionary quantitative genetics, and certain branches and models of phylogenetic comparative methods. Judged by this enormous interest, the adaptive landscape must surely be one of the most successful concepts in evolutionary biology. However, the adaptive landscape has also generated considerable controversy and criticisms, resulting in debates of which some have now been settled, whereas others still remain unsolved. Whether these debates have been useful to evolutionary biology or a waste of time is probably a matter of different opinion among different researchers. However, the adaptive landscape is likely to remain in the center of

evolutionary biology for decades to come, and there are signs that it is now attracting the interest of evolutionary biologists working on molecular evolution. Hopefully, future generations of evolutionary biologists can learn from these debates and avoid repeating misunderstandings and past mistakes about adaptive landscapes.

Adaptive Molecular Evolution: Detection Methods

JP Bielawski and C Jones, Dalhousie University, Halifax, NS, Canada

Glossary

Balancing selection The maintenance of population genetic polymorphisms (alternative alleles) at a locus by the process of natural selection.

Coding DNA A sequence of DNA that codes for a sequence of amino acids that constitute a protein.

Codon A unit of three adjacent nucleotides that correspond to a specific amino acid. Codons are the units of the genetic code.

Empirical Bayes An approach to statistical inference that employs Bayes' rule in combination with a prior probability distribution estimated from a sample of data. This differs from the standard approach to Bayesian inference where the prior distribution is fixed before observing data.

Evolutionary comparative genetics A field of research where differences between genes or genomes are assessed within a phylogenetic framework.

Fixation event The process whereby one allele at a polymorphic locus increases in frequency until it comprises 100% of that population.

Fixation index A summary statistic applied to population genetic data for the purpose of measuring the magnitude of population genetic subdivisions (e.g., a measure of differences in the genetic composition of geographically separated populations).

Genetic code The relationship between 64 unique triplets of DNA (codons) and a set of 20 unique amino acids. The biochemical basis of protein synthesis within a cell is based on this relationship.

Likelihood ratio test A method of hypothesis testing based on comparing the fit of two competing models to a sample of data. One model represents the null hypothesis. The null model must be a special case of the model that is used to represent the alternative hypothesis.

Linkage disequilibrium Non-random association of allelic polymorphism at different loci within a genome.

Locus In population genetics it is the location of a gene, or a specific sequence of DNA, within a genome.

Markov model A model for a stochastic process of change between states where the probability of an event depends only on the current state, and not on any of the states that may have preceded it.

Maximum likleihood A statistical technique for estimating the unknown value of a population parameter from a sample of data. The value of the parameter that maximizes the probability of observing the sample of data is the maximum likelihood estimate of the unknown value.

Negative selection A type of natural selection that causes alleles with deleterious effects on fitness to decrease in frequency within a population.

Neutral theory A theory of evolution where the majority of genetic polymorphism observed within species, and genetic divergence observed between species, is attributed to the process of random genetic drift.

Neutrality test A test developed for detecting gene sequence evolution that does not fit expectations derived from neutral theory.

Noncoding DNA Any DNA sequence that does not code for a protein product.

Nonsynonymous mutation A mutation in coding DNA that alters the amino acid composition of the encoded protein.

Nonsynonymous substitution rate The rate at which nonsynonymous mutations are fixed within a population.

Polymorphism Within the discipline of population genetics, the existence of alternative forms of a gene (alleles) within a population.

Positive selection A type of natural selection that causes alleles with beneficial effects on fitness to increase in frequency within a population.

Purifying selection An alternative name for negative selection.

Selective sweep The reduction, or complete loss, of genetic polymorphism at loci immediately surrounding the region of a genome where an allele was fixed by positive selection.

Statistical power The probability that a statistical test will detect a signal in the data when that signal actually exists.

Substitution The population genetic process whereby one genetic variant at a locus is completely replaced by an alternative genetic variant at that locus.

Synonymous mutation A mutation in coding DNA that does not alter the amino acid composition of the encoded protein. Mutations within coding DNA can be synonymous due to the redundancy of the genetic code.

Synonymous substitution rate The rate at which synonymous mutations are fixed within a population.

Type-I functional divergence A condition of homologous DNA sequences where sites have different substitution rates within subsets of those sequences due to divergence in their function.

Type-II functional divergence A condition of homologous coding DNA where the amino acids of the proteins encoded by different subsets of sequences have different physiochemical properties. The important distinction from Type-I divergence is that evolutionary rates do not differ between the subsets of sequences.

Introduction

Models of molecular evolution provide an important tool for investigating how cells and organisms function, and how they have adapted to environments over time. The challenge is to discriminate between the adaptive changes and the potentially large amount of neutral change occurring within a molecule. Knowledge of adaptive molecular change can have practical benefits such as providing insights into the genetic basis of disease susceptibility, evolution of drug resistance, and the spread of pathogens. This has motivated development of sophisticated statistical methods for detecting the signatures of adaptive evolution within DNA sequences. The purpose of this article is to provide a broad introduction to those methods. Because methods can differ greatly according to the type of sequence data, this article is divided into two sections: one is focused on analyzing within-population polymorphism, and the other is focused on analyzing between-species differences. The latter section is further divided according to the type of DNA (codon, amino acid, and noncoding) under study. The goal is to present a general survey of methods, with additional details provided only for the more frequently used approaches. Because several statistical frameworks are frequently used to detect adaptive molecular evolution, formal introductions to those are provided in three 'boxes.' Readers can skip over those boxes, as well as between different sections of this article, without loss of continuity.

Population Genetic Approaches

The availability of genome-scale datasets has transformed evolutionary biology and genomics. Within the field of population genetics, such data are providing an unprecedented opportunity to identify loci, or genomic regions, subject to adaptive evolution (e.g., Pool *et al.*, 2010). Methods for detecting adaptation from population data are most often used to identify a 'selective sweep' event. The selective sweep is initiated by the mutational origin of an advantageous allele. This allele is subsequently driven to fixation by strong positive selection. Neutral polymorphisms in the surrounding genomic region may increase in frequency along with the selected allele, depending on the degree of genetic linkage. Some of these neutral alleles may be 'swept' to fixation (this is the so-called hitchhiking effect) if the linkage is strong. Thus a sweep refers to the tendency for variation to be lost from the genome in the region immediately surrounding the advantageous allele. Completion of a sweep is expected to reduce nucleotide diversity, create an excess of low-frequency polymorphisms, increase homozygosity, and increase linkage disequilibrium (LD) within a localized region of a genome. A variety of statistical methods have been developed to detect these signatures of a selective sweep. As a sweep is driven by strong selection, most of the methods are expected to have reasonable statistical power. Power will be further improved when genome-scale polymorphism data includes rare genetic variants absent from smaller datasets (e.g., Pool *et al.*, 2010).

A class of methods based on detecting generalized departures from neutrality (Tajima, 1989; Fay and Wu, 2000; Fu and Li, 1993) are routinely used to search for selective sweeps. These 'neutrality' tests attempt to detect departures in the allele frequency distribution from expectations derived from a simple neutral model of population evolution (e.g., assuming random mating, no migration, mutation or selection, etc.). A difficulty with these methods is that they are sensitive to any departure from neutrality (selective sweeps, negative selection, or balancing selection). Their interpretability is improved by taking into account the spatial pattern within a genome because the frequency distribution will be most affected in the region around a selective sweep (Nielsen, 2005). However, a further difficulty with these methods is that they are also sensitive to violations of other assumptions about the population, such as constant size and homogeneity. Thus, population demographic processes, as well as genomic variability in the processes of mutation and recombination, may be misinterpreted as positive selection (Nielsen, 2001).

Another class of methods is based on detecting larger than expected levels of population differentiation. When a locus is subject to a selective sweep in a geographically restricted population, alleles in the surrounding genomic region undergo a rapid change in frequency which leads to a localized increase in the signal for population structure. Methods developed to detect such signal often employ a fixation index (F_{st}) to summarize the level of population differentiation (Akey *et al.*, 2002; Weir *et al.*, 2005). However, there are other means of detecting genomically localized population structure (e.g., Beaumont and Balding, 2004; Nielsen *et al.*, 2009; Chen *et al.*, 2010). Just as with the neutrality tests, variability in the process of mutation and recombination, as well as demographic processes, can increase the within-genome variance in the patterns of population differentiation. Comprehensive demographic models can be used to identify and remove variance due to demographic rather than selective processes (Li and Stephan, 2006; Nielsen *et al.*, 2009).

A selective sweep will also increase the association of alleles at different loci in the region surrounding the target of the sweep. When this association is greater than the neutral expectation, it is referred to as LD. Several tests based on a variety of summary statistics have been developed for detecting selection according to LD (Hudson *et al.*, 1994; Kelly, 1997; Depaulis and Veuille, 1998; Andolfatto *et al.*, 1999; Kim and Stephan, 2002; Sabeti *et al.*, 2002; Kim and Stephan, 2003). All these methods exploit the increase in LD that occurs during a selective sweep. Because signal for LD decays as a function of the local recombination rate, this approach will have lower power to detect older events because recombination will have had more time to break down associations created during the sweep. However, the approach is critical to detecting cases where the fixation process is not yet complete (partial sweep) or the strength of selection varies over time (soft sweep).

An alternative to joint analysis of multiple genomic loci is provided by the Poisson random field (PRF) family of methods (Sawyer *et al.*, 1987; Sawyer and Hartl, 1992; Akashi, 1999a; Bustamante *et al.*, 2001, 2003). PRF differs from the above methods because it does not utilize the pattern of variation in the regions surrounding a positively selected locus. It is attractive because it permits inference of selection intensity for different classes of mutations within a principled statistical framework. To accommodate the potential impact of demographic changes, Williamson *et al.* (2005) extended the PRF

approach via a two-step analytical process. In the first step, a selectively neutral class of mutations is used to test for demographics that would lead to rejection of a simple neutral model. In the second step, the parameters of an appropriate demographic model are used to correct for demographic effects on PRF-based tests for selection.

Inferences about selection can be extended by comparing patterns of within-species DNA polymorphisms to divergence between species. This approach allows detection of loci subject to recurrent selective fixations, as well as differentiating between weak and strong purifying selection. The main idea was first proposed by McDonald and Kreitman (1991) in the context of two classes of coding mutations: synonymous (amino acid preserving) and nonsynonymous (amino acid altering). Under neutrality, the ratio of nonsynonymous to synonymous polymorphisms within species should be equal to the ratio between species. Given comparative population data for closely related species, the patterns of polymorphism and divergence are easily summarized as counts within a contingency table (hereafter referred to as the MK method). Thus, it provides an efficient means of detecting non-neutral loci in large datasets (e.g., Bustamante *et al.*, 2005). Unlike many of the above approaches, this method is generally robust to demographic processes (Nielsen, 2001). However, it cannot discriminate between recent and past selective events, and it is not well suited for detecting the focus of a partial or soft selective sweep (Nielsen, 2005). Notwithstanding these limitations, the MK method can provide considerable information about the direction and intensity of selection, and this has led to its extension to several different forms of molecular adaptation (Akashi, 1995, 1999b; Andolfatto, 2005). The analytical framework of the MK method has been widely employed to estimate the historical fraction of substitutions that were fixed by positive selection (see Eyre-Walker (2006) and Fay (2011) for reviews).

Both the PRF and MK methods exploit the information contained within the frequency distribution of population polymorphisms. They differ in that the PRF methods utilize the full polymorphism frequency spectrum, whereas the MK methods collapse that spectrum into counts of just two types of polymorphism. Both approaches, however, depend on the same key assumptions: site independence and the infinite-sites approximation. Although the MK methods should be less sensitive to assumption violations (Desai and Plotkin, 2008), the interpretation of its results is not free from such concerns (e.g., Fay, 2011). It is best to consider the signal detected using either the PRF or MK methods as potentially sensitive to any non-selective processes that impact the polymorphism frequency spectrum (Desai and Plotkin, 2008). Examples of such processes include biased gene conversion and among-site variability in synonymous substitution rates, but other sources are just as plausible (e.g., Fay, 2011). These limitations can be overcome by relaxing the assumptions inherent in the original methods. Readers are refereed to Desai and Plotkin (2008) and the references therein for examples of this line of method development.

Comparative Evolutionary Approaches

In comparative sequence analysis, the differences between sequences are due to one or more substitution events. A substitution event requires that a novel mutation has passed through a period of polymorphism, and become fixed in a population. This contrasts with population data, where variation among sequences is predominantly attributable to genetic polymorphisms within a population. Comparative data are rich in information about the substitution process over deeper timescales, and the purpose of methods developed for such data is to distinguish between a neutral substitution process and a process that has been impacted by natural selection.

The most widely used comparative methods are derived from the general principle that the substitution rate is inversely related to the level of functional constraint (Kimura, 1985). Methods developed explicitly for coding sequences seek to identify significant differences in the rate of amino acid evolution over time or among sites (e.g., Yang, 1998; Gu, 1999; Susko *et al.*, 2002); either of these can be interpreted as evidence of a change in the intensity of natural selection acting on the protein product. The fact that substitution rates can be measured in two distinct ways for coding sequences – synonymous and nonsynonymous – has led to the development of two different analytical strategies. The first scales the nonsynonymous substitution rate according to the inverse of the synonymous (or neutral) rate. This scaling is intended to normalize the nonsynonymous rate relative to the neutral rate, thereby providing a readily interpretable index of the strength and type of natural selection (Kimura, 1985). Being dependent on the synonymous rate, however, means that this approach can't be used for highly divergent sequences where the synonymous rate is difficult to estimate reliably. The second strategy employs the absolute rate of nonsyonymous substitutions. While this is suitable for highly divergent coding sequences, it cannot be used to distinguish among different types of selection pressure. Comparative methods were also developed for noncoding DNA, and they employ the same principle, i.e., the rate on noncoding sequence evolution will be inversely related to the intensity of selective constraint. When applied alongside an analysis of polymorphism data the comparative approaches contribute to a comprehensive assessment of selective pressure that includes both historical and ongoing evolutionary processes (Nielsen *et al.*, 2005).

Codon Analyses

Protein coding sequences can be analyzed with respect to just the changes between nucleotides (i.e., just A, C, G, and T), but this approach will not capture any information related to the process of amino acid substitution. Analyzing evolution at the codon level provides a way forward: (1) evolution can be placed in the context of a specified genetic code, (2) nonindependence of substitutions at different positions within a codon is accommodated, and (3) the processes of synonymous and nonsynonymous substitution can be explicitly separated. Because the rate of synonymous substitution (d_S) is the rate a coding sequence is expected to evolve had there been no selection on the protein product, each coding sequence can be viewed as containing information about its own neutral rate. Because the majority of nonsynonymous mutations are expected to reduce fitness, they will be removed from a

population by selection more frequently than expected under neutrality, and the nonsynonymous rate (d_N) for the same sequence will be lower than d_S. The size of this effect is a function of the intensity of negative selection pressure, with the ratio of those rates ($\omega = d_N/d_S$) taking values less than 1. If, however, the structure or function of a protein becomes unconstrained for any reason, then synonymous and nonsynonymous mutations will be fixed at about the same rate ($\omega \approx 1$). The only way d_N can exceed d_S is by positive Darwinian selection. In this way $\omega = d_N/d_S$ serves as an index of the strength and type of natural selection pressure (Kimura, 1985).

Early codon models were developed for estimating the distance between pairs of sequences in terms of both d_N and d_S (e.g., Miyata and Yasunaga, 1980; Nei and Gojobori, 1986; Yang and Nielsen, 2000). Because the observed differences between a pair of sequences will underestimate the actual divergence as evolutionary time increases, distance methods attempt to correct d_N and d_S so that they are approximately linear with time. Distance methods have the drawback that they produce nonindependent estimates of d_N and d_S for a multispecies alignment. To avoid this, the approach was extended to phylogenetic trees (Nei and Gojobori, 1986). A simple approach to phylogenetic estimation of d_N and d_S was to reconstruct ancestral states for the interior nodes of a phylogeny and count differences between codons across the tree (Messier and Stewart, 1997).

Estimation of d_N and d_S is a complicated task. Early methods employed *ad hoc* corrections for processes of sequence evolution that can negatively impact rate estimates (e.g., Bielawski *et al.*, 2000; Dunn *et al.*, 2001). Maximum likelihood (ML) estimation of the ratio ω under a Markovian model for codon evolution obviates the need for *ad hoc* corrections (Muse and Gaut, 1994; Goldman and Yang, 1994). **Box 1** uses a very simple probability model (binomial) to present a general introduction to the principle of ML. Although codon models represent a considerable increase in complexity, the principles presented in **Box 1** are directly applicable. Most importantly, the *ad hoc* corrections employed by the early distance methods are not necessary under the ML approach, because corrected estimates of d_N and d_S are a natural consequence of the probability calculations carried out under a Markovian model of codon evolution. A further benefit is that the ML approach permits estimation of ω jointly for all the sequences in the alignment, and so permits use of more complex models in a phylogenetic framework. More recently, fully Bayesian methods have been developed (Huelsenbeck and Dyer, 2004; Angelis *et al.*, 2014). Like ML, fully Bayesian methods employ a probability model for codon evolution. However, they also require prior probability distributions for model parameters which are subsequently modified by the sequence data (under the assumed model) to obtain posterior distributions. Rather than seeking to estimate an optimal value for the ω parameter, Bayesian methods seek to estimate a distribution for ω.

The ML and Bayesian methods have several advantages over methods that rely on estimates of ancestral sequences. They take uncertainty about the ancestral states into account by integrating over all possible ancestors, each weighted by their respective equilibrium frequencies. Furthermore, they provide a natural means to estimate the number of hidden substitutions along a branch. They are also amenable to modeling important aspects of DNA sequence evolution, such as transition bias and codon-usage bias, which have proved to be difficult to accommodate without a probability model. These advantages come at the cost of computational complexity. The time required for analyses involving a large number of taxa can be prohibitive without substantial computational resources.

The ML and Bayesian methods assume that the evolutionary process is Markov, meaning that the probability distribution for the identity of a substituting codon at a given site depends only on the identity of the codon currently

Box 1 Maximum Likelihood

A probability model $f(x|\theta)$ is a function that gives the probability of an event x given a vector of model parameters θ. For example, the probability of getting heads x times in three tosses is given by the model

$$f(x|\theta) = \frac{3!}{(3-x)!x!}\theta^x(1-\theta)^{3-x}$$

where θ is the probability of a heads on one toss. The probabilities of various outcomes $x \in \{0,1,2,3\}$ can be computed if θ is known.

There are many scenarios in science where the parameter vector is unknown. In such cases, the outcome of a set of independent trials can be used to estimate θ. Suppose three tosses resulted in $x=2$. Then, treating the data as fixed and the parameter as the variable, the above equation can be written as:

$$L(\theta|x=2) = \theta^2(1-\theta)$$

This equation gives the likelihood of θ given the data. Note that the likelihood function only retains the components of $f(x|\theta)$ that are dependent on the unknown parameter. Given the results $\{x_1,\ldots, x_n\}$ of n independent trials, we can make use of the fact that the probability of a series of independent events is just the product of the probabilities of the individual events and write:

$$L(\theta|\{x_1,\ldots,x_n\}) = \prod_{i=1}^{n} \theta^{x_i}(1-\theta)^{n-x_i}$$

Since it is easier to work with sums than products, it is customary to take the logarithm of both sides of this equation:

$$\ell(\theta|\{x_1,\ldots x_n\}) = \sum_{i=1}^{n} \{x_i \log(\theta) + (n-x_i)\log(1-\theta)\}$$

The maximum likelihood estimate (MLE) for θ is the value $\hat{\theta}$ that maximizes the log-likelihood function $\ell(\theta|x_1,\ldots, x_n)$.

Although probability models for sequence evolution are considerably more complex than the model presented here, the underlying framework is the same. The principle of maximum likelihood is used to infer values for parameters ($\hat{\theta}$) related to the process of codon (e.g., Nielsen and Yang (1998) in Section Codon Analyses), amino acid (e.g., Gaston *et al.* (2011) in Section Amino Acid Analyses), and noncoding evolution (e.g., Wong and Nielsen (2004) in Section Analysis of Noncoding Sequences).

occupying that site. This property is captured by a rate matrix Q with elements q_{ij} that specify the instantaneous rates at which the i^{th} codon is replaced by the j^{th} codon. In Nielsen and Yang (1998), for example, elements of Q were defined for codons i and j ($i \neq j$) as:

$$q_{ij} = \begin{cases} 0 & \textit{if } i \textit{ and } j \textit{ differ by more than one nucelotide} \\ \pi_j & \textit{for synonymous transversions} \\ \kappa\pi_j & \textit{for synonymous transitions} \\ \omega\pi_j & \textit{for nonsynonymous transversions} \\ \omega\kappa\pi_j & \textit{for nonsynonymous transitions} \end{cases}$$

Model parameters, including transition bias κ, rate ratio $\omega = d_N/d_S$, and branch lengths $b=\langle b_1,\ldots,b_n\rangle$ can be estimated by ML (**Box 1**). The vector of codon equilibrium frequencies $\pi=\langle\pi_1,\ldots,\pi_{61}\rangle$ is usually estimated from the observed nucleotide frequencies. Given the full set of parameter estimates, the matrix that specifies replacement probabilities is $P(t)=e^{Qb}$ along a branch of length b. The probability model is therefore fully specified by the rate matrix Q and the branch lengths (with the assumed tree topology). Readers are referred to the 'See also' section for a more detailed treatment of Markovian models, rate matrices, and an expanded discussion of models for protein coding sequences. Certain simplifying assumptions are standard in the formulation of those models, and they are thoroughly reviewed in that entry.

Since they are based on the same Markov framework, Bayesian methods share many of the same advantages of ML. However, ML is more widely used, likely because it is less computationally costly. Under ML, the values of ω, κ, b and π_1, $\ldots,\pi_{61}$ that maximize the likelihood function given sequence data are considered the optimal estimates. Nested models can be contrasted to test hypotheses using the likelihood ratio test (LRT) (**Box 2** presents a general introduction). LRTs are routinely used to test the hypothesis that a fraction of sites within a dataset have evolved under positive selection ($\omega>1$). Given a significant LRT, an empirical Bayesian analysis (not to be confused with the full Bayesian approach) is typically used to identify those codon sites within the data most consistent with evolution by positive selection (see **Box 3**). A very large variety of codon models have been developed for identifying sites within an alignment, or branches in the tree, whereby positive selection had likely acted. A comprehensive review of these models is not possible here. Readers are referred to excellent reviews by Anisimova and Kosiol (2009) and Delport *et al.* (2009) for additional information.

The introduction of the first codon models for detecting positive selection ($\omega>1$) was followed by a number of studies claiming that the ML approach is inherently prone to produce false positives or is too liberal in inferring positive selection. Most of these claims were later shown to have overstated the problem (Pond and Frost, 2005; Yang *et al.*, 2009; Zhai *et al.*, 2012). However, there are conditions under which false positives occur at rates slightly higher than the level of significance of the LRT. Anisimova *et al.* (2002), for example, showed that false positive rates generally tend to be elevated when information content is low. Analyses are generally at greater risk of producing false positives when they include too few sequences, are comprised of very similar sequences, or are comprised of sequences that are divergent to the point of saturation.

ML estimates of codon model parameters can be viewed as those that cause the model to 'absorb' as much of the variability in the data as possible. Such estimates are unbiased if the model is a good match for the true evolutionary process. However, if the model is misspecified, then parameters such as ω may be forced to absorb variability in the data produced by processes unrelated to the rate ratio d_N/d_S. In such cases its ML estimate may be statistically biased (e.g., Bao *et al.*, 2008; Bay and Bielawski, 2013). This potential for biased parameter estimates is difficult to diagnose or avoid, but can be mitigated by combining the results of multiple modeling approaches that support the same conclusions.

The applicability of $\omega>1$ as a signature of positive selection is limited to detecting cases that produce a comparatively large number of nonsynonymous substitutions (Yang and Bielawski, 2000), whereas the mainstay of molecular evolution may well involve scenarios where a small number of nonsynonymous mutations are fixed, after which the gene resists further modification. There are several scenarios where repeated nonsynonymous substitutions are likely to occur. These include (1) when there are antagonistic interactions between immune surveillance and immune evasion proteins (e.g., Yang and Swanson, 2002); (2) when there are similar interactions between proteins that promote the competing interests of gametes in diploid organisms (e.g., Swanson *et al.*, 2003); (3) when rapid reorganization of a protein occurs in response to a change in the environment (e.g., Bielawski *et al.*, 2004). Such scenarios may be relatively uncommon, however.

It is therefore incumbent on the investigator to make intelligent use of the existing codon models. There will be many

Box 2 Likelihood Ratio Test

The probability model $f_0(x|\theta_0)$ is nested within another model $f_1(x|\theta_1)$ if they differ only in that the parameter vector θ_0 is the same as θ_1 but with some or all of its components fixed according to a null hypothesis. Continuing with the coin tossing example, we might take the null hypothesis to be that the coin is fair: H_0:$\theta=0.5$. The alternative might be that the coin is not fair: H_a:$\theta\neq0.5$. Given the outcomes of n independent trials, the log-likelihood of $\hat{\theta}$ can be contrasted with the log-likelihood of $\theta=0.5$ by computing the likelihood ratio (LR) statistic:

$$\mathrm{LR} = 2\left(\ell(\hat{\theta}|\{x_1,\ldots,x_n\}) - \ell(0.5|\{x_1,\ldots,x_n\})\right)$$

Statistical theory predicts that the sampling distribution of LR is close to χ^2_1, a χ^2 distribution with one degree of freedom, provided n is not too small. A p-value for LR can therefore be computed from χ^2_1. The null hypothesis would be rejected if the p-value was small, less than 0.05, say.

The LRT is often used to formally test hypotheses about evolution of protein coding sequences by positive selection (e.g., Nielsen and Yang (1998) in Section Codon Analyses), divergence in the distribution of selective constraints between proteins (e.g., Gaston *et al.* (2011) in Section Amino Acid Analyses) and evolution of noncoding DNA by positive selection (e.g., Wong and Nielsen (2004) in Section Analysis of Noncoding Sequences).

Box 3 Bayes' Rule

Suppose 5% of the population is afflicted with a disease so that the probability that a randomly selected person has the disease is $P(D)=0.05$. And suppose there is a test for the disease that is 99% accurate, meaning that the probability that the test is positive given that the person tested has the disease is $P(+|D)=0.99$, and the probability that the test is positive for a person without the disease is $P(-|\overline{D})=0.01$. Then according to the Bayes' rule, the probability that a person who tested positive actually has the disease is:

$$P(D|+)=\frac{P(+|D)P(D)}{P(+|D)P(D)+P(+|\overline{D})P(\overline{D})}$$
$$=\frac{0.99\times 0.05}{0.99\times 0.05+0.01\times 0.95}$$
$$=0.84$$

In this Bayesian analysis, $P(D)$ is the prior probability that a randomly selected person has the disease, and $P(D|+)$ is the posterior probability that arises after the outcome of the test is observed. $P(D)$ was considered in this analysis to be known. If it was not known but estimated from data, then $P(D)$ would be called an empirical prior and the analysis called empirical Bayes.

In the context of Markov models for sequence evolution, parameter values estimated from sequence data typically provide the empirical prior probability that a randomly selected site has evolved under a particular evolutionary regime (e.g., purifying or positive selection). Depending on the type of molecular data, the h^{th} site pattern x_h can be a column of nucleotides, codons, or amino acids within a multisequence alignment. Taking positive selection as an example (Section Codon Analyses), the parameters estimated from codon data provide the empirical prior probability that a randomly selected codon site has undergone positive selection, $P(\omega>1)$. The posterior probability of evolution by positive selection at the h^{th} codon site given the observed site pattern, $P(\omega>1|x_h)$, can then be computed using Bayes' rule. Codon sites are selected for further investigation if they have large posterior probabilities for positive selection. The same approach is used to identify amino acid sites subject to divergent selection intensity (Section Amino Acid Analyses) and noncoding sites evolving by positive selection (Section Analysis of Noncoding Sequences).

scenarios where protein function can evolve adaptively without yielding $\omega>1$, and researchers must avoid overinterpreting the significance of any one measure of sequence evolution, including the ω ratio. To avoid an incomplete picture of adaptive sequence evolution, researchers should seek a comprehensive assessment of natural selection pressure, combining information across different levels (e.g., Nielsen *et al.*, 2005) and from different metrics of functional divergence (e.g., Li *et al.*, 2009).

Amino Acid Analyses

Amino acid data can be used to determine whether the process of molecular evolution is related in some way to divergence of molecular function. While this is not equivalent to distinguishing between different types of selection pressure using a codon model, the results of such analyses do have a selective interpretation. If the 'function' of a gene is defined as any aspect of its phenotype that impacts fitness (structural, biochemical, or developmental), then molecular function can be related to the population genetic parameter for selection intensity. Specifically, neutral theory predicts that amino acid sites will evolve slower under strong selective constraints as compared to sites having weak selective constraints (Kimura, 1985); thus, a change in function that changes the distribution of selective constraints is also expected to yield a change in the distribution of substitution rates across amino acid sites (Gu, 1999). Such analyses have been used to infer the functional and adaptive significance of amino acid substitutions at sites within protein coding genes (e.g., Knudsen *et al.*, 2003; Mertz *et al.*, 2009).

Comparative analysis of amino acid substitution rates typically involves comparisons between two groups of sequences. In this context, methods have been developed to detect one of two broad patterns of sequence variability. The first pattern is simply the case where homologous sites within each group of sequences have different evolutionary rates. Although the moniker 'rate shifting' given to this pattern by Abhiman and Sonnhammer (2005) is accurate, the formal classification is "Type-I functional divergence" (Gu, 1999). The second pattern is characterized by homologous sites that are evolutionarily conserved in both groups but are occupied by amino acids with different physiochemical properties. The moniker "constant but different" (Gribaldo *et al.*, 2003) is appropriate, but the formal classification is "Type-II functional divergence" (Gu, 1999). Any evolutionary event where functional divergence can be plausibly hypothesized (gene duplication event, horizontal gene transfer, cross species viral transmission, adaptive radiation, etc.) can be investigated for Type-I and Type-II divergence. This approach has been most effectively used to investigate functional divergence following gene duplication events (e.g., Gribaldo *et al.*, 2003; Mertz *et al.* 2009; Li *et al.*, 2009).

Various analytical methods have been developed to detect Type-I and Type-II divergence. For convenience we divide them into two broad groups. The first group employs any of a wide variety of site-specific conservation statistics (sequence diversity, information theoretic measures of variability, physiochemical properties, etc.) to identify constrained sites within predefined subgroups (e.g., Capra and Singh, 2008). The methods in this group share a single characteristic in so far as they do not exploit the phylogenetic relationships of the sequences. The second group of methods utilize the phylogenetic information within a dataset through the use of an evolutionary tree and an explicit evolutionary model. These phylogenetically aware approaches substantially improve the inference of site-specific rate differences, as well as the accuracy of predictions about function (e.g., Lichtarge *et al.*, 1996; Pupko and Galtier, 2002; Susko *et al.*, 2002; Gaston *et al.*, 2011). Although information theoretic methods such as those of Lockless and Ranganathan (1999) and Suel *et al.* (2003) have been combined with phylogenetically aware analyses to provide additional insights into the context of functional divergence (see Garvin *et al.*, 2011 for an example), here we focus on the phylogenetcially aware methods alone, as they are better able to distinguish patterns of sequence variation arising

by neutral processes from those that arise from a shift in functional constraints (Gaston *et al.*, 2011).

Typically, a phylogeny is divided a priori into two or more subtrees (usually based on a known evolutionary event(s) such as a gene duplication). Then, the distribution of rates is estimated separately for the subtrees. Methods differ in how rate shifts are measured, how they are tested, and how other parameters of the evolutionary process are modeled (Gu, 1999, 2001; Knudsen and Miyamoto, 2001; Gu and Vander Velden, 2002; Pupko and Galtier, 2002; Susko *et al.*, 2002; Knudsen *et al.*, 2003; Gaston *et al.*, 2011). The most widely used approach of this type was developed by Gu (1999, 2001), and is based on probabilistic modeling of gene sequences as a mixture of two types of sites: (1) those with constant rates throughout the tree, and (2) those with different rates in different subtrees. An LRT is employed to test the hypothesis that the fraction of sites with different rates in subtrees is greater than zero (**Box 2**). Following a significant LRT, empirical Bayes (**Box 3**) is then used to identify sites within a gene for which the rates differ across subtrees. Gaston *et al.* (2011) recently extended this phylogenetic mixture-model framework by employing improved models of amino acid exchangeabilties, such as JTT (Jones *et al.*, 1992), WAG (Whelan and Goldman, 2001), or LG (Le and Gascuel, 2008), and among-site variability in the amino acid usage profiles (Wang *et al.*, 2007). The likelihood-based modeling approaches of Gu (1999, 2006) and Gaston *et al.* (2011) offer a formal statistical framework for detecting both Type-I and Type-II divergence. However, such models assume independence of substitution rates among sites. When functional divergence tends to occur within regions of genes, methods that assume independence will be less powerful. To address this limitation, Huang and Golding (2012) developed a model to account for spatial autocorrelation (at the gene sequence level) among sites evolving under Type-I divergence. More recent work by Huang and Golding (2014a,b) to infer spatial correlation of substitution rates at the level of the protein 3D structure offers a promising direction of future model development.

Often there is either no biological information by which a tree can be split a priori into subtrees or there is some reason to think the available prior information is incomplete. In such cases, inferring the locations of rate shifts is a much more challenging computational task. Dorman's (2007) solution was to apply Bayesian techniques to the phylogenetic mixture model of Gu (2001) for the purpose of permitting Type-I divergence to be modeled as a random variable. Inference about where it occurs in the tree, and the fraction of sites involved, is based on an estimate of the posterior distribution. An alternative approach is to explicitly add a second probabilistic process to model the evolution of 'switching' between different evolutionary rates at a site. This class of models is typically referred to as 'covarion-like,' and readers are referred to Wang *et al.* (2007) for both a description of a general form of this type of model and a review of the key literature. Penn *et al.* (2008) developed a covarion model expressly for the purpose of detecting site-specific functional shifts. Inference under this model employs the likelihood framework, where an LRT (**Box 2**) is used to test for rate shifts and empirical Bayes (**Box 3**) to identify the sites and branches in which rate shifts occurred. Regardless of method, the advantage of not having to partition a tree a priori is offset by the additional difficulty of having to infer both the sites and branches that experienced a rate shift. Assuming that appropriate biological information is available, methods based on a priori specification of subtrees will be more powerful.

Just as methods intended either for polymorphism data or for codon level comparative data have their powers and limitations, so too the amino acid-based methods. The biggest single limitation is that they can't distinguish a rate shift caused by positive selection from a rate shift resulting from a relaxation of functional constraints. Further, the methods are not well suited for detecting adaptive evolution in certain types of genes. Genes that tend to be subject to positive diversifying selection (e.g., abalone sperm lysin) will possess sites evolving under continuously high rates, which does not lead to rate shifts within the data. As with codon models, adaptive evolution in genes where novel function evolved by just one, or a very few, amino acid substitutions (e.g., globins) will go undetected. Lastly, evolutionary processes that strongly violate the underlying assumptions of these methods can elevate their error rates. For example, gene duplication events can cause one copy of a gene to change its genomic location; when this also involves a change in local mutation pressure (e.g., from a GC-rich region to a GC-poor region) a false signal for rate shift can be obtained. Indeed, Bay and Bielawski (2013) demonstrated that statistical tests developed for both codon and amino acid data are subject to increased false positive rates in such scenarios.

Notwithstanding their limitations, these methods have proved useful for understanding the evolution of protein (e.g., Knudsen *et al.*, 2003; Mertz *et al.*, 2009). Under the appropriate conditions they provide a powerful means to formally test for sequence patterns consistent with functional divergence. Given sufficient signal, these methods can even be used to extract information about site-specific changes in the distribution of functional constraints. However, the relationship between sequence divergence and function is highly complex, and no single method can be expected to fully capture all of the signal. Increasingly important contributions will be made by incorporating a variety of comparative methods in the design of functional genomic research.

Analysis of Noncoding Sequences

Eukaryotic genomes contain mostly noncoding DNA, an unknown proportion of which is thought to be instrumental in regulating the interaction of the thousands of proteins encoded within those genomes. Very little is known about the evolutionary dynamics of these regulatory sequences, despite the fact that regulation of gene expression is widely considered to be one of the driving forces of phenotypic evolution (e.g., Wray *et al.*, 2003). The problem is that the functional fraction of genomic noncoding DNA is difficult to identify. This is largely because noncoding DNA are not nearly as constrained as protein coding DNA, which must adhere to the structure of the genetic code. For this reason the functional fraction of genomic noncoding DNA remains poorly characterized.

The most powerful method for identifying putatively functional noncoding DNA is based on the principle of

evolutionary conservation. The basic idea is that new mutations which negatively impact functional noncoding DNA will be rejected by purifying selection leading to lower substitution rates. A variety of approaches have been developed for detecting conserved noncoding sequences (CNSs) according to this principle (Duret and Bucher, 1997; Boffelli *et al.*, 2003; Margulies *et al.*, 2007). While such efforts have uncovered large numbers of CNSs, only some have been shown to contain regulatory sequence elements. Further, the known CNSs are unlikely to comprise all of the functional elements within the noncoding fraction of a genome. Identification and characterization of functional noncoding DNA continues to be an important area of active research.

In order to rule out the possibility that CNSs are merely due to a localized reduction in the mutation rate, their substitution rate should be compared to the rate of evolution at an appropriate reference set of neutral sites. Lower than neutral substitutions rates within CNSs indicates that they are evolutionarily conserved due to the action of purifying natural selection. Several methods have been developed for identifying CNSs based on this criterion (Siepel and Haussler, 2005; Cooper *et al.*, 2005; Asthana *et al.*, 2007; Davydov *et al.*, 2010). Interestingly, when CNSs are identified through comparative sequence analysis, and then their evolutionary dynamics are investigated within populations, a clear signal for selective constraint is often confirmed by the polymorphism data (Drake *et al.*, 2006). The consensus opinion is that a large fraction of CNSs have functional significance, and are not merely mutational 'cold spots.'

Methods analogous to the d_N/d_S ratio for coding sequences have been developed to determine whether some of the evolution among a set of noncoding sequences might have been driven by positive selection. Hahn *et al.* (2004) computed the substitution rate of transcription factor binding sites (d_B) normalized by the rate of intervening non-functional sites (d_I). Under the assumption that d_I is an appropriate neutral reference, positive selection is indicated by a ratio $d_B/d_I > 1$. However, the role of selection on the intervening sites is typically unknown, so it is difficult to demonstrate whether d_I is the appropriate neutral rate. Wong and Nielsen (2004) approached this issue by using the synonymous rate (d_S) of nearby coding sequences as the reference neutral rate. Wong and Nielsen (2004) implemented a full likelihood framework for joint modeling of both coding and noncoding sequences. They introduced a new parameter ζ, which is the rate of noncoding substitution (d_{NC}) normalized by the synonymous rate (d_S). This parameter has a familiar interpretation; $\zeta > 1$ indicates positive selection. Because the model is very flexible, permitting a mixture of sites having different values of ζ, it can be applied to a wide variety of scenarios. The model is fit to a dataset by using ML (**Box 1**), which permits estimation of the fraction of noncoding sites having $\zeta > 1$. The LRT is then used to formally test the hypothesis that the fraction is greater than zero (**Box 2**). Finally, empirical Bayes (**Box 3**) is employed to identify sites within an alignment having $\zeta > 1$. A potential limitation is that the rate of synonymous substitutions is assumed to be homogenous and free from selective effects, whereas there is evidence that evolution of synonymous sites in some genomes is subject to at least weak selection.

Perhaps the most interesting setting for positive selection of noncoding sequences is within particular lineages where there has been exceptional phenotypic evolution. For example, many have speculated that adaptive changes in regulatory sequences played a role in the evolution of human speech production and brain size (Hill and Walsh, 2005). The detection of such a role is very challenging, as inferences must be made about a subset of noncoding DNA (usually small) along just one branch of a phylogenetic tree. One approach is to simply test for an accelerated substitution rate within CNSs along a predefined subset of lineages (Pollard *et al.*, 2006a,b; Prabhakar *et al.*, 2006). The difficulty is that a lineage-specific change in rate can be due to either positive selection or a relaxation of constraint (including a complete loss of function). For this reason, many studies attempt to distinguish the two scenarios by testing for rates in excess of those at neutral sites within the lineage of interest (Pollard *et al.*, 2006a,b; Bird *et al.*, 2007; Kim and Pritchard, 2007; Haygood *et al.*, 2007; Pollard *et al.*, 2010). The study of Haygood *et al.* (2007) is noteworthy, as they extended the modeling framework of Wong and Nielsen (2004) to permit a fraction of sites having $\zeta > 1$ along preselected branches. This allowed them to bring to bear all the advantages of the inferential framework (**Boxes 1–3**) that had been very successfully applied to comparative analyses of coding and amino acid sequences. As mentioned above, a major challenge is determining how to obtain the most appropriate estimate of the neutral rate (e.g., Haygood *et al.*, 2007; Parsch *et al.*, 2010).

Identification of functional noncoding DNA, and interpretation of the role that selection may have played in their evolution, is much more challenging than for coding sequences. First, functional elements within noncoding DNA tend to be smaller than coding sequences, they likely depend on nucleotide states in other (unknown) functional elements, and they lack the clear 'footprint' of functional constraint that protein coding sequences have. Second, it may be that many functional elements have high turnover rates and are undetectable by current methods. Third, the capacity to understand their evolution in response to positive and purifying selection depends on a neutral rate estimated from an appropriate set of reference sites, and such sites can be challenge to identify. Fourth, biased gene conversion can lead to patterns of sequence evolution similar to positive selection (Ratnakumar *et al.*, 2010), making it difficult to tease apart the effects of selective and non-selective evolutionary dynamics (Pollard *et al.*, 2006a,b). Last, studies tend to be restricted to more closely related taxa because the alignment of noncoding DNA is more difficult than coding DNA. Despite these potential limitations, methods for detecting and assessing natural selection in functional noncoding sequences have been informative. For example, two independent studies found an excess of CNSs in the vicinity of protein coding genes related to neuronal development and function (Pollard *et al.*, 2006a,b), and subsequent analyses of the promotor regions of neuronal genes suggested evolution by positive selection (Haygood *et al.*, 2007). Many of the challenges posed by noncoding DNA can be met by combining comparative and population-level analyses (Hahn *et al.*, 2004; Rockman *et al.*, 2005; Drake *et al.*, 2006; Torgerson *et al.*, 2009), and future research will likely involve integrating both levels of analysis at the genome scale.

Adaptive Mutation Controversy

S Maisnier-Patin and JR Roth, University of California, Davis, CA, USA

Glossary

Adaptive mutation In standard usage, term describes any genetic change that improves fitness. In recent popular usage, the term refers to a hypothetical mechanism said to vary the specificity or increase the intensity of mutagenesis in response to growth limitation. This proposal challenges a widely accepted tenet in evolutionary biology that mutations form as replication or repair errors, independent of need or consequences.

Directed mutation A process proposed to explain results of some selection experiments. A hypothetical mechanism that senses growth arrest, identifies the genomic sites that can restore growth, and preferentially generates mutations at those sites.

F′*lac* The F-plasmid of *Escherichia coli* is capable of transferring copies of itself to recipient cells (conjugation). This circular plasmid can exist free or can insert into the circular bacterial chromosome. Incorrect excision of an inserted plasmid can produce a plasmid derivative (F′) that includes bacterial DNA adjacent to the attachment site. The F′lac_{128} plasmid carries the chromosomal *lac*, *proAB*, and *dinB* genes. The genes encoding the transfer or conjugation functions of F′$_{128}$ are expressed at a high level due to an IS*3* element inserted in the plasmid *finO* gene, which encodes a regulatory function.

Hypermutable state A hypothetical condition proposed to explain the results of some selection experiments. Nongrowing cells are said to induce a mechanism to create mutations genome-wide (adaptive mutation). The mutable state is attributed to a mechanism that evolved to accelerate adaptation.

Defining 'Adaptive Mutation'

Conventionally, this term describes any genetic change that improves reproductive success. Recently the same term has been used to describe a process by which a proposed mechanism might create beneficial mutations in nongrowing cells. Equivalent terms are 'stress-induced mutation,' 'directed mutation,' and 'stationary phase mutagenesis.' It is proposed that this mechanism evolved to accelerate genetic adaptation by increasing the genome-wide mutation rates or by directing mutations preferentially to sites that improve growth. Used in this way, 'adaptive mutation' challenges an accepted tenet of evolutionary biology.

The Classical View of Mutation and Selection

Experimental genetics of bacteria depends on use of positive selection to identify rare cells in astronomically large populations. Selections serve to detect new mutants, assess mutation rates and demonstrate genetic recombination. This field was put on a sound theoretical footing by demonstrations that positive selection could in fact detect mutants without causing their formation. These classic experiments showed that the mutants detected by stringent, often lethal, conditions actually arose during the nonselective pregrowth period before exposure to selection and therefore could not have been formed in response to selection (Cavalli-Sforza and Lederberg, 1956; Lederberg and Lederberg, 1952; Luria and Delbrück, 1943; Newcombe, 1949; Novick and Szilard, 1950).

The 'fluctuation test' devised by Luria and Delbrück showed that mutations form with a constant probability at each cell division. During unselected growth of a culture, cell number increases exponentially and new mutants are added at an exponential rate – more cell divisions, more new mutants (Luria and Delbrück, 1943). Mutants that arise early in the history of a culture appear in a small population and are thus present at a high frequency that remains constant or is enhanced by new mutation events during subsequent growth. Mutant lineages arising at progressively earlier times in the history of the culture are present at exponentially higher frequencies. This is diagramed in **Figure 1**.

When multiple replicate cultures are compared, the variance in their mutant frequencies reflects this exponential growth and the times at which mutations happened to occur. This frequency variance exceeds the mean and deviates from a Poisson distribution. Methods were developed to use the distribution of mutants between parallel cultures to identify a 'Luria–Delbrück distribution' and calculate the mutation rate per cell per division. These methods have recently been reviewed in detail (Foster, 2006; Rosche and Foster, 2000). In fluctuation experiments, cultures are grown in nonselective liquid medium and mutants are detected as rare colonies formed when these cultures were plated on strongly selective solid medium where only these mutants can grow. Observation of a Luria–Delbruck distribution of mutant frequencies between replica cultures (left graph in **Figure 1**) demonstrates that the mutants detected by selection actually form prior to plating and can be used to calculate mutation rate.

With little additional evidence, the conclusion drawn from these beautiful bacterial experiments was broadened and applied to all organisms and conditions regardless of selection stringency. It was accepted that all mutations reflect random errors in DNA replication or repair, regardless of growth rate or phenotypes. Selection thus was inferred to act later to favor or disfavor preexisting mutations, depending on how their phenotypes influence reproductive success. While this conclusion may well be correct, the classical bacterial evidence

 doi:10.1016/B978-0-12-800049-6.00229-8

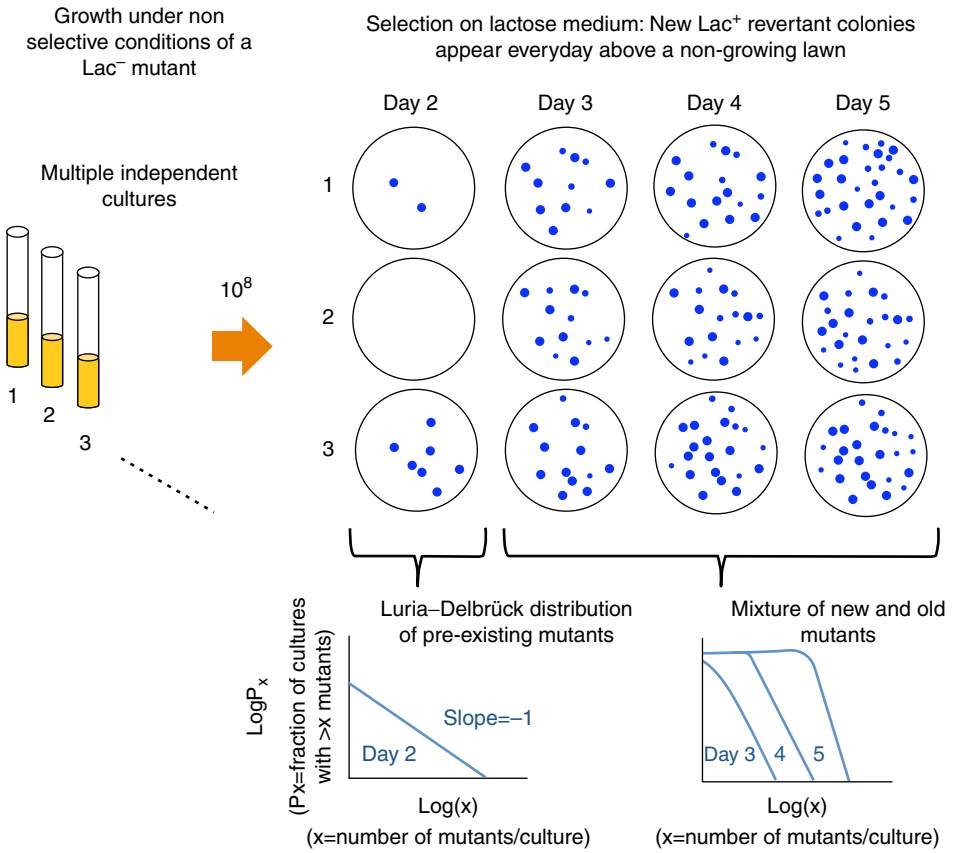

Figure 1 The Luria–Delbrück fluctuation test. Multiple independent cultures are grown nonselectively (left top) and then plated on selective medium to identify mutants that appear over several days (only three cultures are shown). The variance (or fluctuation) in colony number between cultures is used to measure mutation rate (Rosche and Foster, 2000) and also to demonstrate whether the detected mutants arose randomly during nonselective growth prior to plating. Mutants showing a Luria–Delbrück distribution are those that arose during nonselective growth prior to plating and cannot have formed in response to selection. To identify a Luria–Delbrück distribution, the number of mutants (x) in various tubes is plotted as shown at the bottom of the figure above. The horizontal axis displays (log x) for various values of x and the vertical axis shows logP_x, where P_x is the fraction of tubes with a number of mutants equal or greater than x. For a Luria–Delbrück distribution, this plot shows a slope of -1 (as seen in the graph at left). If mutants form only after cells are plated on the selective medium, a Poisson distribution is expected. In the *lac* experiment described below, the few revertants appearing on Day 2, show a Luria–Delbrück distribution and reflect preexisting mutants (Cairns and Foster, 1991). As colony numbers increase with time at a constant rate, the number of mutants on the selection plate shows less variation and deviates from a Luria–Delbrück distribution. (See plots for later days in the graph at lower right). By day 5, the bulk of the mutant colonies seem to have arisen on the plate, consistent with being caused by selection. This conclusion may not be warranted for copy number variants, whose steady-state frequency obscures the Luria–Delbrück distribution (see text).

does not eliminate the possibility that less stringent growth limitation might change the rate or specificity of mutation. This open possibility was addressed by the 'adaptive mutation' challenge described here.

Challenges to the Idea of Random Mutation

In standard bacterial genetic experiments, cell populations are plated on solid selective medium that limits growth. Preexisting mutant cells are detected by the visible colonies they form above the nongrowing lawn of parental bacteria. The procedure reliably detects only preexisting mutants as long as selection is stringent and blocks all growth of nonmutant cells (as was true in the classic experiments). However in practice, this caveat was often forgotten.

In some genetic systems, mutant colonies continue to accumulate for several days after plating, suggesting that selection detects not only preexisting mutants (as did the classic experiments) but also new mutants that arise after exposure to selection. Some authors interpreted this phenomenon as evidence that growth limitation causes the new mutations (Cairns and Foster, 1991; Cairns *et al.*, 1988; Hall, 1988, 1990, 1991; Maenhaut-Michel and Shapiro, 1994; Prival and Cebula, 1992; Pybus *et al.*, 2010; Shapiro, 1984; Sung and Yasbin, 2002; Thomas *et al.*, 1992; Yang *et al.*, 2001).

This conclusion is not warranted when selection conditions are not sufficiently stringent. That is, the new mutants could arise under selection during residual growth of the plated population. In addition, partially revertant cells might arise during pregrowth and initiate the late-appearing colonies under selection. These initially slow-growing clones might

improve (evolve) during colony development. Each act of DNA replication provides an opportunity for mutation and many opportunities are provided during colony growth. This improvement could occur using a constant unenhanced mutation rate.

For most of the exceptional systems used to claim selection-induced mutagenesis, residual growth was not assessed. In some cases, growth and DNA replication proved to be responsible for generating the extra mutants (Gizatullin and Babynin, 1996; Jin *et al.*, 2002; Mittler and Lenski, 1990, 1992; Prival and Cebula, 1996; Quinones-Soto and Roth, 2011). In one system, however, close attention was paid to population dynamics and evidence of associated general mutagenesis. In this system, a *lac* mutant of *Escherichia coli* did not grow on lactose but did give rise to Lac$^+$ revertant colonies on selective plates (Cairns and Foster, 1991; Foster, 1994).

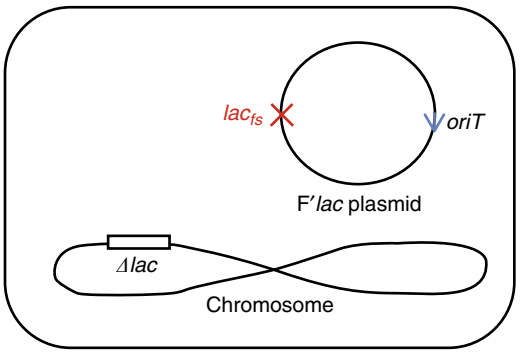

Figure 2 A strain used to seek evidence for selection-induced mutagenesis. The strain FC40 used in the *lac* system carries a leaky (partially functional) mutant *lac* allele on a F′*lac pro* (F′$_{128}$) conjugative plasmid and a deletion of its chromosomal lactose operon. The residual function of the plasmid lactose operon supports slow growth on lactose, which is prevented when cells are plated with a 10-fold excess of scavenger cells. The scavenger cells cannot use lactose but can consume any nutrients revertant than lactose that might contaminate the medium or be excreted by revertant cells on the plate. The tester cells are poised on the brink of growth.

The *lac* System

To explain the high frequency of cancer, which reflects somatic mutations, John Cairns proposed that growth-limited cells – such a mammalian somatic cells – might increase their mutation rate using a mechanism evolved to enhance genetic adaptation (Cairns, 1978, 1998; Cairns *et al.*, 1988). To test the idea of regulated mutagenesis, Cairns and Foster developed a bacterial system in which a cell population is held under selective conditions that prevent growth. Mutants arising in the nongrowing population initiate growth and form colonies that appear and accumulate over several days under selection. The general situation resembles nongrowing somatic cells and derived malignancies.

The parent *E. coli* mutant carries a deletion of its chromosomal lactose operon and a conjugative low-copy F′*lac* plasmid with a *lac* frameshift mutation (see **Figure 2**). A lawn of 10^8 mutant cells is plated on solid lactose medium, where it cannot grow but gives rise to about 100 Lac$^+$ revertant colonies, which accumulate over the course of 5–6 days. The reversion rate of the mutant *lac* allele during nonselective growth is 10^{-8} per cell per division (Foster and Trimarchi, 1994). Under selection, the population produces 100 Lac$^+$ revertant colonies over 6 days. The colonies are of two types. The majority (90%) includes cells that have acquired a compensating frameshift mutation and thereby a fully functional *lac*$^+$ allele. These cells form stable Lac$^+$ colonies when streaked on nonselective medium. The minority type (10%) has an unstable Lac$^+$ phenotype and forms sectored (Lac$^+$/Lac$^-$) colonies when streaked on nonselective rich medium (Andersson *et al.*, 1998). These cells have a tandem *lac* amplification with multiple copies of the leaky mutant *lac* allele (see **Figure 3**).

The course of a reversion experiment is shown in **Figure 4**. The two colony types accumulate on the selection plate with different trajectories. Stable Lac$^+$ colonies accumulate linearly over 5 days, consistent with their arising in a nongrowing population. Unstably Lac$^+$ colonies (10% of total) carry a tandem amplification (10–100 copies) of the original mutant *lac* allele. These colonies accumulate exponentially with time. This suggests that they might develop from a growing

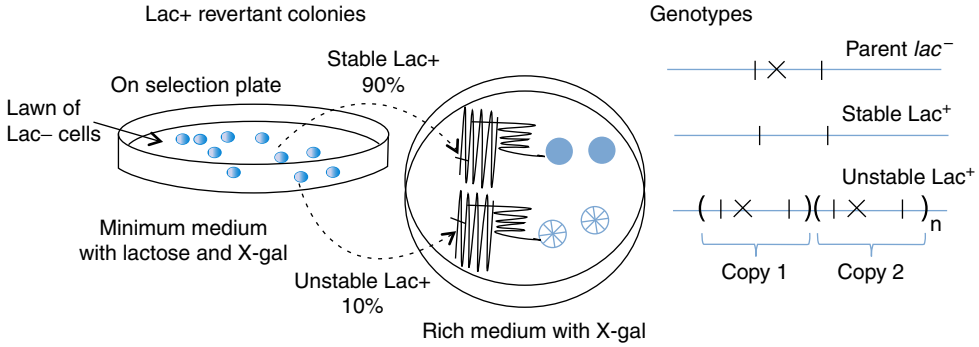

Figure 3 Two types of Lac$^+$ revertant colonies. The majority of the revertant colonies that appear on the selection plate include cells that are stably Lac$^+$ when streaked on nonselective medium with X-Gal, a chromogenic β-galactosidase substrate. These cells have acquired a compensating frameshift mutation and carry a fully functional *lac*$^+$ allele. On day 5, about 10% of revertant colonies are unstably Lac$^+$ and form sectored (blue/white, Lac$^+$/Lac$^-$) on nonselective medium. These cells carry a tandem array of 10–100 (n) copies of the mutant *lac* region and grow under selection by virtue of their multiple partially functional *lac* copies. On nonselective medium, the amplification is frequently lost, leading to a Lac$^-$ (white) colony sector.

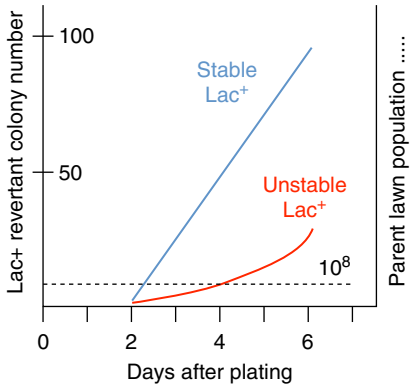

Figure 4 Accumulation of the two revertant types above the nongrowing lawn population. After 10^8 cells are plated on day 0, the lawn shows little or no growth, but revertant colonies accumulate over several days. Revertants are tested by streaking on nonselective medium to test the stability of their Lac^+ phenotype. Colonies of stably Lac^+ revertants accumulate linearly, suggesting formation from a nongrowing cell population. In contrast, unstably Lac^+ colonies accumulate exponentially, suggesting that they form in a growing population. This behavior is explained by a new model described below.

population. The parent lawn population as a whole shows very little growth over the course of the experiment (see **Figure 4**). The question is, 'How does a nongrowing parent population give rise to these two types of Lac^+ revertant colonies?' Some say that growth limitation is mutagenic (perhaps without DNA replication). Others say that selection acts on preexisting partially functional variants allowing them to develop a fully Lac^+ phenotype without mutagenesis (perhaps without cell division).

A clue for solving this puzzle may be the nature of the parent mutant *lac* allele. The *lac* allele carries a leaky frameshift mutation and produces about 2% of the β-galactosidase (LacZ) level found in a revertant. The ability of the strain to grow on lactose using its residual LacZ level is prevented by adding a 10-fold excess of scavenger cells that carry a *lac* deletion mutation. Sufficient scavengers are plated to just barely prevent growth of the tester by consuming carbon sources other than lactose that might contaminate the medium or be excreted by cells on the plate. Thus selection conditions are not stringent – they prevent cell division, but leave cells poised on the brink of growth.

The Adaptive Mutation Paradox

The paradox of this system is that selection appears to cause a 100-fold increase in the number of Lac^+ revertants, but does so with very little evidence of general mutagenesis. Without selection, the parent mutation reverts at 10^{-8} cell per division. Under selection, 10^8 plated cells produce 100 revertant colonies over 6 days. This represents a 100-fold rate increase, if one assumes one division under selection. However, analysis of this system has revealed little evidence of an increase in general mutation rate. That is, the starved lawn population shows no increase in the frequency of unselected mutations on the chromosome (Rosche and Foster, 1999; Slechta *et al.*, 2002b; Torkelson *et al.*, 1997). The revertant Lac^+ colonies show a 10-fold increase in the likelihood of secondary unselected mutation, but that increase is unevenly distributed. About 90% of Lac^+ revertants show no evidence of general mutagenesis, while 10% have experienced a 200-fold increase in mutation rate (Rosche and Foster, 1999). How can the number of Lac^+ revertants increase without exposing the genome at large to mutagenesis?

How Do Lac^+ Mutants Arise under Selection? – Three Models and Their Problems

Directed Mutation

In the initial model, an evolved mechanism senses the physiological situation and directs mutations to genomic sites whose alteration will restore growth (Foster, 1999). Directed mutation would help explain the lack of evidence for genome-wide mutagenesis. The difficulty lies in defining a process that can sense the cause of growth limitation and direct mutations to rare genomic sites that solve the problem. This would seem to require clairvoyance, but there is a precedent in the mammalian immune system, which mutagenizes local genomic regions in response to infection (Teng and Papavasiliou, 2007). Several clever ways to accomplish this in starving bacteria were suggested (Stahl, 1988), but the suggested increase in transcriptional errors or defects in post-replicative mismatch correction system later proved incorrect (Foster and Cairns, 1992; Stahl, 1992). Formation of Lac^+ colonies on selective medium relies on a functional recombinase (RecA) and some DNA replication. The selective amplification model (below) has the effect of directing mutation to valuable sites by amplifying the target gene and selectively maintaining only the revertant copy (Roth *et al.*, 1996).

Selection-Induced Hypermutability

This model proposes that growth limitation induces an evolved mechanism for genome-wide (undirected) mutagenesis in a subset of the growth-limited population. This model was initially suggested by Hall (1990) and supported by Torkelson *et al.* (1997), who found that Lac^+ revertants arising in the Cairns–Foster system were about 20-fold more likely to carry associated, unselected mutations. In this 'hypermutable state' model, mutagenesis of the starved population is not detected because so few starved cells are actually mutagenized. This model, in its simplest form, is not feasible because it requires generation of 100 mutants from a subpopulation 10^5 cells – a rate of 10^{-3} per cell per generation (Roth *et al.*, 2006a). This rate is a 10^5-fold increase over the *lac* reversion rate measured during nonselective growth and is substantially more intense than mutagenesis by any chemical or physical mutagen acting on nongrowing cells (Adelberg *et al.*, 1965; Miller, 1992; Wechsler *et al.*, 1973). The hypermutable state model may explain the modest increase in unselected mutations in revertants, but it cannot alone explain the origin of selected mutants in the *lac* system.

Selective Amplification of the Mutant Gene

This model proposes that mutants with a partially restored LacZ function arise during nonselective growth prior to plating. When placed on selective medium, these cells grow slowly and improve with no increase in mutation rate, leading ultimately to a late-appearing visible colony. It was first suggested that the preexisting cells carry a duplication of the leaky mutant *lac* allele, which supports slow growth on lactose. Growth improves as amplification expands the gene duplication by adding copies successively under selection. Ultimately some copy the *lac* region acquires a mutation that restores a functional *lac*$^+$ allele. The likelihood of such a mutation increases with the number of target sequences – more *lac* copies per cell and more cells in each slowly growing colony. No mutagenesis is required.

The selective gene amplification model has been shown to operate in many biological systems (Andersson and Hughes, 2009; Elliott *et al.*, 2013; Kondrashov, 2012), including adaptation by which poxvirus evades host defenses (Elde *et al.*, 2012), and bacterial acquisition of antibiotic resistance (Nilsson *et al.*, 2006; Paulander *et al.*, 2010; Pranting and Andersson, 2011; Sun *et al.*, 2009). Most notably, this model explains evolution of new genetic functions under continuous selection (Bergthorsson *et al.*, 2007) and has been shown experimentally to underlie evolution of a gene with a novel function within 3000 generations of growth (Näsvall *et al.*, 2012). The model probably explains the *Salmonella* version of the Cairns–Foster system, in which plated cells grow about one division per day (Hendrickson *et al.*, 2002; Kugelberg *et al.*, 2006; Slechta *et al.*, 2002b).

However, despite these successes, the original selective amplification model does not explain the *E. coli* version of system, where plated cells show very little growth. The lack of growth makes it hard to imagine how plated cells with a duplication achieve the amplification and cell number increase needed to explain reversion without mutagenesis.

The Philosophical Problem of Adaptive Mutation – Why Has This Question Been So Hard to Resolve?

Since its first description (Cairns and Foster, 1991; Cairns *et al.*, 1988), this system has been extensively investigated by multiple groups (Foster and Trimarchi, 1994; Galitski and Roth, 1995; Harris *et al.*, 1994; Peters *et al.*, 1996; Powell and Wartell, 2001; Prival and Cebula, 1996; Radicella *et al.*, 1995) from multiple points of view. The accumulated body of data is of high quality and is generally accepted by all participants. However, results have been interpretable in different ways and viewpoints have not converged with time, despite occasional declarations of victory. The subject has been reviewed repeatedly from multiple perspectives (Andersson *et al.*, 2011; Foster, 2004, 2007; Galhardo *et al.*, 2007; Rosenberg, 2001; Roth *et al.*, 2006b). The difficulty in sorting this out may be that many experiments were designed to verify one particular model rather than to decide between models. Resolution of the few data conflicts promises to decide the issue.

The Generally Accepted Body of Evidence

Analysis of the *lac* system has revealed several bits of data that appear central to the mechanism and are not controversial. First, the yield of revertants depends heavily on homologous recombination. Virtually no revertant colonies appear in strains lacking RecA or RecBCD proteins, which are central to recombination initiated at double strand breaks (**Figure 5**; Cairns and Foster, 1991; Harris *et al.*, 1994). However, the opposite effect is seen in strains lacking only the nuclease RecD. In these strains, the number of Lac$^+$ revertants increases in proportion to the increase in F′*lac* plasmid copy number caused by the RecD deficiency (Foster and Rosche, 1999). Second, revertant yield depends heavily on ability of the F′*lac* plasmid to transfer conjugatively to recipient strains (Foster and Trimarchi, 1995; Peters *et al.*, 1996; Radicella *et al.*, 1995). Virtually no revertants are seen when the transfer (*tra*) functions of F′*lac* plasmid are inactive, especially in absence of TraI the endonuclease that initiates transfer replication. Third, the total revertant colony number is reduced about 5-fold in strains that lack the error-prone DNA repair polymerase, DinB (**Figure 5**; Foster, 2000; McKenzie *et al.*, 2001; Slechta *et al.*, 2003). Lack of DinB does not affect unstable revertant number, but reduces the number of stable revertants about 10-fold. Thus without DinB, mutants still arise under selection, but are evenly divided between stable and unstable revertant types.

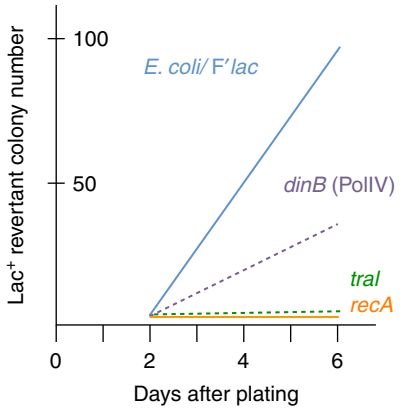

Figure 5 Three requirements for revertant yield in the *lac* system. The revertant yield (blue line) seen in the parent strain is reduced more than 25-fold in strains carrying a *recA* mutation, which blocks homologous recombination (orange line). A similar reduction is caused by a *traI* mutation on the plasmid, which eliminates a single-strand endonuclease needed to initiate conjugational transfer (dotted green line). A functional transfer origin is needed for reversion (Galitski and Roth, 1995; Peters *et al.*, 1996; Radicella *et al.*, 1995), but the role of actual transfer is still unclear. Direct tests show a low frequency of actual plasmid transfer associated with reversion (Foster and Trimarchi, 1995; Maisnier-Patin and Roth, unpublished data). However, in support of mating, Tn*10* is lost during reversion, apparently stimulated by single-strandedness associated with conjugation (Godoy and Fox, 2000). In addition, most Tra proteins are required for reversion, including those needed for mating pair stabilization (Maisnier-Patin and Roth, unpublished data). In the absence of DinB, total revertant yield drops 5-fold (dotted purple line); unstable revertants are unaffected while stable revertants drop 10-fold. Without DinB, residual revertant number is evenly divided between stable and unstable types.

It is interesting that the reversion rate of the same *lac* mutation during nonselective growth is not affected by RecA (Bull *et al.*, 2001) or by the chromosomal DinB allele (Gawel *et al.*, 2008; Kim *et al.*, 2001; Kuban *et al.*, 2004; Strauss *et al.*, 2000; Wolff *et al.*, 2004). The same studies show however a two- to four-fold reduction in mutagenesis on F′*lac* when the *dinB* copy on that plasmid is deleted. The three models outlined above explain the effects of selection in different ways. The key to understanding this system may lie in the conflicting data bits that seem to decide between models.

Resolving Conflicts and Deciding between Models

Do the Cells That Initiate Stable Revertant Colonies Arise Before or After Selection?

Mutagenesis models predict that revertant colonies are initiated on the selection plate by new mutant cells formed in response to the selective environment. In contrast, selection models predict that initiating cells carry a *lac* amplification that forms during nonselective pregrowth. On selective plates, these cells grow slowly and acquire a mutation that generates a *lac*$^+$ allele and allows rapid exponential growth.

The first attempt to decide the 'before or after' question was a classic Luria–Delbrück fluctuation test (Cairns and Foster, 1991). Tests of this type demonstrated long ago that stringent selections detect mutants whose frequency fluctuates from one culture to the next because mutants arise at different times prior to plating (see above). In the *lac* system, the number of revertant colonies formed over several days does not show fluctuation from one parallel culture to the next (Cairns and Foster, 1991). This was taken as evidence that Lac$^+$ mutants were initiated on the selection plate, consistent with either model of 'stress-induced' mutagenesis. Recent results suggest that this conclusion is not warranted for copy number variants whose frequency does not fluctuate.

Unlike point mutants, duplications are not subject to Luria–Delbrück fluctuation. During nonselective growth, cells with duplication or amplification of any gene come to a steady-state frequency maintained by a balance between a high formation rate (typically 10^{-5} per cell per division) on one hand and a higher loss rate (10^{-3} per cell per division) plus fitness cost of the other (Reams *et al.*, 2010). The forces that maintain this steady state obscure fluctuations due to the timing of duplication formation events. If revertants are initiated by copy number variants (as proposed by the selection model), fluctuation tests cannot decide whether they form before or after plating. A different sort of evidence is required.

A new test recently showed that revertant colonies are initiated by preexisting cells with multiple *lac* copies (Sano *et al.*, 2014). These experiments use a *tetA* (tetracycline resistance) gene inserted at various points on the F′*lac* plasmid. The tetracycline analog anhydro-tetracycline (AnTc) induces expression of *tetA*. This induction inhibits growth of cells with multiple copies of *tetA*, but has no effect on cells with a single copy.

The *tetA* gene is located on the same plasmid as *lac* and the two genes are expected to co-amplify. The selection model described above predicts that cells with multiple copies of mutant *lac* allele initiate Lac$^+$ revertant colonies. Pregrowth with AnTc counter-selects rare cells with multiple copies of *tet* (and often *lac*). This reduces then the number of revertant colonies appearing on selective medium. This result was seen regardless of the position of the inserted *tetA* gene on the F′*lac* plasmid, suggesting that the critical cells have multiple copies of the whole F′*lac* plasmid (which includes both *tetA* and *lac*) rather than an internal tandem amplification of the *lac* region. These experiments led to the conclusion that cells with multiple copies of the F′*lac* plasmid initiate stable Lac$^+$ revertant colonies.

Unstable Lac$^+$ revertant colonies are also initiated by cells with multiple copies of F′*lac* (Sano *et al.*, 2014), but the plasmids in these cells appear to carry a tandem amplification of the *lac* region (see **Figures 3** and **4**). Earlier evidence suggested that these unstable revertants are initiated by preexisting cells with a short *lac* duplication (Kugelberg *et al.*, 2006). We suggest that both findings are true – unstable revertants are initiated by cells whose high copy F′*lac* plasmid includes a short *lac* duplication (Kugelberg *et al.*, 2006). In the model below, we will assume that the extra number of *lac* copies supports growth and allows these cells to initiate unstable revertant colonies. Since both stable and unstable revertant colonies are initiated prior to selection, neither revertant type can be induced by selection.

Does the Plated Population Grow Before Mutation?

The lawn population grows very little over the course of a reversion experiment. This has been interpreted as evidence that mutants arise in nongrowing starved cells. However, it is hard to eliminate the possibility that a subset of lawn population grows or that mutations arise within slowly growing colonies (as suggested by the selective amplification model).

Support for reversion within growing colonies was the presence of rare unstable Lac$^+$ cells within colonies of otherwise stably Lac$^+$ colonies. These cells were taken as evidence for unstable precursors of stably revertant cells (Hendrickson *et al.*, 2002). Recently, we confirmed earlier evidence (Hastings *et al.*, 2004) that the unstable Lac$^+$ phenotype of these rare cells is not heritable – all descendent cells are either Lac$^+$ or Lac$^-$ (I. Roush, S. Maisnier-Patin, and J.R. Roth, Unpublished data). This is inconsistent with tandem amplifications of *lac*, which are heritable and suggests that the rare unstable Lac$^+$ cells have multiple copies of the F′*lac* plasmid – some *lac*$^+$ and some *lac*$^-$. Thus the preponderance of evidence implies that plated cells grow very little under selection before the reversion event. This explains the linear accumulation of stable revertants. The new model below explains the mixed plasmid types seen in rare unstable Lac$^+$ cells within otherwise stable Lac$^+$ colonies.

What Activates the DinB Polymerase – Induction or Amplification?

Strains lacking the error-prone DinB polymerase show 10-fold fewer stable revertants, but the same number of unstable revertants (McKenzie *et al.*, 2001). The DinB (polIV)

enzyme, which belongs to the Y-family of DNA polymerases, can accommodate some bulky lesions and catalyze translesion DNA synthesis of damaged template strands (Fuchs and Fujii, 2013; Sale *et al.*, 2012). When overproduced, DinB makes frequent mistakes including many frameshift mutations during replication of undamaged DNA (Kim *et al.*, 2001). Expression of the *dinB* gene is induced by DNA damage as part of the SOS response (Wagner *et al.*, 1999) and by cessation of growth (RpoS) (Layton and Foster, 2003). Mutagenesis models propose that growth limitation induces *dinB* gene expression and consequently causes mutagenesis of the genome (Layton and Foster, 2003; Lombardo *et al.*, 2004). This does not explain the uneven genomic distribution of mutagenesis (Rosche and Foster, 1999). Selection models suggest that the significant increase in DinB levels occurs because the *dinB* gene happens to be located close to *lac* on the F′ plasmid (16 kb away) (Kofoid *et al.*, 2003). This position allows the two genes to be co-amplified during selection for more copies of the mutant *lac* gene.

Determining the effect of *dinB* gene position should be decisive, since mutagenesis models predict no role of position and selection models expect a critical role. Our lab found that revertant yield depended heavily on presence of a functional *dinB*$^+$ allele on the F′*lac* plasmid and not at all on the state of the chromosomal *dinB* gene (Slechta *et al.*, 2002a). Another lab found the position of *dinB*$^+$ to be irrelevant to revertant yield (McKenzie *et al.*, 2001). We have repeated these experiments and are extending the tests, but all current evidence supports the importance of position (I. Roush, S. Maisnier-Patin, and J.R. Roth, Unpublished data). In the model described below, we assume that this conflict will be resolved in favor of a *dinB* gene position effect.

A Model That Fits with All Available Data

Experimental resolution of the remaining conflicts answered the questions listed above, but unfortunately eliminated all three of the initial models. The available data can all be explained by combining aspects of all three models. This latest model (Sano *et al.*, 2014) proposes that revertant colonies are initiated by cells that arise before selection but do not grow (or grow very little) under selection before acquiring a mutation. The central idea of this model is that natural selection can operate without cell division by acting on the population of gene copies made by internal local over-replication of the mutant *lac* region. This model is described in more detail below.

1. All revertant colonies are initiated by preexisting cells with multiple copies of the F′*lac* plasmid (Sano *et al.*, 2014). A single copy of the leaky *lac* allele provides enough energy for reversion (Stumpf *et al.*, 2007), albeit at a very low rate. The latest model proposes that this energy is enough to support plasmid replication, but not enough to initiate replication of the chromosome from its regulated origin. The extra plasmid copies provide more *lac* targets for mutation and multiple copies of the DinB gene. Most importantly, the plasmid provides a means of replicating each copy of the *lac* region. It is the act of *lac* replication that provides opportunities for mutation. (Multiple replicating *lac* copies were aspects of the selective amplification model.)
2. While the mutant cells that initiate stable revertants can replicate their plasmids under selection, they cannot divide or grow exponentially. Cell doubling resumes only after a *lac*+ allele forms by mutation in one copy of the plasmid. (Growth is blocked, as in mutagenesis models.)
3. Initiator cells repeatedly replicate their multiple F′*lac* plasmids using preexisting replication forks, initiated by the plasmid transfer origin or at intermediates in recombination between plasmid copies. These unregulated forks copy the entire plasmid repeatedly over a period of several days with little or no cell division. (Mutations are made more likely by repeated replication of multiple *lac* copies as in the selection model.)
4. The F′*lac* plasmid includes the *dinB* gene, which encodes an error-prone polymerase. Therefore, cells with multiple plasmid copies have more DinB protein and a higher mutation rate. This mutagenesis affects only the plasmid, since the chromosome is not replicating. Mutagenesis is not caused by an evolved mechanism, but is an artifact resulting from the chance location of *dinB* on the F′*lac* plasmid. (Mutagenesis appears directed to the plasmid.)
5. As soon as a mutation event produces a *lac*$^+$ allele in any of the multiple *lac* copies, energy is supplied and cells resume regular division. Revertant cells divide exponentially under selection to maintain their new *lac*$^+$ allele, while losing any non-revertant plasmid copies. The rare unstable Lac$^+$ cells found in a stable revertant colony have a mixture of *lac*$^+$ and *lac*$^-$ plasmid types that have not yet segregated. Selective plasmid retention has the effect of directing mutation to DNA sites that limit growth. Plasmid copy number and repeated replication increases the probability that a mutation will occur on some F′*lac* copy and only the copy with a *lac*$^+$ allele is selectively retained. Recovery of unselected mutations on the plasmid is not enhanced, because only the selected plasmid copy is retained. (Mutagenesis appears directed to the precise sites that limit growth.)
6. Unstable Lac$^+$ revertant colonies are initiated by preexisting cells with a small tandem duplication of *lac* within each of their multiple plasmid copies. Multiple copies of an F′*lac* with a duplicated *lac* region provide sufficient *lac* copies (and therefore energy) to support cell division on lactose. Cells grow slowly under selection and expand their gene duplication into a long amplified array as their plasmid copy number drops by segregation. Cells within these clones grow exponentially and replicate both their plasmid and chromosome, while selectively holding multiple tandem copies of *lac*. Cells whose amplified *lac* region includes *dinB* show increased mutagenesis of their entire replicating chromosome. (This explains the observed modest level of general (undirected) mutagenesis.)

Explaining Behavior of the *lac* System in Terms of Standard Evolutionary Ideas

Basic evolutionary theory predicts that imposed selection will increase the rate at which new alleles become prominent in a

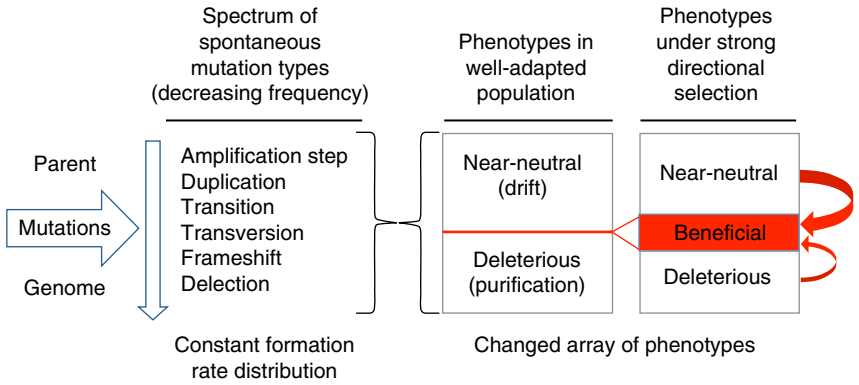

Figure 6 The conventional wisdom and how it can imitate mutagenesis. The primary event is formation of the several mutation types. These arise at a vast array of frequencies and can have phenotypic effects of vastly different magnitude. In *Salmonella*, gain-of-function mutation types arise at rates that vary over a million-fold range. Substitution mutations that cause qualitative changes in a particular protein arise at less than 10^{-8} per cell per generation. Duplications of a gene form at 10^{-5} per cell per generation and further copy number increases at about 10^{-2}. Base substitutions in a particular gene arise at about 10^{-7} per cell per division and most cause a loss-of-function phenotype. The magnitude of their effects range from synonymous and near-neutral conservative missense substitutions that are about third of substitutions to the completely null mutations (nonsense), which, together with frameshift and deletion types make up about 1% of genetic changes. The selective value (or costs) of mutations also varies over a wide range, but beneficial mutations are extremely rare in a well-adapted population. When a population is placed under strong directional selection, a larger fraction of available variability contributes to improved growth. Thus the predominant genotype in a population changes more rapidly under selective, even when the source of variability remains constant.

population, but does this without increasing mutation rates. This is diagramed in Figure 6. Assume that mutations arise as random errors whose frequency and spectrum of types is unaffected by growth limitation. Consider first a well-adapted population growing under optimum conditions. A large fraction of new mutations have phenotypes that are near-neutral (synonymous, silent or conferring a tiny positive or negative effect on growth). These mutations tend to remain in the population as polymorphisms and are subject to random loss by drift. Perhaps a similar fraction of mutations causes a palpable loss-of-function phenotype that impairs growth (deleterious). The latter mutations are continuously removed by purifying selection. Very few new mutations improve growth in a population that is well-adapted to its circumstances.

Consider what happens if one shifts the population to conditions that impair growth but leave open many mutational ways to adapt and improve. A larger fraction of new mutations are beneficial and are brought to high frequency in the population by positive selection. Some of these mutations were previously near-neutral or even deleterious. Due to selection, the preponderant genotypes in the population change progressively. More mutations are being fixed in the genome even though the mutation rate and spectrum of mutation types is unchanged. New mutations form (at an unchanged rate) but rise in frequency and are held in the genome by selection. This looks like mutagenesis, when in fact selection has just detected beneficial alleles in the pool of near-neutral and deleterious types. Selection does not create new mutations but redefines their phenotype. The rate of adding new alleles to the preponderant genome increases due to selection alone. In the 'mutagenesis' models discussed here, these new mutations are attributed to an evolved mutagenic mechanism induced by stress. In the most recent model, polymorphic near-neutral mutant alleles gain a significant phenotype following amplification under selection. Adaptation occurs without mutagenesis.

Evolutionary Insights Provided by the *lac* System

Several principles of broad relevance to evolutionary biology have emerged from study of the *lac* system devised by Cairns. This is true despite the fact that behavior of the system relies on specialized features that are peculiar to the particular strain used. That is, selection is imposed on a *lac* allele that happens to lie near the *dinB* gene, which encodes an error-prone polymerase. Both *lac* and *dinB* genes are carried by a conjugative plasmid with a second replication origin that normally supports transfer from one cell to another. Scavenger cells prevent growth under selection, but poise cells on the brink of growth so even slight improvements initiate growth. Below is a list of generally applicable principles that have emerged from analysis of this peculiar system.

1. Near-neutral beneficial alleles can gain a significant phenotype when amplified under selection. The minimal activity of the mutant *lac* gene in this system supports growth only when present in multiple copies, as seen during formation of unstable revertant colonies.
2. Near-neutral mutations have small phenotypes, such that their frequency is neither strongly increased nor reduced by selection. These mutations are carried as neutral polymorphisms subject only to drift. These polymorphic alleles are available whenever some new selection pressure is imposed. Individuals with multiple copies of a near-neutral allele (and a bigger phenotype) are frequent and a selective response can be rapid.
3. Amplification under selection is rapid and supplies multiple copies of a growth-limiting allele, all of which are

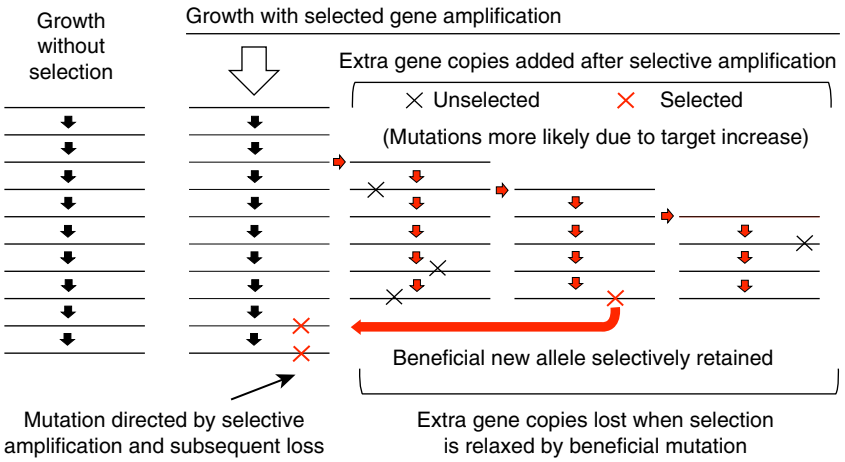

Figure 7 Selective amplification directs new mutations to sites that improve growth. The left column shows a genome region that replicates serially with no selection on copy number. The right column shows the same region that is amplifying under selection for increases in some encoded function. Amplification provides more copies of the entire region and increases the likelihood that a cell carrying this amplification will experience some mutation in this region. If the mutation is beneficial, selection to hold the amplification is relaxed and all copies are lost except the improved version, which is selectively maintained. Any copy with an unselected mutation is lost. The end result is a genome with an improved allele whose probability has been increased without increasing the likelihood of any other mutation in the genome.

subject to mutational improvement. Thus amplification increases the likelihood of sequence improvement by providing more targets (not by mutagenesis). Amplification is reversible such that extra gene copies are lost once selection is relaxed by a beneficial mutation in some copy. This process of selective amplification and later loss has the effect of directing new mutations to beneficial sites.

The apparent direction of mutations to valuable sites by amplification is diagramed in Figure 7. A region including the gene under selection amplifies under selection. This enhances growth and provides more targets for mutation. The extra copies make any mutations in this region more likely, regardless of their effect on phenotype. If a beneficial mutation occurs in some copy, selection for amplification is relaxed and the improved allele is held selectively. This allows all other copies including those with nonselected mutations to segregate and be lost, but retains the copy that has a beneficial mutation. The net effect of this process is to increase the frequency of beneficial mutations in the local region with no effect on nonselected mutations. The chance of retaining an unselected mutation in the amplified region is the same as the likelihood of this mutation arising without amplification. The potential of amplifications to increase apparent mutation rate and to direct mutations to useful site was described some time ago (Roth *et al.*, 1996).

4. Selection can operate in nongrowing cells if a genome region is subjected to local over-replication and beneficial mutations are held selectively. This can be seen in Figure 7, where the extra copies are added by repeated replication even in nongrowing cells. Each act of replication presents an opportunity for mutation. Selection holds only a copy with a beneficial mutation. In essence, the multiple copies of the sub-genomic region serve as a population upon which selection can act in nondividing cells. This process may prove relevant to origins of cancer whose progression is favored by fragile sites in the metazoan chromosome (Albertson, 2006). Repeated breakage and replicative repair of such sites can occur during one generation of a single cell and the lifetime of a single metazoan individual.

Adaptive Radiations: Insights From Evo-Devo

KJ Parsons, Institute of Biodiversity, Animal Health, and Comparative Medicine, University of Glasgow, Glasgow, UK

Glossary

Buccal cavity The whole of the mouth and jaw region and its capacity.

Embryogenesis The early formation of primary structures and patterning that comprise an embryo. Often, most of the developmental events that comprise embryogenesis are shared even among distantly related taxa.

Genetic accommodation The evolution of a developmental system whereby events that are initially induced by environmental cues become an automatic developmental event based on heritable genetic variation. Genetic accommodation can evolve to either increase or decrease the amount of phenotypic plasticity.

Genetic canalization A developmental strategy that is impervious to environmental variation and completely determined by genetic variation.

Gene promoter region An area of the genome adjacent to the sites of gene transcription. These regions are thought to initiate the transcription of genes.

Macroevolution Relatively large evolutionary change that occurs over several million years. Such evolution results in deep splits in evolution creating new genera, families, orders, or kingdoms. This contrasts with microevolution which tends to occur within a single species and can occur rapidly, involving only a few generations.

Multipotent cells Cells that are able to become any number of different tissues through alterations of gene expression, and/or signals from neighboring tissues.

Ontogeny The whole of the developmental process. Development, while often studied at embryonic stages, actually takes place throughout the lifecycle of an organism. Ontogeny, comprised by its often continuous stages, provides a focus for investigation.

Insights into Adaptive Radiations from Evolutionary Developmental Biology

Many early studies in evo-devo focused on investigating large-macroevolutionary patterns and mechanisms that determined phylogenetically deep differences (i.e., between kingdoms and orders). However, evolutionary developmental biology (evo-devo) is now making major contributions to our understanding of adaptive processes down to the level of populations and inter-individual variation (Klingenberg, 2010; Parsons and Alberston, 2013; Nunes *et al.*, 2013). Specifically, evo-devo is providing a mechanistic understanding for how continuous adaptive phenotypic variation arises (and develops), while also providing its own important theoretical contributions for what limits, directs, or enhances adaptive evolution (Pigliucci, 2008; Pigliucci and Muller, 2010). For biologists interested in understanding the evolution of adaptations and more recently their development, there are numerous study systems recognized as 'adaptive radiations.' The hallmark of such systems is that several closely related species exist that arise from a recent single common ancestor, or a few closely related ancestors (Schluter, 2000). These species possess differences in anatomy and behavior that relate to ecological specializations (**Figure 1**). The often rapid nature of evolutionary change in these systems makes comparisons between member species very tractable due to homology in anatomy and similarity in genetic backgrounds (Loh *et al.*, 2008). The process through which adaptive radiations evolve is assumed to be initiated by changes in the environment, or access by a lineage to a new environment through geodispersal events, or perhaps the innovation of a novel trait (Schluter, 2000). These conditions can make new ecological niches available allowing the lineage to persist without competition from other species. Supporting this many adaptive radiations occur across isolated islands or lakes that will be discussed below. Therefore, adaptive phenotypes are often thought to be driven initially by intraspecific competition that drives populations to phenotypically adapt and diverge into species through natural selection.

While the above ecological conditions are commonly thought to drive adaptive divergence, from an evo-devo perspective it is recognized that new environments will also impact developmental processes in novel ways. So far, much of the empirical focus for adaptive radiations has typically come from fields outside of evo-devo. From the late 1980s to the present, evolutionary ecology has repeatedly demonstrated a role for natural selection in the formation of adaptive radiations (Endler, 1986; Schluter, 2000; Kingsolver *et al.*, 2001). Similarly, from the 1990s to present, population genetics (and more recently population genomics) has demonstrated changes in gene flow that coincide with adaptive divergence, while also examining the role of geography in the formation of species (Avise, 1994; Hartl and Clark, 1997; Hartl, 2000). However, while evolutionary ecology has identified adaptive phenotypic variation, and population genetics has identified allele frequency changes in adaptive divergence, there is a significant knowledge gap in evolutionary biology regarding how adaptive variation arises and its mechanisms. In other words, connections between the genotype and phenotype are not yet well characterized in systems displaying adaptive radiations. Given that natural selection only operates directly on phenotypic variation (Mayr, 1997) this is surprising because it is highly relevant to understanding how adaptive phenotypes form, and why specific allele frequencies might change during adaptation. Similarly, the developmental processes that influence both the efficiency and the outcome of

Figure 1 Examples of the phenotypic diversity that figures prominently in cases of adaptive radiation. Darwin's finches (left panels) and African cichlids (right panels) craniofacial anatomy has been the focus of several studies investigating the mechanisms of their development. Finch photographs were generously provided by Jeff Podos. Cichlid images are courtesy of Ad Konings, copyright Ad Konings.

selective processes remain largely unexplored. This is an important area for evo-devo to fill because selection and adaptation can occur over the course of development, and in different developmental environments. Currently most studies of adaptation tend to focus upon performance at a single point in ontogeny (usually in adult phenotypes) in a single environment.

Fortunately, the movement of evo-devo into finer scale evolutionary processes is well underway and seemingly picking up momentum as a wider range of taxa become the focus of study (Nunes *et al.*, 2013). It is now becoming more common for evo-devo approaches and thinking to be applied to cases of microevolution and adaptive radiations to understand how adaptive phenotypes arise (Parsons *et al.*, 2010, 2011; Snell-Rood *et al.*, 2010; Swanson and Snell-Rood, 2014). Further, evo-devo does not simply deal with the outcome of selection (i.e., survival of the fittest), rather evo-devo considers the origins of variation through developmental change

(i.e., arrival of the fittest). This is a key contribution from evo-devo because natural selection cannot occur without phenotypic variation, or be evolutionarily effective without genetic variation. Therefore the study of how variation is formed through development is fundamental for understanding how adaptations evolve – arguably even more fundamental than natural selection (West-Eberhard, 2003). Thus, evo-devo promises and continues to fill current gaps in knowledge by linking the genotype to *adaptive* phenotypic variation through the study of changes in development.

Early Links Between the Study of Adaptive Divergence and Developmental Biology

How did evo-devo enter the realm of adaptive radiations? This involves a long history that continues to unfold. The study of adaptation itself from an ecological perspective did not become rigorous until the 1980s following critiques of the 'adaptationist paradigm' and the publication of landmark volumes that catalyzed approaches for the study of selection at the population level (Gould and Lewontin, 1979; Endler, 1986). At roughly the same time there was a small but fervently renewed interest in the idea that developmental interactions with the environment could contribute significantly to adaptive phenotype variation through phenotypic plasticity – the ability of a genotype to produce a range of phenotypes dependent upon environmental cues (Via and Lande, 1985; West-Eberhard, 1989). Long relegated as 'nuisance' variable or considered developmental 'noise' plasticity was considered unimportant for evolutionary change, and rather was seen as an inconvenience for experimenters especially within the realm of quantifying the heritable contribution to phenotypes.

However, as theory developed it was suggested that plasticity could provide 'alternative' phenotypes that could develop to produce adaptive variation (West-Eberhard, 1989). Further, older theories that hadn't been investigated empirically for decades such as the Baldwin effect – whereby plasticity is favoured because it allows a population to persist in a novel environment through rapid phenotypic change, and genetic assimilation – where an initially plastic response becomes incorporated as part of normal phenotypic development and no longer requires environmental induction – were resurrected by the growing realization that adaptive evolutionary processes were not exclusive to a straightforward change in genetically determined traits. At this time a 'gene-centered' view of evolution still dominated evolutionary biology, whereby genetic variation and allele frequency change were seen as the panacea for evolutionary change (i.e., environmental effects were irrelevant). This slowed progress and acceptance that plasticity, and ultimately variation from development, could be relevant to evolution. For example, some detractors suggested that plasticity provided a 'baroque hypothesis' for how adaptive divergence occurred, or suggested that a renewed interest in plasticity represented a return to Lamarckism (Pigliucci *et al.*, 2006).

Despite these issues, a growing number of biologists viewed plasticity and ultimately development as a relevant contributor to adaptive evolution and began to perform numerous lab experiments across a wide range of taxa. Perhaps one of the most significant findings from these experiments was that plasticity exhibited a degree of heritable variation (Pigliucci, 2005). This meant that plasticity was like other phenotypic traits in that it could itself evolve. In other words, this empirical research showed that the developmental system could evolve and adapt in such a way that it could broaden or narrow its potential range of phenotypes. This was a significant step for bringing developmental thinking into the realm of adaptive divergence, and how population level changes could occur. Notably such thinking is reflected in conceptual models of adaptive divergence (**Figure 2**). For example, the idea of resource polymorphisms, whereby individuals within a population evolve ecological specialization on different ecological resources (i.e., prey, structural habitats), explicitly incorporates developmental thinking through the evolution of plasticity (Skulason and Smith, 1995; Smith and Skúlason, 1996). Specifically, this model suggested how developmental systems would be expected to promote initial variation for divergence through plasticity, and evolve toward increased ecological specialization (**Figure 3**). In the final stages of the model genotypes that can produce adaptive phenotypes without the need for environmental cues are favoured and plasticity is lost (i.e., genetic assimilation) due to its costs (e.g., sensory costs, potential for errors in variable conditions). Thus, resource polymorphism theory provided an early framework for how adaptive evolution could depend on environmentally induced changes in development.

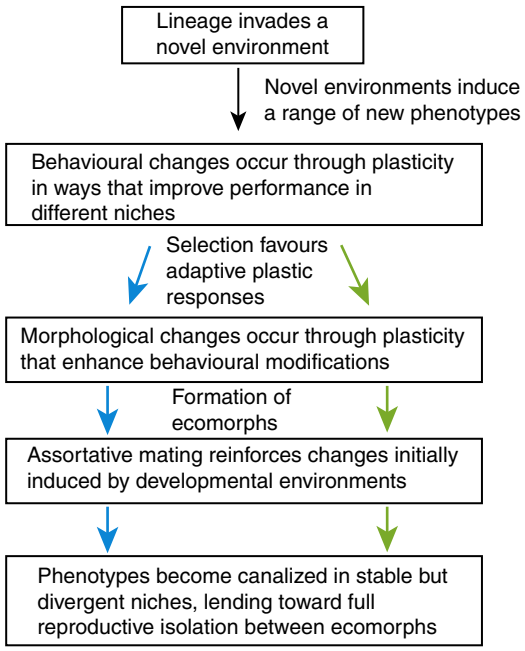

Figure 2 A representative diagram for how adaptive divergence occurs through developmental change within the framework of resource polymorphism theory. Notably, developmental plasticity figures prominently in this model and reflects a process of sympatric divergence. However, it is also recognized that these processes of developmental evolution can occur in allopatry. Modified from Skulason, S., Smith, T.B., 1995. Resource polymorphisms in vertebrates. Trends in Ecology & Evolution 10, 366–370.

Figure 3 Example of ecomorphs from a well-known resource polymorphism of Arctic charr (*Salvelinus alpinus*), in Lake Thingvallavatn, Iceland. Evidence from charr supports the resource polymorphism theory of an evolving magnitude of phenotypic plasticity that coincides with ecological specialization (Parsons *et al.*, 2010, 2011), and some instances of complete reproductive isolation between sympatrically derived charr ecomorphs is documented (Gislason *et al.*, 1999). Within the figure the large benthic (LB), small benthic (SB), piscivorous (PI), and planktivorous (PL) ecomorphs are depicted for head and overall body shape (K. Gunnarsson, and A. Gardarson photo).

More comprehensive challenges to the gene-centered view of evolution were put forth in a series of seminal books through the late 1990s and early 2000s that placed more emphasis on phenotypic development (Schlichting and Pigliucci, 1998; West-Eberhard, 2003). These volumes provide motivation for a great deal of current research as they made the phenomenon of developmental variation much more acceptable as a topic of evolutionary interest. These volumes also helped to reintroduce neglected topics such as how phenotypes may be limited by developmental processes. For example, the idea of phenotypic integration whereby a set of traits are correlated with others became a renewed area of interest (Olsen and Miller, 1958). This is because integration may itself evolve for adaptive reasons, or it can provide limits to adaptive evolution by not allowing a trait to change independently of others (Klingenberg, 2008; Parsons *et al.*, 2012). An extension of phenotypic integration is the idea of modularity whereby subsets of traits can interact tightly, but in a way that is relatively distinct from other traits and modules. The underlying basis of such integration modules can lie in developmental processes, evolutionary history, or functional needs, and now provides an active area of interest in adaptive radiations (Parsons *et al.*, 2011; Claverie and Patek, 2013; Sanger *et al.*, 2012).

While developmental thinking was becoming merged with the study of adaptive variation through the 1990s and early 2000s, pure developmental biology was becoming more directly merged with molecular techniques (Roush and Pennisi, 1997; Dalton, 2000; Goodman and Coughlin, 2000; Hall, 2000). Methodological advances were occurring rapidly with an increasing number of studies beginning to show the expression of genes '*in situ*' where it could be visualized on the embryo, or quantified precisely. This now allowed developmental biology to directly examine the molecular basis of basic phenotypic development such as early embryogenesis (Raff *et al.*, 1999). However, at this time molecular methods in developmental biology were almost entirely limited to 'model' organisms (e.g., zebrafish, mice, xenopus). Through time it became clear that the function of genes during embryogenesis in these widely different organisms was conserved, as was often their nucleotide sequence. This key finding opened the opportunity to take these findings out of the lab and into study systems exhibiting adaptive phenotypic variation (i.e., adaptive radiations). Below, the author provides some examples of where evo-devo has been taking the study of adaptive radiations. Because it is beyond the scope of this article to highlight every relevant system. The author has focused on vertebrate groups because they are among the best characterized in terms of adaptive radiations, and ecology, and currently represent a highly active area of recent investigation.

Fish Adaptive Radiations and the Incorporation of Evolutionary Developmental Biology

Adaptive radiations in fishes, the most species rich vertebrate group, offer an unmatched array of phenotypes that have been investigated from an evo-devo perspective. For example, craniofacial variation is extensive and relates to prey consumption whereby shorter jaws offer a higher mechanical advantage for harder prey, while longer jaws offer a greater volume in the buccal cavity for suction feeding of small waterborne prey (Parsons and Albertson, 2009). Similarly, body shape variation is extensive in fishes with a more elongate fusiform shape conferring an advantage for sustained swimming, while deeper body shapes aid in the navigation of complex structural environments (Webb, 1982, 1983, 1984). Such variation commonly extends across fish adaptive radiations, and is even present within species in the form of 'ecomorphs.' Such ecomorphs are common in fishes, especially those from postglacial environments where competition from other species is lower, allowing for the exploitation of new niches (Taylor, 1999). These attributes whereby ecology can be related to species level phenotypic variation, and even be studied below the species level have made fishes an attractive group for evo-devo studies, especially since many can be readily kept under lab conditions (**Figure 3**).

Fishes can be credited for being a valuable empirical model for helping introduce developmental thinking into the study of adaptive divergence through the study of phenotypic plasticity. For sometime, prior to the emergence of modern evo-devo, fishes have been the focus for studies of morphological phenotypic plasticity (Robinson and Parsons, 2002). Fishes have been shown many times to possess an ability to alter head and body shape in response to diets that mimic the benthic and limnetic prey they often specialize on in nature (Wimberger, 1994; Robinson and Parsons, 2002; Adams and Huntingford, 2004). Such developmental changes correspond to differences in morphology found in nature and ultimately affect the performance of populations (Day and McPhail, 1996; Parsons and Robinson, 2007; Andersson, 2003; Ruehl and DeWitt, 2007). This direct tie between developmental variation, the environment, and adaption suggests broader implications for how plasticity influences evolutionary divergence (**Figure 4**). Indeed, studies have recently shown that

plastic responses themselves can evolve in a number of ways. For example, data from ecomorphs of Arctic charr (*Salvelinus alpinus*) show evidence of genetic accommodation whereby morphological plasticity has been lost with an increasing degree of ecological specialization (Parsons *et al.*, 2010, 2011). Similarly, threespine sticklebacks have been shown to display genetic accommodation in growth rate, whereby recently established populations show a greater degree of plasticity than long established ones. Fishes also demonstrate evidence that plastic responses can determine the initial trajectory of adaptive evolutionary change. For example, the **flexible stem theory** of adaptive divergence posits that the plastic responses of an ancestral population can exhibit the same patterns found between species in a larger adaptive radiation (Wund *et al.*, 2008, 2012). In support of this theory marine threespine sticklebacks, which provide an extant ancestor for contemporary freshwater populations, show a morphological plastic response that matches the patterns of adaptive divergence found between ecomorphs in specialized freshwater populations.

From a molecular perspective, fishes have also contributed to our understanding of the genetic mechanisms underlying adaptive phenotypic development. An advantage of closely related, but adaptively divergent populations of fishes is that different forms can be hybridized to produce offspring that possess a range of phenotypes in the F2 generation. While divergent selection may alter several regions of the genome and cause them to become alternatively fixed for genetic variation between ecomorphs a hybridization event can mix together a number of new combinations. These new combinations allow for relationships between phenotypic variation and genetic variation to be statistically assessed through the methodology known as quantitative trait loci (QTL) mapping. While this method does not typically determine the exact genetic changes related to a phenotype it provides a significant inroad toward this discovery by providing an informed idea of the genomic region where adaptive allelic variation is likely to be present (e.g., Albertson *et al.*, 2003, 2005; Shapiro *et al.*, 2004; Peichel *et al.*, 2001; Parsons *et al.*, 2015; Laporte *et al.*, 2015).

Using the QTL approach, researchers have begun to understand the genetic and developmental basis of a range of phenotypes in fishes. For example, within African cichlids which comprise the largest known vertebrate adaptive radiations, QTL mapping pointed toward the gene bone morphogenetic protein 4 (*BMP4*) as a candidate for adaptive differences in jaw and head shape observed between Malawi cichlid species (Albertson *et al.*, 2005). Indeed, expression of *BMP4* is naturally higher in a species with a more robust jaw morphology, and was shown to alter jaw morphology concordantly in a complementary experiment using zebrafish. A more recent experiment and finer scale sequencing of the QTL region neighboring *BMP4* has now revealed a mutation that is alternatively fixed between species that lies within the gene promoter region (transcriptional co-activator) of the neighboring gene limb bud and heart homolog (*lbh*) (Powder *et al.*, 2014). The function of this mutation was tested using both zebrafish and *Xenopus*, and it was demonstrated that *lbh* mediated the migration of cranial neural crest cells, the cellular source of the craniofacial skeleton (**Figure 5**). The mutation,

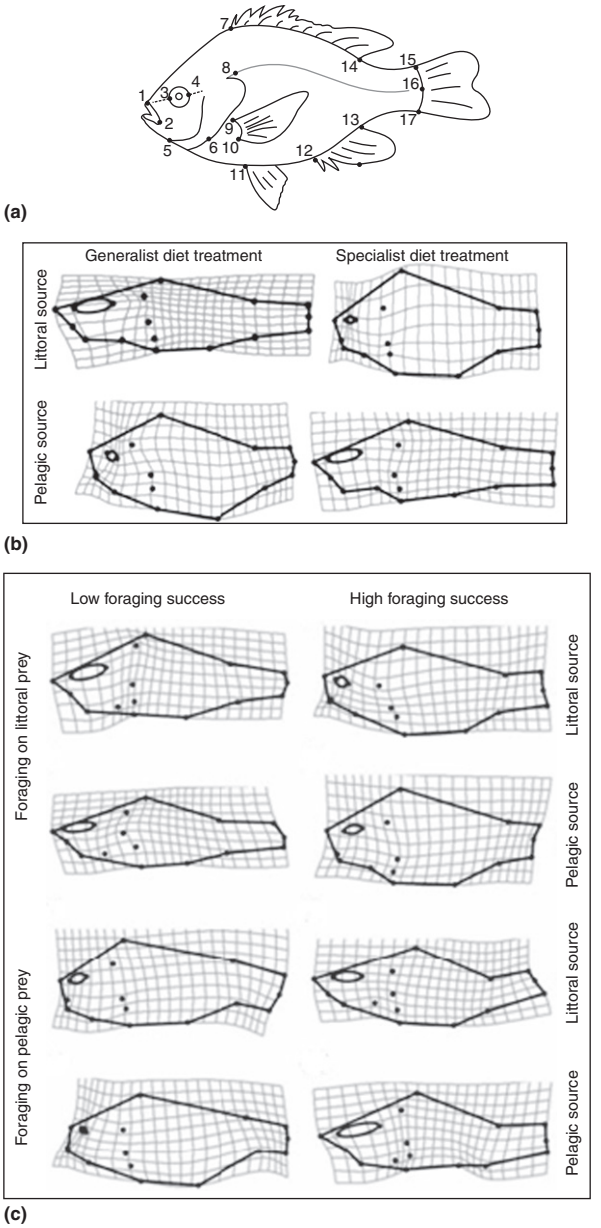

Figure 4 Developmentally plastic responses can mirror adaptive divergence and confer fitness advantages. Here panel (a) shows the shape landmarks collected across the body form of pumpkinseed sunfish (*Lepomis gibbosus*), a species which displays a resource polymorphism between littoral and pelagic habitats. Using measures of geometry to depict shape changes these plastic responses mirror the differences documented between ecomorphs. Panel (b) depicts the plastic responses of sunfish from littoral and pelagic source populations reared under diets that mimic their respective specialist prey, and a generalist diet treatment that alternates weekly between littoral and pelagic prey. Panel (c) depicts the average phenotypes of sunfish from both littoral and pelagic source populations that performed with poor success and high success on littoral (top four grids) and pelagic prey (bottom four grids). Reproduced from Parsons, K.J., Robinson, B.W., 2007. Foraging performance of diet-induced morphotypes in pumpkinseed sunfish (*Lepomis gibbosus*) favours resource polymorphism. Journal of Evolutionary Biology 20, 673–684.

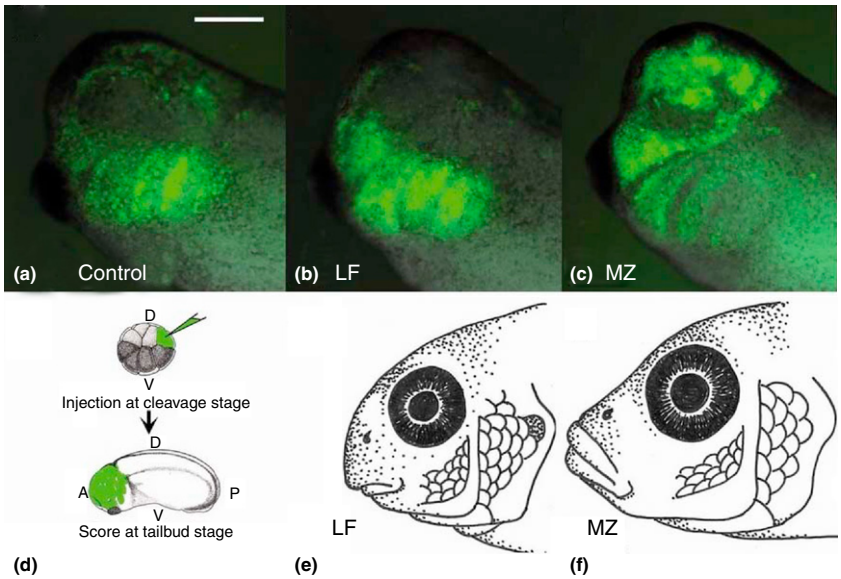

Figure 5 A single amino acid difference in cichlids regulates the migration of neural crest cells, the source cell population for the developing face. Targetted injections of *lbh* transcripts from two species cichlids *Labeotropheus fuelleborni* (LF), and *Maylandia zebra* (MZ) show that they alter cell migration in Xenopus embryos. The top panels depict the differential movement of neural crest cells labeled with green fluorescent protein, including a control (a), LF (b), and MZ (c). The bottom panel depicts the experimental injection of transcripts (d), and the differential facial morphology between species (e,f) that may result from changes in the expression of *lbh*. Images are derived from Powder, K.E., Cousin, H., McLinden, G.P., Craig Albertson, R., 2014. A nonsynonymous mutation in the transcriptional regulator lbh is associated with cichlid craniofacial adaptation and neural crest cell development. Molecular Biology and Evolution 31, 3113–3124.

which comprised of a single amino acid change, resulted in discrete shifts in migration patterns of the multipotent neural crest cells in ways that are consistent with both embryological and adaptive adult craniofacial phenotypes. Among animals, this polymorphism in *lbh* represents a rare example of a coding change that is associated with continuous morphological variation, an important aspect because most adaptive radiations are represented by a continuum of phenotypic variation rather than the presence or absence of traits (Parsons and Alberston, 2013). It is expected that new advances in genomics, and increasingly available resources for fish genomes will continue to enable such precise insights into the developmental genetic underpinnings of adaptive divergence (Brawand *et al.*, 2014; Moczek *et al.*, 2015).

Herpetofauna: Plasticity and Ontogenetic Processes Contribute to Adaptive Divergence

Lizards, amphibians, and snakes exhibit adaptive divergence through a range of phenotypes that correspond with ecological conditions. For example, the anolis lizards form the most species rich genus of amniote vertebrates, and those found across the Greater Antilles provide one of the best studied examples of adaptive radiations. Here anolis occur across isolated islands and have diverged to occupy separate ecological niches. These niches mostly involve the location of foraging within the vegetation with some ecomorphs occupying the crown of trees, the trunk, or underlying shrubs (Losos, 2007). Differential niche use is accompanied by morphological changes mainly related to the diameter of the surfaces they most frequently encounter, with 'twig' ecomorphs having short limbs, while trunk ecomorphs have long limbs. Interspecific comparisons indicate that longer legs confer an advantage for increased running speed on broad substrates, whereas shorter limbs provide greater maneuverability on narrow surfaces.

The anolis system has been the recent subject of evo-devo research. Notably, experimental evidence shows that phenotypic plasticity exists for hind-limb length in *Anolis sagrei* and *Anolis carolinensis*. These plastic responses mirror the pattern of species differences whereby hatchlings exposed only to broad substrates developed relatively longer hind limbs for their body size compared to hatchlings exposed only to narrow substrates (Losos *et al.*, 2000; Kolbe and Losos, 2005). Genetic variation for plasticity is present between species suggesting that plasticity has evolved with and contributed to their adaptive divergence (perhaps in line with the flexible stem hypothesis).

Indeed, other herpetofauna show evidence that developmental flexibility has evolved in concordance with adaptation. For example, comparisons from several populations of tiger snakes (*Notechis scutatus*) isolated (or introduced) on islands from period of less than 30 to more than 9000 years where selection favoured increased head size (adaptive for ingesting large prey) show changes in magnitudes of plasticity (Aubret and Shine, 2009). Specifically, a larger head size is achieved by plasticity in 'young' populations and by genetic canalization in 'older' populations. So far, this system provides rare empirical evidence of genetic assimilation in natural populations, where an adaptive trait has shifted from having a plastic basis to be canalized as part of genetically determined development.

Other developmental processes have been found to influence adaptive radiations in herpetofauna, with recent focus on

ontogenetic processes. For example, allometry, which refers to how a trait changes with increasing size has been viewed as a possible progenitor of variation, but more often a constraint on evolution because of its dependence on size (Klingenberg, 2010). Data from anolis show support for both views in that sexual dimorphisms in cranial shape converge across species and are usually but not always dependant on the same allometric strategy. Specifically, dimorphisms where males have much more elongate faces relative to females are usually the result of the emergence of dimorphism early in ontogeny that gradually increases. However, a novel strategy has also evolved in one clade (*Anolis carolinensis*) whereby dimorphism appears rapidly in the late stages of ontogeny as sexual maturity arises (Sanger *et al.*, 2013). Further research shows that this novel strategy is underlain by sex-specific regulation of the estrogen pathway, in contrast to the androgen or insulin growth factor pathways normally considered to be the primary regulators of sexual dimorphisms within vertebrates (Sanger *et al.*, 2014).

Similarly, allometry plays a role within an adaptive radiation of salamanders. The ontogeny of foot morphology has been investigated using species of European plethodontid cave salamanders (Adams and Nistri, 2010). Foot morphology in this group of salamanders relates to their ecology with the degree of webbing between the toes showing relationships with the ability to cling to substrates. For these salamanders, the ancestral ontogenetic strategy maintains a constant degree of webbing with growth, or little morphological change over ontogeny (i.e., isometric growth). However, at least two evolutionary changes in allometry exist among lineages: one lineage has evolved an allometric growth pattern, where foot webbing increases with size, and a species in this lineage also shows a reversion to isometry. This switch to allometric growth could possibly underlie an adaptation for climbing. Notably, the ontogeny of different species which starts from different juvenile foot morphologies converges toward a shared adult morphology with extensive webbing suggesting an adaptive explanation, and potentially functional optimum (Adams and Nistri, 2010). These and overall findings so far from adaptive radiations of herpetofauna show that they hold great promise for our understanding of adaptive radiations from an evo-devo perspective.

Avifauna: Adaptive Bill Diversity through Developmental Change

Birds are especially noted for variation in bill morphology such as that found in Hawaiian honeycreepers (*Carduelinae*) and arguably the best known example of an adaptive radiation through Darwin's finches (*Geospiza*). *Geospiza* comprise a group of 14 closely related song birds on Galapagos Islands and Cocos Island and have been the focus of several studies focused on the development of bill morphology (Parsons and Albertson, 2009; **Figure 1**). Bills vary among species in ways that are maximally effective for exploiting particular foods, including seeds, insects, and cactus flowers. Broad and deep bills are suited for crushing seeds (small, medium, and large ground finches), whereas long pointed beaks are suited for eating insects or reaching into cactus flowers and fruits. These specializations are apparent during early embryonic development and are clearly influenced by underlying genetic variation. Specifically, the gene transcripts of bone morphogenetic protein 4 (*Bmp4*) and calmodulin (*CaM*) figure prominently in our understanding of finch diversity with deep and broad beak morphology being strongly correlated with *Bmp4* expression (Abzhanov *et al.*, 2004, 2006). Experiments reveal that overexpression of *Bmp4* in chicken embryos causes morphological changes approaching the bill morphology of the large ground finch *Geospiza magnirostris*. Surprisingly, other growth factors such as *fibroblast growth factor* (*Fgf8*) and *sonic hedgehog* (*Shh*), which are expressed in the overlying beak ectoderm and are necessary for patterning of the mesenchyme and cartilage growth (3), do not differ in expression among finch embryos, although recent investigation from other species of birds at earlier stages of development suggests that Wnt signaling, a developmental pathway involved in directing the migration of cells and bone growth in the craniofacial region may actually precede variation in BMP4 (Powder *et al.*, 2010, 2012). Similarly, calmodulin (*CaM1*), a molecule involved in mediating calcium (Ca^{2+}) signaling, is expressed at higher levels in the long and pointed beaks of cactus finches relative to more robust bill types. Also, experiments in which an activated form of the *CaM kinase* (*CaMKII*) was artifically upregulated in the frontonasal prominence of chicken embryos, causes an elongation of the upper beak, similar to cactus finches. Interestingly, this did not affect other beak axes (i.e., width and depth), indicating the potential independence of the pathways controlling beak shape.

Variation in bill width and depth that relates to ecology and bite force shows the potential for extremely rapid evolution through similar developmental mechanisms. For example, such adaptive changes occur in populations of the Sonoran house finch (*Carpodacus mexicanus*), and although variation in bill shape is much less obvious than that found across Galapagos *Geopspiza* species (**Figure 1**), the divergence between urban and rural populations similarly occur in relation to food type. Urban populations feed on larger, harder sunflower seeds, which in turn favor a stronger bite force. Expression analysis during embryonic bill development in urban house finches indicates that *Bmp*s are involved in producing intraspecific differences in bill shape. The bill mandibular primordium of urban finches shows inheritance of an earlier and higher activity of *Bmp*s corroborating the view that the processes involved in speciation (i.e., *Geospiza*) are the sum of smaller but multiple microevolutionary processes.

Conclusions

Evo-devo has an established history of contributions that have shaped our understanding of adaptive radiations. As shown above, environmental influences on development (i.e., phenotypic plasticity) in a range of taxa could contribute to the process of adaptation in a variety of ways and perhaps provide much of the variation that is fundamental for natural selection to operate. As yet, it is largely unknown how such plastic phenotypes arise from a mechanistic perspective, specifically the alleles that determine genetic variation in plasticity. Gaining an understanding of the alleles underlying

plastic responses will provide tractable variation that could directly relate to higher levels of divergence providing an explicit link between early and late stages of adaptive divergence (**Figure 2**). Further, evo-devo has enlightened evolutionary biology about how ontogenetic processes can be altered to produce both novel and convergent phenotypes. These findings suggest a much larger role for ontogeny as a source of variation for adaptive evolutionary change than is currently appreciated. Finally, while lab model organisms initially demonstrated conserved functional roles for genes involved in early development, adaptive radiations also show that 'tinkering' of the same genes or pathways in widely divergent taxa (e.g., *BMP4* for cichlid jaw shape, finch bill shape) can cause roughly similar changes in development to produce adaptive phenotypes (Parsons and Albertson, 2009). Combined these findings are derived from a wide variety of approaches, from those that are highly quantitative to purely molecular approaches (Parsons and Alberston, 2013). However, evo-devo continues to form a synthesis where approaches such as these are becoming increasingly integrated. The advent of newer high throughput sequencing technologies has recently democratized genetic data to any organism of interest which will likely aid in this synthesis. As a more integrative evo-devo moves into this post genomic era it is expected to continue providing novel insights into adaptive processes.

Age-Specific Survivorship and Fertility, Estimating

NG Yoccoz, UiT The Arctic University of Norway, Tromsø, Norway

Glossary

Bias Difference between the expected value of the estimator of a population parameter and its true value.

Precision An estimator is precise if different samples of the same population result in similar estimates.

Robustness An estimator is robust if its properties – bias, precision – are not too sensitive to underlying modeling assumptions.

Introduction

Survivorship is the proportion of individuals within a cohort still alive after a given period of time, and fertility is the number of offspring born per individual or mating pair. Interest in measuring these two traits started over two centuries ago, but it is mostly in the last decades that modern methods have been developed. In fact, one of the difficulties today is to find the appropriate methods for a given context, depending in particular on the questions investigated, the study design and the information available about individuals. But before investigating how we can reliably estimate survival and fertility in a population, how much they vary and what can cause observed changes, we need first to go through some important statistical concepts. Assume we are interested in estimating a given parameter – let's say survivorship of adult females in the year following birth of their calf, called ϕ. To estimate this parameter, we will usually have to rely on (1) a sample of females from the population, and (2) observing which females will be alive at the end of the year. The naïve way of estimating the survival probability is to consider the ratio of the number of females known to be alive 1 year later to the initial number of females. How can we determine if this ratio is a reliable estimator of ϕ? Because this ratio will be affected by many factors – for example, which females happen to be in the sample, which females were observed to be alive – this ratio will usually differ from ϕ and only the statistical properties of the estimator can be used to assess its reliability. The most important properties of the estimator are its expected value or average and its variance (or its inverse, the precision). These properties are usually calculated considering hypothetical repeated samples from the same population. For example, an estimator is said to be unbiased if its average value is equal to its true (but unknown) value. A large part of the work done in statistics aims at finding estimators, which have low bias, and as small a variance as possible. Another aspect is robustness: we prefer methods that are not too sensitive to the assumptions we make, particularly those that are difficult to assess with the available data. Finally, estimates are of limited value without knowledge of their uncertainty, which is often a function of the bias and precision of the estimators. Why are those concepts important for estimating the survivorship ϕ?

First, the parameter ϕ is a construct, a parameter describing a population and not any single individual. Adult females will differ in terms of factors like age, body mass, and genotype. What we are trying to estimate is rarely a type of underlying constant like one often estimates in physics, but instead is a quantity affected by the factors that structure our populations, and therefore may be confounded with environmental and genetic factors. For example, clearly a population made of old females will result in a lower ϕ than a population made of prime-aged ones. Another consequence is in terms of robustness: we will often assume that there is no heterogeneity of survivorship (ϕ is the same for all females in a given age class) to build estimators and we need to know the sensitivity to this assumption. Second, because of this underlying heterogeneity, the way we sample the population is important: if we have only senescent females in the sample, because they are easier to capture, our estimate will be biased (low, on average our estimate of ϕ is lower than the value for the population). Ideally, we should aim for sampling methods that allow us to know the probability that each female is sampled, as in a survey, but this is rarely the case, for the simple reason that we don't know to start with which individuals are in the population (i.e., we don't have a census as in human populations). Third, another source of bias is the way we assess the number of females that survived – females that survived may not be captured or resighted and therefore won't be counted in the number of females known to be alive. This can be because they have left the population – emigrated – or because they escaped the capture process or were hidden from view. Fourth, survival probability is a stochastic process (think, e.g., of encountering a predator), and therefore estimates will vary from year to year, even if environmental conditions are unchanging. This source of variability is often of interest as we frequently want to assess how environmental conditions affect survival probabilities, and separate these effects from sampling and purely random components (demographic stochasticity). The former component of the variability is often called the process variance, as opposed to the sampling variance associated with the observation of a finite sample of individuals. To summarize, when estimating a life history parameter, it is important to consider what the parameter measures (cf. age structure and mean survival probability), how field methods determine the composition of the sample, both the initial sample and which individuals are later observed, and how the parameter may vary over time and space. Statistical models aim at making explicit the distinction among these sources of variability in order to get estimates that have small bias and as small uncertainty as possible given the sample size.

Estimating Survivorship

Many approaches to the estimation of survivorship require an initial sample with marked individuals, either upon capture (rings, pit-tags, etc.), because they have natural marks such as spots, bands, or scars (tigers, whales), or because they don't move and can be relocated (e.g., many plants). The main reason for having marked individuals is to obtain robust statistical estimates, whereas other approaches, such as using age structure or age at harvest data, are sensitive to assumptions which are often hard to assess. For example, we could use the ratio of the numbers of individuals aged $(x+1)$ years to those aged x years to estimate survivorship from age x to age $(x+1)$, but this ratio reflects survivorship as well as age-specific capture rates, population structure (size of annual cohorts) and growth rate.

A naïve estimator for a survival probability is the ratio of individuals known to be alive to the initial number of individuals, sometimes called the return rate. Two processes will affect this estimator: recapture, i.e., the proportion of marked individuals present in the population recaptured or resighted (Gimenez *et al.*, 2008; Kéry *et al.*, 2005); and emigration, i.e., the proportion of marked individuals which have left the population. For the latter, one usually refers to apparent survival as being survival minus emigration, i.e., apparent survival is the probability to survive and stay in the population (Schaub and Royle, 2014). Much work has been done on correcting for recapture probabilities which are lower than one, and often vary between capture sessions, age groups, or sex, and this requires that we have more than one recapture session. The principle is that individuals which are not seen at one recapture session but are seen later must have survived but have not been captured. This makes it possible to separate the two processes, survival and recapture (with only one recapture session, we have an estimate of the product – i.e., they have survived and been recaptured – not of each process separately).

The principle behind the estimation of survivorship, and incidentally of recapture rates, is relatively simple to understand. One needs to write every capture history – i.e., that an animal was caught on year 1 and 3, but not in any other years, as a function of survivorship every year ($s1$, $s2$, …) and recapture rates every year ($p2$, $p3$, …). Being caught in year 3 but not year 2 means the animal has survived the first 2 years with probability $s1*s2$, and regarding recapture the probability is $(1-p2)*p3$. Of course, there is software to calculate probabilities of each possible life history automatically. The next step is to have a distribution for the number of animals associated with each capture history, and a multinomial distribution is a natural starting point. Finally, one can constrain the survivorship and recapture parameter to be function of environmental parameters or individual covariates, in a similar manner to a generalized linear model (remember also that probabilities are numbers between 0 and 1 and a link function like the logit limits the range of predicted values to this range).

Next one has to consider (1) if the model adequately fits the data, and (2) how to compare models in terms of their predictive ability or for estimating a given parameter. The first step is essential – using a model with a poor fit, for example, because animals respond to capture and have a lower recapture rate the year after, or because there is a large heterogeneity in recapture rates among individuals, may lead to biased estimates. In practice, the usual approach to assessing goodness-of-fit (comparing observed number of capture histories to expected numbers) will not be efficient because there are many capture histories and expected numbers are low. It is more powerful to restrict the test to specific patterns of lack of fit (such as the trap-dependence mentioned above), so that one can also expand the model to get a better fit (Choquet *et al.*, 2009). The second step, model selection and model averaging, is now done by calculating the relative weight of models, such as could be derived from information criteria (e.g., AIC, BIC, or DIC). Although there is still disagreement on which approach is 'best,' one should be reminded that statistical criteria often aim at a specific objective (e.g., minimizing a measure of the difference between model predictions and the unknown truth) and that biological considerations and design should also be part of the choice of the models retained for final inference. For example, when comparing survivorship in populations differing by selection pressures or management actions (Frederiksen *et al.*, 2014), pressures or actions should be part of all models considered, in order to focus on the main objective of the study – estimating differences among pressures/actions.

As an example, Gamelon *et al.* (2014) estimated survival patterns of senescence in wild boar, a species which is unusual among large mammals because females invest early and heavily in reproduction. Using capture-mark-recapture data, they showed that wild boar males and females had similar senescence rates, and that wild boar females did not have faster senescence than other ungulates of a similar size. However, wild boar females differed from other ungulates because they began to senesce at an earlier age. This work shows how advanced methods allow for a detailed understanding of evolutionary patterns, distinguishing between timing and rate of senescence.

Recapture parameters are often nuisance parameters, i.e., we are not interested in estimating them but they are needed to adequately fit models to the data. It is therefore also important to model their variation adequately (e.g., recapture rates could be a function of age, as well as of time). Although a few years ago it was not practical to consider all possible combinations of models for both survivorship and recapture, this is now easier to do and it seems likely to be a better strategy than modeling recapture rates first and then survivorship.

There are many other methods available for estimating survivorship (David *et al.*, 2010; Skalski *et al.*, 2005; Williams *et al.* 2002) – for example, in studies using biologging, individuals are followed continuously and an approximate date of death is available (or when the equipment was removed/stopped functioning). Methods like survival analysis can then be used. Other approaches have been developed for harvested populations, using in particular the age composition of harvested cohorts, but they often are less robust than approaches using uniquely marked individuals. They, however, are sometimes the only ones available (think of many harvested fishes or large mammals), and it is then important to assess sensitivity to assumptions, for example, regarding age-dependent selective harvesting. Finally, individuals may not be easily identified – think of clonal plants – and spatial location or genetic methods may be necessary to define units for analysis (Lauenroth and Adler, 2008).

Estimating Fertility

Estimation of the number of offspring born per individual is a relatively less unified field than estimation of survivorship. One reason is that there are many stages at which the number of offspring could be measured: for example, one could estimate pregnancy rates by capturing a sample of females (or individuals in the case of hermaphrodites) before birth (or hatching, etc.), count number of eggs or seeds produced by each female, or count the proportion of females with young a few weeks after birth. Such measures might be hard to compare since mortality around birth/hatching is often high, as, for example, in many insect, fish, or plant species producing large numbers of eggs/seeds. At the same time, interfering too much with individuals around birth or hatching may affect the parameters we want to estimate, and without direct observations or measurements made on individuals, we may not be able to identify which offspring belong to which females. In the latter case, we might be able to estimate the average fertility in the population, but not its variability among individuals. This might lead to considerable biases if, for example, the sample of females includes individuals with large variation in age, including females which are too young or too old to reproduce.

Two other issues are observability – the probability that a female will be observed depending on having offspring or not – and state uncertainty – one is not always sure that a female has bred or not, is with or without offspring, or that an offspring belongs to one-specific female. As for survivorship, relying on individually marked individuals is, when possible, the best solution. One can use models similar to those developed for survival to relate capture/sighting rate to female status (breeder/nonbreeder, offspring or not), and use, for example, repeated observations within a short time frame of the same individuals to assess uncertainty in state. Such models with state uncertainty are increasingly used and relevant. Desprez *et al.* (2011) used this approach to disentangle the relationship between reproduction and age versus experience in kittiwakes, a long-lived seabird. As all birds are not observed every year, past breeding status, and therefore experience, is not known accurately and needs to be estimated. Whereas age did not influence adult breeding rates, unexperienced birds had a lower breeding probability than experienced birds.

Finally, access to individually marked individuals makes it possible to estimate transition rates among reproductive states – for example, if females reproducing 1 year also reproduce the year after. Models investigating transitions among, for example, reproductive states (e.g., having 0, 1, and 2 offspring) include a survival component, and represent a fruitful way to combine analyses of survivorship and fertility components.

Conclusions

There is a wide diversity of statistical models now available for analyzing variation in survivorship, and these methods relate such variation to individual characteristics or environmental variables (Gimenez *et al.*, 2012). While the development of these models continues unabated – for example, including information about the spatial localization of each captured individuals (Royle *et al.*, 2015) – it is important to bear in mind aspects such as robustness and sampling design. Estimating individual fertility in the wild is often more complex, because there are many stages at which offspring can be counted and offspring cannot easily be associated with individual females without using specific techniques or intensive observations.

Aging: Why Do We Age?

JA Moorad, University of Edinburgh, Edinburgh, Scotland

What Is Aging?

Adult plants and animals generally appear to function less well as they age. This senescence is manifested most dramatically in traits related to fitness and most profoundly as decreases in survival and reproductive rates (vital rates). Vital rate declines with age, or 'demographic senescence,' is the best documented examples of aging, and these have been shown to be nearly ubiquitous but highly variable among captive and wild populations of plants and animals (Jones *et al.*, 2014; Promislow, 1991; Ricklefs, 1998). Demographic senescence is caused by 'functional senescence,' or the age-related deteriorations in the phenotypes that support survival and reproduction (Burger and Promislow, 2006; Williams, 1999); however, this sort of aging is not always so clearly expressed and easily detectable (Nussey *et al.*, 2009; Rueppell *et al.*, 2007).

Why aging happens is of immense interest to biologists, who have proposed hundreds of proximate mechanisms to explain how intrinsic or extrinsic changes cause physiological deterioration within individuals (Medvedev, 1990). Like any biological feature, aging can be shaped by evolution. In particular, evolutionary biologists wish to understand how natural selection, a force usually associated with the improved fit of organisms to their environment, can be reconciled with the senescent decline of adaptive function. To this end, evolutionary theory has been developed to guide our study into the origins of the diversity of senescent patterns across individuals, populations, and species. In practice, this requires synthesizing what we can learn about the causal relationships between genes, age-specific phenotypes, and fitness. This article provides an introduction and overview of this theory.

The Origins of the Theory

Several verbal arguments have been proposed to explain the evolutionary cause for aging; these are discussed in this section.

Adaptive Aging

In what might be the earliest evolutionary model of aging, August Weismann proposed that selection will favor aging because the culling of the old directly benefits the young, and this is good for the population as a whole (Weissman, 1889). He argued that death-causing mechanisms should evolve to favor aging, such as deciduous trees have evolved to cast off old leaves in the autumn rather than waste resources to enable them to survive through the winter. However, adaptive aging has been largely rejected by most evolutionary biologists for at least three reasons. First, the model assumes that the old are somehow less important to the population than are the young; this would seem to presuppose the existence of aging. As a result, this model is incapable of explaining an evolutionary 'origin' of aging. A second problem is that an elaborate adaptive mechanism ought to be readily disrupted by environmental or genetic challenges, but no mutation or environmental stressor has been shown to remove aging from a normally senescing organism. Finally, some object to the adaptive aging model because it depends upon some degree of group selection, a perspective of natural selection that has changed dramatically over recent decades and has bred much confusion. While it is not appropriate to reject the model out-of-hand for this reason, a group selection explanation does suggest certain limitations to the strength of such selection, such as the reliance of (perhaps unrealistically) high degrees of relatedness between members of the population. Nevertheless, modern and conceptually formalized versions of group selection (kin selection and multilevel selection) can allow for situations where selection can modify the evolution of aging by further relaxing or enhancing selection for late-age survival or reproduction (Bourke, 2007; Ronce and Promislow, 2010). However, these modifying effects should not be interpreted as strong support for the evolution of aging-adaptations per se.

Mutation Accumulation

In the early 1940s, J.B.S Haldane used evolutionary theory, specifically the antagonistic forces of natural selection and recurring mutation, to explain the persistence of the lethal Huntington disease (HD) in the human population of England (Haldane, 1941). Haldane recognized that the HD allele was largely protected from removal by purifying selection because the disease did not manifest until individuals were in their 40s, a point in most people's lives at which any children they might have were already born. Thus, the genes of individuals that made up the next generation had little do with whether their parents eventually succumbed to the lethal effects of HD. Peter Medawar (1952) extended Haldane's explanation of HD to a more general evolutionary perspective of aging by recognizing that the later the deleterious effect of any gene, the weaker the strength of selection to remove the allele from the population becomes. This age-related attenuation of selection articulated by Medawar forms the conceptual foundation for the evolutionary theory of aging.

In keeping with classical population genetic thinking, Medawar imagined that our genomes were showered with new deleterious mutations every generation. However, he believed that many genes had ages-of-effect that did not necessarily persist over the entire life of the individuals. For example, genes that are deleterious to childhood survival may be irrelevant to adult function. Alternatively, there may be genes (such as HD) that do not affect early function but negatively affect individuals late in life. The latter type of mutation will tend to accumulate to a greater extent than the former over many generations, and aging will result. Medawar's idea represents the first 'mutation accumulation' (or 'MA') model. Unlike Weismann's model, MA models view aging as a

maladaptation: aging, on balance, costs fitness, but natural selection is not sufficiently strong to remove it completely. It is important to note that MA assumes that there is some age-specificity of genetic effects upon survival or reproduction. It does not make any assumptions about the timing of gene expression. A developmental gene that contributes to a phenotype that wears out in late age could be correctly be considered an MA gene because the fitness effect is manifested late in life.

Antagonistic Pleiotropy

George C. Williams embraced Medawar's argument for relaxed selection with increased age while proposing another genetic model to facilitate the evolution of aging (Williams, 1957). Rather than imagining that genes have single, and relatively narrow, age-windows of effect, Williams suggested that some genes might be so pleiotropic with respect to age that they influence fitness in both the young and in the old. If some of these genes had fitness effects that were positive early in life and deleterious late in life, then natural selection would tend to favor their spread through the population. Eventually, evolution by natural selection would increase survival or reproduction in the young at the expense of these traits in the old. Williams' model, commonly called the 'antagonistic pleiotropy' model (or simply 'AP'), does not contribute to an adaptive theory of aging, as aging per se is not advantageous with respect to fitness. Instead, it may be more appropriate to view AP as a model for the evolution of aging by constraint because genetic trade-offs force senescent declines with age. 'Disposable soma theory' merits attention as a popular and biologically motivated AP model that identifies the allocation of limited resources to both self-maintenance and reproduction as the fundamental trade-off relevant to the evolution of aging (Kirkwood, 1977, 2002).

The Mutation Accumulation and Antagonistic Pleiotropy Dichotomy

MA and AP are usually considered the only viable evolutionary explanations for the origins and maintenance of aging, and a tremendous amount of work has sought to determine the contribution of each. A fuller discussion of this work is delayed until the end of this article, but it is worth noting here that the evolutionary mechanism of aging may not be reliably dichotomized because it is possible to imagine genes that demonstrate qualities of both MA and AP. For example, consider an allele with a small positive effect upon early reproduction and a large deleterious effect upon midlife survival. One might correctly call this an AP allele because it demonstrates an early/late fitness trade-off. Alternatively, one could reasonably categorize this as an MA gene if the fitness effects of its early-age advantage are overwhelmed by the fitness lost by its suppression of late-life survival, and the allele persists in the population due to recurrent mutation. For this reason, empirical investigations into the genetic foundations for aging often include the caveat that MA and AP are not mutually exclusive mechanisms.

W.D. Hamilton: Foundations for a Formal Theory

In the mid-1960s, the evolutionary theory of aging was a collection of verbal arguments and models, with little in the way of conceptual rigor. MA and AP offered two genetic models to explain how an age-related relaxation of selection can cause aging to evolve, but exact descriptions of this change in selection were lacking. This changed with William Hamilton's contribution in 1966, where he made explicit the mathematical relationships between fitness and vital rates (Hamilton, 1966). In doing so, he defined exactly how aging changes the strength of selection acting to decrease age-specific survival and increase fertility (**Figure 1**). Quantitatively, he showed how selection against mortality at some particular age x is proportional to the product of: (1) the frequency of cumulative survival, or the fraction of individuals that survive from birth to x and (2) the expectation of future reproduction given survival to that age discounted by future population growth (i.e., early reproduction counts for more when populations are growing, but less when they shrink). Selection for age-specific fertility is cumulative survival, which is also discounted by future population growth. Importantly, the necessary parameters in Hamilton's model are age-specific survival and fertility, which are readily estimable from laboratory and natural populations (at least in principle). These quantitative descriptions of selection are collectively known as Hamilton's 'sensitivities,' as they express the sensitivity of population growth to changes in vital rates (Charlesworth, 1994), where population growth rate is taken as a valid definition of fitness when the age-structure of a population is stable over time. Hamilton derived his sensitivities by implicit differentiation; since then they have been re-derived using population projection matrices (Caswell, 1978, 2001) and multiple linear regression (Moorad, 2014). These approaches allow Hamilton's basic principle to be applied to more complex problems in ecological modeling and quantitative genetics, respectively.

Significantly, Hamilton's sensitivities show that selection against mortality and for reproduction cannot increase with age. Specifically, they prove the following:

1. Selection against age-specific mortality is at its maximum at birth, stays constant until the earliest age of reproduction, and then decreases.
2. The strength of mortality selection declines until the last age of reproduction, after which it ceases altogether.
3. Selection for age-specific fertility is maximized at birth (regardless of whether reproduction is biologically possible) and relaxes with increased age.

There are two ways to interpret these findings. The most general takes Hamilton's model to be a logically incontrovertible description of phenotypic selection acting on vital rates. Consequentially, all valid evolutionary models of aging must incorporate Hamilton's sensitivities as a definition of phenotypic selection for vital rates. Of course, phenotypic selection is not evolution; a heritable basis for traits is required for selection to have any evolutionary change of trait value (Fisher, 1930). Consequently, this interpretation views Hamilton's model as a necessary, but incomplete, component of an evolutionary theory of aging. A full theory requires a

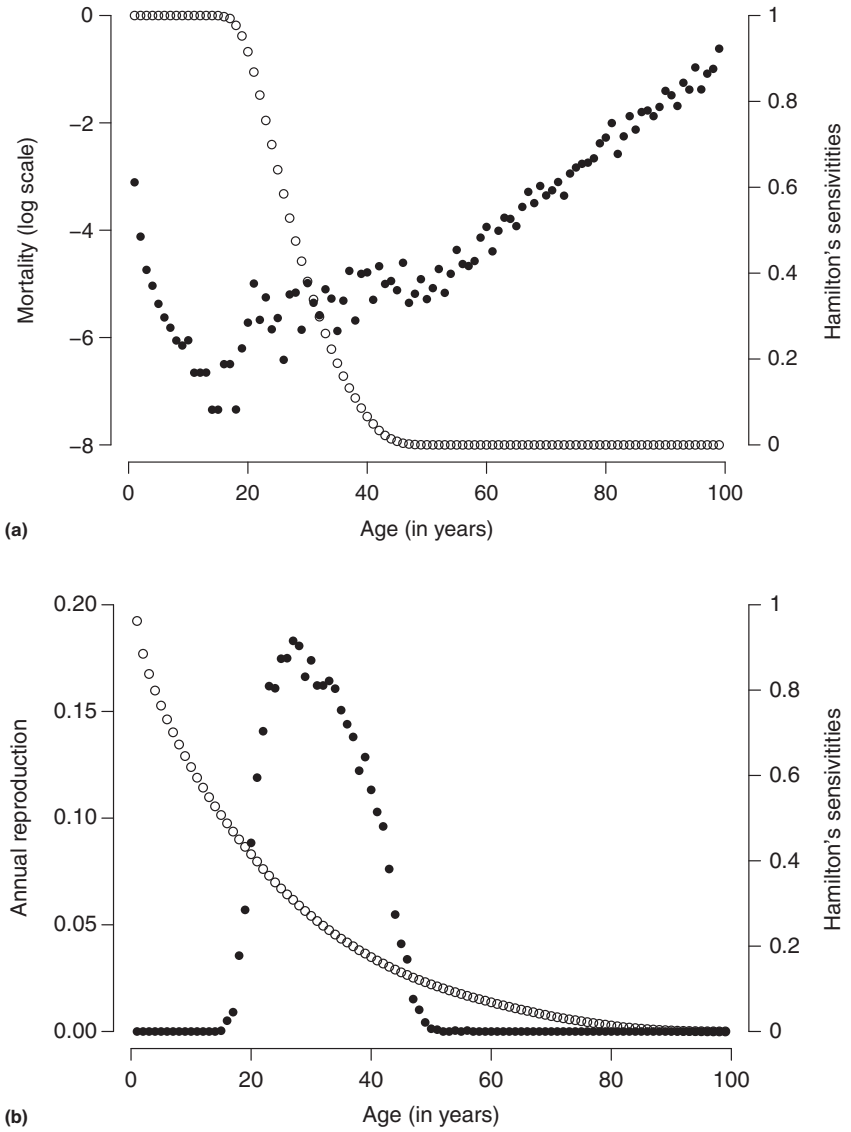

Figure 1 Selection for vital rates in a human population. (a) Age-specific mortality (solid circles) and selection against this mortality (open circles) is illustrated using data from approximately 1600 females born in Utah in 1860. Mortality is log-transformed, and selection against mortality is given by Hamilton's sensitivities calibrated to the generational scale. Note two qualitative departures from the predicted evolutionary endpoints. The first is the elevated juvenile mortality, and the second is continued survival of many females beyond the age of complete cessation of selection. (b) Age-specific fertility (closed circles) and selection for fertility (open circles), also following Hamilton's sensitivities calibrated to the generational scale. Results for both graphs are taken from Moorad, J.A., 2013. A demographic transition altered the strength of selection for fitness and age-specific survival and fertility in a 19th century American population. Evolution 67, 1622–1634.

model of how genes affect vital rates, such as illustrated by MA or AP models.

The second way to interpret Hamilton's sensitivities is to take them to imply directly patterns of aging using a MA model, as Hamilton (1966) himself did. For reasons of simplicity, Hamilton assumed that new mutations had strictly age-specific and additive effects upon mortality (Hamilton, 1966) (i.e., he assumed a linear relationship between mortality and the number of mutations). This simple model permitted him to project his conclusions relating the strength of selection directly to evolutionary endpoints. Hamilton predicted that mortality should be lowest in pre-reproductive years and increase from the age of reproductive onset to the age of reproduction cessation. Beyond this age, the model predicts that nothing can prevent the build-up of deleterious late-age mutation, and mortality will evolve to infinity (a 'wall-of-death'). These qualitative predictions persist over a broad range of more sophisticated population genetic models of vital rates that assume realistic genetic parameters, such as dominance relationships, but still retain Hamilton's assumption of how mutations determine mortality. Significantly, these models can predict the frequently observed log-linear increase in mortality rates in real populations (Charlesworth, 2001). Note that these and many other predictive quantitative evolutionary models of aging often assume many genes of small effect. This practice is adopted in most genetic models of

evolutionary processes to help make them tractable. Applied to aging, this assumption is occasionally confused with a prediction, and the recovery of some longevity genes of large effect has been heralded by some as a challenge to evolutionary theory. However, the fundamental theory is capable of including genes of large effect.

Modifying Hamilton's Model

Clearly, Hamilton's predictions regarding evolutionary endpoints are not always met in real populations. Given the rudimentary nature of his genetic model, which is justified by simplicity rather than any empirical or theoretical insight, this is not too surprising. As a result, his basic model has been refined in various ways to account for departures from theoretical predictions. Observed departures from basic predictions can be grouped into at least three categories. For each, a few examples of appropriate model modifications have been included. By no means is this to be considered an exhaustive catalog of aging models.

Post-Reproductive Survival

Female humans are known to menopause at around 50 years of age. Because reproductive potential ceases at this point, Hamilton's sensitivities indicate that there should be no selection for survival beyond this age. Obviously many women live long beyond this point in clear violation of Hamilton's prediction of a post-reproductive 'wall-of-death.' At least three different evolutionary mechanisms have been proposed to account for post-reproductive survival in human females. First, it has been suggested that late-life survival benefits the females' children (Rogers, 1993) and grandchildren (Lee, 2003). Given that these younger relatives share genes for late-life survival with their older female relatives (one-half of the genes are shared between mothers and offspring and one-quarter between grandmothers and grand-offspring), positive associations are generated between fitness and genes for long-life in younger individuals. These associations are expected to increase the frequency of post-reproductive survival genes over time. A second model recognizes that human males do not menopause, meaning that there is, at least in principle, no age at which selection against male mortality ever disappears completely (Tuljapurkar *et al.*, 2007). If genes that favor late-life male survival also happen to favor female survival, then selection for late-life survival will act indirectly to promote post-reproductive survival in females. However, it is worth noting that this model may be applicable only to humans as men may get more reproduction at later age due to accumulated wealth or social status that may be attractive to some women. Lastly, correlated selection could also encourage the spread of post-reproductive survival genes if positive associations exist between early- and late-age mortality genes (Charlesworth, 2001).

Mortality Deceleration and Plateaus

Hamilton's simple model predicts that mortality should increase ever higher with increased age, but we occasionally observe that mortality rates decelerate late in life; these may even decline sufficiently to create mortality 'plateaus' where mortality risk may actually decline in the very old. Several models attempt to explain these phenomena. The first imagines that all individuals have some amount of 'frailty' which exposes them to some degree of age-independent mortality risk. Cohorts of similarly aged individuals can exhibit 'heterogeneity,' or among-individual variation in frailty. Importantly, correlations between frailty and mortality will cause the cohort's composition to change as it ages, favoring a decrease in mean frailty over time. Even if all individuals' risk of mortality increases linearly (or log-linearly) with age, the biased extinction of high-frailty individuals will cause the population's mean mortality risk to be deflected downwards (Vaupel *et al.*, 1998; Vaupel and Yashin, 1985). Frailty need not imply a genetic basis, but if it does, then variation among individuals for genes with deleterious survival effects at many ages can cause mortality deceleration to evolve (Charlesworth, 2001). Other genetic models can predict mortality decelerations by relaxing Hamilton's assumption that genetic factors act additively on the mortality scale (Baudisch, 2005; Moorad and Promislow, 2011). Still other models point out that if fewer mutations increase mortality late in life compared to early in life, or if late acting mutations have a smaller effect upon mortality, then mortality decelerations can evolve (Moorad and Promislow, 2008). There is some evidence to suggest that these sorts of mutational biases may exist in fruit flies (Pletcher *et al.*, 1998).

Elevated Pre-Reproductive Mortality

Mortality at birth and in early development is often quite high before dropping to a minimum in early adulthood. Hamilton's model, on the other hand, predicts low and constant mortality until the first age of reproduction. As this discrepancy between theory and observations is strikingly general, several explanations have been proposed (Levitis, 2011). Hamilton himself recognized this disagreement between his model and reality and suggested that family-level or kin selection for early or accelerated death in frail individuals could benefit the immediate relatives of the individual (Hamilton, 1966). In this way, he argued, early-death genes would have a fitness advantage over genes that would allow the doomed individual to linger and consume resources that would be put to better use (from the perspective of the genes) if they were consumed by more capable relatives. This idea has been modeled more formally and under a wider range of relationships by Lee (2003), who predicted the widespread evolution of elevated juvenile mortality. Heterogeneity, the demographic phenomenon that might contribute to mortality deceleration, may also cause this pattern if very early mortality removes the most frail individuals from the population before they can be exposed to mortality hazards later in childhood (Vaupel and Yashin, 1985). Another model points out that because the very young are often dependent upon care provided by parents, there are more genetic targets relating to early-age mortality than to mortality later in life to be disrupted by mutation (Moorad and Promislow, 2008). Finally, if the ecological context of the population places the very youngest at a relatively greater risk of mortality, such as by

disease, competition for space or resources, or predation, then high-juvenile mortality may reflect the high frailty of the youngest members of the population, and the phenomenon may simply have no evolutionary explanation.

Tests of the Theory

Extrinsic Mortality

The evolutionary theory of aging couples an age-related decline in selection to various genetic models to predict decreases in mean vital rates with age, and both aspects of the theory are subjected to experimental and descriptive testing. Some researchers have investigated how different degrees and types of environmental risks affect the selection pressures that shape aging rates. However, much of this work is undermined by a misunderstanding in the evolutionary theory that emerged in the early years of its development. Williams (1957) suggested that the strength of selection for survival at some age is proportional to the probability of survival to that age, leading him to predict that selection for late-life survival should be reduced in situations where age-independent (or 'extrinsic') mortality was highest. This prediction is often characterized as a powerful predictive tool for understanding the diversity of aging patterns that have evolved in nature. Williams's intuitive logic proved false, however, as Hamilton's results point out a more complex relationship between cumulative survival and survival selection; we now know that the sort of mortality risk envisioned by Williams should have no effect on selection (Caswell, 2007). In fact, Hamilton's sensitivities show age-related declines in the strength of selection even in immortal populations. Interestingly, some comparative studies appear to support Williams's prediction; these are typically presented as support for the evolutionary theory of aging (e.g., Austad and Fischer, 1991; Shattuck and Williams, 2010). However, predictions made using Hamilton's formal theory recognizes that there are situations where decreased extrinsic mortality can increase or decrease selection for long-life. Indeed, results from natural and laboratory populations can also be interpreted to refute Williams's prediction (e.g., Chen and Maklakov, 2012; Reznick *et al.*, 2004). Neither the theory nor the empirical evidence supports the use of Williams' extrinsic mortality hypothesis for a general test of an evolutionary basis for aging, but there is value in understanding how extrinsic mortality risk affects age classes differently because this kind of mortality has the potential to shape evolution.

Segregating Genetic Variation

Evolution by natural selection requires and consumes additive genetic (heritable) variation. As selection is strongest for traits that determine early survival and reproduction, a straightforward prediction from simple evolutionary models of aging is that there should be less additive genetic variation for early-effect traits compared to traits with late effects (Charlesworth and Hughes, 1996). This prediction is occasionally, but not universally, supported in actual populations. Indeed, even for the same trait within the same species, age-specific mortality in *Drosophila melanogaster*, additive genetic variation has been observed both to increase (Hughes and Charlesworth, 1994) and decrease (Promislow *et al.*, 1996) with age. However, because aging models that include a genetic contribution to heterogeneity can predict nonincreasing additive genetic variance over some ages (Charlesworth, 2001), decreasing additive genetic variance with age does not necessarily provide evidence against the evolution of aging.

Because some MA and AP models make somewhat different assumptions about how genes involved with aging work, age-related changes in nonadditive sources of genetic variation and its derivatives, such as dominance variance, variation among inbred-lines, inbreeding depression, and heterosis, have been suggested as diagnostic of the preeminence of one evolutionary mechanism or the other (Charlesworth and Hughes, 1996; Hughes and Charlesworth, 1994). This suggestion has generated much interest in measuring genetic variation of aging-related traits in laboratory (e.g., Snoke and Promislow, 2003; Tatar *et al.*, 1996) and natural populations (e.g., Charmantier *et al.*, 2006; Nussey *et al.*, 2008). However, it has since been argued that because other AP models can generate the same nonadditive genetic variance predictions as MA models, the diagnostic value of the tests are suspected (Moorad and Promislow, 2009).

Segregating Genetic Covariances

As the AP model is predicated upon genes with early beneficial and late deleterious effects, it is expected that genetic variation at these loci will contribute to negative additive genetic correlations across age-specific traits (such as early reproduction and late survival). These negative correlations can be resolved by artificial selection experiments that find antagonistic responses to selection (e.g., Zwaan *et al.*, 1995) or by direct, quantitative genetic estimates of negative genetic correlations (e.g., Rose and Charlesworth, 1981). These results do seem to offer strong evidence for AP genes, with the caveat that they do not argue against a role for MA (recall that a gene can contribute to aging by being AP and MA). Also, tests for negative genetic correlations might be fairly viewed as conservative, because genes with nonnegative correlated effects (such as some MA and frailty genes) can overwhelm the AP signal by contributing positively to the across age genetic correlations.

De novo Mutational Correlations

Because new mutations are the ultimate source of genetic variation, and genetic variation permits and shapes evolutionary endpoints, it has been suggested that investigating the genetic variation and covariation caused by *de novo* mutation upon vital rates can help us better understand the constraints placed upon the evolution of aging. These studies, so far performed exclusively on *Drosophila* and *Caenorhabditis elegans*, attempt to reduce or remove the editing effects of natural selection through careful breeding designs or the use of balancer chromosomes (e.g., Estes *et al.*, 2005; Gong *et al.*, 2006; Pletcher *et al.*, 1998), with the goal of allowing new mutations to accumulate. These mutation accumulation studies (not to be confused with the MA model of aging) interpret the difference in genetic variances and covariances between

mutation accumulation and control lines as reflecting the contributions of new mutations. These studies show no support for AP-type aging genes and ample support for MA genes. Some aging theory does predict that new AP-type mutations should emerge extremely rarely, perhaps too infrequently to be detected experimentally, but they may still influence the evolution of aging when they do arise (Moorad and Hall, 2009).

Conclusions

The evolutionary theory of aging integrates models of selection and inheritance to explain the diversity of life span and aging patterns across metazoan life. Early aging models identified the age-related attenuation of selection as the evolutionary impetus behind aging, and they provided feasible genetic models for how these age-related differences in selection generate within individual phenotype change. Hamilton's sensitivities formally define the strength of selection acting to increase survival and fertility at different ages, and these provide readily testable first predictions of how aging should evolve. Ecological, social, and genetic additions to the theory provide finer-scaled predictions and a more detailed understanding of how species differ in how they age.

Amniotes, Diversification of

H-D Sues, National Museum of Natural History, Smithsonian Institution, Washington, DC, USA

Glossary

Amniota A major clade of tetrapods, comprising reptiles, birds, mammals, and related forms. All amniotes have eggs that are characterized by the presence of an amnion, a membrane that encloses the embryo in a fluid-filled chamber.

Clade A group of organisms that comprises the last common ancestor of these organisms and all extant and extinct descendants of that ancestor is called clade.

Cranium The part of the skull that houses the brain and the organs of sense is called cranium.

Diapsida A clade of amniotes characterized by the presence of two openings behind the eye socket on either side of the cranium. Some diapsids no longer retain one or even both of these openings. Present-day diapsids comprise turtles (which have secondarily lost the openings), lizards, snakes, the tuatara, crocodylians, and birds.

Synapsida A clade of amniotes comprising mammals and their extinct close relatives (often misleadingly referred to as 'mammal-like reptiles'). Synapsids are characterized by the presence of a single opening behind the eye socket on either side of the cranium.

Taxon A group of one or more organisms deemed to be a unit within a hierarchical biological classification is called taxon.

Introduction

Reptiles, birds, and mammals and their closest relatives are grouped together as Amniota based on the shared possession of the amniotic (cleidoic) egg (Figure 1). This type of egg is laid on land and differs from that of amphibians in the presence of an outer shell and a set of extraembryonic membranes surrounding the embryo (Packard and Seymour, 1997; Stewart, 1997). The shell is either parchment-like or calcified and protects the egg's contents against desiccation and damage. (With the exception of the platypus and the echidnas, present-day mammals do not lay eggs.) The eggshell is semipermeable, permitting intake of oxygen for respiration and disposal of carbon dioxide. Four membranes surround the embryo. The first is the allantois, which forms a sac attached to the embryo and serves for storage of waste and for respiration. The second is the amnion, which encloses a fluid-filled chamber surrounding and protecting the embryo. The third is the chorion, which envelops the embryo and attached structures and is in close contact with the allantois and with the inside of the shell, facilitating respiration. The fourth is the membrane forming the yolk sac, which provides the developing embryo with nourishment. By contrast, present-day amphibians (and presumably their extinct precursors) typically deposit their eggs in water (Packard and Seymour, 1997). The egg is coated in a jelly-like substance, and the developing embryo receives oxygen and much of its nourishment from the surrounding water. A gilled larva hatches from the egg and continues its development in water. Finally, it undergoes a process of metamorphosis before emerging as an adult capable of life on land. The evolution of the cleidoic egg allowed amniotes to move into drier environments because they were no longer tied to permanent bodies of water for reproduction. No undisputed fossil eggs of amniotes are known from the Paleozoic to date but the fact that present-day reptiles, birds, and mammals all share the amniotic egg suggests that it had already evolved before the reptile-bird and mammal lineages diverged in the Carboniferous. In marsupials and placentals, the eggs develop in the uterus and thus lack a shell; however, the embryo is still surrounded by an amnion (Stewart, 1997).

Amniotic eggs acquire their shell in the oviduct of the female and thus must be fertilized before their encasement. Thus most male amniotes have special organs to deposit sperm inside the female reproductive tract.

Another major difference between amniotes and amphibians is the structure of the skin (Frolich, 1997). The skin of present-day amphibians is relatively thin, weakly keratinized, and rich in glands. By contrast, the skin of reptiles and birds is much less glandular and protected by keratin in the form of scales (Figure 2) or feathers. These features help to reduce water loss through the skin. Although richer in glands than that of reptiles, mammalian skin also contains keratin as well as lipids and is usually covered by hair.

In addition to filling and emptying their relatively small lungs through raising and lowering the floor of their mouth (buccal pumping), present-day amphibians rely extensively on

 doi:10.1016/B978-0-12-800049-6.00279-1

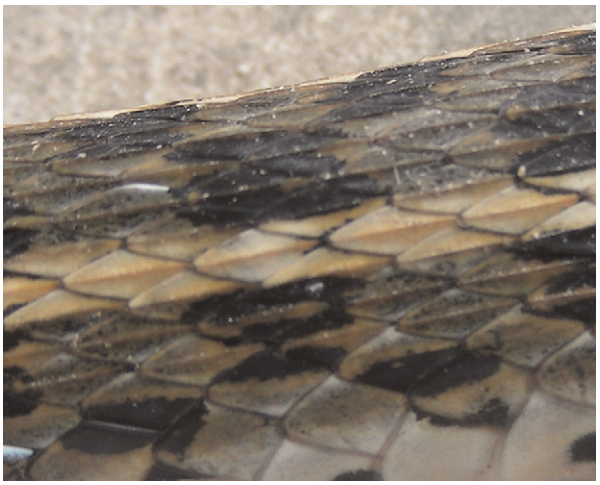

Figure 2 Keeled scales of the buff-striped keelback snake (*Amphiesma stolatum*). The scales protect the skin of reptiles against mechanical damage and help reduce water loss through the skin. Reproduced from AshLin/Wikipedia.

their skin for the intake of oxygen and excretion of carbon dioxide (Frolich, 1997). By contrast, amniotes largely abandoned cutaneous respiration. They fill and empty their larger, more complex lungs primarily by moving their ribs to alter the pressure within the thoracic cavity (Brainerd and Owerkowicz, 2006).

Present-day amniotes comprise six monophyletic groups or clades: mammals (Mammalia), turtles (Testudines), the tuatara (Rhynchocephalia), lizards and snakes (Squamata), crocodylians (Crocodylia), and birds (Aves) (Gauthier *et al.*, 1988). Mammals are characterized by the presence of hair, mammary glands, and many skeletal features. Turtles are distinguished by the possession of a bony shell, which is usually covered by scutes of keratin. Squamates are characterized by the presence of a mobile quadrate bone (along with loss of the lower temporal bar), paired hemipenes, and skin that is composed of superimposed layers of two types of keratin and is shed completely at regular intervals (Vitt and Caldwell, 2013). The tuatara is closely related to squamates but lacks the mobile quadrate bone and elaborate hemipenes. Crocodylians have air spaces in the skull bones surrounding the middle ear, elongate wrist bones, a modified pelvic girdle, and distinctive ankle structure (Nesbitt, 2011). Birds are especially characterized by the presence of wings and other features associated with powered flight, and a greatly reduced tail (Chiappe, 2007). The tuatara and squamates are classified together as Lepidosauria and crocodylians, and birds as Archosauria.

Traditional scenarios of vertebrate evolution held that reptiles separately gave rise to birds and to mammals (Romer, 1956). In recent decades, however, it has been established that the lineage leading to reptiles and their descendants, birds, and the lineage leading to mammals were already distinct by the time both first appear together in the fossil record some 310 million years ago (Gauthier *et al.*, 1988; Clack, 2012).

Amniotes have a vast fossil record worldwide, dating back more than 300 million years. There are over 20 000 known species of present-day reptiles and birds and some 5500 species of extant mammals. Although the Cenozoic is commonly known as the 'Age of Mammals' the combined number of species of reptiles and birds is now almost four times higher than that of mammals.

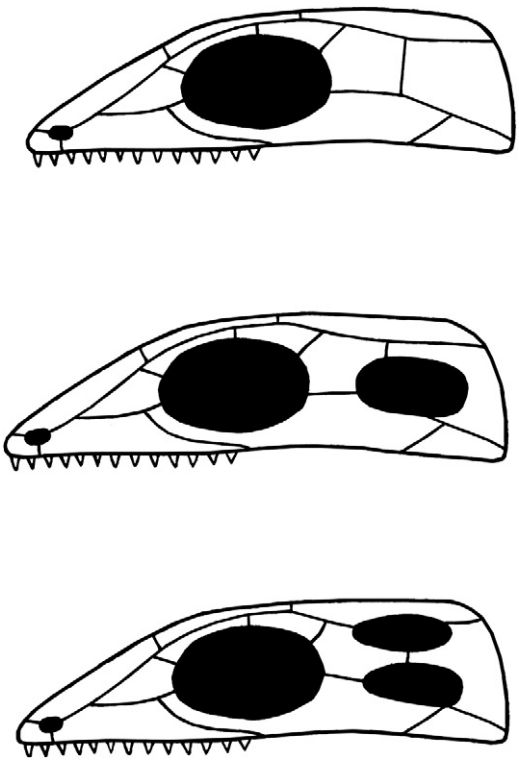

Figure 3 Diagrams of crania of amniote vertebrates. Top: anapsid condition (without temporal openings); center: synapsid condition (with one temporal opening); bottom: diapsid condition (with two temporal openings). Reproduced from H.-D. Sues/Public Domain.

Synapsida

The lineage leading to mammals is characterized by the presence of a single large opening behind the eye socket (orbit) on either side of the cranium (Kemp, 2005). This is known as the synapsid condition (**Figure 3, center**). The opening, called the temporal opening, lightens the skull, and its margins serve for attachment of jaw-closing muscles. Based primarily on this feature, mammals and their precursors are grouped together as Synapsida. Non-mammalian synapsids have traditionally been referred to as 'mammal-like reptiles' but this term has become scientifically meaningless. The earliest synapsids, often referred to as 'pelycosaurs,' are known from the Late Carboniferous and Permian (Kemp, 2005). They included forms with a range of shapes and sizes but superficially lizard-like in appearance. Some were among the first large herbivores whereas others, such as the 'fin-backed' *Dimetrodon* (**Figure 4**), were the first apex predators on land. They retained a sprawling gait, as in other early tetrapods. More derived synapsids, known as Therapsida, comprise a range of increasingly more mammal-like forms that came to dominate global land ecosystems during the latter half of the Permian and much of the Triassic

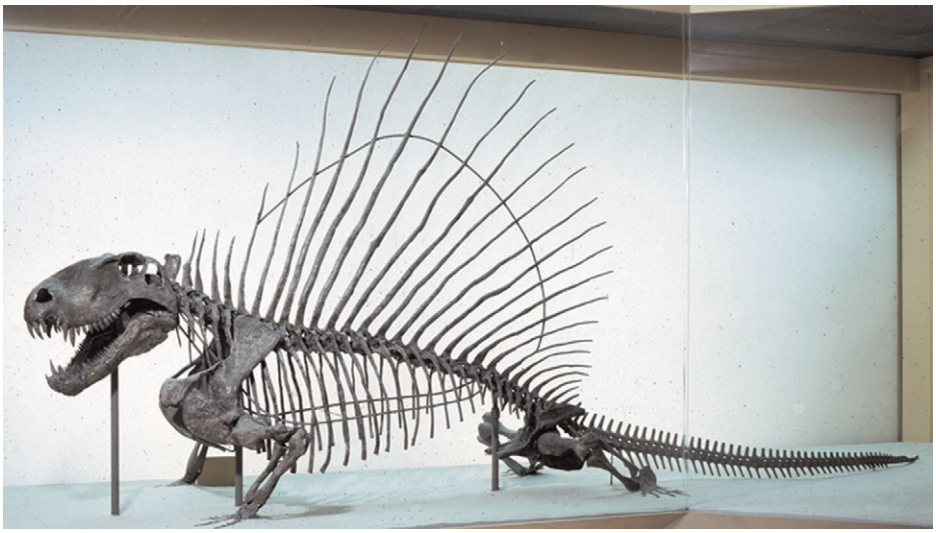

Figure 4 Skeleton of *Dimetrodon grandis*, an Early Permian synapsid. Superficially resembling certain reptiles, *Dimetrodon* is actually closely related to mammals. Reproduced from National Museum of Natural History/Public Domain.

(Kemp, 2005). Therapsids have a much larger temporal opening than 'pelycosaurs.' They also have a relatively larger upper canine, a groove for the ear canal on the squamosal bone, and the angular bone bears a distinct process, which supported the precursor of the eardrum in mammals. The girdle bones of therapsids are less massive and their limb bones are more slender than those of early synapsids, suggesting greater freedom of limb movement and greater ability to lift the body further off the ground. One therapsid group, Cynodontia, includes the immediate antecedents of mammals (Kemp, 2005). Cynodonts have dentitions differentiated into incisors, canines, and postcanine (cheek) teeth, a typically closed secondary bony palate, and a lower jaw in which the tooth-bearing dentary is the principal element whereas the bones behind the dentary became much smaller. The bones behind the dentary subsequently became detached from the lower jaw, attached to the cranium, and formed a chain of three small bones (incus, malleus, and stapes) in the middle ear of mammals. Based on the structure of the dentary bone, the jaw-closing muscles in early cynodonts had already attained a mammal-like differentiation with a superficial masseter and deeper masseter and temporalis muscles. The crowns of cynodont cheek teeth have large cusps and shelves composed of small cusps (cingula), indicating various degrees of oral food processing. The trunk region comprises a thorax with long, mobile ribs at the front and a lumbar region with short ribs further back. The femur (thigh bone) was held closer to the body unlike in 'pelycosaurs,' in which it extended nearly horizontally from the body. Presumably maintenance of a constant high body temperature and higher basic metabolic rates evolved among cynodonts, if not earlier. Development of these physiological attributes was likely accompanied by the development of hair for insulation.

Mammaliaformes, defined as the group comprising Mammalia and their closest extinct relatives, dates back to the Late Triassic (Kemp, 2005). Mammalia, defined as the most recent common ancestor of monotremes, metatherians (marsupials and their closest relatives), and eutherians (placentals and their closest relatives) and all descendants of that ancestor, first appears in the Middle Jurassic. Mammaliaformes is characterized by the possession of a well-developed joint formed by the dentary bone of the lower jaw and the squamosal (temporal) bone of the cranium. (By contrast, the articular bone of the lower jaw and the quadrate bone of the cranium form the jaw joint in other amniotes.) The roots of the cheek teeth are divided, and, in most forms, the upper and lower teeth met in a precise manner (occlusion) to facilitate the chewing of food. Additional characteristic features are present in the structure of the ear region and the braincase, the latter related to a major increase in brain size. Exquisitely preserved fossils from the Early Cretaceous of northeastern China have established that metatherian and eutherian mammals were already distinct groups more than 120 million years ago (Luo *et al.*, 2011). However, the diversification of evolutionary lineages represented by present-day mammals largely postdated the extinction of dinosaurs other than birds some 66 million years ago (Rose, 2006). Today, placentals are the most widely distributed and diverse group of mammals worldwide whereas marsupials are restricted to the Americas and to Australia.

Reptilia

Among reptiles, there are two principal types of skull structure (Rieppel, 1993). In the first type, there are no temporal openings behind the orbit on either side of the cranium (**Figure 3**, top). This is the anapsid condition, which is found only in turtles among present-day amniotes. In the second type, two large openings perforate the side of the cranium behind the orbit (**Figure 3**, bottom). This is the diapsid condition, which is present (often in highly modified form) in most extant and extinct reptiles as well as in birds.

The oldest known reptiles, of Late Carboniferous age, were small and lightly built (Clack, 2012). One group lacks temporal openings but has other skeletal features, such as long

Figure 5 Florida gopher tortoise (*Gopherus polyphemus*). Reproduced from Tomfriedel/Wikipedia.

and slender limbs with slender hands and feet that ally it to diapsid reptiles.

Parareptilia represents an entirely extinct group of early reptiles that were once considered closely related to turtles (Tsuji and Müller, 2009). They ranged in time from the end of the Carboniferous to the end of the Triassic. Some parareptiles have openings behind the eye socket in the cranium but others lack such features. Most have an embayment formed by the squamosal and quadratojugal at the back of the cranium, which probably supported an eardrum. Together with the slender stapes (which conducts sound vibrations from the eardrum to the inner ear), the eardrum formed an impedance-matching ear. This hearing mechanism evolved quite independently from those in other reptiles and in mammals.

All other reptilian groups are united as Eureptilia. Turtles are easily distinguished from other reptiles by their bony shell (**Figure 5**). The shell comprises a dorsal carapace and a ventral plastron, which are linked by a bony 'bridge' on either side (Romer, 1956). Parts of the shoulder girdle and the ribs are integrated into the bony shell. The head, neck, and limbs can be withdrawn into the shell in most present-day turtles. Turtles lack true temporal openings although the back of the cranium is distinctly emarginated in many species (Rieppel, 1993). Thus, most paleontologists assumed that turtles evolved from the earliest known reptiles (Romer, 1956). However, recent discoveries have established that turtles evolved from early diapsid reptiles and some stem-turtles retained two temporal openings on either side of the cranium (Schoch and Sues, 2015).

Aside from turtles, diapsid reptiles comprise archosaurs, lepidosaurs, and their closest extinct relatives. In addition to the two temporal openings, diapsids also share the presence of a large opening in the bony palate, the suborbital fenestra (Rieppel, 1993). Archosaurs and lepidosaurs (which are united as Sauria; Gauthier *et al.*, 1988) share a number of features related to the development of an impedance-matching hearing system with an eardrum (tympanic membrane): the quadrate bone is bowed, the retroarticular process of the lower jaw is long, and the stapes is slender (Rieppel, 1993). These features are still lacking in the oldest known diapsid reptiles. Diapsids also have a more or less L-shaped ('hooked') fifth metatarsal bone, which supports the fifth toe and is thought to assist in extending the foot. The early evolutionary history of diapsid reptiles is still poorly known due to the scarcity of well-preserved fossils from the late Paleozoic. However, from the early Mesozoic onward, diapsids have a rich and varied fossil record (Benton, 2014).

Present-day lepidosaurs include lizards, snakes, and the tuatara (Vitt and Caldwell, 2013). The known fossil record of the tuatara and its relatives (Rhynchocephalia) dates back to the Triassic whereas the oldest fossil lizards are known from the Jurassic and the oldest fossil snakes are known from the Cretaceous. The skulls of lizards have additional joints that allow them to increase the gape of their mouths and manipulate their food more effectively. Lizards generally have slender bodies with long limbs. The two principal anklebones, the astragalus and calcaneum, are fused. Lizards do not grow indefinitely, unlike many other reptiles, and their limb bones have separate ossifications (epiphyses) at their joint ends. Many species reduce or even lose their limbs. Snakes evolved from limbed lizards although their precise relationships remain contentious (Hsiang *et al.*, 2015). They completely lost their forelimbs and shoulder girdle, and the much elongated vertebral column sometimes comprises over 400 vertebrae. The bones of the upper jaws and palate in snakes are loosely joined to each other and to the braincase, and, along with a ligamentous connection between the lower jaws, facilitate the capture and manipulation of prey (Rieppel, 1993). Snakes use constriction or venoms to subdue and kill their prey (**Figures 6–8**).

During the Mesozoic, a number of groups of diapsid reptiles independently adapted to life in the sea (Motani, 2009). They included ichthyosaurs, which are often remarkably fish-like in their body plan, and plesiosaurs, which used four flipper-like limbs for swimming. These groups may be more closely related to lepidosaurs than to archosaurs.

Archosaurs include dinosaurs (including birds), pterosaurs (flying reptiles), crocodylians, and the extinct close relatives of these groups (Nesbitt, 2011). They date back to the Early Triassic. Only birds and crocodylians survived to the present

Figure 6 Tuatara (*Sphenodon punctatus*). The tuatara is the lone present-day survivor of a once diverse group of reptiles closely related to lizards and snakes. Reproduced from Samsara/Wikipedia.

day. Birds descended from small predatory dinosaurs and evolved active, flapping flight (Chiappe, 2007). Most researchers now agree that birds should be classified as a subgroup of dinosaurs. Many features commonly associated with birds, such as feathers, the furcula (wishbone), and a specialized wrist joint, were already present in small predatory dinosaurs. A wide range of often exquisitely preserved fossils, especially from the Jurassic and Cretaceous of China, documents a series of intermediate stages in the evolution of the bird skeleton and flight adaptations in great detail (Chiappe, 2007). The major diversification of birds, during which most major modern groups evolved, took place only during the Cenozoic (Mayr, 2014). Starting at the end of the Triassic, dinosaurs became the dominant carnivores and herbivores in continental ecosystems for much of the Mesozoic (Fastovsky and Weishampel, 2012). They included the largest animals that ever lived on land. Pterosaurs are closely related to dinosaurs and evolved active flight long before and independently from birds (Witton, 2013). The wing membrane was attached to the enormously elongated fourth finger. Pterosaurs dominated the air for much of the Mesozoic and included the largest flying animals of all time. Present-day crocodylians are represented only by some 25 species, which are mostly amphibious ambush predators (Grigg and Kirshner, 2015; **Figure 9**). However, crocodylians and their closest relatives were far more diverse during earlier geological periods. Their earliest precursors were land-dwelling pursuit predators.

Glossary

Amniota Land-living vertebrates (i.e., tetrapods) that have a complex set of embryonic membranes, including the amnion. Also defined as the monophyletic group containing living mammals, reptiles, and birds, their last common ancestor, and all the descendants of this ancestor.
Anapsida Amniotes with no temporal openings in the skull.
Anthracosauia A group of primitive reptiliomorph, albeit still amphibious, tetrapods.
Carboniferous The geologic period that started 359 Mya and ended 299 Mya. Named for the large amounts of coal (carbon) deposited during this period.
Diadectomorpha A group of robust tetrapods of the Carboniferous and Permian that is generally considered to be closely related to Amniota.
Diapsida Amniotes with two temporal openings (dorsal and ventral) in the skull.
Microsauria A group of tetrapods, a part of the Leposondyli, which had an amphibious biology. The microsaurs are usually relatively small and slender compared to other amphibians of the Carboniferous and Permian.
Monophyly The condition that a taxon contains the last common ancestor of all the species included, as well as all the descendants of that last common ancestor.
Reptiliomorpha A group of tetrapods that are more closely related to Amniota than to modern amphibians.
Seymouriamorpha A group of often highly terrestrial reptiliomorphs, with amphibious biology.
Synapsida Amniotes with one ventral temporal opening in the skull. This group is monophyletic, and contains modern mammals.

Introduction

One of the most significant events in the evolutionary history of vertebrates was the origin of Amniota, named for their amnion, which is the innermost of the embryonic membranes found in reptiles, birds, and mammals. This membrane was primitively associated with eggs laid on land (Figure 1), but is also found in all live-bearing amniotes. The amnion is one of the key features that enabled these animals to reproduce and mature in terrestrial habitats, the young generally hatching as miniature replicas of the adults. This is in strong contrast to basal tetrapods with an amphibious way of life, in which the larvae hatch from eggs that are deposited in the water, and only subsequently metamorphose into more-or-less terrestrial adults. The origin of the amniotic egg is linked to the formation of the outer embryonic membrane, the chorion, and an extraembryonic sac called the allantois that grew out of the embryonic hindgut and covered the inner surface of the chorion (Liem *et al.*, 2001). The allantochorion membrane is well supplied with blood vessels and acts as a respiratory organ that allows inward diffusion of oxygen through the permeable shell, as well as the outward passage of carbon dioxide (Strickberger, 1985). The complexity of the amnion and other extra-embryonic membranes which are present in all living squamates, archosaurs, testudines, and mammals, provides strong morphological evidence that amniotes had an ultimate common ancestry not shared by modern amphibians. Thus, both Amniota and Lissamphibia (modern amphibians) appear to be well-defined monophyletic taxa (e.g., Sigurdsen and Green, 2011). Molecular data also supports this basal split between Amniota and Lissamphibia (e.g., Hugall *et al.*, 2007). Sadly, embryonic membranes cannot be found in the fossil record, and fossilized eggs from the period in question are extremely rare (Sander, 2012).

However, amniotes also generally share several osteological features, notably the transverse flange of the pterygoid in the palate (though this character is often far from clear), solidly ossified vertebrae with large pleurocentra, and a fusion of tarsals to form the astragalus in the ankle. Definitions of Amniota based on such morphological features are commonly used, but an alternative exists in the use of a crown-group

definition, such as that proposed by Gauthier *et al.* (1988). In this definition, Amniota consists of mammals, modern reptiles, and birds, their last common ancestor, and all descendants of this ancestor. Either way, the available evidence shows that the origin and early divergence of amniotes took place in the Upper Carboniferous (Carroll, 1964; Voigt and Ganzelewski, 2010; Clack, 2012). Here, we discuss the existing fossil evidence for the emergence of the amniotes, focusing on the known taxa from around the time of their origin. We also review the phylogenetic position of the pertinent taxa, and problems remaining in our understanding of the early evolution of this key group of tetrapods.

Fossil Evidence

The Earliest Known Amniotes

There is general agreement that true amniotes were present by the early stages of the Westphalian (315 Mya) in the Upper Carboniferous (Carroll, 1964; Voigt and Ganzelewski, 2010; Clack, 2012). The evidence of their existence by the Westphalian A (**Figure 2**) consists of both skeletal material (Carroll, 1964) and preserved trackways (Voigt and Ganzelewski, 2010). At present, the oldest known vertebrates whose skeletal anatomy can be closely compared to that of living

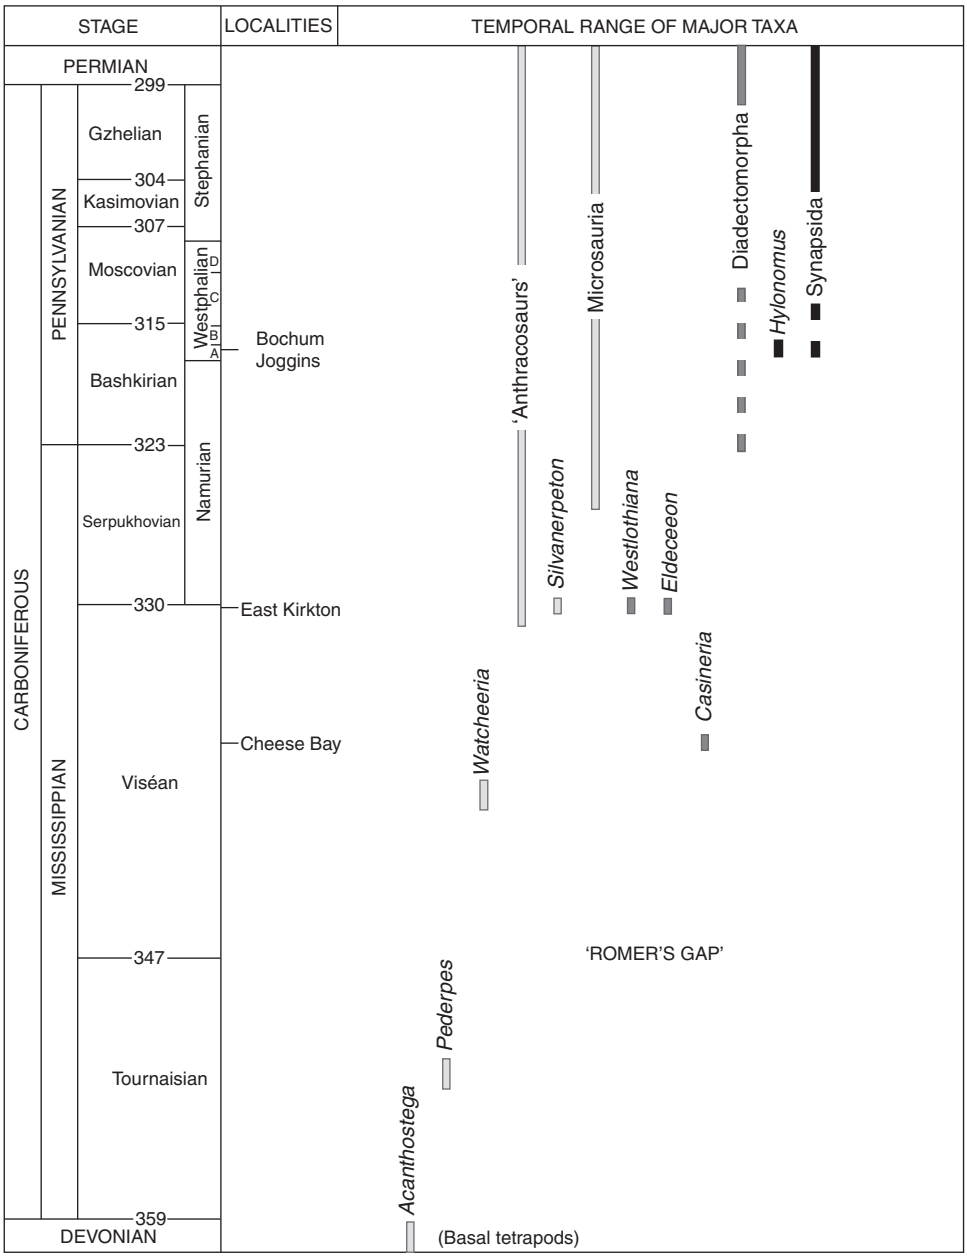

Figure 2 Geological timescale illustrating the time spans of the major groups of terrestrial vertebrates that are associated with the origin of amniotes. The taxa that are generally thought to be more closely related to Amniota are shown in darker shades of gray (taxa considered true amniotes in black). The ages given are in millions of years before present.

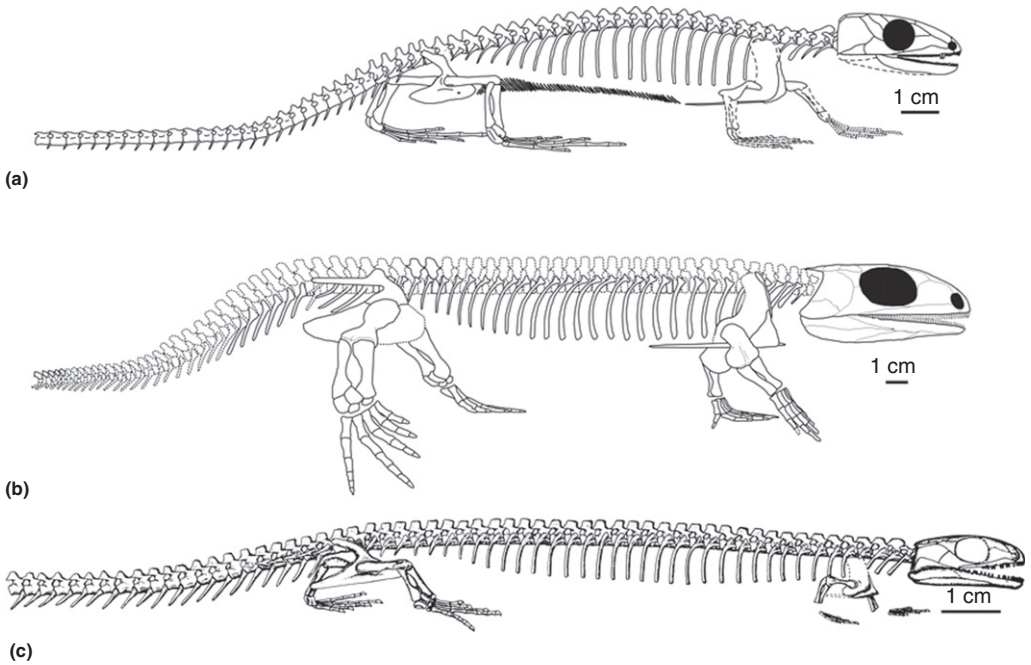

Figure 3 Skeletal reconstructions of three tetrapods from the Carboniferous: (a) The early amniote *Hylonomus lyelli* from Joggins, Nova Scotia. Modified from Carroll, R.L., 1964. The earliest reptiles. Zoological Journal of the Linnean Society 45, 61–83. (b) The basal anthracosaur reptiliomorph *Silvanerpeton miripedes*. Redrawn from Ruta, M., Clack, J.A., 2006. A review of *Silvanerpeton miripedes*, a stem amniote from the Lower Carboniferous of East Kirton, West Lothian, Scotland. Transactions of the Royal Society of Edinburgh: Earth Sciences 97, 31–63. (c) *Westlothiana lizzia*, a reptiliomorph of uncertain phylogenetic position. Modified from Smithson, T.R., Carroll, R.L., Panchen, A.L., Andrews, S.M., 1994. Westlothiana lizziae from the Viséan of East Kirkton, West Lothian, Scotland, and the amniote stem. Transactions of the Royal Society of Edinburgh: Earth Sciences 84, 377–382.

amniotes are specimens of *Hylonomus lyelli* (**Figure 3(a)**) from the Lower Westphalian stage of Joggins, Nova Scotia. This locality (now a United Nations World Heritage Site), is on the shore of the Bay of Fundy, an area that was close to the equator in the Carboniferous (**Figure 5**). The *Hylonomus* specimens, along with many other vertebrates found at Joggins, were preserved within the stumps of upright tree-like lycopodiophytes (plants related to modern clubmosses), of the genus *Sigillaria*. The hollow tree stumps evidently became traps for animals walking on the land surface (Dawson, 1882). The type locality of the Joggins Formation has been dated to the Langsettian (Falcon-Lang *et al.*, 2006) in the Bashkirian (**Figure 2**), more than 315 million years ago (Gradstein *et al.*, 2012). Carroll (1964) established *Hylonomus* as a basal amniote, and this was based on a number of 'reptilian' features of the skeleton (as opposed to stem tetrapod, or 'amphibian' features). These include a transverse flange on the pterygoid, ribs resembling those of modern reptiles, an ankle joint containing an astragalus, as well as phalangeal counts of the manus and pes of 2, 3, 4, 5, 3. Thus, the skeleton of *Hylonomus* had already achieved nearly all of the features associated with modern amniotes.

Apart from *Hylonomus*, Carroll (1964) also suggested that basal synapsids ('pelycosaurs'), the lineage eventually giving rise to mammals, may have been present at Joggins. Although the identification of *Protoclepsydrops* as a synapsid has remained doubtful due to the fragmentary nature of the fossils (see Reisz, 1972), newer studies of tetrapod trackways from the Westphalian A Bochum Formation in Germany support the view that synapsids were indeed present at such an early age (Voigt and Ganzelewski, 2010). The first diapsids, the group containing modern snakes, lizards, crocodiles, and birds, are known from the Upper Carboniferous (Reisz, 1977). Thus, although the evidence is scant, the existing finds suggest that amniotes were already diversifying in the Bashkirian Age (323–315 Mya) of the Carboniferous, perhaps indicating that much of the actual diversity of that period is still unknown to us.

Reptiliomorphs from the Lower Carboniferous

To which group of basal tetrapods are amniotes most closely related? Decades ago, the description of *Hylonomus* and other early amniotes (Carroll, 1964, 1970; Carroll and Baird, 1972; Reisz, 1972, 1977, 1981) significantly extended the known range of amniotes well back in the Upper Carboniferous, but the advanced nature of their skeletons made it difficult to relate them with any other tetrapods known from earlier deposits.

The sister taxon of Amniota within primitive tetrapods remains a problematic topic, as various groups show different amniote-like features to different degrees (for reviews of basal tetrapod groups see Carroll, 2009; Clack, 2012). In general, tetrapods that are more closely related to amniotes than to modern amphibians are known as reptiliomorphs (Clack, 2012). Our knowledge of Early Carboniferous reptiliomorphs is unfortunately limited by the presence of one of the most

notorious gaps in the fossil record; the so-called Romer's Gap (Figure 2). Even though we have recently seen significant finds from these strata (Smithson *et al.*, 2012), the paucity of fossils from this period is still a serious problem to our understanding of the early origin of amniotes. Numerous Carboniferous and Lower Permian tetrapods with amphibious biology have been suggested as possible sister-taxa of ancestral amniotes, and these notably include the anthracosaurs and seymouriamorphs. These problematic groups are significantly more primitive than basal amniotes. However, many of these are known only subsequent to the appearance of clearly recognizable amniotes, and are sometimes specialized in their anatomy and presumed way of life. Still, the possibly paraphyletic anthracosaurs in particular remain a key group in any discussion of the origin of amniotes.

The watcheeriids *Pederpes* and *Whatcheeria* constitute some of the most interesting finds from the early Carboniferous, and when these were first discovered they were tentatively associated with presumed stem amniotes such as anthracosaurs (Lombard and Bolt, 1995). However, recent analyses have left this relationship in serious doubt, and whatcheeriids are now usually regarded as relatively generalized basal tetrapods (Lombard and Bolt, 2006; Ruta and Coates, 2007).

Several sites in Scotland have yielded tetrapods of interest to the study of early amniotes. The Cheese Bay Shrimp Bed of the Gullane Formation near Edinburgh has produced the intriguing potential basal amniote *Casineria kiddi* (Paton *et al.*, 1999). Although fragmentary and lacking most of the skull, *Casineria* shows a very early occurrence of many typically amniote features. The vertebrae are highly ossified with large pleurocentra, and the ribs are long and curved. Not surprisingly, the phylogenetic position of this incompletely known form is uncertain, but it appears to be related to basal amniotes (Paton *et al.*, 1999).

In the mid-1980s, a new fossil-bearing horizon was described at East Kirkton, near Bathgate, Scotland (Wood *et al.*, 1985). The site correlates with the lower part of the Brigantian stage of the Viséan Series in the Lower Carboniferous, estimated at approximately 335 million years ago (Figure 2). Several species collected from this locality have been of special interest in establishing the early evolution of the distinctive characteristics of amniotes. *Silvanerpeton miripedes* (Clack, 1994; Ruta and Clack, 2006) from East Kirkton appears to be a basal representative of the anthracosaurs, and as such shows some features that can be regarded as intermediate between more primitive tetrapods and basal amniotes. It is a robust animal (Figure 3(a)), with well-ossified limb bones. It appears to be adapted to a terrestrial environment, although its phylogenetic position indicates that it might have had an aquatic larval stage (Ruta and Clack, 2006). The skull retains well-developed otic notches of the squamosal bones, and labyrinthine infoldings of the teeth, plesiomorphic features that are typical of basal tetrapods rather than amniotes, although similar otic notches can be found in certain stem amniote groups. *Eldeceeon* also appears to have anthracosaurian affinities (Smithson, 1994). The limbs, especially the rear, were stout and well ossified, indicative of a terrestrial animal with ossified tarsals and a phalangeal formula of 2, 3, 4, 5, 4 (although three terminal elements are missing), which is similar to many basal amniotes. Only the first 14–16 ribs are preserved in the two available specimens, but this is probably due to poor preservation.

Another interesting tetrapod from East Kirkton that may be linked to the ancestry of amniotes is *Westlothiana lizziae* (Smithson *et al.*, 1994). In strong contrast with *Eldeceeon rolfei*, it had a long trunk, with 36 presacral vertebrae, but very short and well-ossified girdles and limbs (Figure 3(c)). The humeri are much shorter than the femora. In addition, the skull shows a combination of traits resembling those of both more primitive tetrapods and amniotes. Most features of the vertebrae closely resemble those of Upper Carboniferous and Lower Permian amniotes, except for the presence of conspicuous ventral lamellae, and the intercentra are conspicuous throughout the trunk region. The greatly elongate trunk and relatively small size resemble many microsaurs, and may perhaps suggest adaptations to a burrowing way of life. *Westlothiana* shows a unique set of features, and its relationships are hard to establish, but it has been suggested to be either a plesiomorphic stem amniote (Paton *et al.*, 1999), or a basal lepospondyl (Ruta *et al.*, 2003).

A noteworthy feature that may link many of these forms to early amniotes is the presence of long, strongly curved, and ventrally pointed ribs. Sigurdsen and Green (2011) argue that such ribs are associated with a clade including reptiliomorphs (with lepospondyls) and amniotes, as opposed to the proposed clade consisting of temnospondyls and modern amphibians.

However, none of these early amniote-like reptiliomorph tetrapods has a definitive astragalus (amniote ankle bone), although some, such as *Eldeceeon*, *Westlothiana*, and *Casineria* appear to have phalangeal counts comparable to that of amniotes. One enigmatic exception is the somewhat later group Diadectomorpha, in which an astragalus sometimes is found (Berman and Henrici, 2003). The diadectomorphs are a group of large and robust reptiliomorphs from the Upper Carboniferous and Lower Permian (Figure 4).

Phylogenetic Studies of Reptiliomorphs and Basal Amniota

Phylogenetic analyses utilizing the theory of cladistics can provide valuable evidence as to potential sister taxa to Amniota within a larger framework of tetrapod evolution. Among the early cladistic studies, Heaton and Reisz (1986) proposed that protorothyrids (including *Hylonomus*, but data mostly based on *Paleothyris*), captorhinids, and Diapsida form a monophyletic clade within Amniota. *Hylonomus* is therefore regarded as the oldest true crown amniote, but hardly representative of the ancestral amniote morphology. It was concluded that the ancestral amniote morphology was not a gracile protorothryrid anatomy, but rather that of slower carnivores, perhaps similar to many synapsid 'pelycosaurs.'

Several authors have found a close relationship between amniotes and diadectomorphs (Gauthier *et al.*, 1988; Laurin and Reisz, 1999; Müller and Reisz, 2006; Ruta and Coates, 2007). Gauthier *et al.* (1988) proposed Diadectomorpha as the immediate sister taxon to Amniota, with *Solenodonsaurus*, Seymouriamorpha, and Anthracosauridae as subsequent sister taxa. Synapsida represents the first group to split off from the rest of the amniotes, and *Paleothyris* is regarded as a stem

Figure 4 Skeletal cast of Limnoscelis, a Permian Diadectomorph. Cast in the Redpath Museum, Montreal.

diapsid. Ruta and Coates (2007) found various diadectomorphs forming subsequently more basal sister taxa (*Diadectes* being closest to *Captorhinus* plus Amniota).

Apart from diadectomorphs, a relatively close relationship between amniotes, *Casineria*, *Westlothiania*, and microsaurs is also well established, albeit the details differ from study to study (Laurin and Reisz, 1999; Paton *et al.*, 1999; Ruta and Clack, 2006). Paton *et al.* (1999) gives an unresolved polytomy at the amniote node. This node includes *Casineria*, *Westlothiania*, and amniotes. The sister taxon to this grouping is microsaurs and, more basally, *Seymouria*. According to Laurin and Reisz (1999) there is no close relationship between seymouriamorphs, embolomeres (anthracosaurs), and Amniota (Lissamphibia being closer to amniotes than these taxa). Diadectomorpha, here regarded as a monophyletic group, is given as the closest sister taxon to Amniota.

Ruta and Clack (2006) focus on 'reptiliomorph' taxa in their analysis, but did not include Diadectomorpha. Here, the sister taxon of Amniota (represented by *Paleothyris*) is a monophyletic clade consisting of *Casineria*, *Westlothiania*, and microsaurs. Seymouriamorphs are a more basal stem amniote group, followed by *Bruktererpeton* and *Gephyrostegus*. Embolomeres and *Silvanerpeton* are the basal-most stem taxa in the clade that includes amniotes, as opposed to the branch leading to temnospondyls.

Focusing on true amniotes, Müller and Reisz (2006) united *Hylonomus*, *Paleothyris*, *Brouffia*, and diapsida in a monophyletic taxon, thus excluding *Hylonomus* from a stem amniote position. This phylogenetic analysis did not include enough non-amniote 'reptiliomorphs' to inform us on the sister-group of amniotes. Synapsida, represented by Caseidae, is given as the basal-most crown amniote clade.

Discussion

Despite more than 100 years of fossil collecting concentrated in North American and Europe, the known fossil record of the Lower Carboniferous remains far less well known than that of the Upper Carboniferous. Broadly speaking, one would expect the fossil record of a given geologic time period to diminish progressively over time as a result of erosion, tectonic processes, continental drift, all of which dissolve, disperse, or cover up carcasses nearly as fast as they accumulate, not to mention normal loss by carnivores and organic decay. As can be seen in the studies by Ruta and Clack (2006), and Carroll (2012), this is a particularly serious problem in tracing the early ancestry of amniotes and other terrestrial vertebrates for which there are extensive gaps within and between major taxa, making it more difficult to establish reliable relationships. It is also notable that the fossil localities that are reasonably well-known from the Carboniferous are from a limited area of the world, paleogeographically speaking. They were actually situated much closer to each other in the Carboniferous than they are today (**Figure 5**), having later been torn apart by continental drift, and it is possible that our relatively small fossil samples may show a skewed picture of the tetrapod faunas of the time. This may add to the great gap in our knowledge of the ancestry of amniotes, as key taxa may have been distributed elsewhere in the world. The fossil preservation seen at Joggins appears to be fairly unusual. Fossilized lycopod trees are known from other horizons subsequent to the Carboniferous, but only four localities, all in Nova Scotia, are known to contain the remains of extinct amphibians or reptiles, and only one other, Sydney, Nova Scotia, contains a diversity of well preserved skeletons.

During the last 50 years, the continued description of tetrapods from the Carboniferous has shed considerable light on the early occurrence of reptile-like tetrapods. However, many problems still remain in the study of the origin of early amniotes. Romer's Gap has been partially filled (**Figure 2**) but the primitive 'reptiliomorph' taxa remain extremely hard to place in relation to the more advanced reptile-like specimens. The difficulties in our studies of early amniote evolution are not unique, and such issues are common to our study of nearly all groups of early terrestrial vertebrates. However, in the case of the origin of amniotes we have the additional obstacle of coping with the paucity of fossils in Romer's Gap, which is still a big part of the problem.

Most authors agree that the sister taxon to crown Amniota is Diadectomorpha (see review by Reisz, 2007), which may or may not be a monophyletic taxon. Diadectomorphs show all the amniote-like characters found in more basal reptiliomorphs, plus some advanced features that parallel true amniotes, such as some taxa within diadectomorpha evolving an astragalus, although the latter is almost certainly

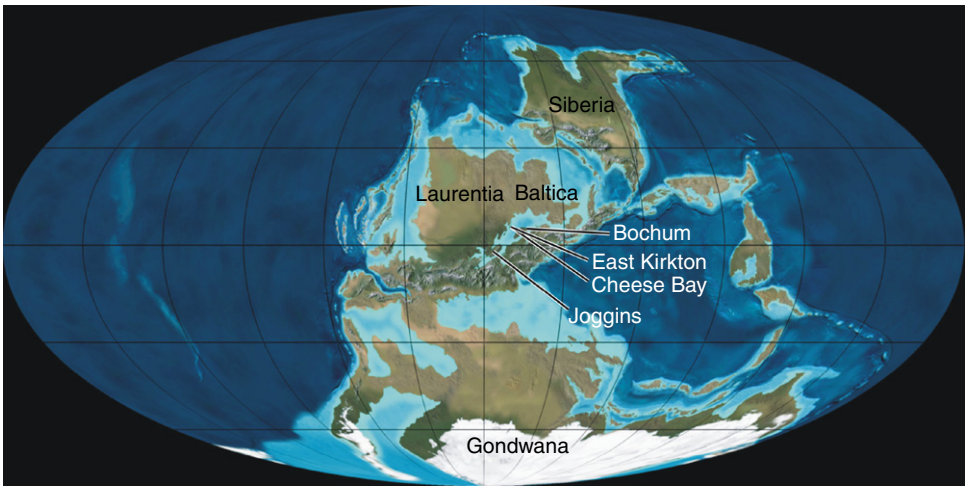

Figure 5 Map of the world in the Upper Carboniferous. Approximate locations of some of the most important reptiliomorph and early amniote localities have been marked. Courtesy Ron Blakey, slightly modified by the authors.

independently derived (see Berman and Henrici, 2003). Microsaurs, seymouriamorphs, and anthracosaurs (monophyletic or not) appear to form subsequent outgroups.

Within Amniota, the traditional classifications divided the major lineages based on the number of temporal openings; the major groups being Anapsida, Synapsida, and Diapsida, with zero, one, and two temporal openings, respectively. This classification has turned out to be problematic, and of these three only Synapsida, containing modern mammals, appears to be unequivocally monophyletic. There is general agreement that the first split within Amniota is likely to have been between Synapsida and the rest of the known groups of amniotes (Gauthier *et al.*, 1988; Müller and Reisz, 2006).

As mentioned above, the earliest known amniotes are represented by *Hylonomus* and some basal synapsid remains (e.g., Carroll, 1964; Voigt and Ganzelewski, 2010). Whereas the position of the synapsids relative to modern animals is clear, the relationships of 'protorothyrids' such as *Hylonomus* have been more contentious. A phylogenetic link between *Hylonomus* and/or *Paleothyris* and Diapsida has been proposed by several authors (Gauthier *et al.*, 1988; Müller and Reisz, 2006). This has been based on the shared presence of slender limbs (represented by two characters in Müller and Reisz, 2006), ventrally keeled vertebral centra, and short postorbital skull length. However, several of these characters are problematic as stem diapsid characteristics, particularly because they also occur in small, gracile synapsids (Romer and Price, 1940). There is a general tendency for smaller animals to have slender long bones. Given its small size, and compared to the basal diapsid *Petrolacosaurus*, the humeri of *Hylonomus* are in fact relatively short and robust (compare Reisz, 1981, Figure 19, and Carroll, 1964, Figure 7). The hind limb proportions are also noticeably more robust than those of *Petrolacosaurus*. Keeled vertebrae and short postorbital skull lengths are common among the early synapsids, and not specific to Diapsida (Romer and Price, 1940). In a preliminary phylogenetic analysis by the present authors, *Hylonomus* belonged to the base of the captorhinid clade (in preparation). Even so, the position of *Hylonomus* is perhaps best regarded as somewhat uncertain, as it retains many basal amniote features, and given the above observations it seems probable that it is more closely linked to both captorhinids and diapsids than to Synapsida. Its anatomy has progressed relatively little beyond that of the most basal amniotes, and a comparison of *Hylonomus* to basal synapsids such a *Varanosaurus* provide a good picture of the anatomy of the last common ancestor of modern amniotes.

Thus, crown amniotes are somewhat better understood than the stem groups. They show several signs of early diversification by the Westphalian A, and at least two main lineages (Synapsida and the species *Hylonomus lyelli*) are present. While *Hylonomus* is possibly linked to the clade containing both captorhinids and diapsids it still shows a morphology that is closely comparable to the expected amniote ancestral state. Interestingly, there is a relatively wide distribution of 'protorothyrid' taxa (including *Hylonomus*) within some phylogenies (e.g., Müller and Reisz, 2006; current authors in preparation). This paraphyletic assemblage share general morphological similarities (albeit symplesiomorphies in some cases), and the fact that such a morphologically homogenous group (reflected in their initial classification as a taxon) might be widely scattered among the earliest amniote lineages could give us an important hint to the basal amniote condition. The ancestor was likely superficially similar to a modern lizard, but with somewhat more stout limb bones and a robust anapsid-type skull, similar to the situation seen in *Hylonomus*.

Glossary

Dynamic programming It is a computer science method for solving a complex problem by breaking it down into a collection of simpler subproblems. Here, it is used to calculate a result for a whole tree by considering progressively larger parts of this tree, starting from the tree leaves for which the desired result can be easily computed.

Markov process Here, this term indicates a probabilistic process in which there exists a finite set of possible states (e.g., the 4 nucleotides, or the 20 amino acids) and a matrix whose terms are the rates at which a state can change per unit time. This conveniently represents the evolutionary process at the molecular level. Such a process is said to be homogeneous when the matrix is constant through time and through evolutionary lineages.

Phylogenetic tree A tree is an object made of nodes connected by edges such that no closed circuit of edges exists, and there exists a path between any pair of nodes. Tree leaves are those nodes connected to a single other node. In a rooted tree, one node has a special status by being the tree root. A phylogenetic tree represents the evolutionary divergence of biological entities, usually species or genes, the leaves, from their last common ancestor, the tree root. Its nodes figure ancestral entities. Its edges figure evolutionary lineages. In a species tree, biological entities are species. In a gene tree, they are homologous genes, that is, genes sharing a common ancestor.

Introduction

The theoretical possibility of reconstructing ancestral molecules from the sequence of these molecules in extant organisms has been formalized by Pauling and Zuckerkandl (1963), and has become practical and widely applied in the recent years. Various types of traits have been considered for ancestral reconstruction: sequence data, either of the nucleotide or protein types, have been extensively studied. Methods for processing sequence data can often be seen in a more general fashion as methods handling characters with a discrete set of values. Therefore, these methods also allow to consider non-sequence data such as binary characters, e.g., presence/absence. Other sets of methods consider continuous characters (e.g., body mass) and allow the reconstruction of their ancestral values.

Ancestral reconstruction of gene content has also been studied with the objective of understanding the evolutionary history of gene repertoires over time. Methods for discrete characters can be applied in this case, but a model incorporating the processes of gene evolution is more accurate. Indeed, the processes of gene evolution in genomes include duplications and horizontal gene transfer, which are improperly rendered when genes are coded as discrete character data. It has triggered the development of new methods specific for the reconstruction of gene history and hence ancestral genic repertoires. Similarly, the order of genes along chromosomes has been considered as a target for ancestral reconstruction. Because this problem becomes very rapidly computationally intractable, the less ambitious target of reconstructing ancestral adjacencies between genes along chromosomes has been studied.

For very shallow divergences, recent attempts have also been performed to reconstruct full ancestral chromosomal sequences, with both genic and noncoding nucleotides.

This article describes major methods for all these problems, which concern the reconstruction of ancestral traits or sequences along a preestablished phylogenetic tree, and starting from a set of observed trait values (e.g., multiple alignment of extant homologous sequences) (see Figure 1). Notably, the procedures described here are those that have been widely used recently to reconstruct ancestral enzymes in order to study the path followed by a protein along evolutionary time.

Ancestral Character Reconstruction

Inferring the ancestral states of a given trait requires a set of values measured in extant organisms, a binary rooted or unrooted phylogeny relating these organisms and a model assuming a particular process of trait evolution. This model may contain parameters, such as rates of change between states or

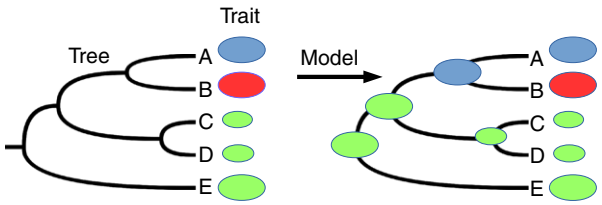

Figure 1 Reconstruction of ancestral characters along a phylogenetic tree.

 doi:10.1016/B978-0-12-800049-6.00166-9

the branch lengths of the phylogeny, which are usually estimated from the data in the case of probabilistic reconstructions. Three methodological frameworks are commonly considered to infer ancestral characters: Parsimony (Sankoff, 1975), Maximum Likelihood (ML) (Schluter *et al.*, 1997), and the Bayesian framework (Pagel *et al.*, 2004).

Discrete Characters

Markov models for a finite state space Ω may contain several parameters, depending on the a priori assumptions that are made about transition rates between states (Pagel, 1994; Yang, 2006). When applied on binary or unordered (excepted nucleotides or amino acids, see Section Ancestral Sequence Reconstruction) sets of characters of size k, the models are called M_k. Extensions of M_k are, for example, the Binary and Multi-State Speciation and Extinction models (BiSSE and MuSSE, respectively) developed to simultaneously infer the process of state change with the estimation of speciation and extinction rates along the phylogeny (Maddison *et al.*, 2007; FitzJohn, 2012). M_k model makes the assumption that transition rates are constant across lineages. The Hidden Rates Model (HRM) relaxes this homogeneity hypothesis and intends to capture the variation of transition rates between states across the phylogeny, yielding more accurate estimations of ancestral states (Beaulieu *et al.*, 2013).

Maximum parsimony reconstructions are approximations of solutions when the rates of events are supposed to be low, so that the probability of multiple events on one branch can be considered negligible. In this case, consider a cost d_{ij} of transition between states on any branch, with $i,j \in \Omega$, and ancestral states are chosen in order to minimize the sum of the costs of transitions on all branches. Calculations typically follow a dynamic programming procedure along the phylogeny (Sankoff, 1975). If the state space is small, a cost $C_u(i)$ is computed for every node u of the phylogeny, and every possible state i, starting from the leaves and following a postorder traversal of the tree. For a leaf l, $C_l(i)=0$ if the state i is present at leaf l, and $C_l(i)=\infty$ otherwise. Then, assuming that u_1 and u_2 are the children of u, apply

$$C_u(i) = \min_{j\in\Omega}(C_{u_1}(j) + d_{ij}) + \min_{j\in\Omega}(C_{u_2}(j) + d_{ij})$$

(For u_1, the cost $C_{u_1}(j) + d_{ij}$ is computed for all possible values $j \in \Omega$, and the minimum is retained. Similarly for u_2.)

One can thus obtain the set F_{root} of minimal cost states at the tree root, those for which $C_{\text{root}}(i)$ is minimal. The set F_p of minimal cost states at internal node p, child of node a, is recursively computed, from root to leaves, with:

```
F_p ← ∅ #Initially, F_p is the empty set
#for each minimal cost state assigned to parent node a
for each i∈F_a do
   m ← min_j(d_ij + C_p(j)) #The minimum cost m is computed
#All states j associated with a cost equal to m are added to
the set of possible values
   for each j do
      if d_ij + C_p(j) = m
         F_p ← F_p ∪ {j}
```

The set F_p gives all most parsimonious ancestral states at node p, and the result does not depend on the position of the root. There are two primary issues with the use of parsimony to reconstruct ancestral states. First, parsimony ignores branch lengths, which are indicative of variation of evolutionary rates between lineages. Second, parsimony does not account for variation of rates between the different states of the character, excepted with weighted parsimony, which assign weights to state changes. But, in this case it is always difficult to attribute appropriate weights a priori.

Likelihood calculations follow the same computational framework, with the advantage of probabilistically accounting for the concerns raised above about parsimony. Let $L_u(i)$ be the probability of observing the state i at node u, p_{ij}^l being the probability for state i to turn into j along a branch of length l, computed according to the evolutionary model. Conditional probabilities are computed recursively along the tree from the leaves to the root. For a leaf l, $L_l(i)=1$ if i is the observed value at leaf l, and $L_l(i)=0$ otherwise. For other nodes,

$$L_u(i) = \Big(\sum_{j_1\in\Omega} p_{ij_1}^{l_1} \times L_{u_1}(j_1)\Big)\Big(\sum_{j_2\in\Omega} p_{ij_2}^{l_2} \times L_{u_2}(j_2)\Big)$$

where u_1 and u_2 are the children of node u, and l_k is the length of the branch between u and u_k, which has to be a parameter of the model.

The probabilistic approach considers two types of ancestral character reconstruction, the marginal and the joint reconstructions. The marginal reconstruction gives the probabilities $P(u=i|S)$ of each state i of a given ancestral node u, where S represents the observed values at all leaves of the tree. Using Bayes formula, we obtain:

$$P(u=i|S) = \frac{P(u=i)P(S|u=i)}{P(S)} = \frac{\pi_i P(S|u=i)}{P(S)}$$

where π_i is the equilibrium frequency of character i. Provided it is computed after rooting the tree at its node r, the vector of conditional probabilities at the tree root defined above corresponds to the term $P(S|r=i)$. This procedure is called 'empirical Bayes' by Yang (2006).

The joint reconstruction gives the most probable set of residues across all ancestral nodes, and necessitates a backward traversal of the tree like in the parsimony case (Pupko *et al.*, 2002).

The computations have a quadratic complexity with respect to the state space size k, which makes dynamic programming a weak tool for large or infinite state spaces. If the state space is the integer set, it is possible to see the cost function $C_u(i)$ as an affine function of i and to propagate only the coefficients of the function along the nodes, instead of every value, to reach a complexity that does not depend on the size of the state space (Csuros, 2014), making parsimony calculations feasible. When the state space is large but without a good structure to order it, as with gene orders (Section Gene Order, there can be $n!$ possible gene orders), then the ancestral reconstruction becomes intractable.

Continuous Characters

When the state space Ω is a continuous set of numbers, the parsimony cost function d_{ij} is usually defined as the absolute

value or the square of the difference between i and j. It is not possible to compute the cost $C(i)$ for all values $i \in \Omega$. Instead, the coefficients of a linear or quadratic function of i is computed at each node, following the same dynamic programming principle (for an exhaustive review on parsimony methods see Csuros (2014)). If $d_{ij}=(i-j)^2$, then the parsimony solution is also the ML one under a Brownian motion (BM) with a constant rate, which is the most commonly used Markovian process under continuous characters. BM assumes that the trait value changes as a random walk, with multiple and independent steps drawn from a normal distribution of mean 0 and variance σ^2. The consequence of the independence between steps is that the net change of the trait value along a branch of length t is drawn from a normal distribution of mean 0 and variance $t \times \sigma^2$. With a BM process, the only parameter is the variance σ^2, the trait changes with a constant rate along the phylogeny and drifts neutrally without directionality or evolves toward an optimum that drifts neutrally (Felsenstein, 2004). BM is a special case of the Ornstein–Uhlenbeck (OU) process, which contains an additional attraction parameter toward a central value, increased with the distance from this central value. OU might be of interest when stabilizing selection acts on the trait under consideration (Martins, 1994). Extensions of these models were proposed to account for the heterogeneity in rate of change over time (Blomberg *et al.*, 2003; Harmon *et al.*, 2010; Eastman *et al.*, 2011). For instance, the Early Burst Model (Harmon *et al.*, 2010) allows the rate of the BM process to exponentially change in time.

The estimation of ancestral continuous trait values can be performed in ML (Schluter *et al.*, 1997). Likelihoods of transitions in state between adjacent nodes are easily derived from the BM process formulation, and the joint likelihood of the Brownian rate (σ^2) and all internal states is maximized over the entire tree. Restricted ML (REML) is also often used (Felsenstein, 1985; Paradis *et al.*, 2004). REML does not analyze the raw data directly, but instead realises the ML estimations using the contrasts among the observations. REML has been shown to produce unbiased estimates of variance and covariance parameters. Ancestral values may be estimated in the Bayesian framework (Huelsenbeck *et al.*, 2002; Pagel *et al.*, 2004), allowing to integrate over uncertainty in the tree topology, branch lengths, and rate parameters.

Two alternative methods are commonly considered: the Phylogenetic Independent Contrast (PIC) (Felsenstein, 1985) and the Generalized Least Squares (GLS) methods (Martins and Hansen, 1997). However, they are not usually employed to infer ancestral character values and were rather designed to control the influence of tree topology on the estimation of correlations between evolving traits. PIC assumes a BM-like model to recursively transform the tip values into statistically independent and identically distributed values, called contrasts, over the internal nodes up to the root. Thus, the ancestral values can be estimated with the data of descendant nodes only, contrary to ML estimations. GLS estimates the unknown parameters in a linear regression model. It assumes the model $Y=DX$, where D is a vector of observed values at the tips, X is a matrix describing both the phylogeny unifying the tips along which the trait evolves and the process of trait evolution (usually a BM process). Y is the vector of ancestral trait estimates. In many situations, ML, PIC and GLS produce similar values, especially when a simple BM process is assumed to model the evolution of traits (Martins, 1999).

Ancestral Sequence Reconstruction

Ancestral sequence reconstruction (ASR) from extant molecular sequences (DNA or proteins) consists in computing ancestral residues, given extant residues at the leaves of a phylogenetic tree. As such it requires a multiple alignment of sequences, a phylogenetic tree, and a substitution model. Computations are usually done independently at each site of the aligned sequences.

ASR inherits from all models and methods for ancestral character reconstruction for small state spaces (DNA or amino acids). But models of sequence evolution have their specificities. First, depending on the number of parameters defining the transition rates between states, the M_k model takes different names (e.g., Jukes and Cantor (JC) when all rates are equal or General Time Reversible (GTR) when all rates are different (Yang, 2006)). Second, the variation of evolutionary rates across sequence sites is usually accounted for, modelled by a gamma distribution discretized in K classes of $\frac{1}{K}$ weight. Then, the likelihood equation of Section Ancestral Character Reconstruction becomes:

$$L_u^s(i) = \sum_{c=1}^{K} \frac{1}{K} \left[\left(\sum_{j_1} p_{c,ij_1}^{l_1} \right) L_{u_1}^s(j_1) \left(\sum_{j_2} p_{c,ij_2}^{l_2} \right) L_{u_2}^s(j_2) \right]$$

With sequences, the marginal reconstruction is the most frequently used algorithm to compute ancestral characters. However, an efficient algorithm developed by Pupko *et al.* (2002) can be employed to perform joint reconstruction. It deals with all ancestral nodes together, and the set of sequence residues at all nodes of largest probability is considered to be the best ancestral reconstruction at a given site. While the marginal reconstruction requires a computation time proportional to the number of sequences, the joint reconstruction is exponential in the sequence number when across-site rate variation is modeled with a discretized gamma distribution (Liberles, 2007). Joint reconstruction is therefore difficult for more than a few tens of sequences.

Yang (2006) indicates that joint and marginal reconstructions usually produce consistent results where the most probable joint reconstruction for a site consists of the best marginal reconstruction at each node. Furthermore, when conflicting results arise, neither reconstruction is very reliable.

In practice, the marginal approach of ancestral sequence reconstruction in ML, retaining the most probable residue for each node at each site is most often employed in ancestral protein resurrection experiments. Several software packages implement this procedure: PAML (Yang, 2007), MEGA (Tamura, 2011), DAMBE (Xia, 2013), and bppAncestor, a part of the Bio++ library (Gueguen *et al.*, 2013).

When the goal is the resurrection of ancestral proteins, the residue with largest probability at each node is often retained. In this case, it is interesting to consider the magnitude of this largest probability: values above .9 indicate high confidence in the reconstructed ancestral residue, whereas residues with

moderate probabilities are those where reconstruction is uncertain. This strategy, though, is biased toward the most frequent amino acid at each protein site (Yang, 2006). An alternative strategy that avoids this bias is to generate an ancestral sequence by randomly drawing at each site one residue according to the probability vector computed for this site. The second strategy also allows to generate a small number of putative ancestral sequences in order to measure the sensitivity of inferences to the uncertainty about ancestral sequences.

Several studies have compared ASRs by the parsimony and probabilistic approaches (Yang *et al.*, 1995; Zhang and Nei, 1997). The general outcome is that probabilistic methods are more accurate than the parsimony approach, except when sequence divergences are weak where the two approaches perform similarly. The probabilistic approach has also the advantage of estimating the uncertainty of the reconstruction at each ancestral site. It was also shown that complex probabilistic models which aim at capturing the compositional heterogeneity of the substitution process provide more accurate estimates of ancestral sequences (Groussin *et al.*, 2013). However, the downside of parameter-rich models is that they may require large datasets to accurately estimate all parameters, and may also increase the time and memory requirements of the algorithm.

Models of insertions and deletions on a multiple alignment are necessary to correctly infer the presence or absence of a residue at some site in an ancestral sequence. For this, alignments have to be computed together with phylogenies, so that indels are scored according to an evolutionary model. It is done in parsimony by Loytynoja and Goldman (2008), and statistical models of insertion/deletion are included in alignment algorithms of Diallo *et al.* (2007). In that case the alignment, phylogeny, and presence or absence of ancestral residues are simultaneously given as an input to ASR methods. Diallo *et al.* (2010) present a software for computing indels (and thus, an alignment) given a phylogeny, while Suchard and Redelings (2006) and Lunter *et al.* (2005) propose a Bayesian co-estimation of alignment and phylogeny.

Finally, Groussin *et al.* (2015) highlighted that an erroneous tree negatively impacts ASR accuracy and that the use of species tree-aware gene trees reconstructed with models of duplication, transfer and loss events (see Section Gene Content) strongly increase ASR accuracy. This calls for an additional integration of duplication, transfer and loss in alignment, and phylogeny algorithms.

Gene Content

Several approaches exist for the reconstruction of ancestral gene content onto a species tree. The first one is the analysis of phylogenetic profiles, i.e., a matrix of binary characters coded as presence/absence of genes at the leaves of a given phylogeny of species (see **Figure 2**). A slightly more sophisticated version of phylogenetic profiles considers counts of homologous genes as discrete characters to allow the reconstruction of ancestral copy numbers for the genes under study. But before reconstructing ancestral gene content, it is important to first consider the evolutionary events that may affect the history of genes. For instance, in all organisms, genes can be duplicated or lost. In addition, many organisms have the ability to integrate genes from distantly related donors via lateral gene transfer (LGT). LGT is believed to be frequent in Bacteria and Archaea, and is beginning to be recognized as important in unicellular eukaryotes. It is still considered to be much rarer in multicellular eukaryotes, although several cases have been described. Hence, the application of methods that ignore LGT as a process for the evolution of gene repertoires should be restricted to very particular cases. Dollo parsimony (Farris, 1977), which allows loss of characters, but forbids gains after an initial origination of the gene, has been very popular for genome reconstruction in the absence of LGT. But more realistic approaches attribute asymmetrical costs for gain and loss to account for the possibility of gene transfer with a relatively high cost. The equivalent likelihood methods use a birth-and-death model in which probabilities of gene loss and gain are different, and can be estimated from the dataset (see e.g., Szollosi and Daubin (2012) for review). When the phylogenetic profile represents the number of copies for each gene, and not only their presence/absence, it is possible to estimate the branch-wise rates of duplication, transfer and loss along a phylogeny of species (Csuros, 2010). There is considerable flexibility in the definition of the birth-and-death model for gene evolution, the most simple models being linear, i.e, with rates of gain and loss that are independent of gene family size.

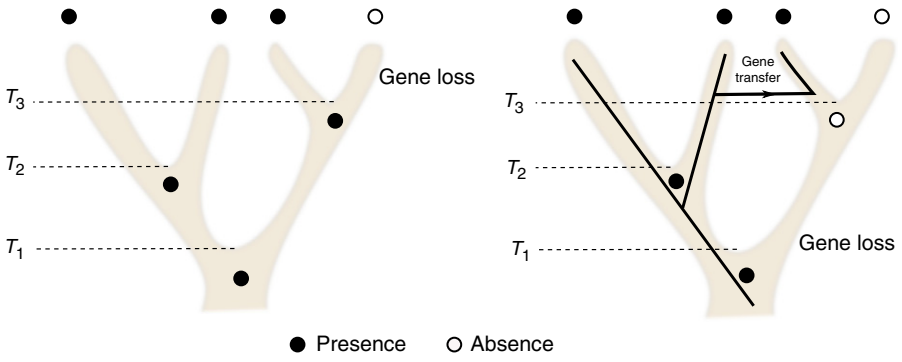

Figure 2 Using phylogenetic profiles or gene phylogenies may reconstruct different ancestral gene contents. The solid lines represent the evolution of the gene within the species tree. Horizontal dotted lines represent the dates of species divergence, restricting lateral gene transfers (LGTs) between species that co-exist in time.

However, the analysis of phylogenetic profiles imperfectly renders the evolution of gene families along the phylogeny of species (see **Figure 2**). Numerous events of duplication and transfer and loss remain invisible to the examination of gene presence/absence or counts. This is the case in particular for gene replacements by LGT. The possibility of reconstructing gene phylogenies based on sequence alignments reveal such hidden evolutionary events. The mapping of a gene family tree onto a species tree, invoking events of duplication, transfer and loss is called reconciliation (Maddison, 1997). A number of algorithms have been proposed, which are more or less complete in the set of events that are modeled (Doyon *et al.*, 2011). An efficient solution to the problem of reconciliation considering duplication and loss is the LCA (for Last Common Ancestor) algorithm (Gorecki and Tiuryn, 2006), which can run in linear time with the number of nodes in the gene tree. The modeling of LGT is more complex. LGT reconciliation has been proposed for the problem of gene replacement specifically. The problem here is to define a minimal number of editing operations to transform the gene tree in the species tree. The Subtree Pruning and Regrafting (SPR) approach reproduces the effect of transfers on phylogeny and has hence been the subject of active research (Nakhleh *et al.*, 2005; Beiko and Hamilton, 2006; Than and Nakhleh, 2008). However, the problem is computationally difficult and only applies to gene families without multicopies. More complete models, that account for duplication, transfer and loss (DTL) and hence apply to the modeling of the evolution of multicopy gene families have been developed, both in a parsimony and probabilistic framework (Doyon *et al.*, 2011; Tofigh, 2009; David and Alm, 2011; Szollosi *et al.*, 2012, 2013; Sjostrand *et al.*, 2014). The problem is still hard, but can become tractable through the addition of biologically relevant restrictions. For instance, an important constraint to include into DTL reconciliation algorithms is the time consistency of gene transfers: LGT can only occur among lineages that are contemporary in the history of species (see **Figure 2**). A promising approach for handling such time constraints is to fully specify the sequence of speciation events in the species tree in which the gene tree is reconciled (Tofigh, 2009), and to allow genes to evolve in lineages that are not explicitly represented in the tree representing the relationships among extant species (Szollosi *et al.*, 2013). A full reconciliation between a species tree and all gene trees yields the best possible reconstruction for the gene repertoire at nodes of the species tree.

Gene Order

Molecular ancestral character reconstruction methods actually began with the organization of genes along chromosomes. Dobzhansky and Sturtevant (1938) constructed the phylogeny and ancestral chromosome conformations of 17 *Drosophila* species, based on the observation of inversions. Already at that time the computational complexity arising from a model of evolution of gene arrangements subjected to inversions was visible (Sturtevant and Tan, 1937): after only a few events, scenarios are difficult to reconstruct even under a parsimony principle. This partly explains that ancestral gene order reconstruction methods seem underage: models are simple but computationally costly, hard to apply to a complex reality and to integrate with other kind of evolutionary signal.

Nevertheless the organization of genes along chromosomes contains valuable information on adaptation and modes of evolution of organisms, which has often been overlooked. And the methodology has slowly come of age.

Dobzhansky–Sturtevant-like methods, modeling chromosomes as permutations subject to inversions, often generalized into double cuts-and-joins to capture more possible events (Yancopoulos *et al.*, 2005), have been used to reconstruct gene orders of some mammalian (Alekseyev and Pevzner, 2009) or angiosperm (Sankoff *et al.*, 2009) ancestors with a parsimony principle. Such techniques are limited to few (typically less than 10) closely related genomes, all with equal gene content, with the notable exception of some including whole genome duplications when ohnologous genes are still present in two copies (Zheng and Sankoff, 2013) or when ohnologous segments can be detected (Gavranovic and Tannier, 2010). A probabilistic model of evolution of permutations by inversions has been implemented in Badger (Larget *et al.*, 2005), and applied to reconstruct animal mitochondria or *Yersinia pestis* ancestral gene orders (Darling *et al.*, 2008). These cannot benefit from the computational facilities of dynamic programming because of the large state space, and use Monte Carlo techniques for space explorations.

A way to bypass the algorithmic complexity and to scale up to hundreds of genomes with unequal gene content is to model the evolution of independent local characters instead of the evolution of a whole genome, just as it is the case for nucleotide sequences and substitutions. This method was also – and is still – applied independently from bioinformatics with cytogenetics data (Svartman *et al.*, 2006). Gene orders may be seen as sequences of adjacencies, which are the links between two consecutive genes (Gallut *et al.*, 2000). Adjacencies can be summed up by a binary character, either two genes are consecutive, or not. The immediate advantage of this view is that it can benefit from the standard methodological arsenal of ancestral character reconstruction on binary characters (see Section Ancestral Character Reconstruction). Yet there are several drawbacks to such an hypothesis of independent evolution of adjacencies. One is that the information connecting the adjacencies, used to estimate inversion distances, is lost. Another is that genomes considered as sets of independently evolving adjacencies are not anymore constrained to be linear arrangement of genes, yet the single cut-or-join model of genome evolution has this linearity constraint (Feijao and Meidanis, 2011; Mikloos *et al.*, 2014). Linearization techniques, often related to Traveling Salesman approaches, have to be applied to sets of reconstructed ancestral adjacencies (Manuch *et al.*, 2012) in order to present bonafide gene orders.

Parsimony approaches (Sankoff or Dollo) on adjacencies have been used, together with linearization procedures to reconstruct ancestors of mammalian (Ma *et al.*, 2006), yeasts (Chauve *et al.*, 2010), monocotyledons (Sankoff *et al.*, 2009), or bacterial (Wang *et al.*, 2006) clades.

Evolution of adjacencies is so simple that it paves the way to integrating gene order and gene content, via gene phylogenies, in a single framework (Sankoff and El-Mabrouk, 2000). Thus, it is now possible to model the evolution of adjacencies along reconciled phylogenies (Ma *et al.*, 2008; Bérard *et al.*, 2012; Louis *et al.*, 2013; Patterson *et al.*, 2013).

Prospective methods have attempted the reconstruction of more ancient animal proto-karyotypes: amniotes (Kohn *et al.*, 2006; Nakatani *et al.*, 2007), bony fishes (Jaillon *et al.*, 2004; Woods *et al.*, 2005; Catchen *et al.*, 2008), vertebrates (Naruse *et al.*, 2004; Kohn *et al.*, 2006; Nakatani *et al.*, 2007), chordates (Putnam *et al.*, 2008), or even eumetazoa (Putnam *et al.*, 2007). However, the accuracy of these ad hoc methodologies has not been studied as thoroughly as for more generic methods, which probably also miss a satisfactory validation process due to the lack of simulators with a diversified enough model of whole genome evolution.

The Complete Reconstruction of Ancestral Genomes

Imagine now a theoretical pipeline that should reconstruct the full sequences of genomes from the past. First give its gene content (Section Gene Content), then order the genes (Section Gene Order), align genic and intergenic regions and reconstruct ancestral sequences (Section Ancestral Sequence Reconstruction).

Although such integration has been attempted and applied to a small fragment of eutherian genomes (Blanchette *et al.*, 2008), or the chromosome of a medieval bacteria (Rajaraman *et al.*, 2013), the problem is still very challenging for several reasons.

One is that there are specific problems to whole genome reconstruction, like borders between genic and intergenic which can be fuzzy: sometimes homologous border sequences are genic in one organism, and intergenic in another, due to the variation of the start and stop positions of genes. Overlapping alignments, possibly with different phylogenetic histories, have to be handled.

Another is that each step highly depends on the others: the construction of phylogenetic trees depends on sequence alignments, while sequence alignment (especially when modeling indels) depends on evolutionary history along a tree (Section Ancestral Sequence Reconstruction); gene order can be informative for gene content (Lafond *et al.*, 2013); every step depends on the accuracy of phylogenetic trees, which in turn are informed by sequence and gene content evolution (Szollosi *et al.*, 2012), and could also benefit from information about the evolution of gene order. The sequencial pipeline adds up the errors of each step without the possibility of any backward correction, while real integrative models are missing. Even small error rates can lead to many errors at the genomic scale.

The validity of all the methods described above is a big issue. True ancestral molecules are unknown and the accuracy of computational estimations can be approached via simulations (but no simulator realistically handles all possible events), via extremely rare cases where an ancient sequence is known (Rajaraman *et al.*, 2013), via expectations about ancestral genomic features (e.g., stability of gene content or linearity of ancestral chromosomes (Boussau *et al.*, 2013)) or via the viability of resurrections (Groussin *et al.*, 2015).

Angiosperm Phylogeny and Diversification

PF Stevens, University of Missouri–St. Louis, St. Louis, MO, USA; and Missouri Botanical Garden, St. Louis, MO, USA

Glossary

Apomorphy Derived feature, an evolutionary novelty arising in the immediate ancestor of a clade and characterizing it.
C4 photosynthesis A mechanism of photosynthesis that is advantageous in conditions of drought and high temperatures. C4 photosynthesis spatially separates components of the process allowing for less water loss and increased carbon assimilation.
CAM photosynthesis A mechanism of photosynthesis that is advantageous in conditions of drought and high temperatures. The components of the process are temporally separated, allowing the stomates to be closed during the day to reduce water loss.
Capitulum An inflorescence with a shortened and often expanded axis bearing numerous sessile flowers in a dense cluster.
Clade Any monophyletic group, i.e., a group composed of its ancestor and all of its descendants.
Column A reproductive structure found in orchids in which the stamen is fused to the stigma/style.
Corolla The collective term for all the petals of a flower.
Determinate The apical meristem producing only a limited number of lateral organs, the axis ceasing extension growth.
Ectomycorrhizal A fungal–plant association in which fungal hyphae completely surround the root, but usually do not penetrate its cells.
Endophyte A bacterium or fungus that lives within the tissues of a plant but does not cause disease symptoms.
Endosperm Nutritive tissue, most often triploid, that results from the process of double fertilization that also forms the embryo and that is characteristic of angiosperms.
Epiphyte A plant that grows on another plant for support but that does not harm the plant on which it grows.
Extrafloral nectary Glandular organs that secrete nectar but that are located outside the flower. These generally do not function in pollination but rather attract animals that protect the plant.
Gametophyte Haploid generation of land plants, produces gametes.
Key innovation An apomorphy that facilitates the subsequent radiation/diversification/success of the clade.
Mycorrhiza A mutualistic association between fungi and land plants.
Pollinia Packets of pollen found in orchids and some other species. The packet is carried by a pollinator in its entirety rather than the pollen being dispersed as grains.
Rhizome A horizontal stem, usually underground; a means of clonal vegetative spread.
Stomata Pores in the epidermis, most often of the leaf, through which gas exchange occurs.

Introduction

In order to fully understand angiosperm diversification, we need to have a robust understanding of relationships, dates of divergence, and numbers and distributions of species. We need to know about morphology and other phenotypic characters, and current and past ecological contexts. Each of these elements presents problems. Progress in elucidating relationships has been substantial, much using sequence data from the chloroplast genome; how current ideas of relationships will fare when we use whole genomes or proteomes is an important question. There are very different estimates in the current literature for the dates of many nodes, and molecular and fossil evidence can be at odds (Wilf and Escapa, 2015); one can make estimations of diversification rates within a clade without dates, but many other questions are left dangling. Species numbers have to be interpreted in the context of a phylogeny, not in terms of categorical ranks – a focus on taxonomic ranks or named clades is often not helpful. Distributions of extant taxa can readily be mapped, however, past distributions may be very different from those of the present. We know far less about basic anatomical and morphological variation in angiosperms than we need, but relatively few people are working on detailed morphological studies. Furthermore, as genetic aspects of development are factored in, our understanding of morphological similarities and differences changes. Finally, although quite a lot is known about flowers and fruits and their interactions with pollinators and dispersers, considering the role of ecophysiological changes in the evolution of angiosperms allows us to think about angiosperm – and biosphere – evolution in new ways. However, understanding past ecological contexts and how they affected angiosperm evolution is difficult.

Looking at overall patterns of diversification, it is particular clades within groups like angiosperms, Orchidaceae (orchids), or Poaceae (grasses) that are notably species-rich, so it may be particular features of these clades ('key innovations') in combination with apomorphies of the larger groups that have spurred diversification. Furthermore, extrinsic features like climate or geography can play major roles in diversification (Donoghue and Sanderson, 2015). It is also often suggested that the origin of many features of flowering plants and their effect on diversification are disconnected in time – there is a lag period. This is true of features like genome duplication

 doi:10.1016/B978-0-12-800049-6.00257-2

(Tank *et al.*, 2015), where diversification of gene function and reorganization of developmental pathways can be invoked to explain this lag period, and also of more conventional morphological features like extrafloral nectaries (Weber and Agrawal, 2014).

The Background – Some Distinctive Angiosperm Features

The evolution and diversification of flowering plants at one level can be thought of as being spurred by the evolution of the flower, a modified determinate shoot, and the fruit, seeds totally enclosed and protected by tissue developed from the ovary. Interactions between plants and animals (pollination, dispersal, herbivory, and more) have led to the diversification of both. The gametophytic stage of angiosperms is physically much reduced: the male gametophyte consists of two gametes and one other cell, while the female gametophyte usually consists of only eight cells, one of which is the single female gamete. In angiosperms, both male gametes are involved in fertilization (double fertilization), one fertilizing the egg, and the other fusing with (usually) two nuclei of the female gametophyte to form triploid endosperm. Endosperm is unique to angiosperms and is an intermediary in providing nutrients to the developing embryo and often reserves for the mature seed. Angiosperms also have a more efficient transport system consisting of vessel elements, dead cells of wide diameter whose walls are reinforced with the complex polymer lignin in distinctive patterns. Vessel elements are stacked to form elongated tubes for water transport, a process which is facilitated by the perforation of the end walls of the cells which allows formation of an unimpeded water column.

All these features are unique to flowering plants, or are pretty close to being unique. However, practically no feature of flowering plants is unique in the sense that it has evolved once and has never been lost, thus some angiosperms have no vessels and some do not develop endosperm. Similarly, extrafloral nectaries characterize a speciose clade within the legume genus *Senna* and may be involved in its diversification, yet at the same time the loss of those nectaries in *Mimosa*, another legume, also characterizes a species-rich clade (Marazzi and Sanderson, 2010). Furthermore, it is arguable whether or not *Amborella*, the extant species that is the sister to all other angiosperms (**Figure 1**), has vessels, and indeed on a per area basis water transport is as efficient in some conifers as it is in basal angiosperms that lack specialized vessel elements.

The angiosperm life cycle is usually notably shorter than that of extant gymnosperms (Williams, 2012). The pollen tube growth rate in angiosperms is much higher than that of extant gymnosperms, fertilization often occurring within about 24 h of pollination as compared to 7 days or often far more in extant gymnosperms. Angiosperms tend to become mature at a younger age than do gymnosperms (Verdú, 2002).

Among extant seed plants, only angiosperms are herbaceous, and the annual habit is unknown in other vascular plants. Molecular evolution is faster in herbs/annuals (e.g., Smith and Donoghue, 2008). Yang *et al.* (2015) found substitution rates in both synonymous and nonsynonymous sites in protein-coding genes up to three times those in their woody relatives. This correlation may be connected with mutation rate or population size and thence to speciation rate (Gaut *et al.*, 2011). There is a general correlation between rates of molecular evolution (substitution rates) and the rate of speciation (Webster *et al.*, 2003), and the evolution of herbs from trees, or at least a shortened time to maturity, has been linked with a rise in the speciation rate of the former (Verdú, 2002).

Patterns of species richness and diversification rates have been examined at scales from angiosperm-wide to particular clades within families, emphasizing situations where diversification has speeded up or slowed down. Below, the author looks both at species richness and at other aspects of diversification; all species numbers are very approximate!

Angiosperm Diversification

Diversification in Basal Angiosperms and Monocots

The basal angiosperm lineages are species-poor (**Figure 1**). The New Caledonian *Amborella* is monotypic, and neither of the two other earliest diverging lineages Nymphaeales (water lilies) and Austrobaileyales (which includes star anise) has many species. Monocots include some 60 100 species. The adoption by early monocots of wet/marshy habitats might explain their vegetative features including an herbaceous habit, growth via rhizomes (underground horizontal stems), and linear leaves, but this is largely surmise, especially since we know little about the evolution of monocot leaves, the immediate relatives of monocots, etc. Monocots lack taproots, instead a network of 'adventitious' roots develops along the stem (**Figure 2**), making some of these plants such as grasses useful for controlling soil erosion.

The monocot family Orchidaceae (27 800 spp.) is the largest angiosperm family, and hypotheses for why they are so diverse are many (Pridgeon *et al.*, 1999–2014). Orchidaceae usually have very bilaterally symmetric flowers with one functional stamen that is fused with the stigma/style to form a unique structure called the column (**Figure 3**). How orchids are pollinated, the interaction of the pollinator and plant, and how that may underlie the rampant speciation in this family, have long interested biologists, including Charles Darwin. The pollen grains are usually aggregated in packets called pollinia (**Figure 3**) that get attached to pollinators in very specific locations by sticky tissue; the often hundreds of thousands of ovules in the ovary are fertilized by a single visit of the pollinator. Deceit pollination, in which the flower mimics another flower or an insect to attract the pollinator but does not offer any reward, is common – indeed, pollination of perhaps one-third of the whole family occurs during the course of pseudocopulation by amorous male insects. However, rewards of various sorts may be provided, and positive Mullerian mimicry, in which both orchid and the flower it is mimicking offer rewards, also occurs.

Flowers and pollination provide one context for thinking about orchid diversity. However, orchids have also specialized in the epiphytic habit, and features related to this may also explain the diversity of this group (Freudenstein and Chase, 2015). One can argue that all or part of the Epidendroideae, with 21 800 species including most commonly cultivated

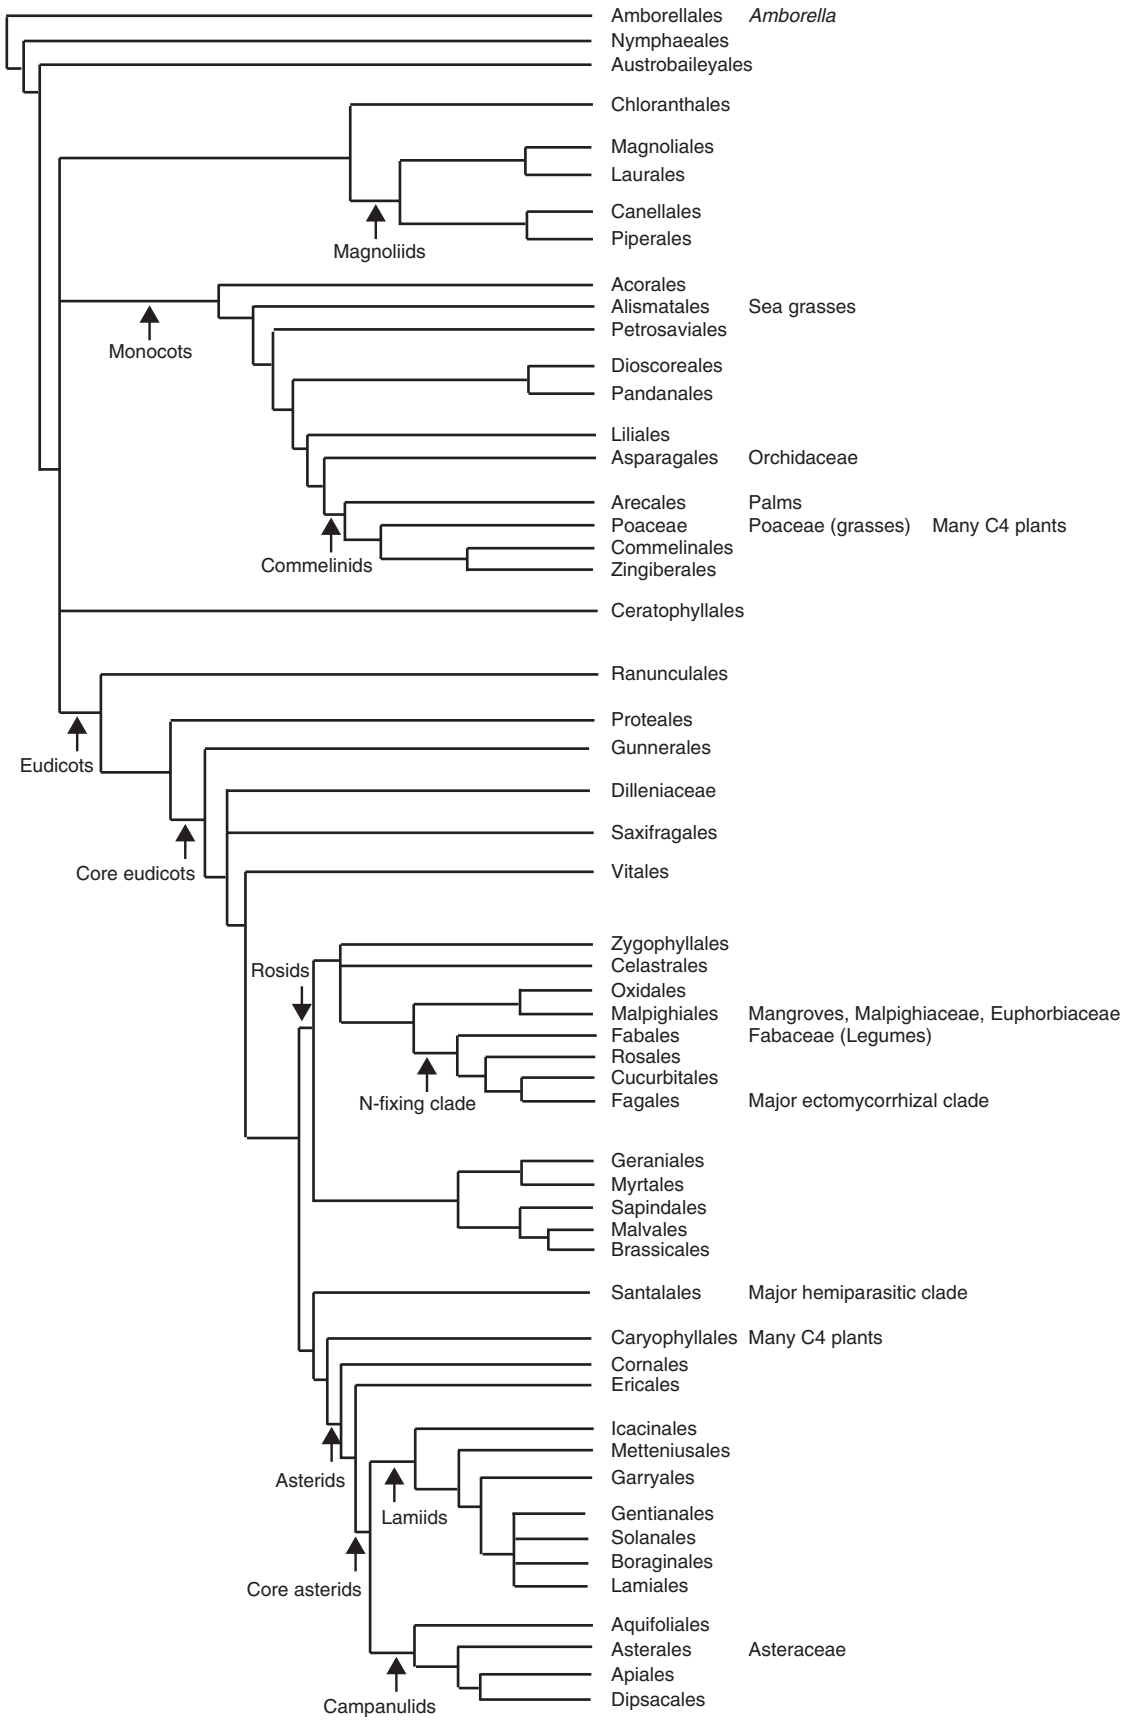

Figure 1 Angiosperm phylogeny, simplified and with additions from Stevens, Angiosperm Phylogeny Website Version 13, accessed 24.viii.2015.

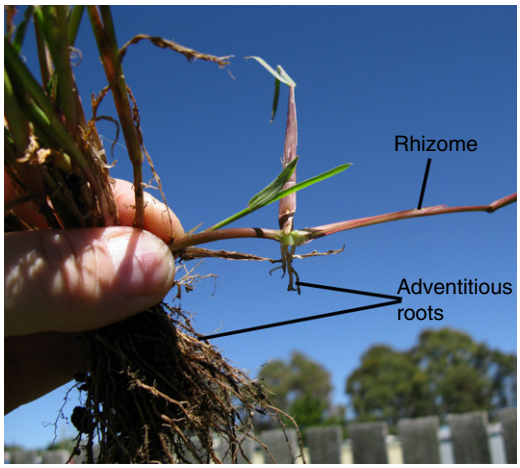

Figure 2 Adventitious roots in the Asian grass *Echinochloa colona*.

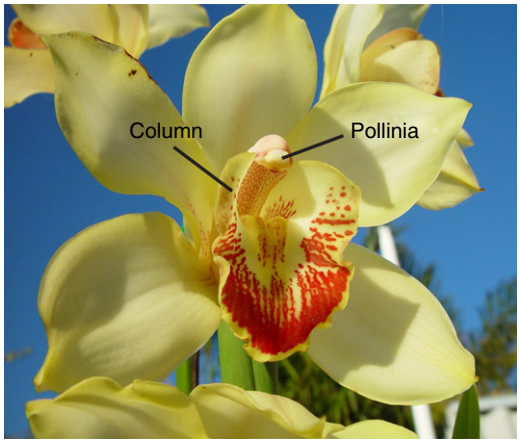

Figure 3 Hybrid *Cymbidium* (Orchidaceae) flower showing column and pollinia.

orchids, are the hyperdiverse clade in contrast to orchids as a whole or to other groups of orchids. Most Epidendroideae are epiphytic. Consistent with life in this aerial environment, with limited access to water, many species employ CAM photosynthesis, they often have exposed fat roots that grasp the substrate and can carry out photosynthesis, and the modified outer surface of the root plays a role in water/nutrient uptake. Such features provide another context for thinking about orchid diversity.

Poaceae (grasses, 11 340 species) are by far the largest wind-pollinated clade in angiosperms, although as with the orchids, it is arguably a single clade within the grasses, called the PACMAD/BOP clade, with 11 310 species, that is most species-rich (Figure 1). This clade includes most familiar grasses such as the economically important cereal grains as well as turf grasses. Even within this group it is particular subclades that are diverse; these subclades have specific features that may have allowed them to diversify: C_4 photosynthesis (PACMAD grasses), a form of woodiness (Bambusoideae, bamboos), association with fungal endophytes, and adaption to cooler conditions allowing the family to move into different climatic zones (Pooideae, including cereal, lawn, and pasture grasses) (Kellogg, 2015). In grasses in particular, fossil and molecular dates are at odds, some molecular estimates being half the age of fossils ascribed to the family.

Diversification in Core Eudicots

One of the distinctive features of nearly all core eudicots, a clade which includes the majority of angiosperm species, is the standardization of floral architecture. Flowers often have 5 sepals, 5 petals, two whorls of 5 stamens, and 3 or 5 fused carpels, with the position of the organs in each whorl alternating with those of the previous whorl (Soltis *et al.*, 2016). It has been suggested that the whorled structure allowed for fusion of floral organs, for instance fusion of the petals into a tube, dish, or bell shape. This allowed for tremendous elaboration of floral morphology, thought to be driven largely by adaptation to pollinators.

One of the largest core eudicot clades is the rosids (roses and much more), with around 85 830 spp. (Figure 1). There are three main groups of rosids that vary in the key features that distinguish them and may have driven their diversification. Malpighiales (16 000 spp.), a heterogeneous group including species such as willows, flax, and violets, represents a disproportionate number of the smaller trees of the lowland tropical rainforest. Diversification in this group is at the subclade level. For instance, Malpighiaceae (1250 spp.) is largely New World, and its members have functionally inverted flowers; oil from glands on the backs of the sepals is the reward for pollinating bees. Malpighiaceae have moved nine times or so to the Old World, but there are few species there, the plant–bee association has broken down, and nectar is often the reward (Davis *et al.*, 2014). Another family in Malpighiales, Euphorbiaceae (*Hevea*, rubber, 6745 spp.), includes one clade of 4860 species characterized by having poisonous latex in the tissues, presumably a defense against herbivory; within this clade the genus *Euphorbia* (poinsettia, crown-of-thorns) alone includes 2420 species. *Euphorbia* species have a great diversity of life forms including succulents superficially similar to New World cacti. Species show both CAM and C_4 photosynthesis (Horn *et al.*, 2014), and the genus is characterized by a unique and remarkable inflorescence in which the flowers are reduced to single stamens or pistils, and these are clustered together and surrounded by showy colorful bracts (Figure 4). Thus the entire inflorescence resembles a single flower, although the adaptive advantage of this is not entirely clear. Thus even within *Euphorbia* high species numbers can be linked with many different factors.

Another large and diverse group within rosids, the 'nitrogen-fixing clade' (31 215 spp.) is characterized by bacterium-mediated nitrogen fixation, of central importance in the global nitrogen cycle and to agriculture (Figure 1). This clade includes legumes, roses, apples, squashes, oaks, walnuts, and much more, and most species do not fix nitrogen. Nonetheless, this bacterial–plant symbiosis appears to have evolved 14 times or more here alone among all angiosperms. In this symbiotic association, bacteria convert atmospheric nitrogen into compounds that are metabolically available to the plants, allowing them to invade and survive in nitrogen-poor soils. The bacteria involved include both gram positive (actinobacteria) and gram

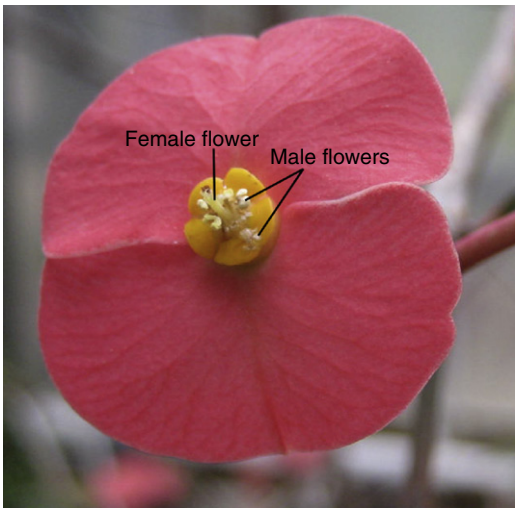

Figure 4 Inflorescence of Gerold's spurge (*Euphorbia geroldii*) showing individual male and female flowers.

negative (alpha and beta proteobacteria). A number of the genes involved in the establishment of these symbioses appear to have been coopted from those involved in mycorrhizal associations, and in legumes, at least, the molecular pathways involved in producing root hairs are also involved in the production of infection threads, structures that facilitate the movement of bacteria deep into the roots where the nodules in which they fix nitrogen develop (Sprent, 2009).

Finally, the core asterids include over 85 000 species (Figure 1). Here the range of floral architecture is further narrowed: petals are fused into a corolla, the stamens are often fused to the corolla, and generally there is only one whorl of 5 or fewer stamens. Like Orchidaceae, basic floral variation is limited, yet overall diversity is very high, the basic floral plan allowing for variation in flower symmetry, organ shape, size, and color; the flowers, when small, may be grouped in inflorescences, the unit of pollinator attraction. One vegetative feature that in some clades is correlated with increased diversification is a transition away from the woody tree habit. In the lamiid (also called euasterid I) clade (mints, nightshades, and many more), the three basal clades are all woody and species poor. Other (largely) woody clades scattered throughout the core asterids are also relatively species-poor. Over 97% of the 23 810 species of Lamiales (including mints) have bilaterally symmetric flowers – and are mostly herbs or small shrubs. Asteraceae (aster family, 23 600 species) predominate within the campanulid (also called euasterid II) clade. They have a characteristic capitulum inflorescence (Figure 5), in which up to hundreds of individual flowers are clustered into a structure that resembles a single flower. Asteroideae is the youngest of 13 Asteraceae subfamilies but includes some 65% of its species. Its members are chemically diverse and have distinctive morphological features, but what spurred their diversification?

Success of a Different Kind

The importance of ecophysiological changes in the tree during angiosperm evolution cannot be overemphasized, since the

Figure 5 Inflorescences of Short's aster (*Aster shortii*) showing individual flowers.

changes have had, and continue to have, major effects on the biosphere. These changes include the evolution of dense leaf venation (above 5 mm mm^{-2}) along with associated changes such as a decrease in stomatal size and increase in stomatal density. Such changes have evolved at least three times in magnoliids, monocots, and eudicots, and were particularly marked in the Late Cretaceous. Their main effects, inseparably linked, are twofold. Photosynthesis can increase, because small dense stomata allow more CO^2 to diffuse in to the leaf, which is well supplied by water from the dense veins (Boyce and Zwieniecki, 2012). At the same time more water is lost through transpiration, and this increases the water content of the atmosphere (the other main component comes from evaporation) and rainfall increases – thus models suggest that venation density may have indirectly facilitated the spread of the diverse lowland tropical rainforest (Boyce and Lee, 2010).

Other ecophysiological changes have occurred in relatively few species, but they have disproportionate effects on the environment (Stevens, 2015). Communities of sea grasses, mangroves, and plants with ectomycorrhizal associations are all involved in massive and surprisingly long-term sequestration of carbon. C_4 plants often dominate in the communities in which they occur, they are often very productive, they cover very large areas of the globe – yet they have come to dominate only within the last 10 million years.

Plant–Pollinator Interactions

The evolution and diversification of flowering plants at one level can be thought of as being spurred by the evolution of the flower and the fruit. Interactions between plants and animals – some kind of coevolution – led to the diversification of both. Pollinator-mediated speciation is thought to be important in evolution, thus for over 150 years the match in corolla and bird bill size and shape has implied coevolution, the bird and flower evolving together. However, looking at what are often thought of specialist pollinators and the plants they pollinate suggests a rather different story.

Some 338 species of hummingbirds pollinate over 4500 species of plants, the plants representing many separate clades in which bird pollination was acquired independently. Hummingbirds began diversifying less than 30 mya, although

the first fossils are from the Oligocene of Europe (Abrahamczyk and Renner, 2015). Two hundred species of orchid bees, also New World, pollinate around 4000 species of plants; the bees evolved around 42 mya. Bumble bees include some 200 species that pollinate around 3000 species of plants. The bees probably diversified within the last 47 my. The story is similar with fruit-eating and flower-pollinating New World bats, and many other insect, bat, bird, and bee groups from all over the world (Stevens, 2015).

It is unclear whether the evolution of the pollinators preceded, was more or less contemporaneous with, or happened after that of the plants they pollinate – all three possibilities have been suggested. Obviously there has been some coevolution between plant and animals, but in many cases the plant may have evolved to 'fit' the morphological and sensory predilections of the animal – much recent evolution has been in the plant, not in the animal (Guimarães *et al.*, 2011; Schiestl and Dötterl, 2012). Diversification of the two parties may have occurred together in hummingbirds, but members of quite different clades of plants can be pollinated by the one hummingbird, and something other than simple coevolution is likely here, too. And classic examples of apparent coevolution such as fig. and fig wasps and yuccas and yucca moths are being reinterpreted (Yang *et al.*, 2015).

Epilogue

All in all, understanding the forces that drive plant diversification can be very tricky. Importantly, how do we measure diversity and success? By the numbers of species in clades, by their morphological, phylogenetic, or ecological, divergence, or their importance to the community/ecosystem/biosphere as a whole? In much literature – especially the earlier literature – on diversification, species numbers are the measure of diversity/success used (c.f. Givnish, 2015), and what they alone can tell us is limited. However, ecologically interesting traits are being mapped onto phylogenies (e.g., Zanne *et al.*, 2014), while databases of critically evaluated morphological characters currently being assembled will allow classical morphology to be mapped to the tree in new ways. Estimates of carbon sequestered in plants, associated fungi, and the soil will allow us to understand better the effects of small clades of ecologically dominating plants on the environment. We are only now beginning to understand diversification.

Animal: What Is an Animal?

SA Nichols, University of Denver, Denver, CO, USA

Glossary

Adherens junction A cell junction that occurs at points of cell contact in adjacent cells (most notoriously in epithelial cells). Adherens junctions are composed of defined protein complexes that include cadherin receptors, and cytoplasmic adapter proteins (catenins) that link to the actin cytoskeleton.

Blastula A hollow sphere of cells surrounding a fluid-filled cavity. Many animals produce a blastula stage embryo early in development, prior to gastrulation.

Cambrian The first geologic period of the Paleozoic era, lasting from ~542 to 485 million years ago. Most modern animal lineages have a fossil record that extends to this period.

Cell junction Molecularly and functionally defined protein complexes that connect cells to each other or to the extracellular matrix and have functions ranging from adhesion to barrier formation to regulate ionic and molecular transport between cells.

Clade Synonymous with 'monophyletic group.' Refers to an ancestor and all of its descendents.

Ediacaran The last geologic period of the Neoproterozoic era, lasting from 635 to 542 million years ago. This period immediately preceded the Cambrian period.

Eukaryote Cellular organisms with membrane bound organelles such as the nucleus. This large diverse group includes all life forms except for Bacteria and Archaea.

Extracellular matrix The external environment of cells, typically composed of molecules secreted by the cells for structural support and for cell communication.

Extant Alive today (i.e., not extinct).

Filopodia Cytoplasmic projections from cells that contain actin as the primary cytoskeletal component. Filopodia frequently function in cell migration.

Gastrulation The developmental process whereby embryos undergo morphological changes to create internal and external tissue layers.

Homolog In the context of this article, homolog refers to two genes in different organisms that are derived from a single gene in their common ancestor.

Microvilli Cellular protrusions that often function to increase cellular surface area (e.g., in the gut or kidney) or in mechanosensation (e.g., cochlear hair cells). Microvilli are similar to filopodia except that they occur in groups instead of singly, they usually have a polarized distribution on the cell, and they have very regular (and regulated) lengths.

Monophyletic A group of organisms that are descended from a single common ancestor. Synonymous with 'clade.'

Mutagenesis screen A laboratory technique used to create genetically modified organisms. The purpose of a mutagenesis screen is to identify genes that affect specific traits.

Phylogeny A branching diagram that depicts the evolutionary relationships of organisms to each other.

Taxa The plural form of the word taxon, which refers to a named group of organisms such as a species, or even a more inclusive clade such as 'vertebrates.'

Ultrastructure In the context of this article, ultrastructure is used to refer to subcellular organization of an organism.

The word 'animal' conjures images of macroscopic, sexual organisms that swim, crawl, fly, run, and that eat plants and other animals. However, when one begins to look across the full spectrum of modern animal diversity, it becomes more challenging to develop a comprehensive definition. For example, all animals move, but sponges and placozoans lack muscles and nerves and move instead by cellular migration or ciliary action. Likewise, sexual reproduction is an ancient trait, ancestral to all modern animals, but bdelloid rotifers have secondarily evolved to reproduce only asexually (Flot *et al.*, 2013; Welch and Meselson, 2000). Indeed, one can find examples that challenge our concepts about how animals feed, the basic construction of animal tissues, and arguably even the idea that animals are exclusively multicellular.

The first part of this article will review modern animal diversity and will highlight the features that are commonly reported to be diagnostic of animals. The second part will examine the question of animal diversity by looking back through time at the early fossil record of animals, and by looking forward to some of the more bizarre trajectories that animal evolution may take in the future.

Modern Animals and Their Closest Eukaryotic Relatives

Animals evolved in the ocean, and here the overwhelming majority of modern animal phyla are found exclusively. Based upon our current understanding of animal phylogeny, we recognize seven major monophyletic groups: sponges, ctenophores, placozoans, cnidarians, ecdysozoans, lophotrochozoans, and deuterostomes (**Figure 1**). These groups are really not equivalent in any way; least of all in terms of body plan complexity. For example, sponges are one of the most ancient animal lineages, but they exhibit a high degree of morphological homogeneity; in contrast, the relatively younger deuterostome lineage includes organisms as diverse as

 doi:10.1016/B978-0-12-800049-6.00268-7

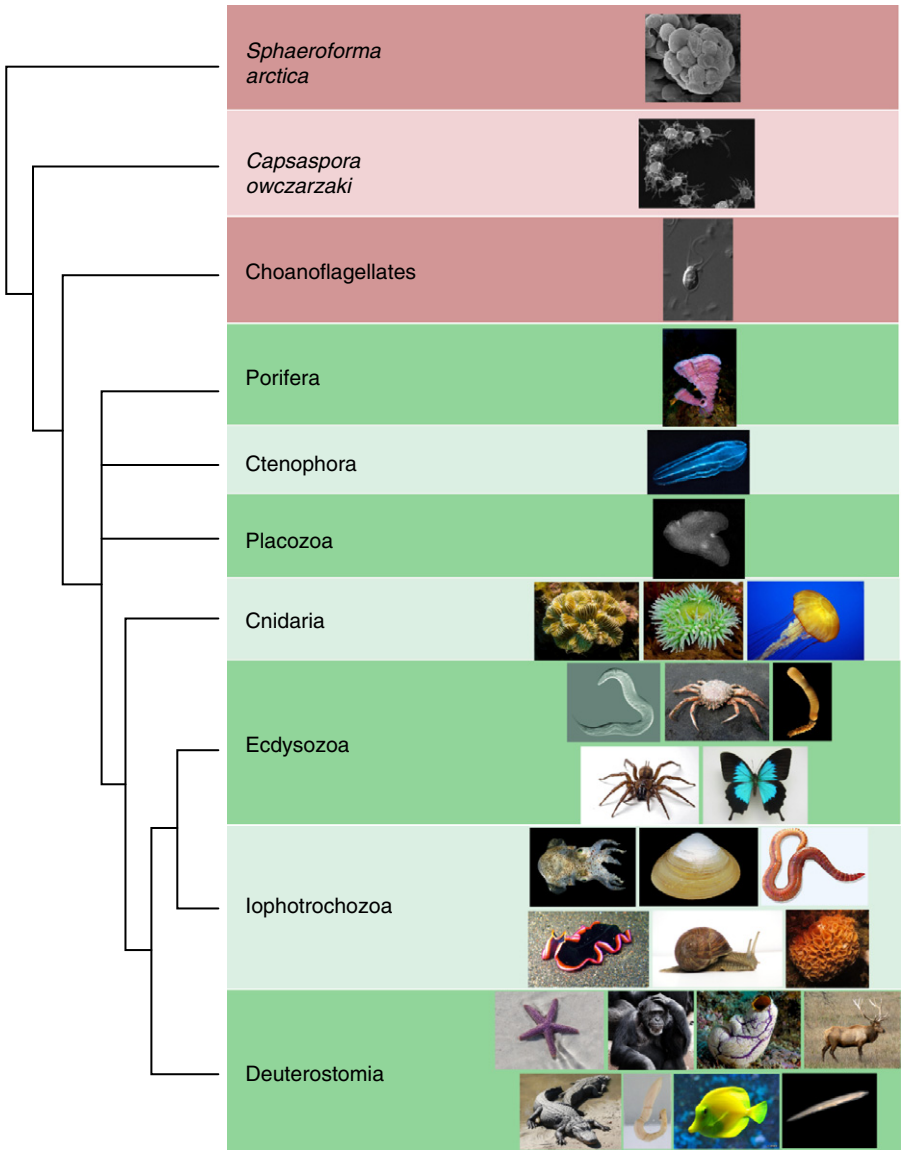

Figure 1 Seven major groups of extant animals and their close relatives. Modern animal diversity (shown in green) is well characterized, but some evolutionary relationships are still uncertain. The largest and most diverse group of modern animals are the bilaterian lineages: ecdysozoa, lophotrochozoa, and deuterostomia. It is from these three lineages that most of our generalizations about animal biology are derived, both because we belong to the deuterostome lineage, but also because the major biomedical research models such as the fruit fly, worm, frog, and zebrafish belong to these lineages. There is considerable controversy about the evolutionary relationships among non-bilaterian animals: the ctenophores, sponges, cnidarians, and placozoans. These lineages diverged from each other and from bilaterians early in animal evolution. Thus, their relative simplicity has long contributed to speculation about the evolutionary sequence by which bilaterian-grade complexity evolved. The evolutionary connection of animals with nonanimals (shown in red) has only recently been discovered. These lineages include choanoflagellates, *Capsaspora owczarzaki*, and ichthysporeans such as *Sphaeroforma arctica*. Research into the biology and genomes of these enigmatic lineages has significantly contributed to our understanding of cellular and genomic evolution in the animal stem lineage.

acorn worms, lancelets, sea squirts, starfish, birds, fish, turtles, and mammals.

Despite major advances in our understanding of animal phylogeny, driven primarily by molecular and genomic data, notable debates continue. For example, there is no community-wide consensus about the relationships among non-bilaterian lineages (**Figure 1**). These are the most ancient animal lineages and it has been proposed that they diverged from each other over a relatively short time period, conditions known to confound current methods of phylogenetic reconstruction (Rokas *et al.*, 2005). Of particular importance is the question of whether ctenophores branch before sponges, or whether sponges branch before ctenophores – a controversy that has emerged from the analysis of large, genome-scale datasets (Dunn *et al.*, 2008; Moroz *et al.*, 2014; Philippe *et al.*, 2009; Pick *et al.*, 2010). Ctenophores have muscles, nerves, and a gut, whereas sponges do not, so resolution of this phylogenetic controversy has implications for how we

interpret their disparate body plans. Did ctenophores evolve these features in parallel with bilaterian organisms, or was the last common ancestor of animals considerably more complex than modern sponges? It may come as a greater surprise that, even within Bilateria, there are a number of taxa that defy confident classification. Examples include acoel flatworms, *Xenoturbellida*, chaetognaths, and Orthonectida (Holland, 2011).

For this discussion of what defines an animal, the most important consideration is that the monophyly of animals is well established. All of the seven major clades identified above (and even the anomalous taxa that so far defy classification) are derived from a single common ancestor, to the exclusion of all other (known) living organisms. Moreover, there is high confidence in the phylogenetic position of the closest eukaryotic relatives of animals. As shown in **Figure 1**, choanoflagellates are the closest relatives of animals, followed by the filasterian *Capsaspora owczarzaki* and icthyosporeans such as *Sphaeroforma arctica* (Ruiz-Trillo *et al.*, 2008). This means that the term animal is phylogenetically well-constrained: even though there are gray areas within the animal tree of life (i.e., about which lineages fit where), there is no ambiguity about which organisms are animals and which are not. As elaborated below, this assertion erodes when the fossil record is taken into account.

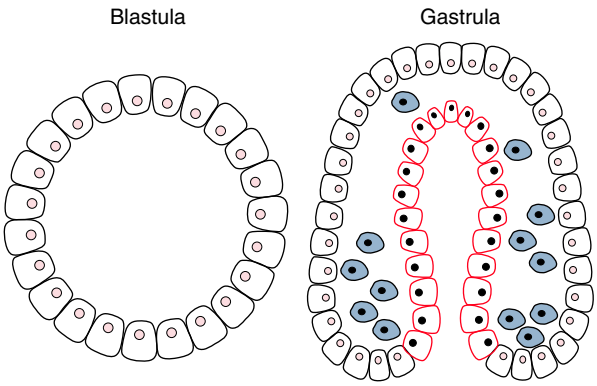

Figure 2 Stereotypical developmental stages of animal embryos. Gastrulation in animals is the transition from a blastula stage embryo (left) to a gastrula stage embryo (right). Whereas the blastula is a hollow ball of cells, the gastrula has an outer layer called the ectoderm, and internal layer called the endoderm (red cells). The cells between these two layers (blue cells) comprise the mesoderm. At this stage, each of these embryonic tissues is fated to give rise to specific adult tissue and organ systems.

What Features Do All Animals Have in Common?

Multicellularity

Perhaps the most fundamental characteristic of modern animals is that they are composed of more than one cell. Moreover, they have differentiated cell types with specialized and integrated functions (e.g., tissues and organs). Whereas multicellularity has evolved many times throughout evolutionary history, the degree of cellular differentiation and integration exhibited by animals is rare. Without delving into a more nuanced discussion of the topic, green plants and possibly fungi, social amoebae, and brown algae also have multicellular states with differentiated tissues, but to a considerably lesser degree than most animals.

So, is there anything unique about animal multicellularity that distinguishes it from other forms of multicellularity across the tree of life? The traditional view is that animals evolved multicellularity independently of other lineages. Part of the evidence for this view comes from distinctive features of animal cell and developmental biology. For example, animals do not have cell walls like fungi and plants, whereas they do have unique features such as specialized cell–cell junctions, adhesion molecules (Abedin and King, 2010), and embryonic features such as a blastula stage that undergoes gastrulation (**Figure 2**). However, the most relevant comparison point for determining whether animals evolved from an immediate unicellular ancestor or an immediate multicellular ancestor is the sister group of modern animals, the choanoflagellates. Multicellular choanoflagellate species (**Figure 3**) are widespread

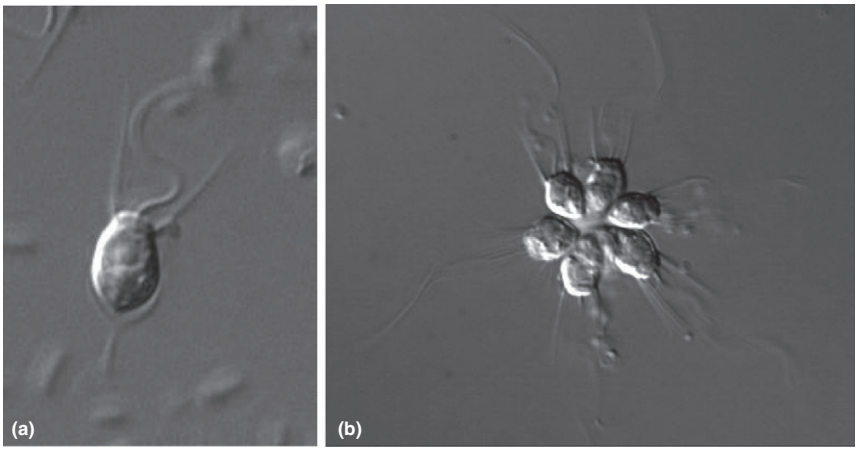

Figure 3 Unicellular and multicellular life history stages in choanoflagellates. Whereas all choanoflagellates have unicellular life history stages (a), some such as *Salpingoeca rosetta* are capable of producing undifferentiated colonies through serial cell division (b). Photo credit: Mark Dayel, Wikimedia commons.

and abundant in nature, but they differ from animals in three important ways: (1) all known species are believed to have free-living unicellular stages; (2) there is no obvious cellular differentiation or division of labor within multicellular colonies; and (3) there are considerable ultrastructural differences between colonies within different choanoflagellate clades, possibly indicating independent origins of multicellular colony formation within choanoflagellates (Nichols *et al.*, 2009). Thus, one possibility is that there may be no evolutionary connection between choanoflagellate multicellularity and animal multicellularity.

A contrasting view comes from recent experimental studies from choanoflagellates. In a study by Fairclough *et al.* (2013), different life history stages of the colony-forming choanoflagellate *Salpingoeca rosetta* were evaluated by gene expression profiling. One conclusion from this study was that genes shared by choanoflagellates and animals were disproportionately expressed in colonial life history stages, and in cells fated to develop into colonies. More recently, Levin *et al.* (2014) used a mutagenesis screen to identify a C-type lectin that is required for the development of a specific multicellular colony morphology (rosettes) in *S. rosetta*. C-type lectins have carbohydrate-binding domains and function in cell adhesion in animal tissues, so this study may indicate a more ancient role for C-type lectins in multicellular evolution.

Finally, evidence for an even more ancient multicellular ancestry of animals may also come from a distant eukaryotic relative of animals, the social ameba, *Dictyostelium discoideum*. On the surface, multicellularity in *D. discoideum* is very different than either choanoflagellates or animals, which both develop clonally through serial cell divisions; *D. discoideum* gives rise to a transient multicellular structure called a 'fruiting body' through aggregation of genetically different individuals (**Figure 4**). Thus, it seems unlikely that there could be any evolutionary or mechanistic connection between these very disparate and phylogenetically disjunct forms of multicellularity. However, a recent study by Dickinson *et al.* (2011) found that candidate homologs of the animal cell adhesion genes α- and β-catenin interact in *D. discoideum*, like they do in animal cells and are required for the organization and polarity of the outer epithelium of the fruiting body in *D. discoideum*. This discovery raises the possibility that transient multicellularity is an ancient feature common to the biology of *Dictyostelium* and animals, and by extension, to intermediate lineages such as choanoflagellates and fungi (Dickinson *et al.*, 2012). However, see Parfrey and Lahr (2013) for a critique of this interpretation.

Figure 4 The fruiting body of *Dictyostelium discoideum*. The social ameba *D. discoideum* is predominantly unicellular in nature. Upon starvation, genetically distinct individuals aggregate to produce a multicellular structure called the 'fruiting body' for the production and dispersal of spores.

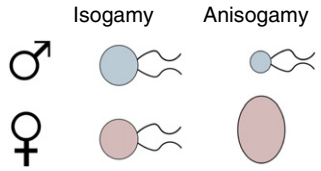

Figure 5 Isogamy vs. anisogamy. Isogamous organisms produce male and female gametes that are indistinguishable in size and shape. In contrast, all sexually reproducing animals are anisogamous and produce large nonmotile eggs and small motile sperm. Indirect evidence suggests that choanoflagellates may also be anisogamous.

Sex and Development

Sexual reproduction is very ancient and vastly predates animal origins, but the details of sexual reproduction in animals distinguish them from their closest relatives, such as choanoflagellates, and also from many other multicellular groups. Specifically, through the process of meiosis, animals typically produce a large haploid egg that is nonmotile, and small haploid sperm that are flagellated (i.e., they are anisogamous (**Figure 5**)). These gametes fuse to produce a diploid zygote that undergoes an orchestrated sequence of cell division, differentiation, and morphogenesis to produce an embryo with internal and external cell layers via the process of gastrulation. How does this compare to sex and development in choanoflagellates?

Sex in choanoflagellates is poorly understood. In fact, sex has only been detected in a single species, the emerging experimental model *S. rosetta*. Specifically, Levin and King (2013) found that the DNA content of isolated nuclei is consistent with a haploid/diploid sexual cycle that could only result from meiosis. Although the ploidy of different cell types and life history stages could not be directly determined in heterogeneous cultures, the existence of considerably distinct cellular size classes (and the observation that these different cell types can fuse) raises the possibility that the anisogamy

Figure 6 The demosponge, *A. queenslandica*, is native to Heron Island, Australia. As the subject of the first sponge genome sequencing, *A. queenslandica* has emerged as an experimental model for studying developmental mechanisms in sponges.

exhibited by animals may have more ancient evolutionary roots.

Comparisons of later steps in development between choanoflagellates and animals yield only one clear similarity: like animals, the development of multicellular structures in *S. rosetta* occurs by serial cell divisions, not by aggregation (Fairclough *et al.*, 2010). However, unlike most animals, cells within colonies are connected by long, thin cytoplasmic bridges rather than the protein complexes that tether animal cells at structures such as adherens junctions (Dayel *et al.*, 2011). Moreover, the process of gastrulation, the morphogenetic event leading to a multilayered embryo (see **Figure 2**), is a hallmark feature of animal development that bears little resemblance to any developmental event in choanoflagellates, or any other eukaryote for that matter.

The (often more varied) patterns of development exhibited by non-bilaterian animals offer a challenge to the idea that gastrulation is a general feature of animal development. In particular, there is currently little consensus over the homology of developmental processes and tissue layers between sponges and other animals. In bilaterian animals, the significance of the layered embryo that results from gastrulation is largely that cells in different regions are destined to different fates. For example, endoderm may give rise to the gut, mesoderm may give rise to muscles, and ectoderm may give rise to the nervous system. Then, how do the developmental programs of sponges, and the resultant adult tissues that arise from development, relate to concepts such as gastrulation and progressively fated tissue differentiation when sponges have neither a gut, muscles, nor a nervous system?

Nagaysu *et al.* (2014) recently used cell tracking methods in the sponge *Amphimedon queenslandica* (**Figure 6**) to examine whether layered tissues in sponge larvae give rise to specific tissue layers in the adult. The results from this study suggest that cells from internal and external larval tissues indiscriminately give rise to both the internal and external tissue types in the adult. Although it is difficult to generalize from the study of a single sponge species, this finding supports the idea that gastrulation is a later evolutionary innovation within animals.

Figure 7 *Riftia pachyptila*. Hydrothermal vent worms of the genus *Riftia* have secondarily lost a functional alimentary canal and instead derive their nutrition from the metabolic activities of symbiotic bacteria.

Feeding

Animals, like the vast majority of living organisms, are heterotrophs: they require organic carbon for growth. So, this is another characteristic that unites animals, but does not distinguish them from nonanimals. Where animals differ from nonanimal heterotrophs is that they are largely micro- or macrophagus, ingesting small or large food particles directly for digestion in a gut. This distinguishes them from osmoheterotrophs like fungi or many bacteria that directly absorb nutrients into their cells through the process of diffusion or active transport across the cell wall. However, even this distinction is not absolute. Animals like tapeworms have secondarily evolved osmoheterotrophy as a means of nutrition. Likewise, hydrothermal vent worms of the genus *Riftia* (**Figure 7**) have evolved to rely on indirect nutrition from symbiotic bacteria and have secondarily lost the need to 'eat' like other animals.

If we look outside of Bilateria, we find more exceptions to the typical modes of animal feeding. For example, placozoans feed in a way that is difficult to classify; they digest food in the space between their ventral surface and the substrate. This resembles digestion in a gut, but occurs outside of the organism. Due to the uncertain phylogenetic position of placozoans, it is unclear if this is an ancestral or derived mode of feeding in animals.

Most sponges feed without a gut altogether. Instead, they have specialized cells that filter bacteria out of the water for direct phagocytosis by individual cells. An exception to this feeding mode are the carnivorous sponges of the family Cladorhizidae (**Figure 8**), which have lost the water canal system and instead capture small animal prey on sticky appendages which undergo morphogenetic changes to surround the immobilized prey with a temporary gut-like structure for extracellular digestion (Vacelet and Duport, 2004).

The ancestral feeding strategy of modern animals remains an open question. It has long been held that the bacterivorous strategy of sponges is ancestral to all modern animals, partly because this feeding strategy is also exhibited by modern choanoflagellates. However, there are two caveats to this view. First, there are diverse multicellular fossils in Ediacaran deposits that are argued to have evolutionary connections to modern animals, either as stem-animals, or as unsuccessful

branches off the animal stem lineage (Figure 9). Many of these organisms are also argued to have bacterial and/or photosynthetic symbionts or to have been osmoheterotrophic (Xiao and Laflamme, 2009).

Another challenge to the view that sponge/choanoflagellate-like bacterivory is ancestral to modern animals is the possibility that modern ctenophores are the earliest evolutionary branch of modern animals rather than sponges (Dunn *et al.*, 2008; Moroz *et al.*, 2014; Ryan *et al.*, 2013). Ctenophores are carnivorous, complete with an alimentary canal much like bilaterian animals and cnidarians. If the proposed phylogenetic placement of ctenophores is correct, then they must have secondarily evolved a gut, or carnivory (or at least macrophagus heterotrophy) is the ancestral feeding mode for modern animals. Indeed, there is compelling fossil evidence that the earliest periods in animal evolution were influenced by interrelated environmental and ecological factors, such as increasing oxygen levels (Knoll and Sperling, 2014) and the evolution of predatory animals (Laflamme *et al.*, 2013). In fact, it has been proposed that the evolution of predation both preceded, and was the primary ecological driver for the diversification of modern animal body plans (Peterson and Butterfield, 2005).

Cells and Tissues

Animals are eukaryotes, and there is little deviation in their basic cellular ultrastructure compared to other eukaryotes. However, a feature common to animal cells that is worth mentioning as a possibly significant evolutionary innovation are the microvilli. Actin-based cellular protrusions are certainly not unique to animals, but a large diversity of animal cells have evolved to use patches of concentrated actin-based microvilli for myriad functions ranging from mechanosensation in vertebrate hair cells and on cnidarian tentacles, to increase surface area for absorption in the gut and kidney, as membrane reservoirs for cellularization of the embryonic epidermis in *Drosophila*, and to lubricate the mucosal epithelium of the vertebrate eye, to name only a few. Thus, it seems that actin-based microvilli represent an ancestral animal innovation that has been the subject of considerable evolutionary tinkering. However, actin-based microvilli are also found in choanoflagellates where they function to capture bacterial prey; as mentioned above, this feature is conserved in sponge choanocytes and possibly reflects the ancestral function for microvilli in the animal stem lineage. Moreover, it has been shown that the microvilli of choanoflagellates are similar in their molecular structure to filopodia (Sebe-Pedros *et al.*, 2013), which are more widespread throughout eukaryotes and are the likely evolutionary precursors to microvilli.

Figure 8 Carnivorous sponge. Demosponges of the family Cladorhizidae have secondarily lost the water canal system used by other sponges for feeding on bacteria. Instead, these sponges have independently evolved carnivory, whereby fine projections capture macroscopic prey which are immobilized and digested extracellularly.

In general, animals exhibit a huge diversity of cell/tissue types (e.g., muscles, nerves, etc.) and common ultrastructural features such as cell junctions (e.g., tight junctions, adherens junctions, etc. (Figure 9)) that are not found in nonanimals. However, the problem remains that it is difficult to generalize due to exceptions such as placozoans and sponges, which each lack some of these features, cnidarians which are argued to have independently evolved striated muscles (Steinmetz *et al.*, 2012), and ctenophores which have been argued to have independently evolved their nervous system (Moroz *et al.*, 2014).

Perhaps the only cell/tissue type that is ubiquitous among animals are epithelial tissues. Epithelia are thought to have been the first animal tissues to evolve (Tyler, 2003). However, there is still no structural or developmental evidence that the tissues of sponges are homologous to epithelia in other animals. They certainly have conserved homologs of the adhesion and polarity markers known from bilaterian epithelia (Fahey and Degnan, 2010; Nichols *et al.*, 2006, 2012), but it has not been experimentally determined how these proteins function in sponges.

A Genomic Perspective

The idea of using molecular characteristics of cells and tissues to distinguish animals from nonanimals is not new. One long-standing example is that an extracellular matrix composed of

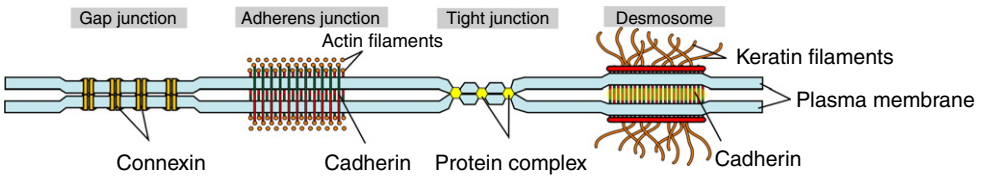

Figure 9 Cell junctions. The cells of animal epithelia have specialized contacts critical for their function. Gap junctions create pores that connect the cytoplasm of neighboring cells and are used for intercellular communication. Adherens junctions and desmosomes tether neighboring cells and mechanically integrate their cytoskeletons. Tight junctions pinch the membranes of neighboring cells together to restrict and transport of materials across tissues via the paracellular space. Each of these junctions is composed of a discrete, defined set of proteins.

collagen has long been considered to be diagnostic of animals (Exposito *et al.*, 2002; Garrone, 1999). However, the dramatic expansion of available genome/transcriptome/proteome scale data from animals and nonanimals in the past 10 years has set the stage for unprecedented molecular comparisons. One such comparison revealed that choanoflagellates have fairly typical eukaryotic mitochondrial genomes, which are larger and contain many genes that are absent in the reduced mitochondrial genomes of animals (Burger *et al.*, 2003). This serves as important corroboration for molecular phylogenetic analyses that support choanoflagellates as sister to animals, rather than being nested within animals (e.g., derived from sponges).

More recent genome/transcriptome sequencing efforts (far too vast to review here) have further revealed that genes required for basic multicellular processes in animals (e.g., developmental patterning, cell adhesion, tissue polarity, etc.) are highly conserved in all modern animals. Even genes that contribute to features such as the neuronal synapse are largely present in all animals, even those such as sponges and placozoans which lack neurons (Burkhardt *et al.*, 2014; Moroz *et al.*, 2014; Sakarya *et al.*, 2007; Srivastava *et al.*, 2008). Thus, there are certainly many genes and protein families that are so far known from all animals, and only from animals, and can therefore be considered to be diagnostic features of animals. However, it is worth noting that there are a number of exciting exceptions to the idea that genes involved in multicellularity are restricted to animals. Examples include the early discoveries that the genome of the unicellular choanoflagellate *Monosiga brevicollis* encodes more receptor tyrosine kinases than the human genome (King and Carroll, 2001; King *et al.*, 2008), and has as many as 23 cadherin-related genes (Abedin and King, 2008). However, these exceptions notwithstanding, the overwhelming pattern to emerge from comparative genomic studies is that all modern animals are united by many genomic features found nowhere else in the tree of life, suggesting that there was considerable genomic innovation in the animal stem lineage.

Extinct Animals and Future Directions of Animal Evolution

It is one thing to define animals based upon the characteristics shared by extant lineages, but things get more difficult when the fossil record is taken into account. The problem is not necessarily with tracing the ancestry of extant lineages; for the most part, most modern animals (at least those that preserve well) can be traced back to the Cambrian. Instead, the problem arises when we ask what life was like prior to the appearance of modern lineages. There has been considerable debate over the identity and interpretation of the so-called 'Ediacaran Biota' that existed just prior to the Cambrian (**Figure 10**). While it is beyond the scope of this article to review the diversity of, and debate about the Ediacaran Biota, it is worth noting that these were among the first multicellular, macroscopic organisms on earth. They existed for more than 60 million years before they suddenly disappeared and were replaced by more modern-like animals at the Cambrian/Pre-Cambrian boundary. One possibility is that members of the Ediacaran Biota represent early animal ancestors. Another possibility is that they represent early branches off the animal stem lineage. Finally, it is possible that they are multicellular eukaryotes with no special relationship to animals at all. Arguments can be made in favor of any one, or combination, of these possibilities. If these were indeed the first animals, then the animals of the past were considerably different from modern animals.

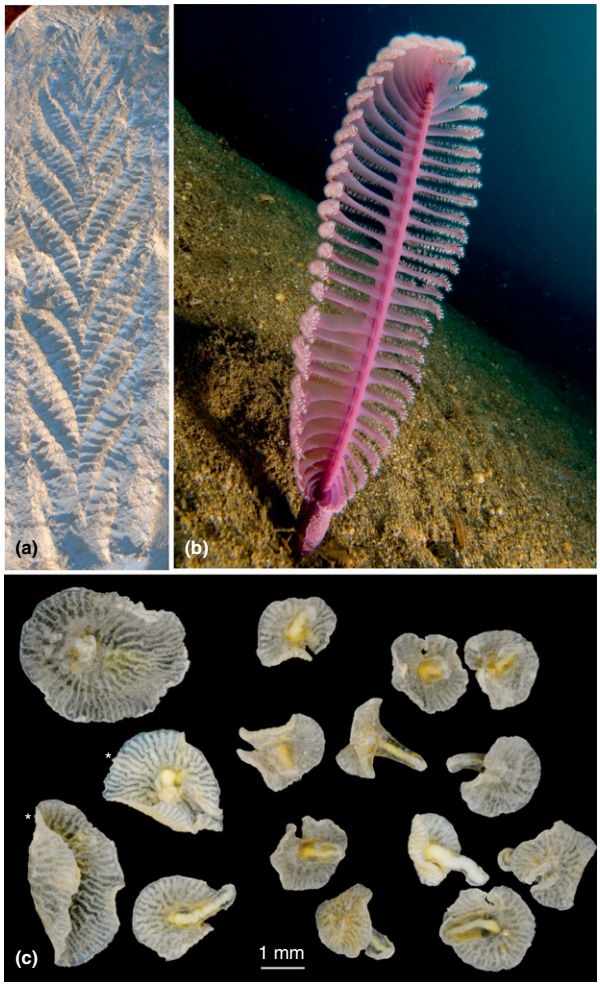

Figure 10 Ediacaran biota. Ediacaran organisms predate the appearance of animals in the fossil record. They may be stem-group animals, or they may represent an entirely independent experiment in multicellularity. Some, such as the members of the genus *Charnia* (a) have a frond-like appearance that resembles modern animals such as sea pens (b). However, the resemblance is believed to be superficial and does not reflect a direct evolutionary connection. Two recently discovered species of the genus *Dendrogramma* (c; Animalia, *insertae sedis*) also have been argued to share features with Ediacaran genera.

It is also worth considering whether any comprehensive definition of animals should be robust to future discoveries of anomalous animals, or even the future evolution of animal lineages away from their modern incarnations. There is still possibly room for the discovery of new, bizarre animals that further challenge our notions of modern animal diversity, albeit slight. One recent example is the recently described deep sea species, *Dendrogramma enigmatica* and *Dendrogramma discoides* (Just *et al.*, 2014; **Figure 10**). These species are intriguing

in that they superficially resemble cnidarians and ctenophores, although they lack diagnostic features of these lineages (cnidocytes and colloblasts). It has been argued that they share similarities with three Ediacaran genera, *Albumares*, *Anfesta*, and *Rugoconites*. At the time of this writing it is unknown if *Dendrogramma* has any evolutionary connection to non-bilaterian animals, much less to Ediacaran genera thought to be extinct for more than 500 million years. Nevertheless, this controversy highlights the potential for future discoveries of cryptic animals (particularly in the deep sea) to challenge our understanding of early animal diversity and evolution.

Finally, an even more controversial, but intriguing, possibility is that the emergence of sexually transmitted cancers may represent speciation events in which new unicellular animal species have evolved from vertebrate ancestors. One example is the canine transmissible venereal tumor (CTVT) (Dingli and Nowak, 2006). The tumor cells themselves are transmitted from one individual to the next during copulation and are not derived from the dog they infect. This tumor cell line has persisted as a self-maintaining, naturally occurring lineage for at least several hundred, and possibly several thousand years (Murgia *et al.*, 2006). Although controversial, CTVT can be argued to represent a novel, unicellular lineage derived from a canine ancestor: in short, a unicellular dog species. This provocative view can certainly be challenged, but it does at least open the door to imagining how future animals could depart dramatically from their modern ancestors. Thus, perhaps the most useful answer to the questions of 'what is an animal?' should not rely upon a checklist of traits, whether morphological, molecular, physiological, genomic, or otherwise. Instead, the only enduring definition may need to be phylogenetic in nature.

Phylogenetic Definition of Animals

In biology, there are seldom absolute answers to even the most basic questions. This is because biology is the result of a dynamic process, evolution, which is contingent upon past events that are often unknown. Moreover, evolution does not stop. Even as you read, evolution continues to 'tinker' with each and every living species, and the future trajectories of these species are entirely unknowable – there are simply too many variables, most subject to chance, to make such predictions. Thus, the challenge to define an animal (or plant, or fungus, etc.) in absolute terms, is fraught from the onset.

The only valid answer to the question, 'What is an animal?,' is that they are all organisms descendent from the last common ancestor of sponges, ctenophores, and mammals. The virtue of this definition of animals is that it includes living and extinct organisms, and it is immune from change. As we discover new lineages that challenge our current concepts of animal diversity, or if in the future animals evolve toward bizarre, unrecognizable forms, this definition holds true.

Antagonistic Interspecific Coevolution

M Neiman, University of Iowa, Iowa City, IA, USA
P Fields, University of Basel, Basel, Switzerland

Glossary

Allopatric Organisms that do not coexist and that do not have a recent history of coexistence.
Arms Race coevolution Coevolution between pairs of biological antagonists driven by positive directional selection imposed upon each species by the other member of the pair. This type of coevolution can lead to the reciprocal acquisition of novel adaptations in the coevolving partners.
Directional selection Selection on more extreme values of a phenotype (e.g., toxicity and resistance to toxin). Directional selection can either be positive, whereby larger phenotype values have higher fitness, or negative, whereby smaller phenotype values have higher fitness. The former is considered to be the main source of selection underlying Arms Race coevolution.
Environment-allele frequency correlations Analytical approach to detect local adaptation that is based on identifying correlations between environmental variables and allele frequencies while correcting for population structure.
Frequency-dependent selection A form of natural selection driven by a relationship between the population frequency of a given phenotype or genotype and the fitness of this phenotype or genotype. Frequency-dependent selection can be positive, whereby fitness is a positive function of frequency, or negative, whereby fitness is a negative function of frequency. The latter is one of the main mechanisms driving host–parasite coevolution.
Genetic drift Nondeterministic shifts in allele frequencies.
Local adaptation A situation where native individuals possess higher relative fitness than individuals from other populations when measured in the native environment.
Outlier analysis Analytical approach aimed at identifying loci that show significantly distinctive values of population genetic statistics (e.g., Tajima's D, F_{ST}) as a means of, for example, detecting the loci likely to be involved in evolutionary responses to natural selection.
Population structure Nonrandom distribution of alleles across populations, typically detected as a significantly positive F_{ST}.
Red Queen coevolution Coevolutionary dynamics driven by negative frequency-dependent selection favoring rare phenotypes.
Resistance Host ability to reduce the fitness costs of parasitic infection and/or ability of the parasite to infect.
Sympatric Organisms that coexist within the same habitat and have a recent history of coexistence.
Virulence The extent to which a parasite reduces the fitness of its host. Higher fitness reductions translate into higher virulence.

What Is Antagonistic Coevolution?

All organisms face constant attack from biological enemies. Parasites and pathogens (hereafter, 'parasites', except when a particular pathogen species is being discussed) reallocate critical resources from their hosts, release toxins that cause serious host illness, or exploit host bodies for offspring production. Predators and parasitoids (hereafter, 'predators') take a more deadly approach, killing prey and hosts, respectively, to provide food for themselves or for their offspring.

As Darwin recognized in *The Origin of Species* (1859), interactions between species are likely to be a common driving force of evolutionary diversification, speciation, and adaptation. This idea can be taken one step further if we imagine that evolutionary responses in one species generated by selection imposed by a second species will generate new selection on the second species to adapt to the evolutionary change in the first species, a process of reciprocal selection and adaptation that could continue indefinitely. The evolution of reciprocal adaptations as a response to reciprocal selection, so-called 'coevolution' (originally defined by Erlich and Raven, 1964; see also Janzen, 1980), is increasingly recognized as a common and broadly important mechanism driving evolutionary change, adaptation, and diversification in nature (Erlich and Raven, 1964; Woolhouse *et al.*, 2002; Thompson, 2005; Laine, 2009).

The ubiquity of hostile interspecific interactions means that coevolution will often be a product of biological antagonism. Coevolution that is driven by antagonistic interactions, so-called 'antagonistic coevolution,' can be defined as reciprocal adaptation and counter-adaptation of two interacting species for which fitness is negatively correlated. In other words, an adaptation that increases fitness in one species will decrease fitness of the other species (Woolhouse *et al.*, 2002; Brockhurst and Koskella, 2013).

Besides the importance of understanding a common mechanism of evolution in natural populations, antagonistic coevolution is of special significance because of its perhaps unique potential to drive rapid diversification and speciation (Buckling and Rainey, 2002; Thompson, 2005; Paterson *et al.*, 2010; Schulte *et al.*, 2010; Karasov *et al.*, 2014) and the acquisition of novel adaptations (e.g., Hanifin *et al.*, 2008). Antagonistic coevolution is also thought to play a central role in the evolution of disease virulence (Ebert and Hamilton, 1996; Woolhouse *et al.*, 2002; Gómez and Buckling, 2011), mutation rates (Pal *et al.*, 2007), and sexual reproduction (Jaenike, 1978; Hamilton, 1980).

How Does Antagonistic Coevolution Work?

Theoretical and empirical studies of antagonistic coevolution have generally focused on two distinct mechanisms, one driven by negative frequency-dependent selection and the other by positive directional selection (Buckling and Rainey, 2002; Woolhouse *et al.*, 2002; Burdon *et al.*, 2013). These two mechanisms are expected to have fundamentally different influences on important evolutionary phenomena (e.g., the maintenance of genetic variation and sex) (Woolhouse *et al.*, 2002; Neiman and Koskella, 2009; Brown and Tellier, 2011; Hall *et al.*, 2011). Here, we make the distinctions between these two mechanisms clear. We also summarize many of the important distinctions (or lack thereof) between these mechanisms in **Table 1**.

Negative Frequency-Dependent Selection: Red Queen Coevolution

Frequency-dependent selection is defined as a situation where fitness is dependent upon the frequency of a phenotype or genotype in a population. Our focus here is on negative frequency-dependent selection, whereby fitness of a phenotype or genotype increases as its frequency in a population decreases. Negative frequency-dependent selection is believed to be a primary driver of coevolution between biological antagonists (e.g., Hori, 1993; Neiman and Koskella, 2009; Burdon *et al.*, 2013).

The idea that selection favoring rare genotypes or phenotypes might drive antagonistic coevolution began with J. B. S. Haldane (1949). In 1949, biologists were just beginning to discover that many species featured surprisingly high levels of genetic variation for 'resistance' to various diseases – diversity that should quickly be lost if only one or a few phenotypes or genotypes consistently conferred resistance. Haldane (1949) suggested that the maintenance of this diversity could be explained by a situation where parasites disproportionately attack common host types – simply because the parasites have adapted to exploit a common host resource. Here, a mutation that conferred a rare 'biochemical phenotype' (Haldane's words) could confer parasite resistance because parasites have not yet had an opportunity to adapt to this rare phenotype. Because rare hosts are disproportionately uninfected by parasites, they have high fitness relative to the heavily infected common hosts and, as such, do not stay rare for very long.

Table 1 Comparison between the characteristics and signatures of Arms Race and Red Queen coevolution[a]

	Arms Race	*Red Queen*
a. General properties		
Type of selection	Positive directional	Negative frequency-dependent
Fate of selected variation	Selected variants often fix; other variants lost	Cycles
Potential to generate evolutionary innovation	Relatively high	Relatively low
b. Virulence/resistance phenotypes		
Virulence/resistance is inherent property of genotype	Yes	No
Systematic increase in virulence/resistance over time	Yes[b]	No
Universal virulence/resistance	Yes	No
Tradeoff or cost associated with virulence/resistance	Often	Sometimes
c. Molecular signatures		
Local maintenance of polymorphism	No	Yes
Trans-species polymorphism	No	Yes
Linkage disequilibrium associated with selected locus	High relative to mean genome linkage disequilibrium	No clear expectations
F_{ST} of selected locus (in the absence of overall population structure for either member of the coevolving pair)	Low relative to neutral loci	Sometimes low relative to neutral loci
F_{ST} of selected locus (with the presence of overall population structure for either member of the coevolving pair)	High relative to neutral loci	Sometimes low relative to neutral loci
Tajima's D (in the absence of overall population structure for either member of the coevolving pair)	Low relative to neutral loci	High relative to neutral loci
Tajima's D (in the presence of overall population structure for either member of the coevolving pair)	High relative to neutral loci	High relative to neutral loci
Coalescence time of selected locus (in the absence of overall population structure for either member of the coevolving pair)	Short relative to neutral loci	Long relative to neutral loci
Coalescence time of selected locus (with the presence of overall population structure for either member of the coevolving pair)	Long relative to neutral loci	Long relative to neutral loci
d_N/d_S	Elevated relative to neutral loci	Often elevated relative to neutral loci

[a]All cases invoking presence/absence of population structure assume that analyses are across all populations.
[b]Rate of increase of virulence/resistance may slow as costs increase and/or as genetic variation is lost (e.g., Hall *et al.*, 2011).

In parallel, the parasites reduce the fitness of common hosts to the extent that the common hosts are soon made rare, the timing of which will be determined by the degree to which parasite adaptation lags behind the host (Dybdahl and Lively, 1998). The implications are that host rareness could provide a profound fitness advantage that would dissipate as parasites adapted to the formerly unfamiliar host genotype, preventing common host genotypes from fixing and avoiding the loss of rare host genotypes (**Figure 1(a)**). These ideas were further developed by biologists such as Donald Levin (Levin, 1975), Bryan Clarke (Clarke, 1976), John Jaenike (Jaenike, 1978), and William Hamilton (Hamilton, 1980; Hamilton *et al.*, 1990).

Negative frequency-dependent selection is considered by many evolutionary biologists to be a particularly important and interesting form of natural selection because, unlike directional and stabilizing selection, negative frequency-dependent selection favors rare genotypes and can thus maintain high levels of genetic diversity. In contrast to Arms Race models (see below), coevolutionary models like the Red Queen that are based exclusively on negative frequency-dependent

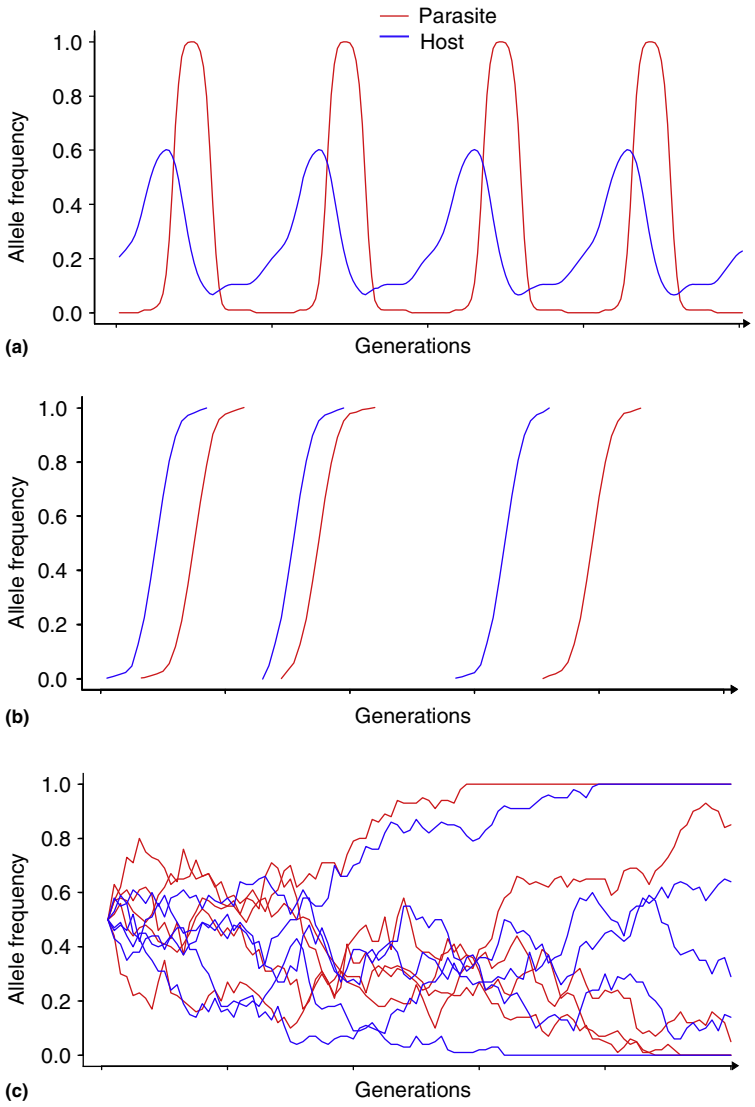

Figure 1 Changes in allele frequencies of loci responsible for coevolutionary dynamics of host (blue lines) and parasite (red lines) under different theoretical models. (a) After Lively (1999), a Red Queen dynamic describes the cyclical, time-lagged increase in the frequency of the parasite allele that infects the common host followed by a decrease of frequency of this parasite allele as the target host allele becomes less common, (b) an Arms Race dynamic wherein the fixation of alleles occur in series in a reciprocal, escalating manner as the coevolutionary process takes place, and (c) shifts in allele frequency resulting from neutral genetic drift, with each line a separate iteration of the same stochastic process. Panels (a) and (b) are adapted from Woolhouse, M.E., Webster, J.P., Domingo, E., Charlesworth, B., Levin, B.R., 2002. Biological and biomedical implications of the coevolution of pathogens and their hosts. Nature Genetics 32, 569–577 and Neiman, M., Koskella, B., 2009. Sex and the Red Queen. In: Schön, I., Martens, K., van Dijk, P. (Eds.), Lost Sex. Amsterdam: Springer, pp. 133–159, with permission from Macmillan Publishers Ltd., © 2002. Panel (c) is the result of the repeated simulation of a population of 50 diploid individuals for 100 generations. Each simulated population was initiated with equal frequencies of two alleles, with individuals randomly selected to reproduce and contribute to the next generation based upon a binomial distribution.

selection rely on standing genetic variation. As a consequence, these negative frequency dependence-based models do not spur the evolution of novel functions (Ebert, 2008).

Positive Directional Selection: Arms Race Coevolution

Under directional selection, relative fitness increases as the value of a trait increases (positive directional selection) or decreases (negative directional selection). Dawkins and Krebs (1979) argued that reciprocal positive directional selection exerted by coevolving hosts and parasites could lead to a situation where hosts continually become more resistant to parasitism while parasites respond by becoming more virulent or evolving new mechanisms of evading host immunity.

Unlike negative frequency-dependent selection, this so-called 'Arms Race coevolution' does not generate a rare advantage per se. Instead, host resistance and parasite 'virulence' are inherent properties of the individual genotype and do not depend on the frequency of the other genotypes. In this scenario, repeated selective sweeps favoring resistant hosts and virulent parasites will lead to the evolution of reciprocal host and parasite adaptations that, once overcome by a counter-adaptation, will not again incur resistance/virulence (**Figure 1(b)**; Woolhouse *et al.*, 2002; Burdon *et al.*, 2013). Another important distinction between Red Queen and Arms Race coevolution is that the latter, in favoring traits that counter adaptations in the biological antagonist, has a high potential for evolutionary innovation (e.g., Kerns *et al.*, 2008; reviewed in Daugherty and Malik, 2012).

A Critical Role for Population Structure

Spatial 'population structure' is both ubiquitous in nature (Slatkin, 1987; Jones and Wang, 2012) and is expected to be one of the major determinants of the presence, extent, and trajectory of coevolution (Gibert *et al.*, 2013). With respect to antagonistic coevolution, the existence of population structure can generate conditions in which there is opposing selection at the individual and group levels and in which the outcomes of coevolution are different than when population structure is absent. For example, theory suggests that with population structure, groups of parasites that are more damaging to their hosts tend to go extinct while groups of parasites that exploit their hosts in a more 'benevolent' way tend to persist (O'Keefe and Antonovics, 2002; Eshelman *et al.*, 2010; Wade *et al.*, 2010). This prediction is in stark contrast to the expectations of antagonistic coevolution between hosts and parasites in the absence of population structure, which is instead expected to culminate in the evolution of relatively high virulence (Eshelman *et al.*, 2010).

A good empirical example of how population structure can affect antagonistic coevolution is provided by Kerr *et al.* (2006) and Eshelman *et al.* (2010), who showed that when coexisting populations of the bacterial host *Escherichia coli* and the viral pathogen T4 coliphage are relatively isolated (migration happens only between neighboring populations or from a randomly selected population within a larger metapopulation), host–pathogen species are more likely to coexist. By contrast, under panmictic or well-mixed conditions (all populations from the full metapopulation are fully mixed and reallocated as individual populations), 'rapacious,' or more virulent, strains of pathogen tended to evolve, eventually resulting in extinction of both host and pathogen.

An additional consequence of spatial structure is an asynchrony in coadaptedness, wherein a subset of a metapopulation that has, for example, been more exposed to an antagonist, has had an opportunity to progress further in the coevolutionary process. In turn, asynchrony in coadaptation can lead to differences in the rates of colonization and/or extinction of host and pathogen due to trade-offs associated with host resistance, wherein more susceptible hosts are likely to colonize new sites (Thrall and Burdon, 1997, 2002; Laine *et al.*, 2011). This particular consequence of population genetic structure is particularly important because by generating variation in host and parasite phenotypes, asynchrony in coadaptation can facilitate the generation and maintenance of genetic and phenotypic diversity (Burdon *et al.*, 2013).

Finally, the presence of population structure and small population size, through the effects of genetic drift, may lead to a scenario in which random changes in allele frequencies in one or both interactants of a coevolving pair can lead to maladaptation (**Figure 1(c)**; Thompson *et al.*, 2002).

How Is Antagonistic Coevolution Detected?

While antagonistic coevolution is likely to be a common feature of natural populations, studying coevolutionary dynamics is not straightforward. Evolutionary biologists have risen to the occasion, developing approaches to study coevolution that either sidestep or directly address these methodological challenges. Here, we present several of the most important established methodologies as well as some newer genomic-based approaches.

The principal method to detect ongoing coevolution of any type is based on controlled experimental exposures of sympatric versus allopatric interactants (e.g., host exposure to sympatric parasites versus host exposure to allopatric parasites). Assuming antagonistic coevolution will result in a process of reciprocal adaptation between sympatric antagonists, direct exposure of allopatric interactants is predicted to result in a different and potentially maladaptive response relative to exposure of sympatric interactants ('phenotypic mismatch'). In the case of predator–prey Arms Race coevolution, phenotypic mismatch may result in an (at least temporary) escape for one of the interactants (Hanifin *et al.*, 2008). Similarly, in the case of Red Queen coevolution, hosts that are resistant to the most frequent sympatric parasite strain may be susceptible to a similarly frequent strain from an allopatric population. Depending upon the genetic basis of resistance/virulence (e.g., gene-for-gene or matching allele models; Luijckx *et al.*, 2013), the degree of asynchrony of coevolutionary processes (which will be driven by variation in population structure), and the spatial scale at which selection takes place (Vale, 2013), some parasite strains may even be incapable of infecting allopatric hosts (Antonovics *et al.*, 2011).

Coevolutionary processes will take place within a spatially structured context (Thompson, 2005), with 'local adaptation'

an expected outcome. As such, many newer methods that have been developed to study local adaptation can also be applied to the study of coevolutionary processes (see also **Table 1**). One such example is 'outlier analysis,' an increasingly common approach focused on the identification of polymorphisms that are enriched within some populations and that can be directly linked to particular biological processes related to local adaptation. While outlier methodology has seen only limited application to detecting coevolution (but see Orsini *et al.*, 2013), a related, more recently derived method, so-called 'environment-allele frequency correlations' (Coop *et al.*, 2010; Günther and Coop, 2013), is emerging as a more effective indirect strategy to determine the genetic basis of adaptation. Fumagalli *et al.* (2011) used this approach to suggest that interactions with parasites have been a principal selective force leading to shifts in allele frequencies amongst human populations experiencing different environments.

It is still unclear whether outlier analysis and environment-allele frequency correlations will provide broadly effective means of identifying the extent and type of coevolution. Because these methods typically rely on molecular summaries gleaned from samples taken from a single time point, they are also limited in their ability to pinpoint the exact genomic regions associated with a given coevolutionary process, which by definition occurs over multiple generations (see Decaestecker *et al.*, 2007, and so-called 'resurrection ecology'). This limitation is particularly clear in the case of Red Queen dynamics: while fluctuating selection will maintain multiple alleles over many generations, in any single generation and any particular population there exists positive selection for individual alleles, each of which may be subject to a different selective regime in different populations. In such cases, distinguishing the type and magnitude of coevolution will be difficult (Tiffin and Moeller, 2006).

Methods based on evaluation of patterns of polymorphism in a (co-)phylogenetic context can present some level of improvement relative or in addition to outlier analysis and environment-allele frequency correlations, providing insight into the presence, extent, and type of coevolution. Under this particular framework, researchers evaluate whether the phylogenetic patterns of the interacting species are concordant (have similar topologies), as expected under coevolution. Because a number of other processes may also generate phylogenetic concordance, the detection of concordance comprises only the first step toward identifying and characterizing coevolution (Althoff *et al.*, 2014). More recently derived comparative phylogenetic tools can provide more information regarding coevolutionary mechanisms and represent a relatively powerful means of evaluating hypotheses relating to the causes of diversification. Specifically, by linking phylogenetic and trait data for a given set of species, one can determine whether coevolutionary dynamics are causal factors in phylogenetic concordance (FitzJohn, 2012; Althoff *et al.*, 2014). Insight into the type of coevolutionary dynamics can come from these approaches as well. For example, Arms Race coevolution is expected to increase diversification rates, as was shown by Smith and Benkman (2007) in the crossbill/lodge pole pine system, while Red Queen dynamics are less likely to provide the sustained source of directional selection that can lead to diversification.

An exciting new approach that could potentially resolve a number of outstanding questions regarding coevolutionary processes and that is just beginning to see wide application is the combined use of experimental coevolution and re-sequencing. Here, experimental populations of species that comprise a potential coevolutionary system are established within a controlled environment. The genomes of each species are sequenced to establish a preexperiment baseline. Next, replicated populations of sympatric and allopatric interactants are exposed to one another for multiple generations in order to allow coevolution to take place. Following this exposure period, the populations of each interactant are re-sequenced in order to identify derived single nucleotide polymorphisms and/or highly diverged genomic regions relative to the initial parental populations (Eshelman *et al.*, 2010; Baldwin-Brown *et al.*, 2014). Comparisons of patterns of molecular evolution in the genomes of the two species before and after experimental manipulation allows evaluation of the magnitude of effect that a particular coevolutionary dynamic has on particular genomic regions, potentially distinguishing (for instance) the role of Arms Race versus Red Queen coevolution. Enrichment of particular alleles across populations relative to the pre-coevolution baseline is a predicted consequence of Red Queen coevolution, where the particular allele increasing in the population of one of the species in the coevolving pair will depend upon the most common allele in the second species. In other words, for Red Queen coevolution, the initial allelic distribution in the coevolving pair will determine the relative increase and/or decrease for the loci responsible for the coevolving dynamic (Thompson, 2005). By contrast, Arms Race coevolution is expected to result in fixation of particular alleles, potentially in series, as each reciprocal adaptation continues to escalate the coevolutionary arms race (**Figure 1(b)**). Confirmation of these predictions will require careful experimental design as well as a detailed understanding of the ecological dynamics of each species.

Recent theoretical work has also suggested that, depending upon the type of coevolutionary process taking place, one or the other interactant may actually be more effective for detecting the type and magnitude of coevolution. For example, Tellier *et al.* (2014) use a simulation approach to find that the genomic signature of Arms Race coevolution can be effectively determined in both interactants through the use of Tajima's D. By contrast, the typical signature of Red Queen, balancing selection, is often undetectable in the host species but apparent in the parasite.

Evidence for Antagonistic Interspecific Coevolution in Nature

Here, we provide brief summaries of two exemplar cases of Red Queen and Arms Race coevolution that have been documented in natural populations. We also discuss some new evidence that both types of coevolution can occur in series or even simultaneously.

Red Queen Coevolution: Snail and Trematode

Potamopyrgus antipodarum, a New Zealand freshwater snail, is often infected by sterilizing trematode parasites

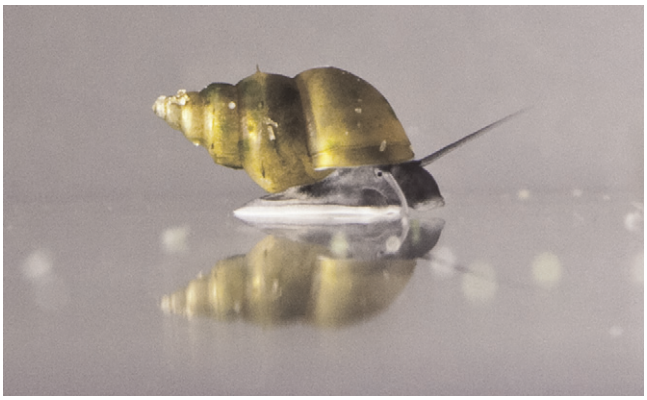

Figure 2 Adult female *Potamopyrgus antipodarum* (Photo Credit: Bart Zijlstra).

(Winterbourn, 1973). The possibility that these trematodes, and particularly *Microphallus* sp., contribute to the maintenance of sexual versus asexual reproduction in *P. antipodarum* (e.g., Lively, 1987; King *et al.*, 2009) has inspired multiple empirical studies aimed at addressing whether the interactions between snail and trematode fit those expected under a scenario where negative frequency-dependent selection driven by disproportionate infection of common host genotypes (i.e., Red Queen coevolution) helps favor sexual reproduction. Proof of Red Queen coevolution has several key requirements, including demonstration of advantages to rare alleles, tight genetic specificity for infection/resistance, and a time lag between increase in frequency of a (formerly) rare host genotype and disproportionately high infection of this now common host genotype (reviewed in Neiman and Koskella, 2009). Direct or indirect empirical support exists for all of the necessary components of Red Queen coevolution in the *P. antipodarum–Microphallus* system (e.g., Dybdahl and Lively, 1998; Dybdahl and Krist, 2004; Lively *et al.*, 2004; Jokela *et al.*, 2009), providing a very convincing example of antagonistic coevolution driven by negative frequency-dependent selection in natural populations (**Figure 2**).

Arms Race Coevolution: Newt and Garter Snake

Newts of the genus *Taricha* are a major prey of multiple species of garter snakes of the genus *Thamnophis*. *Taricha* newts generate a neurotoxin called tetrodotoxin (TTX) that has evolved independently in a number of *Taricha* taxa (Brodie, 2009, 2010). TTX is stored in the skin and acts as a chemical defense to most predators. In turn, the garter snakes have evolved resistance to the TTX produced by the newts, generating one of the best-characterized examples of coevolutionary arms race dynamics (Castoe *et al.*, 2011). The intensity of this arms race varies over the shared range of the snakes and newts. In some locations, the resident newt population can produce a much higher skin concentration of the TTX and the garter snake population is capable of resisting much higher TTX concentrations than in other parts of the range, generating what is sometimes referred to as a geographic mosaic of coevolutionary interactions (Thompson, 2005). Importantly, there is no known instance of a newt reaching concentrations of TTX that the local garter snake cannot overcome. The absence of

Figure 3 *Thamnophis sirtalis* consuming *Taricha granulosa* (Image Credit: Edmund Brodie III).

universal newt toxicity suggests a rare, and probably temporary, Arms Race escape for the garter snakes (Hanifin *et al.*, 2008; McGlothlin *et al.*, 2013). While the exact genetic basis of variation in TTX concentration is unknown, the genetic basis of variation in TTX resistance has been localized to functional amino acid substitutions in the skeletal muscle sodium channel (NA_v 1.4), though other parts of the genome (potentially other sodium channels) may contribute as well (Feldman *et al.*, 2010; McGlothlin *et al.*, 2013). Greater understanding of the genetic mechanisms underlying TTX resistance generated an additional line of evidence that clearly marks the newt–garter snake coevolutionary system as an Arms Race: there are multiple, independently derived alleles responsible for adaptation to increased TTX that now exist at high frequency within garter snake populations. By contrast, under Red Queen coevolution, alleles for generalized resistance to TTX would not exist. Instead, resistance would be connected to whichever particular resistance alleles happened to be recently or presently rare (Feldman *et al.*, 2010, 2012; **Figure 3**).

Simultaneous and Sequential Red Queen and Arms Race Coevolution: *Daphnia*, Bacterium-Microsporidian, and Bacterium-Phage

While we have focused primarily on pairs of distinct interactants, coevolutionary processes might involve more than two

taxa (Noguchi and Arakawa, 2008; Koskella, 2013; Ryder *et al.*, 2014), which themselves may act on the same or different components of individual genomes. Once such example is provided by the coevolutionary interactions between the cladoceran water flea *Daphnia magna* and two of its parasites, the sterilizing bacterium *Pasteuria ramosa* and the microsporidian *Hamiltosporidium tvaerminnensis*. Routtu and Ebert (2015) used a quantitative trait locus (QTL) approach to both uncover distinct genetic architectures for resistance to the two pathogens and describe evidence that the coevolutionary dynamic taking place between *D. magna* and *P. ramosa* is best characterized by Red Queen dynamics, while that of *D. magna* and *H. tvaerminnensis* instead fits the framework of Arms Race coevolution.

There is also evidence that these two distinct types of coevolution can occur sequentially within a pair of antagonists. For example, Hall *et al.* (2011) show that in coevolving populations of the bacterium *Pseudomonas fluorescens* and pathogenic phage SBW25Φ2, initial Arms Race dynamics are succeeded by Red Queen-like fluctuating selection, likely resulting from costs associated with host resistance. While identification of sequential coevolutionary dynamics will often be rendered difficult if not impossible due to the necessity of observation of the initial coevolutionary interactions, a powerful exception may be provided by coevolution in the context of biological invasions (Burdon *et al.*, 2013). Here, coevolutionary associations can arise across relatively recent and short time scales allowing biologists a powerful means of understanding how incipient coevolutionary processes arise. An especially important potential consequence of connections between biological invasions and coevolution is provided by the possibility that naïve interactants, especially a naïve host, may be unable to adapt to a novel parasite. The implications are that the host, and, eventually, the (now hostless) parasite, may go extinct in the new range, with potentially disastrous consequences for native taxa. As such, understanding the sequence of events that take place during the emergence of a new coevolutionary system and how Red Queen and Arms Race dynamics affect the maintenance of biological diversity is of primary importance to conservation efforts (Thompson, 2005).

Outstanding Questions and Future Directions

The increasingly widespread availability of inexpensive ways to generate large amounts of sequence data means that we are on the verge of addressing important questions like the extent to which antagonistic coevolution drives evolution in nature, which mechanisms of antagonistic coevolution are the most common, whether antagonistic coevolution is likely to be a main contributor to the maintenance of sexual reproduction, the genetic/genomic basis of coevolution, and how coevolution is affected by the presence of more than two interacting partners. The applicability of these methods to characterizing the nature of coevolution of hosts with their microbiota and of microbiotal components presents an especially exciting angle for future research. Identifying and discriminating between particular coevolutionary mechanisms remains a challenge. As such, future research efforts should include some focus on the continuing development of analytical methods that can be applied effectively to coevolving systems.

Archaeplastida: Diversification of Red Algae and the Green Plant Lineage

R McCourt, Academy of Natural Sciences of Drexel University, Philadelphia, PA, USA

Glossary

Gametophyte The haploid life cycle stage that is the conspicuous stage in most green algae and in bryophytes; called gametophyte because it produces haploid gametes through mitosis.

Glaucophytes They are relatively rare unicellular protists possessing primary plastids with chlorophyll a and have several similarities to free-living cyanobacteria.

Oogamy Sexual reproduction involving a large nonmotile egg and a smaller swimming sperm.

Peptidoglycan Chemical making up the cell wall of cyanobacteria and certain other bacteria.

Phragmoplast A type of cell division found in charophyte algae and land plants, with a distinct arrangement of microtubules and mode of cell-plate formation; this mode of cell division is thought to enable persistent intercelllular cytoplasmic connections called plasmodesmata.

Phycobilisomes Small round cellular structures on the photosynthetic membranes of cyanobacteria and in the plastids of glaucophytes and red algae.

Plasmodesmata Microscopic tube-like connections that extend across the walls between plant cells that maintain cytoplasmic continuity throughout the plant.

Pollen tube The tube that grows from a pollen grain that has landed on the receptive surface of the female portion of a flower; the tube carries the sperm cells to the egg inside the flower without them being exposed to the outside world.

Primary endosymbiosis The acquisition in the ancient past of a prokaryotic cell into a eukaryotic host cell to become an organelle; for Archaeplastids, cyanobacteria were engulfed by a eukaryotic host cell and transformed into a primary plastid.

Secondary endosymbiosis The acquisition of a eukaryotic red or green alga into a host cell to produce a secondary plastid.

Sporophyte The diploid life cycle stage in land plants and certain algae; in vascular plants this is a large, conspicuous stage, whereas in bryophytes it is a less conspicuous stage that grows on the haploid gametophyte; called a sporophyte because it produces haploid spores through meiosis.

Thallus A general term for the body of an alga.

Introduction

The Archaeplastida are a large and diverse group of photosynthetic organisms that include all of the green land plants that we are familiar with, as well as the red and green seaweeds and freshwater algae, plus a small group of rare and relatively obscure freshwater single-celled protists called glaucophytes (Figure 1). These three main groups of Archaeplastida diverged from a common ancestor at least 1.5 billion years ago, or perhaps much earlier (Butterfield *et al.*, 1990).

Evolutionary Origins

The Archaeplastida are the product of an ancient evolutionary partnership of a single-celled eukaryotic protist with a prokaryotic oxygen-producing photosynthetic bacterium (Delwiche, 1999). This well-accepted endosymbiosis hypothesis is that a eukaryote, already possessing a nucleus and mitochondria, engulfed a free-living cyanobacterium, which then became permanently incorporated as a plastid within the protist (Figure 2). (Mitochondria are also believed to have been acquired through an endosymbiotic acquisition of a nonphotosynthetic bacterium.) This merger of a cyanobacterium with a eukaryotic host cell resulted in a green algal-like cell that could harness sunlight to produce sugars through photosynthesis. Cyanobacteria, which had much earlier evolved the innovation of capturing sunlight to manufacture carbon-containing sugars, thus became permanent intracellular boarders, or organelles called plastids, whose sugars fueled the now photosynthetic host protist. This process, known as endosymbiosis, set the stage for the evolution of hundreds of thousands of species of algae and land plants, from single-celled phytoplankton to giant redwoods, that are found in nearly every habitat on Earth.

Although protists, red seaweeds, green algae, and plants are very different in appearance, the evidence of their evolutionary kinship is clear (Figure 3). Their cell structure and physiology exhibit a number of unique similarities, including the light capturing green pigment chlorophyll a in the plastid, inherited from the ancestral cyanobacterium. Two membrane layers surround each plastid, one a membrane from the engulfing host cell and the second inner membrane a vestige of the original cell wall of the cyanobacterium. Additional evidence of their shared ancestry is the arrangement of membranes within their mitochondria into flat layers, or cristae, and the production of starch as the primary storage product of photosynthesis.

In recent decades, studies of DNA in the Archaeplastida have reinforced the hypothesis that these three major lineages are evolutionarily related. DNA exists in three compartments in the cell: the nucleus where most of it is stored, and in separate clusters of organellar DNA inside the mitochondria and plastids, each of which contains a handful of genes that are essential to their function. These compartments are the nuclear genome, mitochondrial genome, and plastid genome, and though separate in the cell they are interdependent in helping the cell function. The relatively small amount of DNA

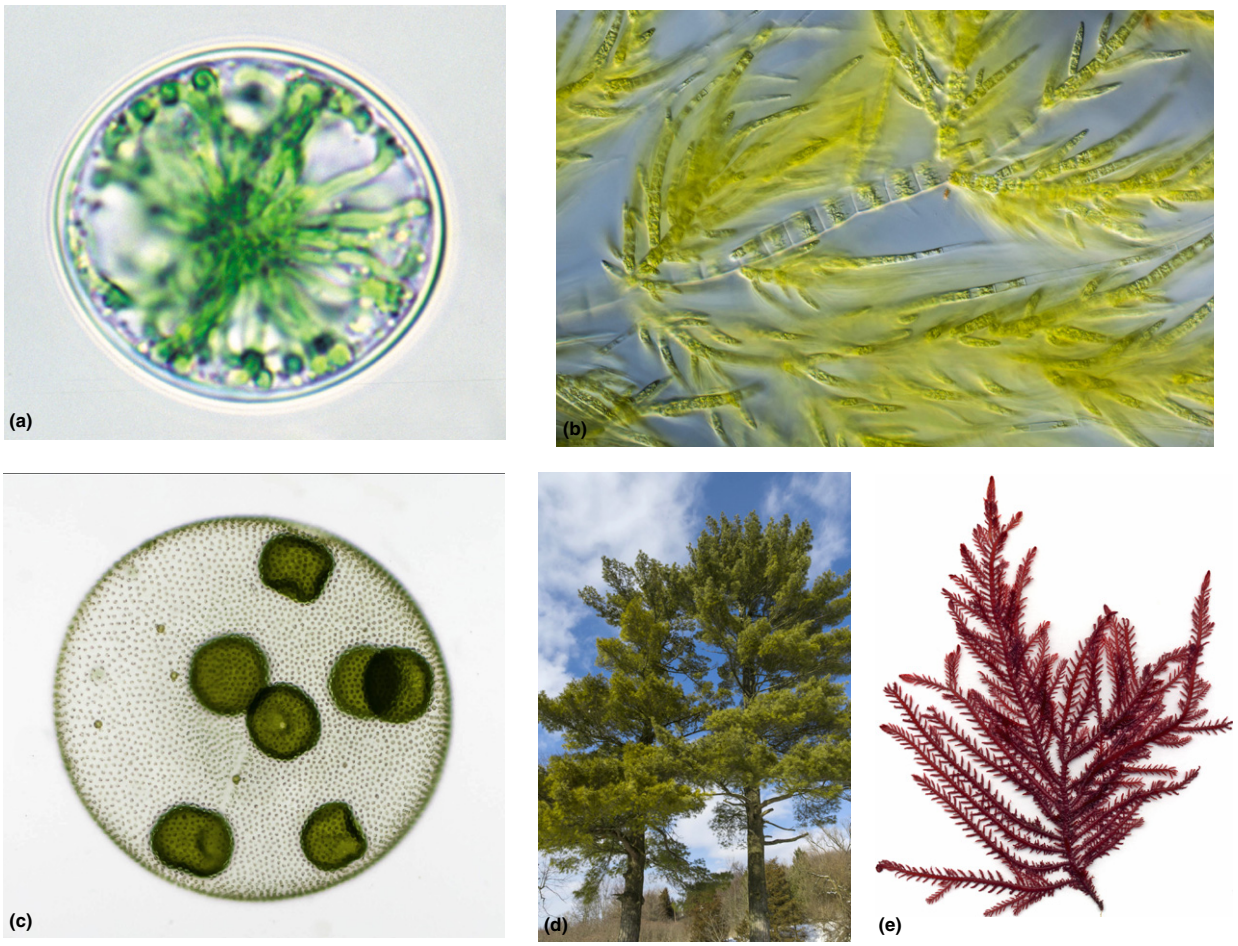

Figure 1 Unicellular glaucophyte, *Glaucocystis* (a); branching filamentous green alga, *Draparnaldia* (b); colonial green alga, *Volvox* (c); typical large land plant (pine tree) (d); red alga or seaweed, *Delisea* (e). All photographs copyright of L.W. Wilcox.

in mitochondria and plastids is a result of a large transfer of the genes they had when free-living into the nuclear genome, a process that occurred over the long period of time since their divergence from a common ancestor. This downsizing of these organellar genomes means the three DNA compartments in a cell form an integrated and interdependent evolutionary unit. Analysis of DNA sequences of many genes reveals a deep, underlying kinship among the many species of red and green algae and green plants and strongly supports the endosymbiosis hypothesis, which was proposed long before DNA was even discovered (Delwiche, 1999).

Morphology

The morphology of Archaeplastida exhibits a remarkable range of thallus or plant body types. The simplest are single cells for their entire existence (**Figure 1(a)**), while others such as many green algae form long chains of cells in linear strands or with sparse to profuse numbers of branches (**Figure 1(b)**). Such thalli are very common among the green algae and glaucophytes. More complex thalli are found in red and green algae, which form large colonies such as *Volvox* (**Figure 1(c)**), or three-dimensional tissues, internal architecture for transporting water and organic materials, and multicellular reproductive structures. The most complex plant bodies are found in the land plants, including trees, flowers, and shrubs, and among them are the largest living organisms on the planet.

The Glaucophyta (**Figure 1(a)**), the smallest group (about a dozen species in total) in the Archaeplastida, are unicellular, some swimming by means of flagella and others nonmotile. The plastids contain chlorophyll a only and have a peptidoglycan layer that is considered an evolutionary remnant of the walls of cyanobacteria made of this substance. Glaucophyte plastids have photosynthetic membranes studded with microscopic round structures called phycobilisomes, also found in cyanobacteria and red algae, that capture light outside the wavelengths absorbed by chlorophyll and channel the energy captured to the chlorophyll molecule. A close look at the plastids reveals a metallic blue-green hue. Once considered a variety of green algae, glaucophytes are now thought to be a distinct, albeit small, lineage in the Archaeplastida (Rodríguez-Ezpeleta *et al.*, 2007).

The red algae, or Rhodophyta, are also a distinct lineage of Archaeplastida, with about 6000 to 10 000 species, and probably many more to be discovered. They range in size from tiny unicells and microscopic filaments to larger leafy or bushy

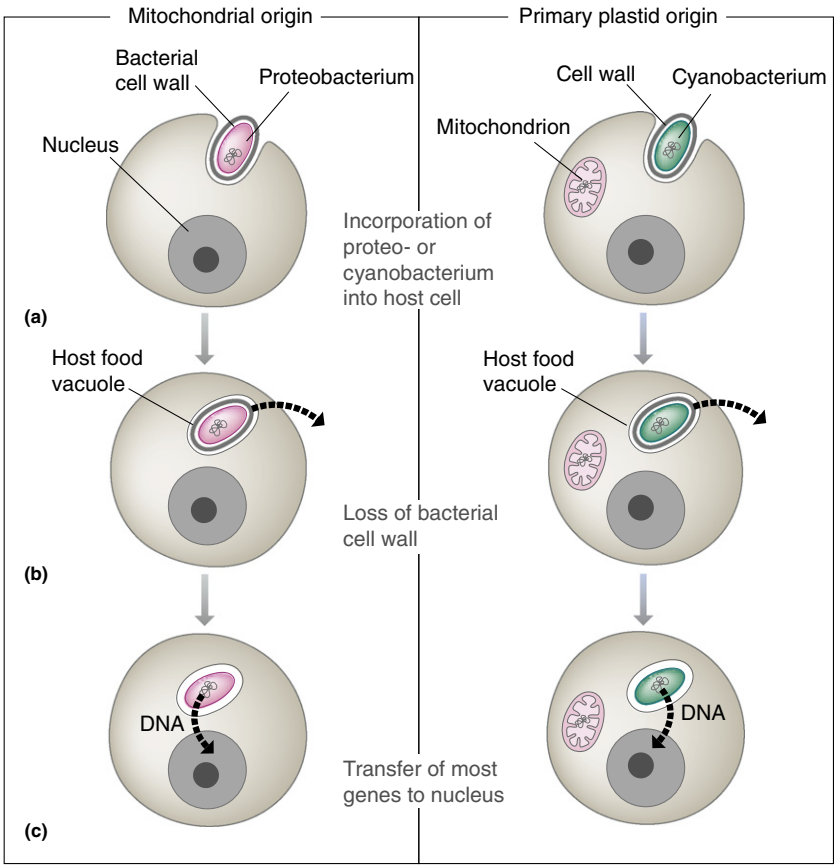

Figure 2 Endosymbiotic hypothesis for origins of mitochondria and plastids. A nucleated cell is hypothesized to have engulfed a proteobacterium (left) to produce a nonphotosynthetic protist; this then engulfed a cyanobacterium to form a photosynthetic eukaryotic cell. Reproduced from Figure 20.17 in Graham, L.E., Graham, J.M., Wilcox, L.W., 2015. Plant Biology, third ed. Madison, WI: LJLM Press.

seaweeds about the size of a small fern (**Figure 1(e)**). Most species of red algae are multicellular leafy seaweeds, although the unicellular forms and filamentous varieties are intensely studied because of their occurrence in extremely hot, acid habitats, such as the unicelluar *Cyanidium* (Yoon *et al.*, 2006), and their ancient fossil records (fossils of *Bangia* 1.3 billion years old, Butterfield *et al.*, 1990). The construction of the red algal thallus is basically filamentous, that is, even the large frondlike or gelatinous straplike species have thalli composed of microscopic filaments compacted and arranged into these larger structures. Red algae have a series of stages in their life cycle with varying numbers of chromosomes and complexity apparently correlated with more sets of chromosomes. The life cycle is complex for the most diverse group of red algae known as Florideophytes, but interestingly no red algae are known to produce cells with flagella, so the reproductive spores and gametes do not swim. Thus, though red algae are relatively large and complex, not to mention beautiful, they are not as diverse in species or habitats as green algae and plants.

Green algae (**Figures 1(b)** and **1(c)**) and land plants (**Figure 1(d)**) make up the third lineage, which is the largest in terms of number of species and organism size, as well as the most familiar to us, since the most diverse lineage of green plants surrounds us on land. There are two large groups of green algae. One is the Chlorophyta, or green algae sensu stricto, which includes most freshwater green algae, plus all of the green seaweeds. It is likely that there are many undiscovered species in this group, especially in the form of tiny unicellular species. The other main group is called the Streptophyta (Bremer, 1985), or Charophyta (Karol *et al.*, 2001), and it comprises several smaller groups of freshwater algae plus the huge evolutionary branch that we call land plants. Another term for land plants is embryophytes, because multicelluar embryos develop from the diploid zygote. This is in contrast to Chlorophyta and Charophyta, in which the single-celled zygote undergoes meiosis and produces a haploid life stage.

Scientists were surprised to find that not all green algae are each other's closest relatives. In fact, the Charophyta are actually more closely related to land plants than they are to the Chlorophyta and share a number of unique features with land plants. Technically speaking, this means the green algae do not form a monophyletic group. This surprising finding was initially discovered through studies of the internal structure of cells and how they divide (Pickett-Heaps, 1975), and it was later corroborated by analysis of DNA sequences (Karol *et al.*, 2001; McCourt *et al.*, 2004; Leliaert *et al.*, 2012). Therefore we now hypothesize that land plants descended from a small group of green algae about 450 million years ago (Lewis and

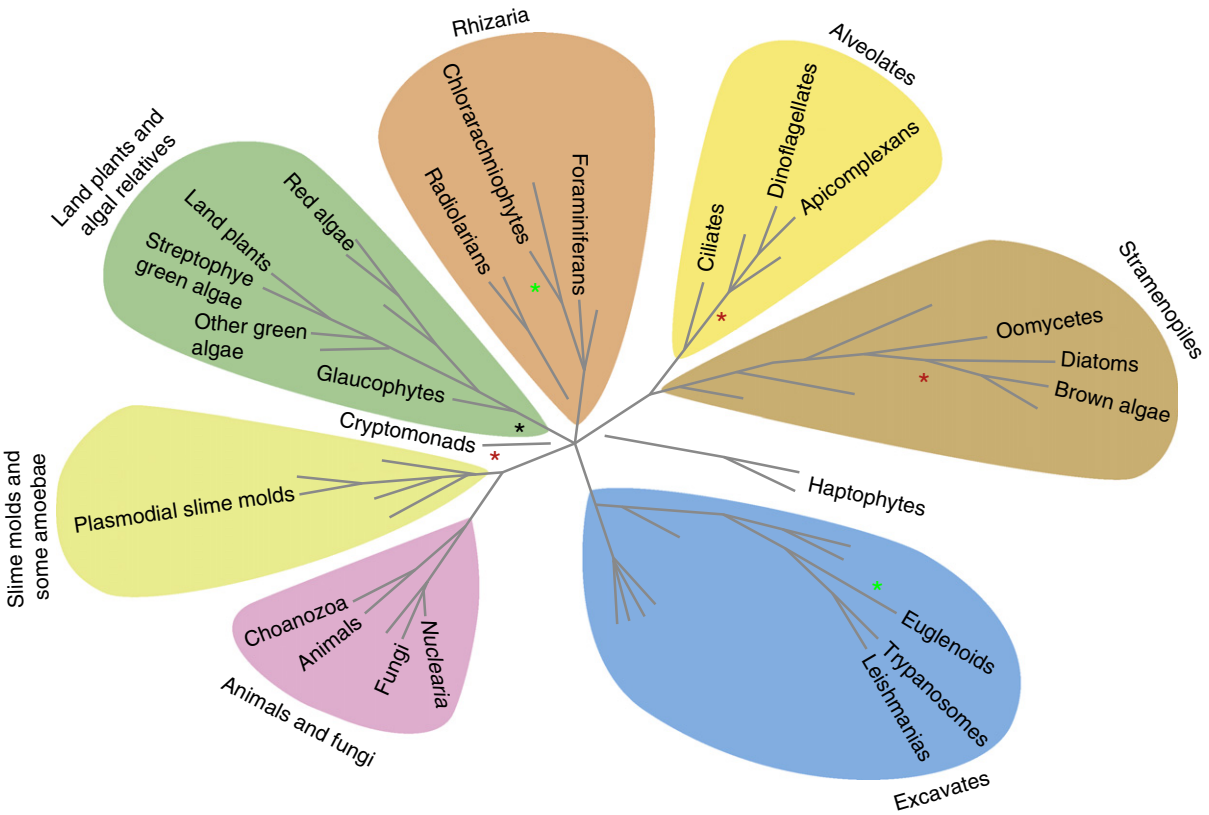

Figure 3 Evolutionary tree of eukaryotes showing the relationship of Archaeplastida to other photosynthetic organisms. The Archaeplastida are shown outlined in green. Shown on the tree with asterisks are branches on which occurred the endosymbiotic events described in the text. The black asterisk shows the acquisition of cyanobacteria in primary endosymbiosis. The red asterisks indicate three independent acquisitions of a red alga in secondary endosymbiosis (Chlorarachniophytes and Euglenoids) (there may have been more than three, Delwiche, 1999). The light green asterisks show independent acquisitions of green algae in secondary endosymbiosis. Modified from Figure 20.8 in Graham, L.E., Graham, J.M., Wilcox, L.W., 2015. Plant Biology, third ed. Madison, WI: LJLM Press.

McCourt, 2004; Leliaert *et al.*, 2012) (**Figure 3**), and this single lineage adapted to a dry existence and diversified into over 400 000 species of plants.

The Archaeplastida are indirectly responsible for even more of the photosynthetic life on Earth than just the three lineages mentioned above. This is because the Archaeplastida lineage is the source of plastids in several other important groups of algae, including diatoms, dinoflagellates, and brown algae (Delwiche, 1999). The plastids in these groups were acquired through endosymbiosis, but instead of taking in prokaryotic cyanobacteria, called primary endosymbiosis, host cells engulfed eukaryotic red or green algae in several independent lines of evolution, in a process called secondary endosymbiosis (**Figure 3**). Among these, the diatoms and dinoflagellates are very important primary producers in the sea, and are responsible for much of the oxygen we breathe.

Fossil Record

The fossil record of Archaeplastida is quite ancient. Fossil filaments very similar to living marine red alga *Bangia* (Butterfield *et al.*, 1990) have been found in rocks possibly older than 1.2 billion years. The finding of recognizable red algal filaments in rocks this much old means that the three main groups of Archaeplastida diverged much earlier. However, the delicate and fragile nature of most unicells and filaments means that they are less commonly fossilized than land plants (Stewart, 1993), and the age of the oldest Archaeplastida remains yet to be determined.

Habitats and Diversity

The three major lineages differ in their species diversity and modern day habitats. Very few glaucophytes are known, and they are all unicellular freshwater organisms. Red algae generally are larger, complex multicellular organisms, and more than 10 000 species are known to science. Most are found in salt water, and they make up the predominant plant life on some shorelines. A few species of red algae have successfully adapted to freshwater streams, and one group of red algae incorporate calcium carbonate into their thalli and are a major component of coral reefs in the tropics. The green algae and plants share a more recent common ancestor with each other than with the other Archaeplastida groups, and they are by far the most diverse of the three main lineages. More than 12 000 species of green algae are known (Lewis and McCourt, 2004),

found in both freshwater and marine ecosystems, with a significant but smaller number living in aerial habitats on land.

From molecular and fossil evidence, it is clear that multicellular algae evolved several times from unicellular ancestors. These independent origins of larger, complex algae led to a diversity in thallus types, from fleshy tubular marine algae, to branching freshwater species with the form of tiny trees, to colonial microscopic forms with thousands of component unicells (**Figure 1(c)**).

The Archaeplastida exhibit both asexual (vegetative) and sexual reproduction, although sex is apparently absent for many species. Asexual propagation of fragments of thalli or special asexual spores that may swim or lie dormant is common. Sexual reproduction involves gametes of two sexes or mating types. In many green algae the gametes are morphologically identical cells that swim by means of flagella. In some cases, one swimming gamete is larger, and in others one gamete is much larger and nonswimming (i.e., an egg) and the other much smaller and motile (i.e., the sperm). The latter process is called oogamy and is the universal pattern of sexual reproduction in the land plants that evolved from green algal-like ancestors. In the case of the most common land plants we encounter, conifers and flowering plants, the gametes are contained throughout the sexual process entirely within or closely associated with the tissue of the parent plant, i.e., within the flower or pollen grain or reproductive structures produced in the cone. The sperm lacks flagella (with a few exceptions, such as ginkgos and cycads), although the sperm cells do move through a pollen tube to the larger egg inside the female plant body. The trend towards dimorphic gametes that never leave the parental flower, pollen tube, or reproductive structures produced in the cone of the parent plant probably was important for the success and diversification of land plants through the provision of nutrients and materials from the parent plant to the large egg, the zygote, and the growing embryo.

Green Plant Origins and Diversification

Why only one green algal line of evolution produced the highly successful and diverse land plants is a particularly intriguing question. One hypothesis is that a shift in the reproductive life cycle allowed for greater complexity of form (Graham, 1993). The closest green algal relatives of land plants live in freshwater and for most of their life cycle, these algae are haploid. After sexual reproduction, a single-celled diploid zygote is produced, but a series of reduction divisions apportions the chromosomes into daughter cells such that they are all haploid. In the evolution of land plants, this single-celled zygote appears to have delayed these reduction divisions while a series of mitotic divisions occurred. The result was an intercalated multicellular diploid life cycle stage, a key part of the land plant life cycle. In the most complex land plants, this diploid stage, called a sporophyte, is the conspicuous plant that we are familiar with – woody trees, colorful and elaborate flowering plants, large fern fronds. The haploid phase, called the gametophyte, is often small and inconspicuous in land plants. In the most extreme cases, the haploid form is reduced to a growth stage of just a few cells that remain inside the parent sporophyte (e.g., inside flowers or pollen). One hypothesis is that the evolution of a plant stage with two sets of chromosomes released a flurry of genetic and morphological complexity in evolution and was a major factor in producing the diversity we see in land plants.

Another hypothesis on why the Charophyta were the green algae that gave rise to land plants is that during mitosis they produce a structure known as phragmoplast. This structure, which provides a scaffold for the new cell wall, leaves small channels that cross the wall between the new daughter cells. The phragmoplast is thought to have played a role in the evolution of size and complexity in land plants by allowing the movement of cellular material (proteins, hormones) from cell to cell, which produced a greater integration of plant form.

The evolution of desiccation resistant spores, first found in the Archaeplastid fossil record in the Charophyta green algal relatives of land plants, probably played an important role in enabling algae and their land plant descendants to survive periodic dry conditions at the margins of ponds. Such spores were likely present in the most ancient photosynthetic organisms that we would have recognized as land plants, which were probably similar to today's bryophytes, also known as mosses and liverworts (Graham, 1993). Bryophytes are often found in moist terrestrial habitats, and they lack some of the elaborate structures that are thought to have played a role in land plant diversification. For example, mosses have a small diploid sporophyte stage that grows upon and depends upon the large green mossy carpets made up of the haploid stage in the moss life cycle. Mosses also lack true vascular tissues that move water and sugars between roots and leaves, and only simpler tiny leaf-like and root-like rhizoids are found in bryophytes. Nevertheless, mosses are very successful, even in the driest habitats, although their diversity pales in comparison to that of true vascular plants.

Summary

The Archaeplastida are one of the major evolutionary lineages of photosynthetic organisms, and arguably the most important for animals, including humans, because the ancestors of one group (green algae and plants) was able to invade land and set the stage for the evolutionary movement onto land of many animal groups. Their great importance in the world's ecosystems and to human health and welfare are difficult to exaggerate. The three lineages of Archaeplastida contain most of the large algae, seaweeds, and plants that support life on Earth, and life as we know it would not be possible without Archaeplastida.

Glossary

Additive genetic variance The component of the phenotypic variance that causes offspring to resemble their parents.
Covariance A measure of the lack of independence between the values of two traits.
Effective population size (N_e) The size of an idealized population that would experience the same magnitude of genetic drift as the population of interest.
G-matrix The set of additive genetic variances (on the diagonal) and covariances for a group of traits.
Genetic correlation The standardized genetic covariance between a pair of traits.
Genetic covariance The component of covariation between two traits caused by variation at shared gene loci (pleiotropy) or pairs of genes (linkage disequilibrium).
Linkage disequilibrium A nonrandom relationship between the alleles present at two or more loci, which can cause a genetic correlation.
Narrow sense heritability A standardized measure of the degree of resemblance between offspring and their parents, defined as the additive genetic variance divided by the total phenotypic variance.
Pleiotropy It occurs when one locus affects more than one phenotypic trait, contributing to a genetic correlation.
Random genetic drift Fluctuations in allele frequency that occur by chance, particularly in small subpopulations, as a result of random sampling error in the gametes that form the next generation.
Response to selection The change in trait mean across one generation.
Selection differential A measure of the strength of directional selection equal to the mean of the selected group minus the mean of the entire population, or the covariance between relative fitness and trait values.

Introduction

Artificial selection is the process by which humans choose individual organisms with certain phenotypic trait values for breeding. If there is additive genetic variance for the selected trait, it will respond to the selection, that is, the trait will evolve. All of our domesticated species, including crop plants, livestock, and pets, are the products of artificial selection for desirable traits, such as seeds and fruits that do not disperse readily, increased meat and milk production, and docile behavior. The earliest artificial selection may have been unconscious, but it developed into a sophisticated science of plant and animal breeding; indeed, much of the field of quantitative genetics was developed to improve breeding programs.

The importance of artificial selection to the field of evolutionary biology dates back to Darwin, who was likely the first to use the term artificial selection in the '*Origin of Species*' (Darwin, 1859). Darwin used the obvious evolutionary results of domesticated species to show the power of selective breeding as an analogy to natural selection. One of the earliest uses of experimental artificial selection to address evolutionary questions was by Holtorp (1944). He selectively bred *Brassica* plants that produced an extra cotyledon and reported an increase in frequency of plants with three and even four cotyledons in subsequent generations. Similarly, Huether (1968) was able to increase and decrease the number of corolla lobes in *Linanthus* through five generations of artificial selection. These early studies established that even traits that are conserved at higher taxonomic levels could evolve.

Artificial selection differs from what has been called laboratory natural selection (Rose *et al.*, 1990) or controlled natural selection (Conner, 2003). In artificial selection the experimenter chooses specific phenotypic traits to select upon, while in controlled natural selection an environmental factor is manipulated and evolution of the populations in response to this selective agent is monitored. While artificial selection is certainly a form of experimental evolution, often the meaning of the term 'experimental evolution' is confined to controlled natural selection, excluding artificial selection (e.g., Kawecki *et al.*, 2012). Because artificial selection applies a known strength and direction of selection to specific phenotypic traits, it is one of the most powerful methods available for understanding the underlying genetic variation and thus evolvability of those traits; in controlled natural selection the strength and direction of selection cannot be determined by the investigator.

Fundamental Concepts

The rate of adaptive phenotypic evolution depends on the strength of natural selection and the amount of additive genetic variation for the trait in the population. This principle is encapsulated in the breeder's equation:

$$R = h^2 S \qquad [1]$$

in which R is the response to selection, defined as the evolutionary change in the trait mean across one generation, h^2 is the heritability, defined as the proportion of the total phenotypic variance due to additive genetic variance, and S is the selection differential, which measures the strength of selection. This form of the equation is useful for evolutionary biologists,

because it allows the prediction of short-term phenotypic evolution (R) from knowledge of the heritability and strength of selection. Additive variance is crucial, particularly in sexual species, because without additive variance a trait will not evolve; if the heritability is zero, so is R in the breeder's equation. The primary utility of artificial selection to evolutionary studies is that it provides the most powerful means of testing for presence of additive genetic variance for a trait. In artificial selection the selection differential is imposed experimentally and the response is measured, yielding an estimate of heritability for the selected trait, as shown by a rearrangement of the breeder's equation:

$$h^2 = R/S \qquad [2]$$

This is called the realized heritability (**Figure 1**).

A serious shortcoming of the breeder's equation for evolutionary studies is that it is univariate, that is, it relates to only a single trait. However, traits commonly covary genetically, which means they share gene loci in common (called pleiotropy) or that allele frequencies at loci that independently affect the two traits are correlated (called linkage disequilibrium; see Conner and Hartl, 2004 Chapter 5 for a fuller explanation). Genetic covariance is commonly standardized as the genetic correlation, just as additive variance is commonly standardized as the heritability. Genetic variances and covariances for a set of traits are expressed in matrix form, called the G-matrix; analogous to the univariate breeder's equation, the rate of evolution of a set of traits is the product of the G-matrix and the strength of direct selection on each of the traits (Conner and Hartl, 2004). If there are traits that covary genetically with a trait under selection, then those traits will also evolve, a phenomenon termed correlated responses to selection. Thus, artificial selection is an excellent way to test for genetic covariance between the selected trait(s) and other traits, in an analogous manner to how additive variance is tested, that is, by measuring phenotypic changes in other traits that were not subjected to artificial selection.

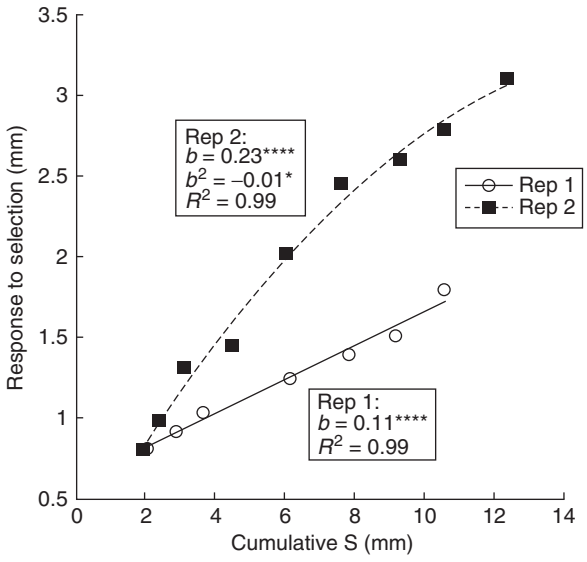

Figure 1 Realized heritability of anther exertion in wild radish, estimated as the slope (b) of the regression of response to selection (R) on the cumulative selection differential (S). Here the two replicates show quite different realized heritabilities, with Replicate 1 less than half that of Replicate 2. Reprinted from Conner, J.K., Karoly, K., Stewart, C., *et al.*, 2011. Rapid independent trait evolution despite a strong pleiotropic genetic correlation. American Naturalist 178, 429–441. © 2011 the University of Chicago.

Basic Design Considerations

Careful attention to design is important for producing a convincing outcome of any experiment, and artificial selection is no exception. Only some highlights of experimental design will be addressed here, as excellent detailed discussions are available (e.g., Bohren, 1975; Hill, 1980; Hill and Caballero, 1992). The main issue is to be able to definitively attribute the observed phenotypic response to the selection treatment, as opposed to random genetic drift or differences in the environment across generations. The latter can never be eliminated, even in a growth chamber. First, selection lines need to be replicated; because artificial selection can be time-consuming, often there are only two replicates of each selection treatment, but replication is necessary to separate the effects of selection from random genetic drift.

It is also ideal to include the same number of randomly mated (that is, unselected) control lines, which directly estimate phenotypic change due to drift and environmental differences combined; with replicated controls these two nonselective factors can be distinguished. However, selection can be separated from drift and the environment without control lines in the usual case where a trait is selected in opposite directions in separate replicated selection lines. This is because the response to selection can be tested between the high and low lines; if pairs of high and low lines are grown interspersed randomly in the same environment, the high–low phenotypic difference is due to selection, not the environment, and parallel high–low differences across replicate pairs are most likely due to selection rather than drift. In general, all the lines within one replicate (e.g., high, low, control) should be grown and measured together, so that average phenotypic differences among them are not due to environmental differences.

Besides replication to separate drift from selection, it is important to minimize drift by maximizing the effective population size (N_e) within each selection line, both to increase the precision of estimates of additive variance and also to minimize loss of fitness in multigeneration experiments. Thus, the design of an artificial selection experiment is a trade-off between the number of replicates, control lines, and the effective population size within each line. If the number of organisms that can be maintained is limited, then each set of lines within one replicate (e.g., high, low, and control) can be raised together, but separated in time from other replicates. The trade-off with this procedure is that each generation will take longer.

Another way to increase N_e without increasing the number of organisms is to perform within-family selection rather than mass selection. In mass selection, the most extreme individuals in each line are selected regardless of whether they are related to each other; if the trait is heritable, then families with alleles

for high or low values of the trait will be overrepresented. In within-family selection, a number of offspring of each family are raised and measured, and the same number (often one) of most extreme individuals within each family is selected for the next generation. This maximizes N_e; in fact, if one individual is chosen per family, and each selected individual has equal numbers of offspring in the next generation, then N_e is double the actual number of individuals selected. The main drawback of within-family selection is that the strength of selection will be weaker than with mass selection.

Weaknesses of Artificial Selection

The more common methods of testing for additive genetic variance and covariance use a breeding design to create known genetic relationships among organisms (parents and offspring, siblings, etc.), or estimating these relationships (i.e., the pedigree) in a natural population using genetic markers, in both cases without selection. Here the disadvantages of artificial selection compared to the more common methods are briefly discussed; the advantages will be made clear under 'Applications in Evolutionary Biology with Examples' section.

Perhaps the biggest disadvantage of artificial selection is that it requires fairly large numbers of individuals to be measured and mated, so this approach is not feasible for many, if not most, species. The traditional quantitative genetic breeding designs also require this, but molecular genetic markers make pedigree analysis possible for some wild populations, and this approach has been used in a few wild mammal and bird populations (e.g., Reale *et al.*, 2003; Kruuk *et al.*, 2000; Charmantier *et al.*, 2008). An advantage of any quantitative genetic study done in the field, pedigree-based or not, is that the G-matrix can be very dependent on the environment due to changes in the expression of additive genetic variances and covariances (e.g., Conner *et al.*, 2003). Artificial selection can in principle be conducted in nature especially in plants or birds in nest-box populations (Postma *et al.*, 2007), but this has rarely been done and for most organisms it will not be feasible.

Another disadvantage of artificial selection is that the number of traits that can be selected is very limited, usually to one or two at a time (but see Hine *et al.*, 2014). In a breeding or pedigree study the full G-matrix for as many traits as can be measured can be estimated. In artificial selection the additive variance for the trait selected upon can be estimated, as well as the genetic covariances between the selected trait and any others that are measured after selection, but the variances of, and covariances between, any traits that were not directly selected upon cannot be estimated. Thus, artificial selection is best reserved for cases where a particular trait is of interest, and to questions other than the full G-matrix (see Applications in Evolutionary Biology with Examples).

Applications in Evolutionary Biology with Examples

Evolutionary Constraints

As noted above, artificial selection is the most powerful test for additive genetic variation and covariation. This is because it is based on comparisons of means across generations rather than estimating variances and covariances from a breeding design or pedigree; means can be estimated with more precision than variances and covariances. In addition, artificial selection can be conducted over a number of generations, so that very small amounts of genetic variance and covariance can be detected as the response to selection accumulates across generations. This is very important in evaluating whether a lack of evolution, that is, an absolute evolutionary constraint, is caused by a lack of additive variance, because a lack of response to several generations of strong selection is more convincing evidence of constraint than a variance estimate that is not statistically different from zero. The pioneering artificial selection experiments of Holtorp (1944) and Huether (1968) were able to demonstrate additive variance for traits that were highly conserved, showing that this evolutionary conservation is not due to a lack of variance for those traits.

Most artificial selection experiments produce a significant response, suggesting that a lack of additive genetic variance rarely constrains evolutionary change. This is even true in most of a handful of studies that have selected perpendicular to the major axis of a genetic correlation, that is, in the direction of minimum variance in bivariate space (**Figure 2**; reviewed in Conner *et al.*, 2011). However, some have argued that a fully multivariate approach to constraints is needed, and that for groups of traits there will be directions in multivariate space (typically estimated as eigenvectors) that will lack variance (Blows and Hoffmann, 2005; Walsh and Blows, 2009). To test this hypothesis, Hine *et al.* (2014) applied artificial selection along all eight eigenvectors of eight cuticular hydrocarbons in *Drosophila serrata*; these hydrocarbons have been shown to be involved in mate choice. Significant responses to selection were found for all eight eigenvectors, and for the five eigenvectors that explained the most variance this response was significant for all three replicates. However, for the three eigenvectors that exhibited the least variance, the response was significant for only one or two of the three replicates.

Despite the fact that most artificial selection studies report a statistically significant response to selection, a few studies have not (e.g., Baer and Travis, 2000; Allen *et al.*, 2008; Dorn and Mitchell-Olds, 1991; Hoffmann *et al.*, 2003; Hall *et al.*, 2004). In, perhaps, the most convincing demonstration of a lack of additive variance in a wild species, Hoffmann *et al.* (2003) found no statistically significant response to 28 generations of selection for increased dessication resistance in a rainforest fly (*Drosophila burchii*; **Figure 3**), suggesting that adaptation to drier conditions predicted with global warming would be severely constrained. This study is convincing because the large number of generations of selection increases the ability to detect small responses in each generation, and because there was also no response in crosses among the different selected lines, making inbreeding depression caused by drift an unlikely explanation for the lack of response. However, there was an 11% increase in dessication resistance in two of the three selection lines; while this difference is not statistically significant, the presence of additive genetic variance in the population cannot be ruled out, illustrating the general difficulty in proving that something is absent.

Another important and less common role for artificial selection is investigating the short-term evolutionary effects of

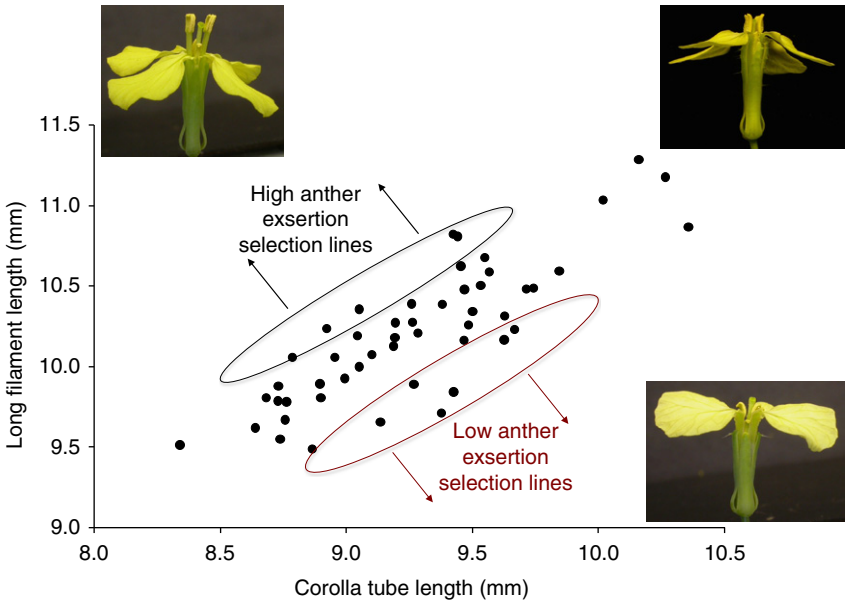

Figure 2 Graphical depiction of selection perpendicular to the major axis of variation for two traits. The genetic correlation of 0.85 between filament and corolla tube in wild radish flowers is depicted by the points in the graph. Anther exsertion is a composite trait defined as filament minus corolla tube, which describes how far the anthers protrude from the corolla tube. The picture at upper right shows a plant from the natural population with zero exsertion, with the bottom of the anthers at the opening of the corolla tube. Each set of arrows shows the direction of selection for one set of lines; in the high exsertion lines the individuals selected have long filaments relative to their corolla tubes (points enclosed by the black ellipse) while in the low lines individuals selected have long tubes relative to their filaments (red ellipse). The two sets of lines are separate, that is, high line individuals are mated to each other, not with low line individuals. Thus, this is directional selection in two directions on the composite trait of anther exsertion. Examples of flowers after each direction of artificial selection are shown in the upper left and lower right corners. Redrawn from Conner, J.K., Karoly, K., Stewart, C., *et al.*, 2011. Rapid independent trait evolution despite a strong pleiotropic genetic correlation. American Naturalist 178, 429–441.

selection on the genome. A major unresolved issue in evolutionary biology is the stability of the G-matrix across generations (reviewed in Arnold *et al.*, 2008); if the G-matrix is not stable, it is less likely to cause evolutionary constraint. Theory predicts that directional selection on a trait or combination of traits, which is what is almost always conducted in artificial selection studies, will eventually deplete additive genetic variance for that trait, which then constrains further response to that selection. This is one cause of what is called an evolutionary limit or plateau, that is, when a response to artificial selection ceases; however, a plateau can also be caused by natural selection in the opposite direction to the artificial selection, without a depletion of variance (**Figure 4**). Conner *et al.* (2011) showed that the selection depicted in **Figure 2** produced no consistent change in the G-matrix for these two floral traits in wild radish. Delph *et al.* (2011) conducted a different form of selection specifically designed to change the G-matrix. The negative correlational selection imposed significantly reduced the genetic correlation in flower size between male and female plants in two of three replicates. This selection was similar to that depicted in **Figure 2**, except that the high and low selected plants were mated to each other rather than mated within each group.

Understanding the Genetic Basis of Phenotypic Evolution

The examples discussed above are all of the most common use for artificial selection in evolutionary biology, that is, as a powerful method for detecting the presence of additive genetic variation for a trait or group of traits. Artificial selection can also be combined with quantitative trait locus (QTL) mapping to help identify gene loci responsible for genetic variation within a natural population, where adaptive evolution occurs. QTL designs generally use crosses between genetically and phenotypically divergent populations, which can be created from a single natural population by artificial selection. Chromosomal regions identified by a QTL analysis of a cross between these lines are those responsible for the response to artificial selection, and must have had allelic variation for loci affecting the trait in the natural base population. This approach was used to discover 26 QTLs for bristle number in *Drosophila melanogaster*, and 20 of these included likely candidate genes for this trait (Long *et al.*, 1995; Gurganus *et al.*, 1999; Nuzhdin *et al.*, 1999).

If there is already a strong candidate gene for a given trait, then allele frequency changes can be tracked across generations of artificial selection on that trait. For example, *FRIGIDA (FRI)* and *FLOWERING LOCUS C (FLC)* are loci affecting flowering time in the model plant *Arabidopsis thaliana*. Scarcelli and Kover (2009) selected for early flowering under growth chamber conditions simulating fall or spring germination, both of which occur naturally in this species. A large decrease in flowering time occurred in both growth conditions, and a concomitant change in *FRI* allele frequency also occurred, but only under spring germination conditions. *FLC* allele frequencies did not change significantly under either condition.

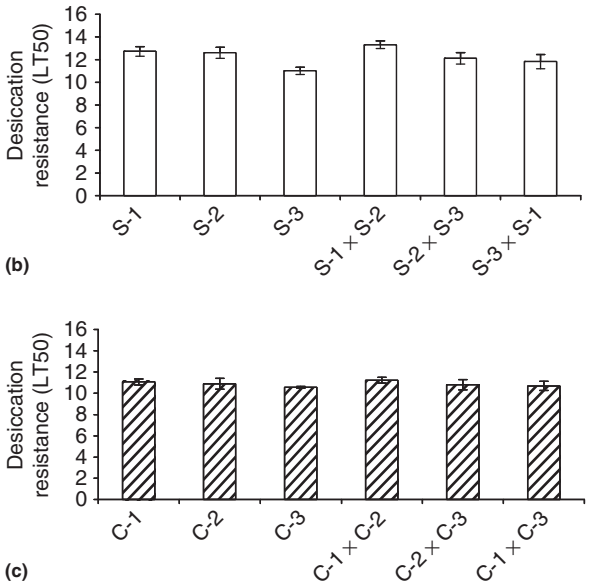

Figure 3 Lack of significant response to 28 generations of artificial selection for increased dessication tolerance. LT50 is the number of hours it took for 50% of the flies to die in the absence of water. Panel (b) shows the means for the three selection lines and all possible crosses between them, and (c) shows the same results for control lines. S-1 and S-2 show a higher dessication resistance than controls, but the overall difference between selected and control lines was not statistically significant. Reprinted with permission from Hoffmann, A. A., Hallas, R.J., Dean, J.A., Schiffer, M., 2003. Low potential for climatic stress adaptation in a rainforest *Drosophila* species. Science 301, 100–102.

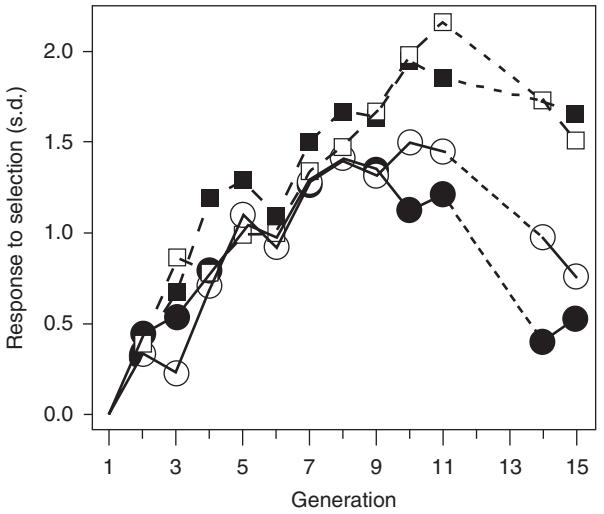

Figure 4 Reversal of response to artificial selection due to natural selection. Cuticular hydrocarbons in *Drosophila serrata* were artificially selected using two different treatments (circles and squares) with two replicates of each. The response to selection reached a plateau at generation 7 in the treatment denoted by circles, and all lines evolved back toward the means in the base population after the artificial selection was stopped ('relaxed'; dashed lines). This indicates that the artificial selection moved the populations away from their laboratory optima, and that the plateau was not caused by a depletion of additive genetic variance for the trait. Reprinted with permission from Hine, E., Mcguigan, K., Blows, M.W., 2011. Natural selection stops the evolution of male attractiveness. Proceedings of the National Academy of Sciences of the United States of America 108, 3659–3664.

Thus, variation in loci other than *FRI* and *FLC* were responsible for the phenotypic change under fall germination conditions, demonstrating the important point that expression of additive genetic variation for any trait (flowering time in this example) can depend on the environment (e.g., Conner *et al.*, 2003); this is one type of genotype–environment interaction. Thus, in combination with molecular genetic techniques, artificial selection can be used not only to demonstrate the presence of additive genetic variance, but also to understand what gene loci are responsible for this variance, and how this depends on the environment.

Understanding Natural Selection

The discussion and examples above make clear that artificial selection has most often been used to understand additive genetic variation, which is appropriate based on eqn [2]. By itself, artificial selection does not provide information about natural selection, but it can be used to create experimental populations with altered phenotypic means and variance for additional studies of adaptation and natural selection. If a trait is an adaptation, then we expect that the mean value for that trait will be near the optimum in natural populations due to past selection, assuming that the population is near equilibrium. Thus, artificial selection on an adaptive trait should move it away from this optimum, increasing the strength of natural selection to return the trait to the optimum. Laboratory artificial selection studies have produced many examples of selected traits that evolve back toward their original mean values when artificial selection is stopped (or 'relaxed'; Figure 4); this is good evidence that the trait means were moved away from their optimum in the lab environment (Falconer and Mackay, 1996). This same approach could be applied to study natural selection in the wild, by placing organisms that have been artificially selected for a putatively adaptive trait in the field and following their phenotypic evolution across multiple generations. This approach is most practical in sessile organisms like plants.

The approach above requires observing a response to natural selection over several generations. Another way to use the new phenotypic distributions created by artificial selection to understand natural selection is to combine divergent selection lines into a single experimental population that as a result has increased variance in the selected trait. This population can then be placed in the field and natural selection acting on the trait can be estimated as the slope of the regression of fitness on the trait (Lande and Arnold, 1983). It has long been recognized that studies of hypothesized adaptive traits are hampered by a lack of variance, because if a trait is adaptive, past directional or stabilizing selection will have removed the unfit variants from the population. Thus, the increased variance in the experimental population can increase the power of measurements of natural selection (Schluter, 1988; Haller and Hendry, 2014). This approach was used to show that different pollinators selected on different floral traits in wild radish (Sahli and Conner, 2011).

Summary and Future Directions

As this article has stressed, artificial selection is the most powerful way to test for additive genetic variance for a phenotypic trait, which in turn means that it is an ideal way to determine if a trait can evolve in response to selection. Molecular genetic techniques by themselves will not be able to accomplish this goal until the loci responsible for most of the additive variance in the trait are known, and it is known how each locus contributes to additive variance. However, as discussed above, the combination of artificial selection with molecular genetic techniques can greatly enhance our understanding of the mechanisms underlying genetic variance thus trait evolution, so more studies of this type are clearly needed.

A major challenge for future work is the environmental dependence of additive genetic variance for traits, evidenced by direct measurements of additive variance (e.g., Conner *et al.*, 2003 and references therein) as well as the environmental dependence of QTL (see the discussion of Scarcelli and Kover, 2009 above; Ungerer *et al.*, 2003). Ideally, artificial selection could be conducted in the field (Postma *et al.*, 2007), but this will prove very difficult for most organisms. A more feasible approach is to test the fitness and trait values of populations created by artificial selection in the field (e.g., Sahli and Conner, 2011; Galloway and Burgess, 2012; Kristensen *et al.*, 2007), but this does not test for the presence of additive genetic variance in the field environment.

One exciting future direction for the use of artificial selection in evolutionary biology would be to follow both phenotypic and genetic changes during artificial selection, with the latter done through whole-genome sequencing. This is an extension and combination of some of the approaches described above, enabling an unprecedented understanding of the molecular genetic underpinnings of a phenotypic response to selection. The resulting lines could then be placed in the natural population that the selection lines were derived from and tracked phenotypically and genetically for several generations. The prediction is that both phenotypic means and allele frequencies should evolve back toward those found in the natural population before artificial selection began, but interesting surprises seem likely.

Bacterial Diversity, Introduction to

OA Ogunseitan, University of California, Irvine, CA, USA

> Life on earth is such a good story you cannot afford to miss the beginning... Beneath our superficial differences we are all of us walking communities of bacteria. The world shimmers, a pointillist landscape made of tiny living beings.
>
> Margulis and Sagan (1986)

> What you see is that the most outstanding feature of life's history is a constant domination by bacteria. This is the age of bacteria. The bacterial mode, the mode being the most common form of life, is never altered in 3 1/2 billion years. We don't see it that way because bacteria are tiny and they live beneath us, but bacteria live in a wider range of environments.
>
> S.J. Gould (2006)

Introduction

Humans have probably always been aware that invisible, life-like agents influence living and nonliving phenomena, but the attribution of such influences to discrete life forms that we now call bacteria occurred recently – less than five centuries ago. The Italian scholar, Girolamo Fracastoro (1476–1553) is credited with the first to propose, in 1546, an atomistic theory of disease, linking epidemics to particulate contagion. The invention and use of microscopes by Antoni van Leeuwenhoek (1632–1723) initiated an unprecedented era of scientific discoveries in the field of bacterial diversity. However, the appreciation of the consequences of bacterial ecological diversity had to await theoretical and empirical advances, for example, through the works of John Snow (1813–1858) and Louis Pasteur (1822–1895) that finally overturned the prevalent 'miasma theory' in favor of the 'germ theory' of disease causation (Ogunseitan, 2005). Despite the remarkable progress in visualizing, dissecting, and analyzing bacteria, we continue to refine our understanding of the causes and consequences of bacterial diversity, including the current focus on the human microbiome and the role of complex communities of diverse bacteria, as opposed to individual specific pathogens (NIH, 2015).

Until relatively recently, there was a paucity of sensitive tools for investigating bacterial diversity in nature. Most of the accumulated evidence and literature on the generation and coexistence of various species dating from Darwin's (1859) original observations, focused on eukaryotes with phenotypes that are relatively easy to identify and count (Dykhuizen, 1990; Hubbell, 2001). Yet, studies of diversity in prokaryotes have yielded insights into the process and its outcomes that would otherwise be difficult, if not impossible to acquire (Dykhuizen *et al.*, 2009; Feldgarden *et al.*, 2003; O'Malley, 2014). With cultivation on artificial solid nutrient media, many bacteria form visible colonies that take on distinctive phenotypic features such as size, shape, color, texture, and odor. Historically, bacteriologists relied on colony morphology and its heuristic associations with desired functions such as fermentation or undesirable effects such as disease causation as the fundamental basis for bacterial systematics.

The advent of high-resolution microscopy added information on the biochemical reactions of cell wall (i.e., Gram stain) and the shape of individual cells such as coccoid, bacillary, or spiral; and the structure of micro-colonies such as clusters (i.e., *Staphylococcus*) or chains (*Streptococcus*). But scientific consensus on the definition of bacterial species remained elusive because of the somewhat fluid nature of morphological expression under various environmental conditions. Moreover, relatively recent applications of molecular genetic analyses, particularly the sequencing of 16S rRNA that has contributed to a rapid increase in the number of taxonomic groups described for prokaryotes over the past two decades (Cole *et al.*, 2003; Scholss and Handelsman, 2004). Advances in ecological sampling and meta-molecular studies (Renella *et al.*, 2014) have also challenged traditional species concepts for prokaryotes with major consequences for contemporary understanding of bacterial diversity. This article covers the main developments in the theoretical and empirical investigations of bacterial diversity with emphasis on the challenges and opportunities presented by studying isolated bacteria in the laboratory and bacterial communities in nature.

Theoretical Approaches to Describe Bacteria Diversity

Extinction, strictly defined in a planetary sense, has never been demonstrated for bacteria (Rankin *et al.*, 2010). Moreover, there is considerable evidence in the natural history of

 doi:10.1016/B978-0-12-800049-6.00224-9

prokaryotes that creative mutualism, endosymbiosis, and nonsexual exchange of genetic materials have led to new taxonomic lineages, possibly in response to environmental stressors that might have resulted in natural selection toward extinction (Hillesland and Stahl, 2010; Margulis and Sagan, 2003; Ogunseitan, 2008). Therefore, for this group of organisms, it has been difficult to reach consensus on a universal measure of the unit of natural selection and its outcome in diversification of species, especially without common understandings of geographic scope, niche specificity, mechanisms through which variable environmental parameters influence population size and community diversity, and ultimately, of the parameters of speciation in prokaryotes (Fraser *et al.*, 2009; Gevers *et al.*, 2005; Retchless and Lawrence, 2007; Venter *et al.*, 2004; Woese and Fox, 1977). There have been numerous theoretical excursions to illuminate these issues, although they remain primarily unresolved topics of active research.

For example, after nearly a quarter of century, Baas-Becking (1934) often quoted adage "*everything is everywhere……*" continues to generate considerable debate, hypotheses, and excursions in bacterial geography. Most bacteriologists will agree that it is impossible to know by direct count the number of individual bacterial cells or the number of bacterial species existing on Earth at any given point in time. Nevertheless, we have credible theoretical estimates (Curtis *et al.*, 2002; Hughes *et al.*, 2001; Whitman *et al.*, 1998), which place the total count in the vicinity of 10^{30} and the number of species at 10^{9}. Theoreticians estimate that more than half a million bacterial species are present in thirty grams 30 g of forest soil because speciation is easy and extinction is difficult for this group of organisms. This implies an implausibly infinite increase in the number of species over time, with no real impact of natural selection, except perhaps under narrowly defined local situations (Dykhuizen, 1998). Achieving precision in these estimates is neither possible nor useful for practical purposes, except for the fact that our knowledge of Earth's biosphere and its potential for sustainability is remarkably inadequate, and will not improve without understanding prokaryotic diversity and its myriad linkages to fundamental ecosystem functions (Ogunseitan, 2005).

Attempts to measure the rate of production of new bacterial species have focused on assessments of quantitative change in species richness over time, or the change in the magnitude of a phenotype, for example, enzyme activity, speed of motility, and output of bioluminescence, in response to selective pressure. The theoretical underpinnings of such measurements derive from attempts to quantitatively reconstruct the historical influence of natural selection or to determine the most vulnerable stages in the life cycle of organisms (Haldane, 1930). For example, natural selection intensity for a trait that follows statistically normal distribution in a population is computed as:

$$I = \log_e[s_o \div S]$$

where I is Haldane's intensity of natural selection, s_o is the chance (percentage) of survival of an individual (species) with the optimum trait (phenotype), and S is the mean chance of survival in the population (community).

There have been numerous renditions of this equation, depending on a variety of assumptions regarding mortality rates and the statistical profile of the distribution of the trait under selection within the population (Demetrius *et al.*, 2007; Lipstich and Sousa, 2002; Marcus, 1964; O'Donald, 1968).

Measuring the level to which natural selection increases the mean generational fitness has also been a popular topic for theorists. That quantity, often described as the additive genetic variance of fitness (V_w^2), resulted from the so-called 'fundamental theorem of natural selection' (FTNS) (Fisher, 1930) redefined for clarity as 'the rate of increase in the mean fitness of any organism at any time ascribable to natural selection acting through changes in gene frequencies is exactly equal to its genetic variance in fitness at that time' (Edwards, 1994). V_w^2 and its attributes have been popular for theoretical analyses regarding change in trait distribution following natural selection, but it has been notoriously difficult to measure, in part due to the long generation periods of model eukaryotic organisms with easily tracked phenotypes (Burt, 2000; Crow, 2002). Hence, there is a distinct advantage for using bacteria in studies of fitness and genetic variance. In this regard, the interaction of bacteria and bacteriophage, including genetic transduction, is one of the most thoroughly investigated and measured natural selection processes.

For example, mathematical models have been developed to describe the role of transduction (bacteriophage-mediated gene transfer from donor to recipient bacteria cells) in the selection and establishment of new phenotypes in bacterial communities. The model describes the selective advantage of beneficial genes under the selective pressure of, for example, antibiotics. The ratio of transductants to total cell numbers (T/N) at time zero and at a later time t, modified by a selection factor f is given by:

$$(T/N)_t = (T/N)_0 f$$

when new transductants are added to the population, and provided transductants have a selective advantage ($f > 1$), the ratio of transductants to total cell numbers after g generations is given by:

$$(T/N)_g = f_g\{(T/N)_0 + \Delta(T/N)_{trans} \div f - 1\}$$

$$-\Delta(T/N)_{trans} \div f - 1,$$

where $(T/N)_{trans}$ represents new transductants. Therefore, it is possible to predict the trend of accumulation of transductants, given assumptions about the selective pressure acting on specific genotypes. This mathematical model can predict stable transduction of specific antibiotic resistance genes in environments contaminated with antibiotics (Ogunseitan, 2005).

The small physical size of bacteria, their relatively brief generation periods and susceptibility to selective pressures that can be calibrated renders them attractive for use as model organisms for conducting experiments that test the predictions of evolutionary theories including natural selection. But as noted, there are several difficulties against unsophisticated interpretation of the results and conclusions based on of the outcomes of artificial selection experiments conducted with isolated bacterial cultures under laboratory conditions.

Experimental Approaches to Describe Bacteria Diversity

Despite relative anatomical and metabolic simplicity, bacteria exhibit complex characteristics that have been investigated for the purpose of advancing empirical knowledge of natural selection. Such features include susceptibility to bacteriophage infection, plasmid content, transposable elements, toxin production, motility, and pigmentation. The sensitivity of these features to natural selection has been exploited to engender major industrial processes. However, until recently, experimentation with bacteria on solid, batch and continuous cultures have not been very prominent in informing the theoretical advances about natural selection (Dykhuizen, 1990).

Sergie Winogradsky did not explicitly set out to investigate the theoretical underpinnings of bacterial diversity, but his invention – the 'Winogradsky Column' – has become a classic model for experiments on selection in bacterial ecology (Zavarin, 2006). By creating a nutrient gradient, the column facilitates the enrichment of certain species of bacteria at the expense of other species across the gradient. The inventor's statement on the purpose of the selective culture approach epitomizes the experimental manifestation of Darwin's (1859) principle of 'survival of the fittest.'

> The culture will be elective if it is favorable for the detection of the sole function … By supporting the microbe in question, engaged in the life contest with other microbes, we will have a significant prevalence of this microbe in our cultures …The application of pure cultures eliminates the most essential ecological factor, I mean competition, since it is precisely this factor that determines the distribution of the processes implemented by microbes in nature, and automatically directs the succession of these processes (Winogradsky, 1952).

Adoption of the selective enrichment culture has contributed greatly to the expansion of our knowledge of bacterial diversity and the discovery of new species that are crucially important for ecological processes. However, the approach is not easy to query at the fine level of quantitative detail needed to pursue specific questions about bacterial diversity. Instead, the pure culture approach, so detested by Winogradsky, has come to be regarded as indispensable for investigating the diversity of bacteria at the species and molecular levels.

For example, the bacterium *Escherichia coli* has long been the quintessential model for various investigations of bacterial diversity, physiology, molecular genetics, and evolution. A remarkable example of niche colonization and bacterial geography is the ubiquitous presence of *E. coli* in the lower intestines of warm-blooded organism regardless of the geographical distribution of the host. There is also a remarkable diversity of organisms collectively grouped as *E. coli* – whereas most members of the specie are harmless commensals, many can cause life-threatening diseases among humans. Although several mechanisms have been proposed on one hand as the causes of molecular diversity in *E. coli*, other mechanisms are also known to reinforce the common features that select for a certain level of homogeneity easily recognizable among strains within the species (Blattner *et al.*, 1997; Hayashi *et al.*, 2001; Jackson *et al.*, 2011; Noble *et al.*, 1998).

Experiments with long-term laboratory cultivation of *E. coli* have been among the most well described that address questions related to the emergence of polymorphism and variability in the context of natural selection and ecological opportunities for expansion or restriction (Barrick and Lenski, 2013; Plucain *et al.*, 2014; Kawecki *et al.*, 2012; Wiser *et al.*, 2013). Experiments with bacteria are particularly suited for querying causal issues in natural selection, including gene-environment interaction, how specialization leads to ecological diversification, and negative frequency-dependent selection (Feldgarden *et al.*, 2003). Despite the remarkable success of this approach, questions frequently arise about whether the small size of bacteria limit the application or generalizability of results from experiments conducted with them to test evolutionary principles. For example, it has been pointed out that there is considerable disparity between the genomic mutation rates observed in laboratory culture experiments compared with the rates estimated by sequence comparisons (Ochman *et al.*, 1999). In part to resolve these discrepancies, the use of artificial life or digital organisms to investigate natural selection has gained increasing attention (Clune *et al.*, 2012; Lenski *et al.*, 2003; Wilke *et al.*, 2001). In this regard, the *Avida* and *Tierra* software artificial life platforms are among the most developed for studying 'evolution' of self-replicating programs (Adami, 1998). Among the surprising finds from the series of studies of digital organisms is the potentially constructive role of deleterious mutations in adaptive evolution (Covert *et al.*, 2013).

Implications and Applications of Bacteria Diversity

There is possibly no greater threat to the global healthcare system than the one posed by the emergence of resistance to multiple antibiotics among pathogenic bacteria that cause diseases in humans. This threatening phenomenon results from the natural processes that generate and maintain bacterial diversity. In its first-ever comprehensive report on surveillance and information on antibacterial resistance at country-level worldwide, the World Health Organization declared that 'very high rates of resistance have been observed in bacteria that cause common healthcare associated and community-acquired infections (e.g., urinary tract infection, pneumonia) in all WHO regions' (World Health Organization, 2014). The United States Centers for Disease Control and Prevention, in its first-ever snapshot of the burden of antibiotic resistant bacteria noted that each year in the United States at least 2 million people are infected with bacteria that are resistant to antibiotics, resulting in at least 23 000 deaths as a direct result of the infections (CDC, 2013). This 'reversal of fortune' is the outcome of a global experiment in natural selection following large-scale manufacture and use of antibiotics hailed less than a century ago as magical interventions in public health and agriculture. We know now that many genes encoding for antibiotic resistance are located on mobile genetic elements that can rapidly disseminate in bacterial populations through well-studied genetic exchange processes of conjugation, transduction, and transformation (Ogunseitan, 1995). There is an extensive literature on the quantification of genetic exchange processes in natural bacterial communities, particularly on the rates of transmission of antibiotic resistant genes. However, there is an urgent need to further explore theoretical

frameworks, including group theory, for the purposes of generating predictive models of bacterial diversity, the limits of genetic dispersal, and phenotype stability (Ogunseitan, 2008).

The understanding of qualitative and quantitative boundaries of bacterial diversity is also applicable to the investigation of coevolutionary processes governing the interactions between pathogenic bacteria and human, animal, and plant hosts. Several theoretical models have been developed to explain the outcome of bidirectional selective pressures on bacterial diversity, emergence of genomic pathogenicity islands, and host immune response. Exploratory research in this direction includes testing among the predominant models, including balanced polymorphism ('trench warfare model'), arms race (red queen model), and positive selection on favorable alleles (Toft and Anderssen, 2010). The extent to which infection by pathogenic bacteria exerts selective pressure and influences natural selection in humans is also a rich area of research, especially with respect to the geography of human diseases. There are very few quantitative measures of this hypothesis, with the exception of attempts to explain the decline in mortality from pulmonary tuberculosis in Europe and North America just before the emergence of antibiotic therapy (Lipstich and Sousa, 2002).

In agriculture, there is increasing interest in understanding the vulnerability of critical crop–bacterial interaction and the possibility of local extinction of, for example, nitrogen-fixing *Rhizobium* species due to natural or anthropogenic pressures (Marco *et al.*, 2009). Remarkably, the experimental evolution approach has been used to investigate and confirm the transformation of a plant pathogen to mutualistic relationship between leguminous plants and Rhizobia (Marchetti *et al.*, 2010).

Finally, measuring natural selection in bacteria is increasingly important for understanding global environmental change phenomena, including attempts to mitigate climate change through manipulating the role of bacteria in the global biogeochemical cycles. Work on this topic includes experimental evolution to investigate the emergence of mutualism between methanogenic bacteria and sulphate-reducing bacteria (Hillesland and Stahl, 2010). Adaptation is life's most persistent question, and natural selection is the executioner's forum whereby death and extinction result for individuals and species not prepared to respond correctly. Through their remarkable ability to generate new forms and functions and to adapt constantly, bacteria are the only group of organisms that have probably inhabited the planet continuously since the emergence of life on Earth. This group of organisms have survived numerous episodes of climate change and various other kinds of selective pressures, and they have successfully navigated the natural selection forum. We have much to learn about and from bacterial diversity.

Bacterial Species Concepts

FM Cohan, Wesleyan University, Middletown, CT, USA

Species – A Special Level of Taxonomy?

Life's diversity is organized into clusters of related organisms that are similar in structure, function, and genomic properties. These phenotypic and genetic clusters are found from the most complex organisms to the prokaryotes and at all levels of life's diversity, from the domains and phyla to species (Caro-Quintero and Konstantinidis, 2012; Mallet, 1995). Between these clusters are gaps that represent intermediate phenotypes that we can imagine but do not actually exist in the natural world (Cohan, 2013). This pattern of clusters and gaps reflects the genealogical continuity of all organisms, taking into account that some lineages have been extremely successful while nearly every lineage that has ever existed has gone extinct (**Figure 1**).

Systematists and evolutionary biologists have taken a special interest in diversity at the species level. Above the species level, systematists have widely agreed that the taxa they demarcate are merely categories of convenience (McDonald *et al.*, 2012). Many believe the same about species (Hey, 2001; Doolittle and Zhaxybayeva, 2009), but others hold that there is something special about species – that they hold certain dynamic properties that transcend human attempts at classification (Cohan and Perry, 2007; Mayr, 1942; de Queiroz, 2005). Among these proposed properties are that each species is ecologically distinct and irreversibly separate from other species, that each species is cohesive in that some force constrains diversification within a species, and that each species is recognizable as a DNA sequence cluster for genes that they share (de Queiroz, 2005; Kopac *et al.*, 2014). Whether all these species properties apply to newly divergent lineages in the prokaryotic world is not yet resolved.

Prokaryotic Systematics: Species as Clusters of Similar Organisms

Prokaryotic systematists have aimed to identify species as closely related groups of organisms that differ in their ecological roles in biological communities, their ecological relationships with other organisms, and their physiological capacities (Rosselló-Mora and Amann, 2001). To this end, systematists have defined species as clusters of close relatives separated by large gaps in phenotypic and molecular characters (Rosselló-Mora and Amann, 2001; Vandamme *et al.*, 1996). This cluster-based approach has proved remarkably robust, even as the criteria for defining prokaryotic species have changed over the decades from exclusively phenotypic characteristics (usually metabolism) to include various molecular properties, such as multilocus sequences, whole-genome content, and whole-genome average nucleotide identity (Rosselló-Mora and Amann, 2001; Kopac and Cohan, 2011; Konstantinidis and Tiedje, 2005; Goris *et al.*, 2007) (**Figure 2**).

At present, systematics demands that members of a species share at least 70% of their genes, as determined by DNA–DNA hybridization, have at least 98.7% sequence identity at the 16 S rRNA gene, and differ from other species in at least one diagnostic (non-overlapping) phenotypic character (Stackebrandt and Ebers, 2006; Stackebrandt *et al.*, 2002). With the knowledge that genome content more reliably yields the number of shared genes than DNA–DNA hybridization, and that whole-genome average nucleotide identity more accurately predicts relatedness than a single gene, many taxonomists are demanding change in the criteria for demarcating species in systematics (Goris *et al.*, 2007; Vandamme and Peeters, 2014). Systematists have traditionally attempted to describe the phenotypes of new species as comprehensively as possible (Tindall *et al.*, 2010), and it appears that comparisons of whole-genome content may be the most efficient and reliable route to this goal. For example, in silico mapping of genomes to phenotypes has resulted in much more comprehensive species descriptions than was possible before genomics (Vandamme and Peeters, 2014; Amaral *et al.*, 2014; Thompson *et al.*, 2014). Beyond describing the phenotypes, systematics might also prioritize as fundamental a description of the habitats of isolation of any new taxon, since habitat descriptions have proved essential for characterizing the ecological and physiological differences among close relatives (Yilmaz *et al.*, 2011; Hunt *et al.*, 2008; Becraft *et al.*, 2011; Martiny *et al.*, 2009).

The species clusters recognized by systematics typically hold an enormous amount of diversity in genome content, physiology, biochemistry, and ecology (Manning *et al.*, 2008; Smith *et al.*, 2006; Dykhuizen *et al.*, 2008; Walk *et al.*, 2009; Hunt *et al.*, 2008; Koeppel *et al.*, 2008; Connor *et al.*, 2010; Sikorski, 2008; Ward, 1998). This presents a practical problem for microbiologists outside of systematics. The animal ecologist G. Evelyn Hutchinson suggested that a species' membership should be homogeneous in its physiological, biochemical, morphological, and ecological characteristics because this would yield the useful property that the characteristics of any individual classified to a species could be easily predicted (Hutchinson, 1968). If species could be defined as homogeneous units, the total membership of a pathogenic species, for example, would have the same disease-causing properties, the same tissue tropisms, the same transmission properties, and the same host range, while organisms with significantly different properties would be recognized as different species. The reality of prokaryotic species taxonomy is that much ecological diversity is subsumed within a recognized species (Ellegaard *et al.*, 2013).

The broad species demarcations of prokaryotic systematics can lead to errors in population genetic estimates of population sizes and the rates of processes such as migration (Kopac and Cohan, 2011). The problem is that many of these analyses require focus on a single, ecologically homogeneous population (Volz, 2012; Ho and Shapiro, 2011), but microbial population

biologists may implicitly and wrongly assume that the diverse members of a prokaryotic species taxon in a particular community are equivalent and interchangeable. Taxonomy can be a false friend to microbial population biologists.

By defining species so broadly, prokaryotic systematics does not encourage full exploration of all the ecological, physiological, and genomic diversity among close relatives that is subsumed within a species taxon. How might we arrive at a systematics of species that recognizes more finely demarcated groups that may differ in important properties? One possibility would be simply to reduce the fixed level of molecular divergence allowed within a species. Alternatively, systematics could aim to identify more finely demarcated populations that hold the dynamic, evolutionary properties ascribed to species outside of microbiology (Cohan and Perry, 2007).

Bacterial Species as Dynamically Defined Groups

Most systematists outside of microbiology have understood species to be more than closely related groups separated by gaps, that species have a reality beyond human attempts at classification (de Queiroz, 2005; Mayr, 1982). The property of cohesion has come to be understood as a quintessential aspect of species (de Queiroz, 2005; Mayr, 1982; Templeton, 1989). In this view, species are real because they are the largest groups whose diversity is constrained by a force of cohesion. In the case of the highly sexual animals and plants, the force constraining diversity within species is understood to be genetic exchange (Mayr, 1963). In Mayr's Biological Species Concept, the origin of species by one species splitting into two (speciation) requires that newly divergent populations break free of cohesion caused by recurrent, high-frequency genetic exchange; speciation has therefore been understood to be rare.

Recently, however, zoologists and botanists have questioned whether animal and plant species are really cohesive across their geographic ranges, and whether cohesion by genetic exchange actually prevents speciation (Mallet, 2008; Schluter, 2009). Similarly, microbial ecologists have debated whether genetic exchange has a role in preventing speciation in prokaryotes (Wiedenbeck and Cohan, 2011; Cadillo-Quiroz *et al.*, 2012; Retchless and Lawrence, 2010), whether bacterial speciation is rare or difficult (Hunt *et al.*, 2008; Doolittle and Zhaxybayeva, 2009; Cohan and Perry, 2007), and even whether bacterial species are cohesive at all (Cohan, 2011).

Genetic Exchange and the Nature of Prokaryotic Species

Several aspects of genetic exchange may affect the character of species and speciation in prokaryotes. First, recombination is not tied to reproduction as it is in many eukaryotic groups. Instead, recombination occurs only when an opportunity arises through uptake of DNA in the environment or when a virus or plasmid (a vector of recombination) takes up DNA from one cell (the donor) and then infects another cell (the recipient), allowing for genetic transfer of DNA from donor into recipient; in addition, some archaea can exchange genes through cell fusion (Naor *et al.*, 2012; Cohan and Aracena, 2012). Consequently, homologous recombination in prokaryotes occurs at an extremely low rate, usually not much greater than the rate of mutation (Vos and Didelot, 2009; Wiedenbeck and Cohan, 2011).

One consequence of such low recombination rates is that recurrent recombination appears unlikely to hinder adaptive divergence. The principle is that when niche-specifying genes from another population are introduced only rarely, natural selection in the recipient population can successfully eliminate these genes (Wiedenbeck and Cohan, 2011; Vos, 2011; Haldane, 1932) (**Figure 3**). Given that recombination even among very close relatives is already extremely low, reduction of recombination from this already-low rate (i.e., evolution of sexual isolation) is not likely a necessary milestone for ecological diversification and speciation (Wiedenbeck and Cohan, 2011).

Recombination is not known to have reversed the adaptive divergence between any ecologically distinct bacteria, although recombination was originally understood to have reversed the adaptive divergence between two *Campylobacter* taxa (Sheppard *et al.*, 2008). However, recombination was later interpreted to have effected an adaptive change within the recipient population that did not undo the ecological distinctness of the populations (Sheppard *et al.*, 2011).

One caveat to the conclusion that recombination cannot constrain speciation is that perhaps recombination might be more frequent than has been estimated, especially among the closest of relatives. It is possible that studies on recombination rates have pooled multiple, ecologically distinct populations that recombine at a reduced rate because they live in different microhabitats (Shapiro *et al.*, 2012).

Another consequence of rare recombination is a phenomenon known as 'periodic selection,' in which the entire genome-wide diversity within an ecologically homogeneous population is purged by natural selection. Because of the rarity of prokaryotic recombination, nearly the entire genome of the original adaptive mutant will reach 100% frequency before the adaptive gene can be recombined into other genetic backgrounds (**Figure 4**). Dynamic models of selection and recombination have shown that genome-wide purging within an ecologically homogeneous, prokaryotic population is inevitable whenever an adaptive mutation appears (Cohan, 2005).

Nevertheless, various empirical studies of sequence diversity have concluded that genome-wide sweeps do not occur.

Figure 1 Clustering of organisms as a property of the genealogy of life, as well as extinctions of nearly every group that has ever lived. (a) The only figure in Darwin's *Origin of Species* (Darwin, 1859). There is continuity of all life as we look one generation at a time into each organism's past until the ancestry of any two organisms coalesces into a common ancestor (e.g., the continuity of the *a* and *m* lineages through their common ancestor, indicated by the arrow), while there is discontinuity among living organisms because many intermediates have gone extinct (e.g., lineages *d*, *l*, *k*, *l*, and *s*). (b) Clustering and lack of intermediates among the bacterial phyla. Here each phylum (in a unique color) is clearly indicated as a sequence cluster, based on 31 shared genes (Wu *et al.*, 2009). Beyond the clustering by sequence, each phylum also clusters as a group with unique architectural properties that are profoundly divergent (Cohan, 2010). While clustering is most evident here at the phylum level, all taxonomic levels from the divisions to species also show clustering. Reproduced with permission from Nature Publishing Group.

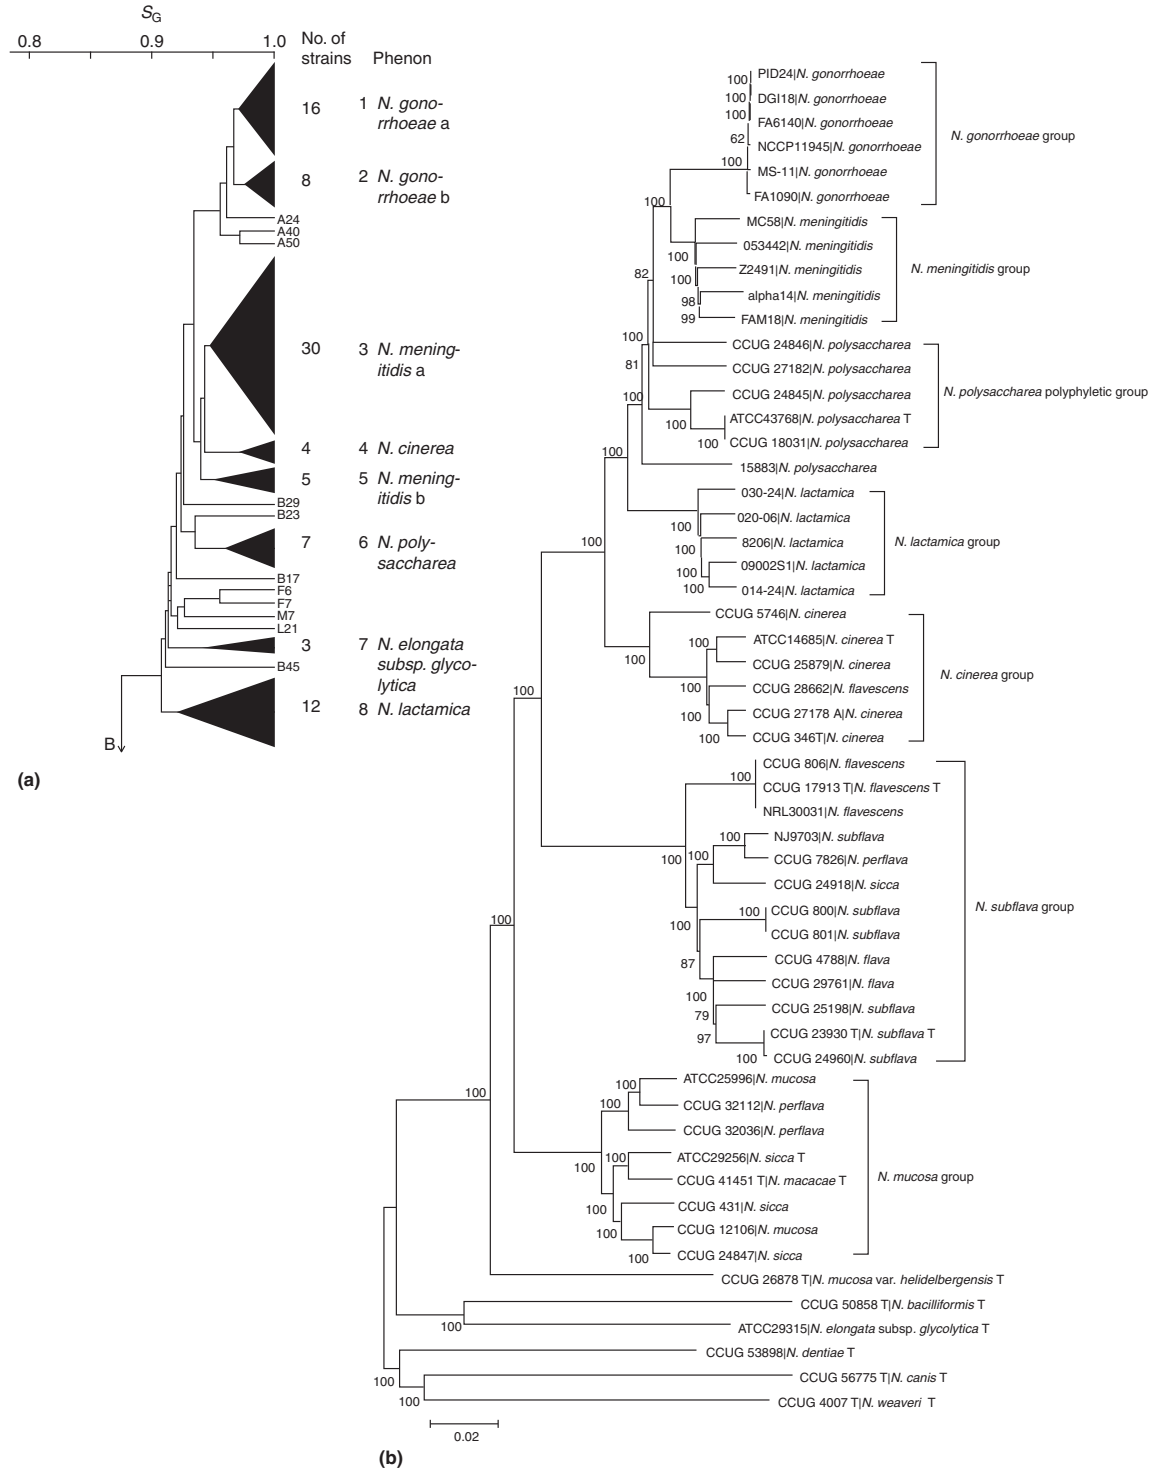

Figure 2 Species as morphological and molecular clusters, as shown in the genus *Neisseria*. (a) Clustering of close relatives of *N. meningitidis* by 155 phenotypic, largely metabolic, characteristics (Barrett and Sneath, 1994). (b) Clustering by a multilocus approach, here a concatenation of 246 shared genes from fully sequenced genomes (Bennett *et al.*, 2012). The groups recognized as species can be observed as clusters by either morphological or molecular criteria. Note that within many taxa the molecular criteria suggest multiple clusters, and that it is only by convention that we recognize a particular level of clustering to demarcate species. Reproduced with permission from the Society for General Microbiology.

They showed that a single chromosomal region increased in frequency over a set of ecologically distinct populations without purging genome-wide sequence diversity (Guttman and Dykhuizen, 1994; Papke *et al.*, 2007; Shapiro *et al.*, 2012). However, these studies did not take into consideration that genome-wide sweeps are predicted only within a single

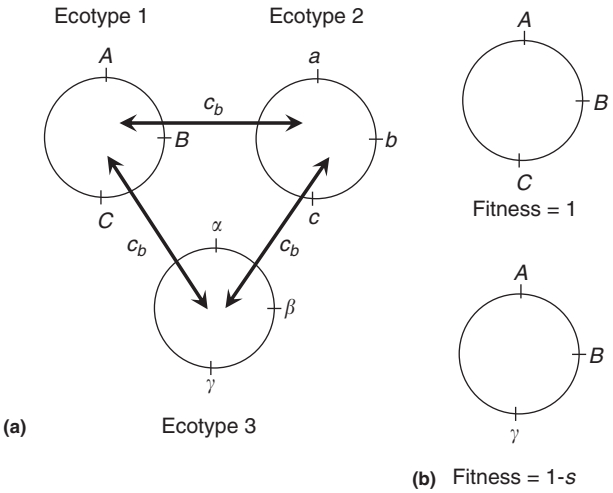

Figure 3 Why recurrent recombination is unlikely to prevent adaptive divergence in prokaryotes? (a) Model of recurrent recombination between closely related, adaptively divergent populations (ecotypes). Here the ecological niche differences are determined by homologous alleles at three loci, where capital alleles confer the adaptation for Ecotype 1, lower case alleles for Ecotype 2, and so on. Recombination occurs recurrently between populations at the rate c_b. (b) Fitness penalty for having a niche-determining allele from another population at one locus. (c) The equilibrium frequency of the maladaptive foreign allele is determined by c_b and s. The rate of recombination among closest relatives within the same population has been estimated at 10^{-6} per gene per organism per generation; so even if the rate of recombination between populations is as great as that within them, the equilibrium frequency of maladaptive foreign alleles is predicted to be negligible (Wiedenbeck and Cohan, 2011).

population of ecologically homogeneous organisms (**Figures 5–6**) (Kopac and Cohan, 2012). While some have argued that periodic selection does not occur in nature (Cordero and Polz, 2014), a metagenomic approach recently demonstrated genome-wide sweeps of diversity within various bacterial populations in nature (Bendall *et al.*, 2016).

The origin of bacterial species is also impacted by the ability of prokaryotes to acquire genes across extremely distantly related groups. A single genetic acquisition (by horizontal genetic transfer) can dramatically alter the ecological niche of a recipient organism, and some have argued that as a result prokaryotes speciate at a prodigious rate (Doolittle and Zhaxybayeva, 2009).

Recombination-Based Approaches to the Origin of Bacterial Species

In many studies of the origin of prokaryotic species, recombination has been viewed as a rampant process that can erode the distinctness of nascent species (Doolittle and Zhaxybayeva, 2009). Speciation theories based on Mayr's Biological Species Concept see the breaking of recombination between populations as a critical step in population divergence: populations can diverge ecologically and irreversibly only after their genetic exchange is blocked (Coyne and Orr, 2004).

Several studies have concluded that reduced recombination is necessary for the origin of ecological divergence in prokaryotes (Cadillo-Quiroz *et al.*, 2012; Ellegaard *et al.*, 2013). For example, in *Sulfolobus islandicus* isolated from the same hot spring, rates of recombination were higher within each of two ecologically distinct clades than between them (Cadillo-Quiroz *et al.*, 2012). In such studies, ecological divergence between sexually isolated clades was taken as evidence that recombination must be lowered to allow irreversible divergence among close relatives into ecologically distinct populations.

However, these studies did not address whether ecological divergence may have also occurred *within* each clade, where recombination rates are higher. One recent study, on *Synechococcus* in Yellowstone hot springs, revealed ecological diversification within clades that included the closest known relatives, which showed the highest rates of recombination (D. M. Ward, pers. comm.). While recombination is often reduced among ecologically distinct clades that are easily distinguished as sequence clusters, it appears that the reduction in recombination may follow, rather than precede, their ecological divergence (Mallet, 2008), especially if the clades prefer different microhabitats (Shapiro and Polz, 2014).

Consider next how ecological divergence among populations may reduce their recombination. First, random, non-adaptive sequence divergence that accumulates between populations directly reduces the recombination between them. This is because homologous recombination between a donor segment and the recipient cell's chromosome requires near-identity between donor and recipient at one or both ends of the donor segment, resulting in exponential decay of recombination rate with sequence divergence (Majewski and Cohan, 1999b; Vulić *et al.*, 1997).

Also, adaptive divergence between populations can reduce their recombination, especially if they have diverged by integrating unique sets of novel genes that improve adaptation to their particular niches. In the 'fragmented speciation' hypothesis (Retchless and Lawrence, 2010), homologous recombination between populations is reduced in each chromosomal region where one population has acquired an adaptive gene that the other population lacks.

Recombination between already-divergent populations will be further reduced if populations become adapted to different microhabitats (Shapiro and Polz, 2014). Another possibility is that ecological divergence will result in differences in the vectors of recombination, whereby the viruses and plasmids that infect one population cannot infect the other (Jensen *et al.*, 1998). Systems analyses of genetic transfers among hundreds of fully sequenced genomes have revealed two primary obstacles to recombination: divergence in habitat and phylogenetic distance (Popa and Dagan, 2011).

Ecological Speciation in Bacteria

Theories of ecological speciation hold that ecological divergence is the critical, initial step in the origin of diversity, and that patterns of recombination play only a minor role in

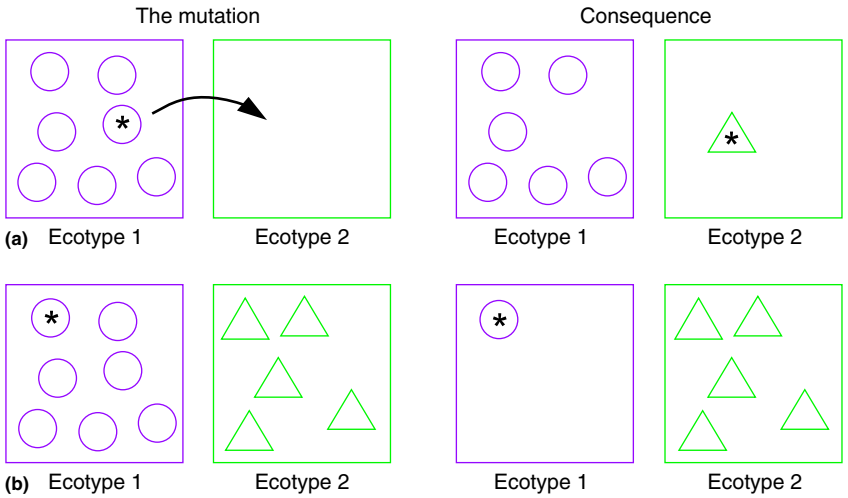

Figure 4 The dynamics of ecotype formation and periodic selection within an ecotype. Circles represent different genotypes, and asterisks represent adaptive mutations. (a) Ecotype formation event. A mutation or a recombination event allows the cell to occupy a new ecological niche, founding a new ecotype. A new ecotype can be formed only if the founding organism has undergone a fitness trade-off, whereby it cannot compete successfully with the parental ecotype in the old niche (Wiedenbeck and Cohan, 2011). (a) Periodic selection event. A periodic selection mutation improves the fitness of an individual such that the mutant and its descendants outcompete all other cells within the ecotype; these mutations do not affect the diversity within other ecotypes because ecological differences between ecotypes prevent direct competition. Periodic selection leads to the distinctness of ecotypes by purging the divergence within, but not between ecotypes (Cohan, 2005). Reproduced with permission from Landes Publishers.

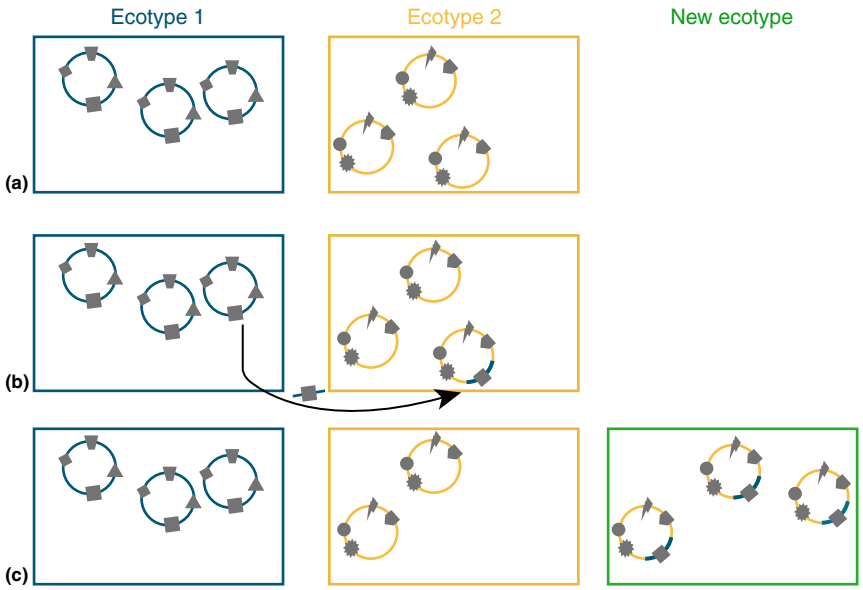

Figure 5 The consequences of an adaptive genetic transfer between ecologically distinct populations when an adaptive transfer creates a new ecotype. The niche-determining genes for each ecotype are represented as unique symbols on the circular chromosome (e.g., a trapezoid in Ecotype 1), which is a unique color for each ecotype. The addition of the 'square' gene to the genome of Ecotype 2 creates a new ecotype, which can coexist with both pre-existing ecotypes. Because the adaptive gene is transferred on a small segment, the part of the chromosome that is homogenized across ecotypes is short (Majewski and Cohan, 1999a; Kopac and Cohan, 2012).

the subsequent fate of newly split, ecologically distinct populations (Van Valen, 1976; Mallet, 2008; Schluter, 2009). Evidence for ecological speciation is accumulating even for animals and plants where recombination is obligately tied to reproduction every generation. Recombining populations of animals or plants in adjacent microhabitats are able to diverge, owing to the modest (but apparently sufficient) reduction in genetic exchange across habitats, allowing natural selection to eliminate niche-specifying genes entering from the adjacent population (Mallet, 2008). A fortiori, ecological speciation is

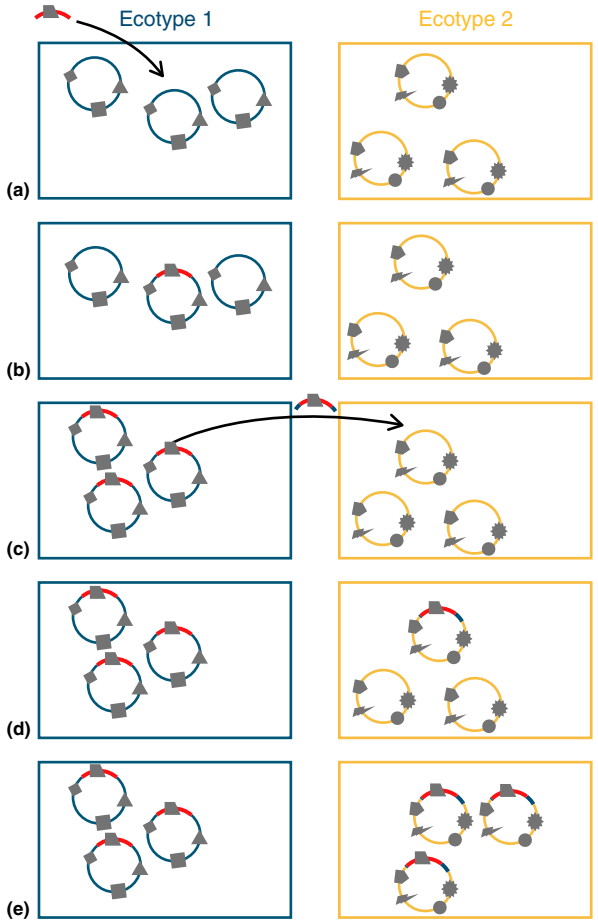

Figure 6 The consequences for adaptive genetic transfer between ecotypes when the adaptive transfer creates a periodic selection event in the recipient ecotype. (a) and (b) A 'trapezoid' gene, which is of adaptive value across different ecotypes, enters Ecotype 1 from another ecotype (whose chromosome is marked as red), and creates a recipient individual that can outcompete all the other organisms within Ecotype 1. (c) The recombinant creates a periodic selection event within Ecotype 1, yielding a genome-wide purging of diversity within the ecotype. (d) The generally adaptive 'trapezoid' gene then transfers into Ecotype 2, and creates a recipient individual that can outcompete all other members of Ecotype 2. (e) This causes a genome-wide purging of diversity within the ecotype. Note that even though there is genome-wide purging of diversity accompanying periodic selection events within each ecotype, the only chromosomal part that gets homogenized across ecotypes is the short segment that transfers across ecotypes (Kopac and Cohan, 2012).

all the more likely in prokaryotes, given the intrinsically very low, mutation-like frequencies of recombination in prokaryotes (Wiedenbeck and Cohan, 2011).

Geographic isolation (and the ensuing reduction in recombination between populations) is therefore not expected to be essential for ecological divergence between prokaryotic populations (Cohan, 1994). Indeed, recent studies have shown sympatric diversification of one population into multiple, ecologically distinct, indefinitely coexisting populations, in both laboratory studies (Treves *et al.*, 1998; Blount *et al.*, 2012; Rainey and Travisano, 1998; Koeppel *et al.*, 2013) and in nature (Connor *et al.*, 2010; Hunt *et al.*, 2008; Becraft *et al.*, 2011; Denef *et al.*, 2010).

It is not yet known which of the species-like properties attributed to species of animals and plants follow from ecological speciation in prokaryotes. To identify these properties for newly divergent prokaryotic lineages, it is useful to define these lineages in a way that does not presuppose the properties they will have beyond ecological divergence. To this end, 'ecotypes' may be defined as lineages that are ecologically distinct, such that the ecotype lineages can coexist indefinitely as a result of their ecological divergence; while there may also be ecologically distinct lineages *within* an ecotype, their differences are not sufficient to allow their indefinite coexistence (Kopac *et al.*, 2014). Microbial ecologists studying the origins of ecological diversification have focused on the origin of ecotypes (or similarly defined, newly divergent ecological populations) rather than the broadly defined species of taxonomy (Hunt *et al.*, 2008; Connor *et al.*, 2010; Sikorski, 2008; Shapiro *et al.*, 2012).

What species-like properties follow from ecological divergence? In the 'stable ecotype' model of speciation, the origin of new ecotypes is rare, and each ecotype is recurrently purged of diversity, genome-wide, through periodic selection events over its long lifetime (Cohan and Perry, 2007) (**Figure 7(a)**). Different ecotypes have the species property of being irreversibly separate because, owing to their ecological differences, periodic selection cannot prevent divergence among newly split ecotypes; moreover, ecological divergence between ecotypes is not prevented by recurrent genetic exchange (Wiedenbeck and Cohan, 2011; Vos, 2011). Stable ecotypes are discernible as sequence clusters because longstanding ecotypes have had opportunity to accumulate neutral sequence divergence at every locus, while diversity within ecotypes is recurrently purged (Cohan and Perry, 2007) (**Figure 7(a)**). In summary, slow speciation and indefinite coexistence of emergent species yields all the species-like properties attributed to animal species.

However, depending on the rates of ecotype formation and extinction, as well as the magnitude of ecological divergence, ecotypes may hold only a subset of species-like characteristics. In the 'speedy speciation' model, species are subject to recurrent cohesion by periodic selection, but speciation is so rapid that species are not discernible as sequence clusters (**Figure 7(b)**). In the 'nano-niche' model, the most newly divergent, ecologically distinct populations are only *quantitatively* different (**Figure 7(c)**). Here each ecologically distinct population has no unique resources but utilizes the same set of resources in different proportions (Cohan and Perry, 2007; Wiedenbeck and Cohan, 2011; Kopac *et al.*, 2014). This pattern of ecological divergence is common in animal and plant speciation (Schluter, 2000) and extends to some bacteria. A recent comparison of genomes within *Bacillus subtilis* has suggested nano-niche diversification (Kopac *et al.*, 2014). Nano-niche populations are predicted to be ephemeral because each is vulnerable to competition to extinction by another population using the same set of resources, and thus nano-niche populations are not irreversibly separate (Cohan, 2005). Hence, nano-niche populations do not meet the ecotype criterion that ecotypes must be able to coexist indefinitely as a result of their ecological divergence. Individual nano-niche populations likely have the species-like property of cohesion.

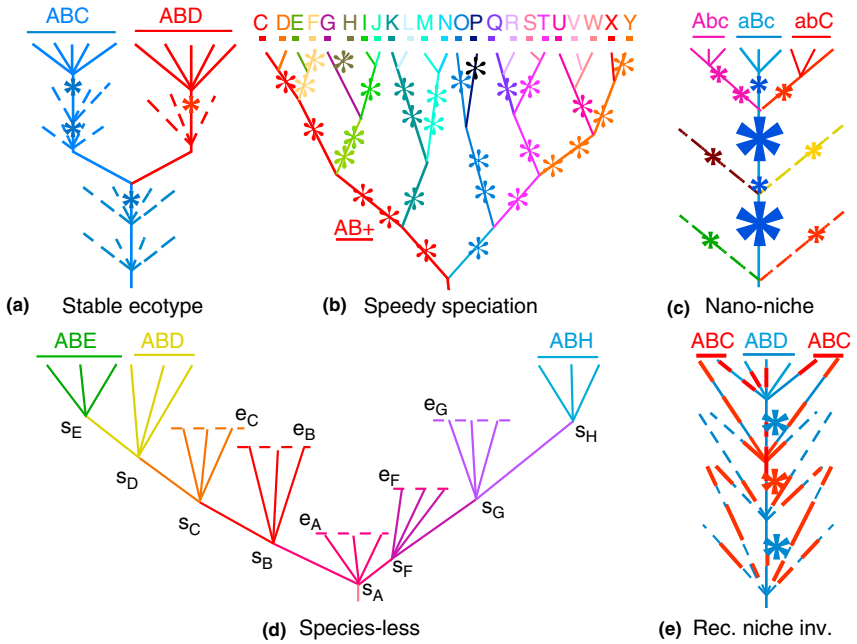

Figure 7 Models of ecological speciation in prokaryotes. Ecotypes are represented by different colors; periodic selection events are indicated by asterisks, and extinct lineages are represented by dashed lines. The letters at the top represent the resources that each group of organisms can utilize. In cases where ecotypes utilize the same set of resources but in different proportions, the predominant resource of each ecotype is noted by a capital letter. (a) In the Stable Ecotype model, each ecotype endures many periodic selection events during its long lifetime. The Stable Ecotype model generally yields a one-to-one correspondence between ecotypes and sequence clusters. The ecotypes are able to coexist indefinitely because each has a resource not shared with the others. (b) The Speedy Speciation model is much like the Stable Ecotype model, except that speciation occurs so rapidly that most newly divergent ecotypes cannot be detected as sequence clusters in multilocus analyses. (c) The Nano-Niche model. In the figure, there are three Nano-Niche populations that use the same set of resources but in different proportions (noted by Abc, aBc, and abC). Each Nano-Niche population can coexist with the other two because they have partitioned their resources, at least quantitatively. However, because the ecotypes share all their resources, each is vulnerable to a possible speciation-quashing mutation that may arise in the other populations. This could be a mutation that increases efficiency in utilization of all resources. These speciation-quashing mutations are indicated by a large asterisk; each of these extinguishes the other Nano-Niche populations. Thus, in the Nano-Niche model, cohesion can cut across ecologically distinct populations, provided that they are only quantitatively different in their resource utilization. (d) In the Species-Less model, the diversity within an ecotype is not limited by periodic selection but instead by the short time from the ecotype's invention as a single mutant until its extinction. The origination and extinction of each ecotype *i* is indicated by s_i and e_i, respectively. In the absence of periodic selection, each extant ecotype that has given rise to another ecotype is a paraphyletic group, and each recent ecotype that has not yet given rise to another ecotype is monophyletic. (e) In the Recurrent Niche Invasion model, a lineage may move, frequently and recurrently, from one ecotype to another, usually by acquisition and loss of niche-determining plasmids. In the figure, the red lines indicate the times in which a lineage is in the plasmid-containing ecotype; the blue lines indicate the times when the lineage is in the plasmid-absent ecotype. Periodic selection events within one ecotype extinguish only the lineages of the same ecotype. For example, in the most ancient periodic selection event shown, which is in the plasmid-absent (blue) ecotype, only the lineages missing the plasmid at the time of periodic selection are extinguished, while the plasmid-containing lineages (red) persist. Ecotypes determined by a plasmid are not likely to be discoverable as sequence clusters (Kopac *et al.*, 2014). Reproduced with permission from the American Society for Microbiology.

If both ecotype formation and extinction are frequent, quotidian events, the 'species-less' model can apply (Ward and Cohan, 2005; Cohan and Perry, 2007) (**Figure 7(d)**). Here, each ecotype lives only briefly before going extinct, so the diversity within an ecotype is constrained by the short time of its existence, from its founding by a single mutant or recombinant cell until the ecotype's early extinction. There is no time for cohesion by recurrent forces like periodic selection. Related to the 'species-less' model is the 'opportunitroph' model, where various generalist lineages adapt convergently to similar types of ephemeral particles (Polz *et al.*, 2006). The only species-like property that applies for the species-less model is ecological divergence (Kopac *et al.*, 2014).

Another kind of rapid diversification of bacterial lineages is fostered by plasmids (**Figure 7(e)**). These are infectious circles of DNA that can provide an ecological adaptation for the bacteria that host them. For example, a given 'symbiosis' plasmid confers to its *Rhizobium* host the abilities to infect a particular legume species and fix nitrogen. So, a particular *Rhizobium* lineage can change its ecological niche by acquiring a new symbiosis plasmid and losing its old one (Kumar *et al.*, 2015). In this 'recurrent niche invasion' model of bacterial speciation, lineages can change ecotypes very quickly (Kopac *et al.*, 2014). The lineages of different plasmid-based ecotypes are not irreversibly separate, as lineages are recurrently moving from one ecotype to another. However, the ecotypes themselves may persist indefinitely. Plasmid-determined ecotypes may be cohesive, since diversity within these ecotypes can be limited by periodic selection.

A longstanding question is whether the rate of ecological diversification is always so fast that even the closest relatives

are usually ecologically distinct (e.g., the species-less model), or whether diversification may be so slow that ecotypes hold huge populations of interchangeable organisms (stable ecotype model) (Doolittle and Zhaxybayeva, 2009). One possible determinant of the rate of diversification is metabolic plasticity (Cohan, 2016). Generalist heterotrophs such as *Bacillus* can easily change their ecological niche by acquiring a new gene or metabolic pathway and may thus speciate rapidly (Kopac *et al.*, 2014). On the other hand, photoautotrophs of the Cyanobacteria and Chlorobi utilize few organic resources and so have many fewer dimensions in which to diversify. Indeed, these two groups of photoautotrophs do appear to have diversified at a much slower rate than *Bacillus* (Becraft *et al.*, 2015; Bendall *et al.*, 2016).

It is not straightforward to identify the most newly divergent products of ecological speciation. Owing to the importance of horizontal genetic transfer in ecological speciation of prokaryotes (Gogarten and Townsend, 2005), one cannot anticipate the ecological dimensions by which ecological divergence occurs (Cohan and Perry, 2007). One promising approach to identifying ecotypes is based on finding closely related phylogenetic groups that are significantly different in the microhabitats from which they are isolated (Hunt *et al.*, 2008; Becraft *et al.*, 2011; Connor *et al.*, 2010). This approach is limited, however, by the investigator's knowledge about the ecological dimensions of speciation and whether speciation occurs principally through changes in microhabitat (Cohan and Koeppel, 2008).

Alternatively, systematists can attempt to identify the most newly divergent ecotypes even without knowing the ecological dimensions of divergence. Provided that there are periodic selection events purging the diversity within but not among ecotypes, ecotypes can be identified as sequence clusters for any gene(s) in the genome, using various algorithms (Francisco *et al.*, 2014; Koeppel *et al.*, 2008; Corander *et al.*, 2008; Barraclough *et al.*, 2009). Whether the most newly divergent ecotypes can be discovered as sequence clusters depends on the rate of speciation. In groups with extremely rapid speciation, such as *Bacillus* and perhaps other generalist heterotrophs, the resolution of the entire core genome may be required (Kopac *et al.*, 2014). However, in groups with slow speciation, such as *Synechococcus* and *Chlorobium*, even a single gene may provide the resolution to discover the newly divergent ecotypes (Becraft *et al.*, 2015).

Two genome-based approaches combine the advantage of providing molecular resolution to identify newly divergent ecotypes, while not requiring advance information about the ecology of speciation. First, if two lineages differ in their histories of positive selection on genes they share, one can reasonably conclude that the lineages are ecologically distinct (Vos, 2011; Kopac *et al.*, 2014). Alternatively, one can infer ecological distinctions among lineages that differ in the content of their genes, particularly when the dimensions of ecological divergence are implied from the genes unique to each lineage (Guttman *et al.*, 2014; Shapiro *et al.*, 2012).

These approaches do not require the cultivation of the species we seek to identify. Single-cell genome sequencing of uncultivated organisms has yielded the diversity of ecological species in *Prochlorococcus* (Kashtan *et al.*, 2014; Malmstrom *et al.*, 2013), and high-throughput sequencing of DNA from the environment (metagenomics) has yielded evidence of groups with species-like properties in *Chlorobium* (Bendall *et al.*, 2016).

Should all of the ecotypes in the prokaryotic world be named as species? This may be possible in groups where the origin of new ecotypes is slow, such as the photoautotrophs and perhaps the chemolithotrophs, with little metabolic plasticity. However, in rapidly speciating groups such as generalist heterotrophs and perhaps pathogens, the naming of diversity may have to be limited to ecological variants of particular interest to microbial ecology, public health, or biotechnology (Kopac and Cohan, 2011), and that are expected to have some permanence (Thompson *et al.*, 2014).

Conclusion

Species may be demarcated as clusters with a predetermined level of diversity, as in the practice of systematics. The high threshold of diversity stipulated by systematics has yielded unhelpfully diverse species, but the threshold could be changed to yield more homogeneous species taxa. Alternatively, demarcating species as units of recombination or as ecologically distinct populations yields homogeneous groups with at least some of the dynamic properties attributed to species. In either case, genomes provide an efficient way to discover diversity at the species level and to infer the ecological roles of each species.

Glossary

Evolutionary trap When there is a phenotype–environment mismatch (see below), organisms can behave in maladaptive ways that can pose a serious threat to species survival.

GMO Genetically modified organism (GMO) is an organism whose genes have been altered using genetic engineering techniques.

Phenotype–environment mismatch This occurs when the environment in which an organism has evolved changes quickly, significantly, or both, so that the phenotype is no longer adapted to it.

Phylogenetic methods A broad category of statistical methods employed to determine the relatedness of species or types. These analyses can be done with morphological and/or genetic traits.

In 1993, an estimated 2.5 million people worldwide had AIDS (acquired immune deficiency syndrome), and many of the few lucky enough to get treatment were dying. Zidovudine, one of the first antiretroviral drugs developed to treat AIDS, would induce resistance in HIV, the virus that causes AIDS, and render the drug useless. However, by 1996, combination therapy of multiple antiviral medicines was dramatically increasing survival of HIV-infected patients. This standard combination therapy relied on knowledge that resistance mutations are rare and arise independently for each type of antiviral treatment. Using many treatments at once minimizes the chances that any one virus can evolve resistance in all fronts. This new standard of care, in use today in almost a third of the 35 million people infected with HIV, emerged as the direct consequence of our knowledge of evolution, in particular, how organisms adapt to their environment.

This is just one example among many of the relevance of evolutionary biology to society. The work of evolutionary biologists involves studying the mechanisms and consequences of evolutionary processes. However, as illustrated in the example above, their work is not entirely abstract. Beyond helping to redefine the boundaries of knowledge, understanding evolutionary principles is central to our health care, food safety, and biodiversity conservation.

Surprisingly, despite the direct connections between quality of life and application of evolutionary principles, these principles are not known or accepted as fact by some percentage of citizens in many countries around the world, but particularly in the USA, where only 30% of adults express a definite belief in evolution (Miller *et al.*, 2006). At the same time, government support for evolutionary biology research and other basic sciences is stagnant in the USA and Europe, barely keeping up with inflation (Brennan *et al.*, 2014a,b; Global R&D forecast by Batelle, 2014).

There is, therefore, a disconnect between the impact of basic evolutionary science, the government support that goes into it, and the public understanding of how knowledge of basic evolutionary principles affects their daily life. This article discusses the distinction between basic and applied science, the current state of funding for basic science, and gives some examples of the impact of evolutionary research, to make these connections explicit.

Impacts of Evolutionary Biology

In 2008, the National Research Council's Board on Life Sciences convened a committee to examine the current state of Biology, and make recommendations on how to use biological advances to further societal well-being. The report identified four areas where such advances are both necessary and achievable: increasing food security by developing new locally adapted plant crops, increasing the maintenance of ecosystems and biodiversity in a changing environment, expanding non-fossil fuel energy, and developing an individual approach to health care (Carroll *et al.*, 2014). A recent review on applied evolution identified two major causes of global challenges: rapid contemporary evolution and a phenotype–environment mismatch (Carroll *et al.*, 2014). Rapid contemporary evolution results in the emergence of pesticide and antibiotic resistance, while phenotype–environment mismatch contributes to low yield of food crops in a changing climate, and loss of biodiversity. Evolutionary biology principles that allow us to understand how organisms adapt to environmental change, and how they diversify, have played and will continue to play an important role in solving challenges in all these areas (Hendry *et al.*, 2011; Losos *et al.*, 2013; Carroll *et al.*, 2014).

Food Security

Feeding a growing population given current climatic unpredictability is a central challenge of the twenty-first century. The emergence of high yield crops in the 1950s was made possible by the application of evolutionary principles to plant breeding. However, the use of monocultures and genetically modified (GMO) crops, bred to produce higher yields, requires heavy pesticide use, and in recent years, yields have suffered from the emergence of pesticide resistance in species that attack such crops (Hendry *et al.*, 2011; Losos *et al.*, 2013; Carroll *et al.*, 2014). Heavy pesticide use has well-known detrimental effects to the environment and public health (Wilson and Tisdell, 2001). Further intensifying food production by continuing the current monoculture approach of both GMO and non-GMO crops is likely to cause more environmental damage. Therefore, an agricultural approach based on evolutionary theory and ecological principles that takes into account how the

 doi:10.1016/B978-0-12-800049-6.00290-0

relationships between species affect their evolution offers a safer alternative for the environment. Such an approach can minimize the evolution of pesticide resistance and preserve biodiversity, while maintaining long-term productivity (Bommarco *et al.*, 2013).

At the same time, selective breeding of crops that can cope with unpredictable climatic conditions resulting from global climate change will be crucial to producing enough crops to feed the world (Hendry *et al.*, 2011; Losos *et al.*, 2013; Carroll *et al.*, 2014). This can involve the production of drought and flood tolerant genetically modified crops, as well as selective breeding and hybridization of crops that already have some resistance traits, such as flood-resistant rice currently cultivated in Bangladesh and India (Carroll *et al.*, 2014).

An interesting and relatively new avenue for evolution to affect food production is to apply selection at the level of the group rather than the individual. This approach decreases the individual fitness, but increases overall group productivity by decreasing selfish genes. This concept was applied to the breeding of poultry, where group selection to lower competitive interactions among laying hens resulted in higher egg-laying rates and lower mortality rates, and can also be applied to other domesticated animals (e.g., Wade *et al.*, 2010). In food crops, genes that produce individually larger roots or leaves can be selected against to favor smaller roots and leaves that can result in a higher yield for the group (Carroll *et al.*, 2014).

Preserving Biodiversity, and Predicting and Mitigating the Effects of Global Climate Change

The challenge of preserving biodiversity can be addressed by protecting habitats that are identified as being crucial to several species, or those that serve as nurseries or refuges for many species (e.g., mangroves and wetlands); by establishing captive breeding programs that specifically reduce inbreeding and maximize genetic diversity; and by recognizing which species are most likely to be threatened by changes in the environment given their low adaptability (Hendry *et al.*, 2011; Losos *et al.*, 2013; Carroll *et al.*, 2014). This latter approach can be particularly useful when considering the potentially negative effects of global climate change in wild populations. While some species may thrive, others will undoubtedly be at risk.

Non-Fossil Fuel Energy

One of the challenges of expanding alternative fuel sources such as wind and solar energy is anticipating and mitigating their potential impacts on wildlife. Collisions with wind turbines are a known cause of mortality for birds and bats, and avian mortality at solar panel farms has also been reported. Knowledge of how animals behave can help solve these potential problems. A recent report suggested that the impact to wildlife in terms of habitat changes and the turbines themselves is likely to be minimal (American Wind Wildlife Institute, 2014 report). However, knowledge that bats are more active at low wind speed has resulted in policy recommendations to switch off turbines when wind speed is low (Arnett *et al.*, 2010). A recent report on avian mortality at three solar powered facilities in California suggested that solar panels may be acting as 'evolutionary traps,' if they look like water that attracts insects and birds. A diverse array of evolutionary-based solutions can be implemented to reduce avian mortality at these sites, once the conditions that lead to mortality are known.

Health

In 2013, the CDC (Centers for Disease Control and Prevention) issued a report on antibiotic resistance threats in the United States. The list of potential threats is long, and divided into urgent, serious, and concerning microbial species. The much-publicized MRSA (methicillin-resistant *Staphylococcus aureus*) only reaches the serious level, while the relatively new CRE (carbapenem-resistant Enterobacteriaceae) makes the top of the list of urgent concerns (CDC, 2013). CRE comprise multiple bacteria species that have become resistant to carbapenems, the strongest antibiotics currently in use. Similar to the beginnings of the MRSA pandemic, CRE are currently limited to health care settings, hospitals, and elderly homes. However, in contrast to the 20% morbidity rate of MRSA, CRE causes deadly infection in 50% of those affected (CDC, 2013). These and many other antibiotic resistant superbugs constitute a serious health threat. Our best hope of managing not only their spread, but the emergence of further resistant strains is to apply evolutionary principles to our knowledge of their biology. For example, highly adaptable organisms when placed under strong selection can quickly evolve to mitigate the effects of selection on their survival. Rather than applying a continuous homogeneous source of strong selection, such as long-term single pesticide or antibiotic use, a better strategy to control the emergence of resistance often includes varying the selection regime in space or time (Hendry *et al.*, 2011; Losos *et al.*, 2013; Carroll *et al.*, 2014). Bacteria are highly adaptable because they can replicate quickly, and are adept at horizontal gene transfer, so individuals can pass on resistance genes to other unrelated individuals in the population, not only their descendants. For this reason, regulating and monitoring the use of the strongest antibiotics and using combination therapies as described for the treatment of AIDS can help to slow down the evolution of resistance (Carroll *et al.*, 2014).

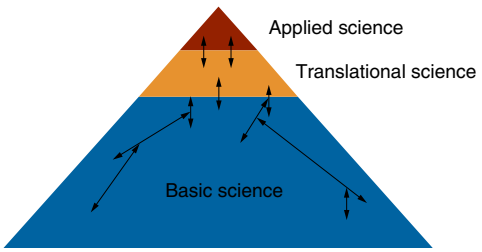

Figure 1 Applied science build upon the foundation of basic science. Though not all basic science projects contribute directly to an application, all applications require basic science. Translational science occurs at the interface between the two where targeted questions require specific basic scientific knowledge.

In addition, evolutionary medicine is helping us to understand and work with the body's naturally evolved defense mechanisms when faced with disease, and is even helping to understand aging and degenerative diseases (Wallace, 2005; Losos *et al.*, 2013). For example, morning sickness affects many pregnant women during the first trimester of their gestation, at the time when the fetus is most vulnerable to potential teratogenic compounds and infection in the mother could cause miscarriage (Profet, 1995). The types of food aversions that are typically shown by pregnant women ensure that foods that can potentially make them sick or affect the fetus are not consumed during this window, and women who suffer from morning sickness are known to have lower rates of miscarriage (Flaxman and Sherman, 2000; Flaxman and Sherman, 2008). This evolutionary understanding should prevent unnecessary treatment and help women understand the potential utility of morning sickness.

Justice System

Evolutionary methods relying in genetic analyses of samples have been used in trials in recent years. Phylogenetic analyses are now an accepted method to establish facts according to the United States criminal system (Losos *et al.*, 2013). This method has been used to determine whether intentional inoculation of HIV virus into victims occurred at the hand of doctors, by analyzing the relatedness of viral strains while accounting for their evolution in the body of infected patients (Metzker *et al.*, 2002; Scaduto *et al.*, 2010).

Basic and Applied Science

The benefits of science to the advance of society are undeniable, and yet sometimes it can be difficult to see the benefit of

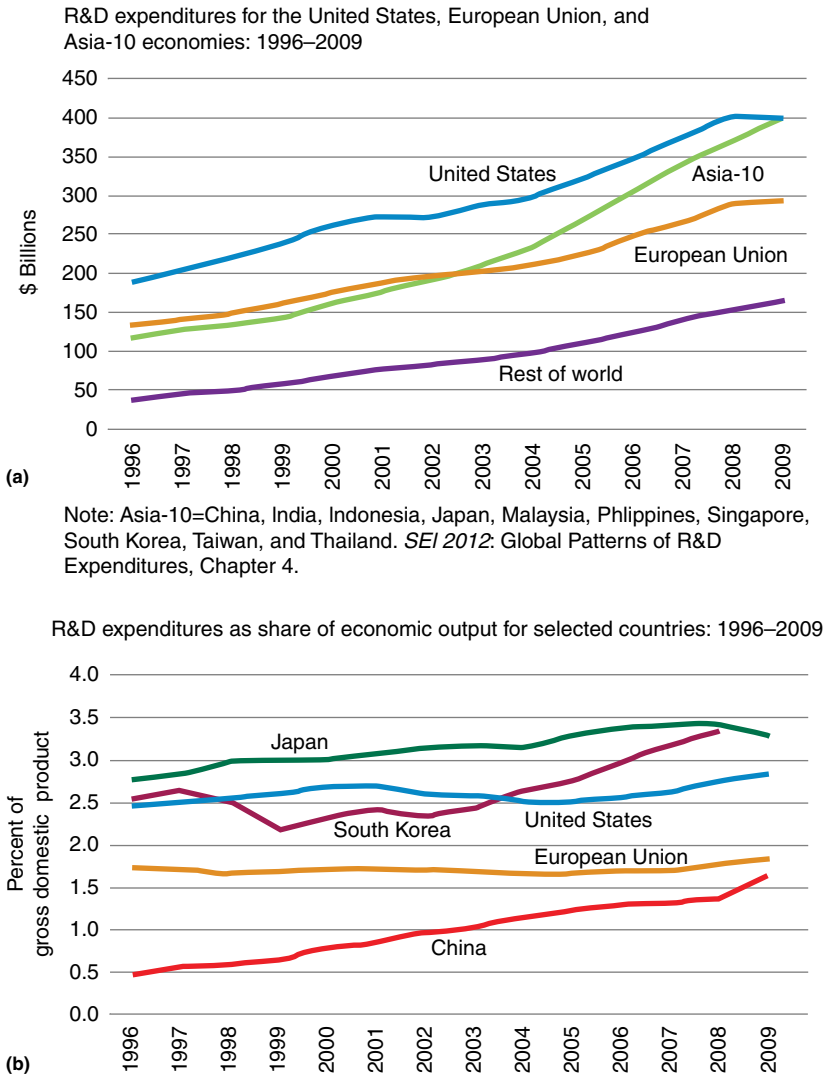

Figure 2 USA expenditure in research and development both in absolute number of dollars (a) and as a percentage of GDP (b). Reproduced from National Science Board's Science and Engineering Indicators Digest, 2012. Available at: http://www.nsf.gov/statistics/digest12/nsb1202.pdf (accessed 05.10.15).

individual studies. This is because many scientific projects are fundamental or basic science, that is, they are driven only by the desire to increase knowledge and redefine its boundaries. This fundamental knowledge is the basis upon which applied sciences are built. Applied science, on the other hand, is problem driven, seeking to find solutions to specific problems. At the interface between the two is translational (also known as developmental) science, that targets promising fundamental science for development into an application. Both translational and applied science result in incremental advances and progress because they seek to answer specific questions in a targeted manner. In contrast, basic science that does not have a specific problem to solve can have a transformative effect and result in groundbreaking innovation: completely novel ideas that fundamentally change or create new fields of inquiry, or result in a completely new technological approach.

The relationship between basic, translational, and applied science can be illustrated by a pyramid graphic (**Figure 1**). The base of the pyramid is basic science, comprising the majority of our scientific knowledge, and the apex illustrates the applications. The applications are built upon the basis of fundamental science. Though not all of basic science contributes to applied science, all of applied science 'requires' the existence of a broad base of basic knowledge, and critically, it is impossible to predict a priori which basic science will in fact turn out to be useful in solving a particular problem. An alternative scenario is to imagine a tree, where the fruits are the application of science, and the rest of the tree, the basic knowledge required to produce the fruit. Regardless of what the most fitting illustration of these connections may be, the important message is that without basic science, there would be no progress. Because we can't predict which projects will be used in solving a specific problem, the best strategy is to continue to support basic science that expands our knowledge of how nature works.

Scientific unpredictability derives in part from the interconnected nature of science. Many scientific breakthroughs occur because of unforeseen connections between unrelated projects within a discipline, or between unrelated fields. Recognition of the unpredictable relationship between basic and applied science led to the recent creation of the Golden Goose Award by the American Association for the Advancement of Science (AAAS), in partnership with other organizations. Dr. Paul Schanberg and members of his lab, as well as Dr. Tiffany Field, were awarded the Golden Goose Award in 2014. The work of Dr. Schanberg involved studying growth of rat pups. His team found that when they separated rat pups from their moms, they stopped growing. After a series of experiments, they identified that mechanical stimulation from the mom licking the babies was needed to elicit growth. Dr. Field was a psychologist studying growth in human infants, and after a chance meeting with Dr. Schanberg, she decided to explore the possibility that touch may also be important for human baby growth. Her research lead to the now well-established infant massage technique, that introduced regular massage and contact to babies born prematurely. This technique has saved the lives of countless babies, as well approximately $4.7 billions on healthcare costs. Dr. Schanberg would have never predicted that his work would result in such a remarkable application.

Another example is the work of Professor Craig Tovey, who inspired by a talk on the biology of honeybees went on to develop an algorithm to determine how close to optimality the bees were at gathering nectar. He found that through their 'waggle dance' behavior to recruit foragers to the nectar sources, honeybees were within 8% of their optimal nectar gathering ability. Almost 10 years after he concluded this research, Sunil Nakrani, a PhD student from Oxford came to seek Prof. Tovey's advice in solving the problem of developing a web-hosting algorithm to optimally allocate bandwidth to different client's needs. Prof. Tovey immediately saw the potential use of his honeybee research to solve this problem. The honeybee algorithm that Tovey and Nakrani developed, improved the efficiency of server allocation drastically, leading to an increase of 5–25% in revenue generation by the servers (Nakrani and Tovey, 2007). Due to the competitive advantage gained through the implementation of such algorithms in industry, it is hard to quantify the economic impact of Prof. Tovey's research on honeybee foraging. However, algorithms similar to the honeybees are continuously being developed for many different applications. What started as a curiosity has become fundamental to the efficient use of the internet.

The National Research Council's (US) (2009) report on Biology for the twenty-first century explicitly sought out to apply current knowledge of biology to some of the most pressing societal problems. However, it explicitly acknowledged that its success depends on fundamental research. Even as evolutionary biology has been widely applied for the health

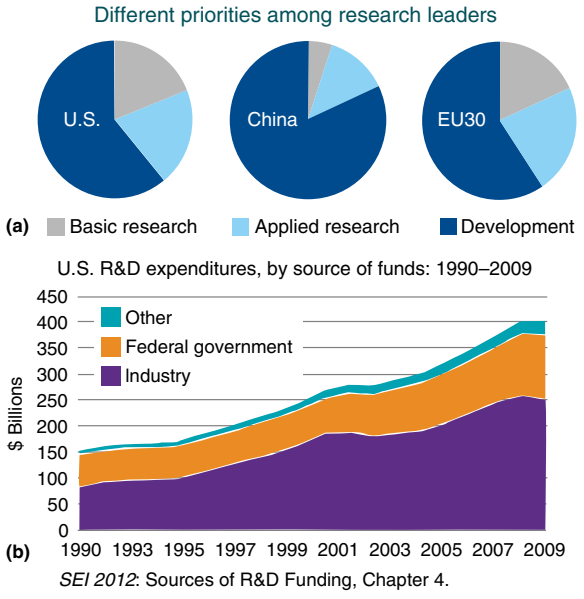

Figure 3 Investment in Basic Science is much smaller in China, the only nation with rapidly increasing investment in R&D. (a) Reproduced from Global Research and Development Forecast, 2014 (Funding sources for all R&D in the USA) Produced by Batelle. and economic benefit of society as discussed above, most research is conducted without such applications in mind.

Funding for Basic Science

The USA has traditionally invested more money than any other country in research and development (**Figure 2(a)**). However, the percent of gross domestic product (GDP) that the USA invests in research and development (R&D) has been steadily declining over the past few years (**Figure 2(b)**), and currently nine other nations invest a higher percentage of their GDP in R&D, including Israel, Finland, Sweeden, South Korea, and Japan. China, India, and Brazil, the world's fastest growing economies, have been steadily increasing their investment in R&D. With the current trends, they will surpass USA investment within a decade (National Science Board Digest, 2012; Global R&D forecast by Batelle, 2014). Europe has also been steadily declining its investment in R&D, and the current weak economic trends in both the USA and Europe suggest that increased investment is unlikely in the near future (Global R&D forecast by Batelle, 2014). Both the USA and Europe have typically invested close to 20% in basic science, while Chinese investment in basic science is barely 5% (Global R&D forecast by Batelle, 2014, Batelle Institute; **Figure 3(a)**). Therefore, lack of growth of R&D funding in the USA and Europe will disproportionately impact basic research around the world.

The money the USA invests in R&D includes investment by industry, the federal government, as well as a small (but growing) proportion being spent by private individuals (**Figure 3(b)**). In 1990, the federal government in the USA contributed nearly 50% of the R&D expenditure of $150 billion. In 2009, the figure was closer to 30% of the nearly $400 billion spent ($135 billion) (National Science Board Digest, 2012), and even this reduced investment has elicited political battles in Washington D.C.

In the USA, the federal government is the source of funding for the majority of the basic science, particularly through funding the National Science Foundation (2012). However, NSF is not charged only with funding basic science, but many scientific projects at large, many of them translational. Most basic research is performed at universities and academic institutions. Therefore, cuts and reduced growth of the basic science budget primarily affect academia (**Figures 4(a)** and **4(b)**). In contrast, applied science is funded and performed largely by industry (**Figures 4(c)** and **4(d)**). Out of the $144

billion allocated to the R&D budget in 2014, only $6.3 billion were allocated to NSF. The Biological directorate budget went from $511.14 million in 2001 to $678.93 million in 2013, which is equivalent to $514.83 million in 2001 (Brennan *et al.*, 2014a,b).

Despite the low priority that basic science funding is getting from the government, a recent Pew Research Center survey found that 71% of the public believes that government investment in basic science pays off in the long run. However, even as 60% of adults surveyed stated that government investment in science is essential for progress, a full 34% believe that private investment will be enough. This section of the public is likely unaware of the distinction between basic and applied science, and that private funds already contribute the majority of the money spend in science in the USA as shown in Figure 4. Government investment in science is needed not only to fund basic science performed in universities and academic institutions, but this science is also generally free of special interests, and available for the benefit of the general public.

Even as funding for basic science and the Biological science directorate at the NSF has stagnated, government-led programs to increase the appeal of STEM fields have been very successful in the USA. In 2011, roughly 36 000 STEM PhDs were awarded in the USA, almost double the number in 1982 (19 000 PhDs) (Schillebeeckx *et al.*, 2013). As a result of this increase of available scientists in STEM fields, competition for the shrinking pool of money at NSF (and the National Institutes of Health, NIH) has become fierce, and funding rates in some programs are as low as 3.5% when the number of submitted pre-proposals is taken into account. According to the NSF's Fiscal Year 2012 report: "The number of investigators submitting proposals has grown steadily over the past decade at a rate that exceeds the rate of growth of NSF's normal appropriation in inflation adjusted dollars. Consequently, the success rate of PIs has declined … The number of PIs who submitted proposals in 2010–2012 was 42% higher than the number in 2001–2003." As a result of increased competition for funding in the USA, many excellent scientists have found it difficult to continue their research programs, leading to both laboratory closures (Wadman, 2009; Startford, 2013), and the emigration of young scientists to pursue better research opportunities abroad (Rae-Dupree, 2013; Non-defense discretionary science survey, 2013). Many scientists around the world (36% in the USA and 29% elsewhere) cite lack of external funding as the main challenge to conducting research (Global R&D forecast by Batelle, 2014).

Public Perception of Evolutionary Science

A Pew research center poll in 2009 found that 61% of the general public in the USA agrees that humans and other creatures have evolved over time, but only 32% agree that this change is the result of natural processes, while 22% believe the change to be directed by a supreme being, and 31% believe that everything has existed in its present form since the beginning of time. A more recent Pew Research Center survey (2015) on public and scientists' views of science and society revealed large gaps between the percentage of scientists who believe science-related statements, and the percentage of the public who do. When asked whether humans have evolved over time, 98% of scientists responded yes, whereas only 65% of adults from the general public did, not much of a change since 2009. The United States has the lowest agreement with evolution than any other developed country in the world, but most countries have some percentage of evolution deniers (Figure 5).

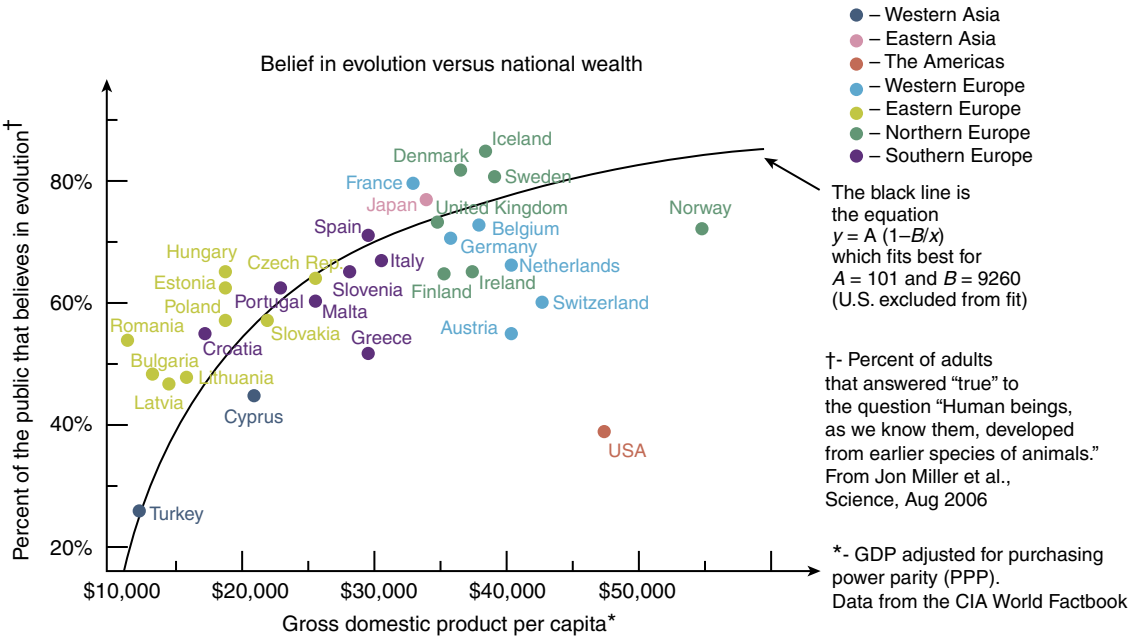

Figure 5 The USA has the lowest belief in evolution of any developed nation in the world. Reproduced from http://www.data360.org/image_view.aspx?Uploaded_Image_Id=1246 (accessed 08.10.15).

Perhaps the perception that there is not complete agreement among scientists over all the details of how evolution proceeds, contributes to public skepticism of science as shown in debates over climate change (Aklin and Urpelainen, 2014). In response, perhaps it is best to simply quote Adam Gopnik: "Darwinism is true in the complex sense that scientific theories always are – not fixed in its particulars, immutable and imposing, but rich, changing, and evermore explanatory" (Gopnik, 2015).

Evolutionary biology is a fundamental scientific field of study that has impacted and will continue to impact every major area of human well-being. Basic evolutionary research is crucial to our continued ability to improve human health, agriculture, and conservation.

Bayesian Phylogenetic Methods

Z Yang, University College London, London, UK

Introduction

Bayesian statistics has the unique feature that uncertainties in all unknowns (such as the unknown parameters in a model or the competing hypotheses for explaining the same data) are described using statistical distributions. In classical statistics (such as the maximum likelihood method), parameters and hypotheses cannot be assigned distributions. Suppose one wants to analyze the data (x) to estimate the unknown parameter θ under a model. In a Bayesian analysis, one assigns a distribution on θ before the analysis of the data. This is called the 'prior distribution' and reflects one's knowledge or belief about the possible values of θ. The Bayesian analysis of the data then produces the distribution of θ given the data, $f(\theta|x)$, called the 'posterior distribution.' The two are related through the Bayes theorem

$$f(\theta|x) = \frac{f(\theta)f(x|\theta)}{f(x)} \propto f(\theta)f(x|\theta) \quad [1]$$

Here the probability of the data given the parameter θ, $f(x|\theta)$, is the likelihood, and represents the information about the parameter θ in the data x. The marginal probability of the data, $f(x) = \int f(\theta)f(x|\theta)\mathrm{d}\theta$, is a normalizing constant, and its role is to ensure that $f(\theta|x)$ is a proper statistical distribution and integrates to 1. Equation [1] thus says that the posterior is proportional to the prior times the likelihood, or equivalently, the posterior combines information in the prior and in the data sample.

Note that the likelihood function is the basis for classical statistical methods, especially the maximum likelihood method. Thus all models developed for the maximum likelihood method can be implemented in the Bayesian framework. In analysis of large datasets, the two methods often produce numerically very similar results even though the interpretations differ. However, different results may be obtained by the two methodologies if the data are not informative, and in particular, if the focus of the analysis is on model selection.

In molecular phylogenetics, the data x is an alignment (or alignments) of sequences of nucleotides, codons, or amino acids from several species. Here, we assume that the sequences are already aligned and we ignore alignment errors. Our focus is the phylogenetic tree, which consists of the tree topology (τ) and the lengths of branches (denoted collectively as $\boldsymbol{b}$). The branch length is measured by the expected number of substitutions per site, and quantifies the amount of evolution along the branch. Given the tree, the sequence data at the tips of the tree (for extant species) are the product of the process of sequence evolution along the branches. This process is typically described by a continuous time Markov chain (Felsenstein, 1981). The model of substitution may include additional parameters, denoted ϕ, such as the relative substitution rates between nucleotides and the equilibrium frequencies of the nucleotides. More complex models may include parameters to describe the rate variation across sites in the sequence or the nonsynonymous/synonymous substitution rate ratio in comparisons of protein-coding gene sequences (Yang, 1993; Goldman and Yang, 1994). For more details on various models used in molecular phylogenetics.

The posterior distribution of the tree topology, branch lengths, and substitution parameters is then given by eqn [1] with parameter θ replaced by τ, $\boldsymbol{b}$, and ϕ:

$$f(\tau,\boldsymbol{b},\phi|x) \propto f(\phi)f(\tau,\boldsymbol{b})f(x|\tau,\boldsymbol{b},\phi) \quad [2]$$

Here $f(\phi)$ is the prior distribution on substitution parameters, $f(\tau, \boldsymbol{b})$ is the prior on tree topology and branch lengths, while $f(x|\tau, \boldsymbol{b}, \phi)$ is the likelihood or probability of the sequence data given the tree topology and branch lengths, given by the model of sequence evolution (Felsenstein, 1981).

The Bayesian approach to molecular phylogenetics was introduced by Rannala and Yang (1996), Yang and Rannala (1997), Mau and Newton (1997), and Li *et al.* (2000). The early studies used simple models of sequence evolution and assumed a constant rate of evolution (the molecular clock). Nowadays, we have several Bayesian phylogenetic programs that implement a wide range of complex models that account for various aspects of the sequence data. General Bayesian programs for phylogeny reconstruction include MrBayes (Ronquist *et al.*, 2012), BEAST (Drummond and Rambaut, 2007), and PhyloBayes (Lartillot *et al.*, 2009). A number of Bayesian programs are also available for estimating species divergence times incorporating information in both fossils and molecules, such as MCMCTREE (Yang, 2007) and DPPDIV (Heath *et al.*, 2012).

For an extensive discussion of Markov chain Monte Carlo (MCMC) algorithms used in Bayesian phylogenetics, see Chapters 7 and 8 of Yang (2014). The edited book by Chen *et al.* (2014) summarizes recent developments, especially concerning model selection in Bayesian phylogenetics.

Priors

The prior distribution is supposed to summarize one's objective information (according to 'Objective Bayesian') or personal beliefs (according to 'Subjective Bayesian') about the likely values of the model parameters. In Bayesian phylogenetics, the tree topologies (τ) represent discrete statistical models, the branch lengths ($\boldsymbol{b}$) are continuous parameters that are defined only on specific trees, while the substitution parameters (ϕ) are often defined for all possible trees. The parameter space of the inference problem is high-dimensional and also complex. Specification of the prior is thus a nontrivial task. Indeed, a few cases have been identified in which innocent-looking priors adopted in common Bayesian programs lead to unreasonable extreme results.

Here we describe a few commonly used prior distributions in Bayesian phylogenetics. First we consider the prior on the tree topology. Most phylogenetic analyses are conducted

without assuming the molecular clock and use unrooted trees. The total number of unrooted trees T_n for n species is

$$T_n = (2n-5)(2n-7)\cdots 1 \quad [3]$$

It is common to assign a uniform prior on all possible trees, with each assigned the probability $1/T_n$.

If the species are closely related, the evolutionary rate may be roughly constant among species. One can then use the molecular clock to infer rooted trees. Rooted trees are also used to infer species divergence times in the so-called molecular clock or relaxed-clock dating analysis. A prior distribution over the rooted trees and node ages (branching times) can be generated using a model of cladogenesis. For example, a birth–death process conditioned on the number of observed or sampled species can be used to describe the biological process of speciation and extinction, and to generate a prior on the rooted tree topologies and node ages. The birth–death process includes the Yule pure-birth process as a special case. Parameters for the birth–death model include the birth rate, the death rate, and the sampling fraction (the proportion of extant species that are actually included in the data). Those parameters in the prior can be changed to assess the impact of the prior on the posterior inference, or they may be estimated from the data by assigned prior distributions on them (called 'hyper-priors').

For DNA sequences sampled from the same species, Kingman's (1982) coalescent process provides a prior distribution for the gene genealogies. However, this is not a suitable prior model for inferring species phylogenies.

Next, we consider the prior for branch lengths. A binary unrooted tree for n species has $2n-3$ branches. Given each unrooted tree topology, the $2n-3$ branch lengths can be assigned independent and identical distributions (i.i.d.) such as the uniform or exponential. In the case of the uniform, an upper bound (such as 100) is specified by the user. However, those i.i.d. priors on branch lengths have been found to be problematic, as they may be very informative and unreasonable about the tree length (sum of branch lengths) (Rannala *et al.*, 2012). For example, a tree of 100 species has 197 branch lengths. If each is assigned the uniform prior U(0, 100), the tree length will have the prior mean 9850 and the 99% prior interval (8806, 10 894), with ~10 000 substitutions at an average site. When the data are not very informative (as is the case when the sequences are highly similar), this unreasonable prior can overwhelm the Bayesian analysis and leads to unreasonably long trees with large tree lengths (Brown *et al.*, 2010). An alternative has been suggested to fix this problem (Rannala *et al.*, 2012; Zhang *et al.*, 2012), in which a gamma prior is assigned to the tree length and then the sum is partitioned into branch lengths according to a uniform Dirichlet distribution (a multivariate extension of the uniform distribution).

Markov Chain Monte Carlo

Note that the normalizing constant $f(x)$ in eqn [1] involves an integral. When there are many parameters in the model, this integral will be multidimensional and may be very hard to compute. Modern Bayesian inference is often achieved through a computational algorithm called MCMC. This is an iterative simulation algorithm that generates a sample from the posterior distribution $f(\theta|x)$.

Here we illustrate the main features of the MCMC algorithm by applying it to the simple phylogenetic problem of estimating the distance θ between two sequences under the JC69 model (Jukes and Cantor, 1969). The data consist of the human and orangutan mitochondrial 12S rRNA genes, with $x=90$ differences at $n=948$ sites. The parameter θ is the expected number of nucleotide substitutions per site between the two sequences. Given θ, the likelihood or the probability of observing the data is given by the binomial probability

$$f(x|\theta) = p^x(1-p)^{n-x} = \left(\tfrac{3}{4} - \tfrac{3}{4}e^{-4\theta/3}\right)^x \left(\tfrac{1}{4} + \tfrac{3}{4}e^{-4\theta/3}\right)^{n-x}, \quad [4]$$

where $p = \frac{3}{4} - \frac{3}{4}e^{-4\theta/3}$ is the probability that a site is occupied by two different nucleotides in the two sequences separated by a distance θ. We assign a uniform prior on θ in the range (0, 1) so that $f(\theta)=1$ for $0<\theta<1$. The posterior is then given by eqn [1] as

$$f(\theta|x) = \frac{1}{f(x)} f(\theta) f(x|\theta) = \frac{1}{f(x)} \left(\frac{3}{4} - \frac{3}{4}e^{-4\theta/3}\right)^x \left(\frac{1}{4} + \frac{3}{4}e^{-4\theta/3}\right)^{n-x} \quad [5]$$

The following algorithm generates a sample from this posterior distribution.

1. Initialize: $n=948$, $x=90$, $w=0.25$. Set initial state: $\theta=0.1$, say.
2. Loop
   a. (Propose a new value θ^*.) Generate $u \sim U(0, 1)$ and set $\theta^* = \theta + w(\frac{1}{2} - u)$. Note that θ^* is a uniform random variable over the interval $U(\theta - \frac{w}{2}, \theta + \frac{w}{2})$. If $\theta^* < 0$, set $\theta^* = -\theta^*$.
   b. (Accept or reject the proposed value.) Compute the posterior density ratio $\alpha = \frac{f(\theta^*|x)}{f(\theta|x)} = \frac{f(\theta^*)f(x|\theta^*)}{f(\theta)f(x|\theta)}$. If $\alpha > 1$, accept θ^*. Otherwise accept θ^* with probability α. This can be achieved by drawing another random number $v \sim U(0, 1)$, and accepting θ^* if and only if $v < \alpha$. If θ^* is accepted set $\theta = \theta^*$. Otherwise set $\theta = \theta$.
   c. Print out θ.

It is easy to see that the algorithm simulates a Markov chain; the next θ value the algorithm will visit depends on the current θ only, but not the θ values visited in the past. Second, the algorithm tends to visit θ values with high posterior more often than θ values with low posterior. Indeed, the probability that the visited θ value is in the interval $(\theta, \theta + \Delta\theta)$ is $f(x|\theta)\Delta\theta$. In other words, the θ values generated by the algorithm constitute a sample from the posterior distribution $f(x|\theta)$. Lastly, there is no need to compute the normalizing constant $f(x)$ of eqn [5] since it cancels in the calculation of the posterior ratio α in Step 2b. This is the feature that allows us to avoid the calculation of the high-dimensional integrals, making it possible to implement sophisticated parameter-rich models that may not be feasible for maximum likelihood implementation.

Figure 1(a) shows the paths of two Markov chains from two runs of the algorithm, using different starting positions. Figure 1(b) shows the histogram and smoothed density estimate of posterior using a large sample from a long chain.

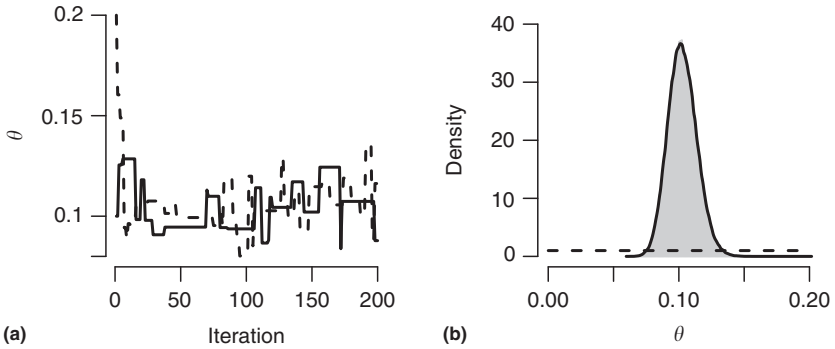

Figure 1 Markov chain Monte Carlo algorithm to sample from the posterior for the JC69 distance θ between two sequences. (a) Trace plot of two chains which started from different positions (0.1 and 0.2), each run over 200 iterations. (b) Histogram (shaded area) and smoothed density (solid curve) of the posterior sample obtained by running the algorithm over 10^6 iterations. The prior (dashed line) is shown as well for comparison.

The posterior mean is 0.1027, standard deviation is 0.0110, and the central 95% posterior credibility interval is (0.0824, 0.1253). In comparison, the famous JC69 distance formula gives the maximum likelihood estimate to be $\hat{\theta} = 0.1015$.

In phylogenetic reconstruction, the parameter space consists of several components: the tree topology τ, the branch lengths $\boldsymbol{b}$, and the substitution parameters ϕ. In each iteration, the different components may be updated in turn. For example, variants of tree search algorithms such as nearest neighbor interchange (NNI) and subtree pruning and regrafting (SPR) can be used to update the tree topology. The branch lengths and substitution parameters can be updated using sliding windows, as in the simple MCMC algorithm above. See Chapter 8 of Yang (2014) for a detailed discussion of MCMC proposal algorithms in phylogenetics. The phylogenetic MCMC algorithm generates a sample from the joint posterior distribution of the tree topologies (τ), the branch lengths ($\boldsymbol{b}$), and the substitution parameters (ϕ).

Output Analysis from Simulation

The MCMC sample from the posterior distribution can be summarized in different ways.

For scalar parameters such as branch lengths ($\boldsymbol{b}$) and substitution parameters (ϕ), the posterior means or medians are often used, together with the 95% posterior credibility intervals (CIs). Two types of intervals are commonly used. The 95% central (equal-tail) CI lies between the 2.5% and 97.5% quantiles of the posterior sample. The highest posterior density (HPD) CI includes values that make up 95% of the posterior probability and that have the highest posterior density. When the data are informative so that the posterior of the parameter is nearly symmetrical, the two intervals will be nearly identical. Otherwise they can be very different. The HPD interval is generally preferred over the equal-tail interval since it has the shortest length and includes only the most likely parameter values.

For the tree topology, a simple summary is the 'maximum a posteriori' (MAP) tree, which is the tree topology with the highest posterior probability (that is, the tree topology that is most visited during the MCMC algorithm). This gives a point estimate of the true tree. However, when the data are not very informative, the MAP tree may have a very low posterior probability, and is a poor summary. We also have an analogue of interval estimates for trees. The 95% credible set of trees contains those trees that have the highest posterior probabilities such that the total probability of the entire set is at least 95%. However, if this set contains a large number of trees, it will not be very useful.

The most commonly used summary is the so-called majority-rule consensus tree. Note that each internal branch defines a split (a bipartition) of the species. The majority-rule consensus tree includes splits that appear in at least half of the trees sampled, with the posterior probability of each split indicated on the internal branch of the tree. For more details on constructing consensus trees.

Conservation Biogeography – Origins and Aims

The field of Biogeography is devoted to understanding the spatial distribution of species and their shifts over time. As such, Biogeography is central to conserving biodiversity on Earth (Heaney and Lomolino, 2009). Conservation Biogeography emerged from the fusion of Biogeography and Conservation Biology, as an applied science seeking to preserve biodiversity through informed management decisions at regional, continental, and global scales (Whittaker *et al.*, 2005). To this end, Conservation Biogeography applies biogeographical methods, principles, and theories to case studies related to the conservation of biodiversity (Richardson and Whittaker, 2010). From its onset, Conservation Biogeography has focused on the development of context-explicit plans, especially maps, to identify priority areas for protection based on patterns of species distribution and biodiversity metrics (Dinerstein *et al.*, 1995; Long *et al.*, 1996). Data and methods that measure and map species diversity, endemism, and human-imposed threats have been central to the establishment to the discipline (e.g., Olson and Dinerstein, 1998; Myers *et al.*, 2000).

Insights from biogeographical studies have long been applied to conservation. The 1970s, for instance, witnessed a lively debate about the equilibrium theory of island biogeography and its application to Conservation Biology (MacArthur and Wilson, 1967). At that time, particular focus was given to whether the theory supported the establishment of large biological reserves worldwide, as opposed to several small protection areas of the same total size (the SLOSS debate; Simberloff and Abele, 1982). On one hand, biogeographic principles were used to justify an expectation of reduced levels of extinction in large reserves (Wilson and Willis, 1975; IUCN, 1980). On the other side, multiple small protected areas, when dispersed across geography, were known to complement each other in species composition and collectively hold more species. It was only in the mid-1980s, when species-specific ranges and population sizes became broadly acknowledged as important determinants of extinction (and hence central for reserve planning; Soulé and Simberloff, 1986), that the emphasis on a 'one-size-fits-all' approach to reserve design was abandoned.

Large-scale efforts to map species distributions and guide management and policy started in the mid-1990s, driven by nongovernmental organizations actively engaged in conservation (see Dinerstein *et al.*, 1995; Long *et al.*, 1996; Myers *et al.*, 2000, for studies by The World Wildlife Fund, BirdLife and Conservation International, respectively). At that time, much attention was given to how and where to design biological reserves while ensuring the maximum amount of biodiversity representation and complementarity under small social and economic costs (Csuti *et al.*, 1997; Pressey *et al.*, 1997; Edwards *et al.*, 1998). At the core of those analyses laid a vision to compile and combine information about the diversity and the geographical distribution of many large groups of species – providing general snapshots of the state of biodiversity. Mapping efforts such as those have been flagged as one of the most influential products of Conservation Biology (Whittaker *et al.*, 2005). By guiding management through targeted fund raising, landscape restoration, or reserve implementation, maps of diversity patterns and diversity metrics have effectively bridged scientific knowledge and action on the ground, liaising scientists, policy-makers, and stakeholders (Dalton, 2000; Myers and Mittermeier, 2003).

Yet it did not take long for Conservation Biogeography to expand within the academic world. The early 2000s witnessed an explosion of studies of the distribution of biodiversity at local and regional scales, often targeting comparatively small taxonomic groups in well-defined yet understudied ecosystems. The diversity of datasets compiled and analyzed in the beginning of the new century was noteworthy: from analyses of amphibians of the Brazilian Cerrado (Diniz-Filho *et al.*, 2006) to vertebrates of Northeast India (Pawar *et al.*, 2007), snakes of China (Chen, 2009), oak trees in Middle America (Torres-Miranda *et al.*, 2011), Mediterranean Islands butterflies (Dapporto and Dennis, 2009), and terrestrial and marine species in Antarctica (Terauds *et al.*, 2012), to mention a few. As a result of these efforts and of the pioneer NGO initiatives, government agencies worldwide began to employ maps of biodiversity metrics, human impacts, and biogeographical realms into conservation and prioritization plans (see MMA, 2002 for protocols applied in Brazil, for instance). Collectively, these academic and case studies built from and contributed to an unprecedented increase in the amount and quality of georeferenced locality data from species across the globe (several now publically available through online repositories such as The Global Biodiversity Information Facility, Flemons *et al.*, 2007; Vertnet, Guralnick and Constable, 2010; among others), worldwide environmental descriptors (e.g., Bioclim, Hijmans *et al.*, 2005; CliMond, Kriticos *et al.*, 2012), and novel correlative methods to model species distributions based on environmental features (e.g., Phillips *et al.*, 2006). Importantly, however, the growth of Conservation Biogeography over the past 10–15 years allowed the field to expand its methodological approaches, aims, and ties with other scientific disciplines.

Evolving Maps

The biodiversity metrics and variables mapped by Conservation Biogeography studies have unquestionably evolved during the last decade. Going beyond analyses of species diversity, recent research demonstrated the relevance of mapping the distribution of phylogenetic diversity in geographic space, assessing, for instance, the proportion of the Tree of Life represented in a given area or reserve system (see Carvalho *et al.*, 2010 for a study of Cerrado mammals, McGoogan *et al.*, 2007 for African primates). Estimates of phylogenetic diversity and

phylogenetic (even phylogeographic) endemism have also expanded the classic use of species diversity and endemism measures (Chen, 2009; Carnaval *et al.*, 2014).

By incorporating historical thinking into Conservation Biogeography, a vast number of studies also began to look beyond present-day mechanisms to explain and predict spatial patterns of biodiversity. Past (Late Quaternary) habitat stability, as inferred through correlative distribution models projected into paleoclimatic scenarios, have been reported to predict species richness more effectively than contemporary conditions in the Australian Wet Tropics (Graham *et al.*, 2006) and the South American Savannahs (Werneck *et al.*, 2012). Former climates have likewise been shown to explain spatial patterns of intraspecific lineage diversity (Carnaval *et al.*, 2009) and lineage endemism (Carnaval *et al.*, 2014) in Atlantic Rainforest vertebrates (**Figure 1**). Moreover, the use of species distribution data and community composition analyses to delimit biogeographic regions for conservation (e.g., Chen, 2009; Terauds *et al.*, 2012) has been expanded to incorporate information about the evolutionary history of regional biotas. As a result, maps of spatial turnover in the phylogenetic composition of communities are becoming increasingly available (see Holt *et al.*, 2013 for a global study of the vertebrate biota).

Biodiversity metrics in Conservation Biogeography have also moved beyond species and genes. Novel studies map the distribution of functional diversity in geographic space, and integrate new and exciting data about the ecological roles of communities into conservation guidelines and reserve planning (Carvalho *et al.*, 2010; McGoogan *et al.*, 2007). The mapping of non-biodiversity elements relevant for reserve design has also advanced: new studies incorporate refined landscape measurements of anthropogenic impacts on natural habitats such as estimates of human population size, crop production, and cattle ranching (Diniz-Filho *et al.*, 2006).

Evolving Approaches

Small-scale investigations – both spatially and taxonomically – have also been recently attributed to the realm of Conservation Biogeography. Within those, important insight emerged from studies of the biogeography of invasive species – a timely topic in the face of human-facilitated movement of species (see Tolley *et al.*, 2008 for an example of how molecular data can pinpoint potential sources of invasions in South African frogs). Other examples include the development of models of environmental favorability for endangered top predators and their prey (Real *et al.*, 2009), and species-specific models of distribution under future climatic scenarios (Hu and Liu, 2014).

Going beyond the compilation and analysis of empirical information from ecosystems and biological groups, studies in Conservation Biogeography have also incorporated new types of data. Simulations, for instance, were recently used to evaluate temporal changes in the composition of species and to examine what biodiversity metrics best describe community response to habitat changes (Devictor and Robert, 2009). The results argue for a need to expand the dimensions of biodiversity targeted by Conservation Biogeography, showing the

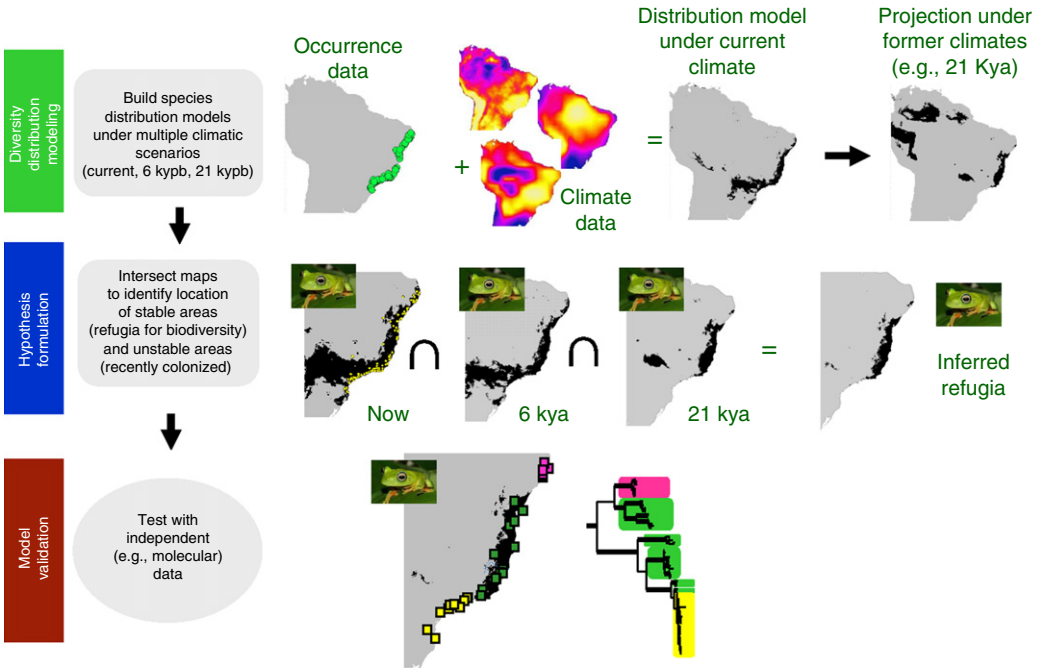

Figure 1 Integrative framework to map species-specific areas of climatic stability (refugia), where genetic diversity may be expected to accumulate over time (see Carnaval *et al.*, 2009). In step 1, information on species occurrence and present-day climate are combined into a correlative model of the distribution of the species, which is projected into the past given available reconstructions of former environmental conditions. In step 2, models of species distribution under multiple time periods are intersected to identify areas that have been suitable for the species over time (stable areas, or refugia). Extinction is expected to be low (hence genetic diversity is expected to be high) in these areas. In step 3, independent data (for instance, sequence data from molecular markers) are used to validate those hypotheses.

power of metrics that reflect the ecological traits and ecological role of species within trophic cascades (e.g., proportions of generalists vs. habit specialists). Empirical data from distinct ecosystems also support this view: species of distinct ecological and life history traits show different spatial distribution patterns; the inclusion of ecological data improves resolution of community analyses (Pawar *et al.*, 2007).

Evolving Aims

Conservation Biogeography has moved beyond the mere mapping of present-day patterns of diversity to become increasingly model-based and predictive. Expanding on the concept of distribution congruence across large numbers of species (see Diniz-Filho *et al.*, 2006; Pawar *et al.*, 2007), recent studies have explored correlations between biodiversity measurements, environmental descriptors, and geography to model spatial turnover in the taxonomic (Ferrier *et al.*, 2007), phylogenetic (Rosauer *et al.*, 2014), and functional structure of communities (Swenson *et al.*, 2011). Moreover, novel approaches are validating the use of genetic data from wild populations, when analyzed in a spatially-explicit context, to estimate unknown demographic parameters (e.g., migration rates, carrying capacity) for use in simulations of the geographic distribution of lineage diversity under future environmental conditions (Brown *et al.*, 2016).

Evolving Cross-Disciplinary Links

Conservation Biogeography currently feeds off high quality data on species identification (taxonomy), species occurrences (distribution), species history (phylogenetics and phylogeography), and their roles in the environment (ecology), as well as fine-scale environmental information. As a result of its interdisciplinary nature, the lines separating the realm of Conservation Biogeography from those of Ecology, Macroecology, Evolution, Macroevolution, and Environmental Sciences have somewhat blurred over time. 10 years ago, the spatial scale of focus was said to render Conservation Biogeography studies distinct from those at the intersection of Biogeography and Ecology (which traditionally focused on metapopulation dynamics, short-term effects of habitat fragmentation, and impact of matrix composition on species assemblages), as well as those at the intersection of Biogeography and Macroecology (Whittaker *et al.*, 2005). Yet, as biogeographical research became more integrative over time (Riddle *et al.*, 2008; Morrone, 2009), so did Conservation Biogeography.

This integrative aspect poses challenges. The limited quality and availability of data on species attributes (Diniz-Filho *et al.*, 2006; Loiselle *et al.*, 2008), our incomplete understanding of the processes governing biodiversity structure (Whittaker *et al.*, 2005; Olden, 2006; Diniz-Filho *et al.*, 2010), the inherent difficulties of integrating information from multiple data sources (Richardson and Whittaker, 2010), and the uncertainties associated with future climate predictions (Ackerly *et al.*, 2010) all need to be addressed as the discipline continues to evolve. Yet, it is precisely the complex and integrative aspect of Conservation Biogeography that makes this such a fascinating field of study – and one with the potential to help guide us through the drastic environmental changes that are fast approaching.

Biogeography, Ecological Theories in

AJ Rominger, University of California, Berkeley, CA, USA

Glossary

Geographic range The total geographic area covered by the populations of a species.

Species abundance distribution (SAD) The function describing probability of observing a species with a given abundance. In theory this function can be represented by a mathematical equation. Empirically the SAD refers to the collection of abundances for all species in a sample and thus the probability of a species with an abundance n is simply the frequency of species in the sample with abundance n.

Species area relationship (SAR) The relationship between the number of species found in a sample and the geographic area over which that sample is taken. This relationship inevitably increases (more area intuitively harbors more species) but the exact rate at which species number increases with area varies across ecosystems. Often this relationship is approximated as $S = cA^z$ where S is species number, A is area and c and z are constants that depend on the system under study.

Imagine you travel to a tropical archipelago and on each island you painstakingly search out and record the identity of every unique ant species. After months of fieldwork your data begin to reveal patterns. Islands that are more isolated have fewer ant species and islands that are larger have more ant species. Perhaps from your training as an ecologist you are not entirely surprised by this finding, but you are intrigued to know how general it is: do plants, birds, mammals, and other arthropods all follow similar patterns across similar island archipelagos? Indeed the fact that species richness increases with area is a well-known phenomenon in ecology. Arrhenius in 1921 documented that for a diverse array of plants and animals a tenfold increase in area yields approximately a tenfold increase in the number of species found in that area. If this pattern is so pervasive what processes might causes it? We can imagine these were the questions running through the head of biogeographer and ant systematist Edward O. Wilson and ecological theoretician Robert H. MacArthur as they pondered the data that Wilson had collected that would inspire the groundbreaking theory of island biogeography (MacArthur and Wilson, 1967).

The goal of theory in any science is to identify the core set of processes responsible for producing persistent patterns. Simple assumptions are a core feature of scientific theories, which seek to be as general as possible and thus cannot consider every minor detail of possible mechanisms in a diverse world. In the case of biogeography, the patterns of interest concern repeatedly documented patterns in the distribution of species and biodiversity across geographic space. These patterns include the increase of species richness with area, decrease with isolation, increase toward the tropics, and the prevalence of rare species across space.

Theories of Species Richness and Composition

The following set of theories seek to explain the species richness of a given area based on its geophysical characteristics and/or the commonness or rarity of the species comprising that area's ecological community.

The Equilibrium Theory of Island Biogeography

The young systematist Edward O. Wilson brought his observations of ant species composition to a young ecologist Robert H. MacArthur and together they developed a theory that would revolutionize the fields of ecology and biogeography and help found the field of conservation biology. MacArthur and Wilson (1967) proposed that the number of species present on an island results from a balance between the number of new immigrant species that arrive to the island from the mainland and the number of species lost due to extinction on the island. If immigration depends on isolation (more isolation, less immigration) and extinction depends on area (more area, less extinction; **Figure 1**) then the theory of MacArthur and Wilson (1967) predicts the pervasive pattern that species richness increases with area and decreases with isolation. The increase of species richness with area (the species area relationship, SAR) had captured the interest of biologists for decades and so predicting it from simple first principles constituted a huge advance in theoretical ecology. This simple theory transformed ecology and biogeography from sciences of description to sciences of prediction and paved the way for future conservation practitioners to begin planning for land conservation based on the expected number of species they could preserve (Diamond, 1975; Diamond *et al.*, 1976; Gilpin and Diamond, 1980).

MacArthur and Wilson's (1967) theory is said to predict a dynamic equilibrium because it predicts a constant number of species through time that arises from a balance between immigration and extinction. MacArthur and Wilson posited that, as the number of species on an island increases, immigration rate will drop due to the fact that the number of unique (i.e., not already on the island) colonists from the source pool will become limited. Similarly they proposed that extinction would increase with the number of species on the island both due to each species' per capita extinction rate contributing to the next extinction rate, and decreased population sizes per species if, as they assumed, the total number of individuals on the island was fixed by resource constraints. As species richness increases on an island eventually immigration rate will equal extinction rate (**Figure 1**) and at this point the island is in

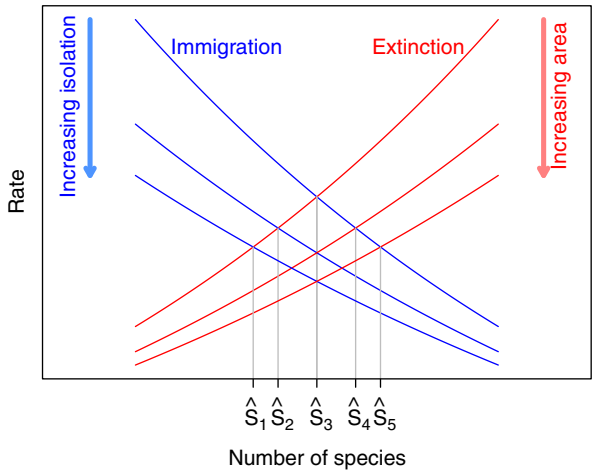

Figure 1 Graphical representation of MacArthur and Wilson's (1967) theory of island biogeography. Across the *x*-axis is the species richness of a hypothetical island. Several potential immigration rates are shown in blue while potential extinction rates are shown in red. Because immigration rate decreases and extinction increases as the number of species on an island increases a stable equilibrium in species number can occur where these two rates intersect. Several such equilibria are denoted by $\hat{S}_i$. The different rates correspond to different island characteristics, with more isolated islands experiencing less immigration and larger islands experiencing less extinction. Thus MacArthur and Wilson's (1967) theory predicts a positive relationship between island area and equilibrium species richness (e.g., $\hat{S}_3$ is the species richness of a small island and is less than, $\hat{S}_4$ of a bigger island and less still than $\hat{S}_5$ of an even bigger island). Their theory also predicts a negative relationship between island isolation and equilibrium species richness (e.g., increasing isolation leads to less species richness going from $\hat{S}_3$ to $\hat{S}_2$ to $\hat{S}_1$.

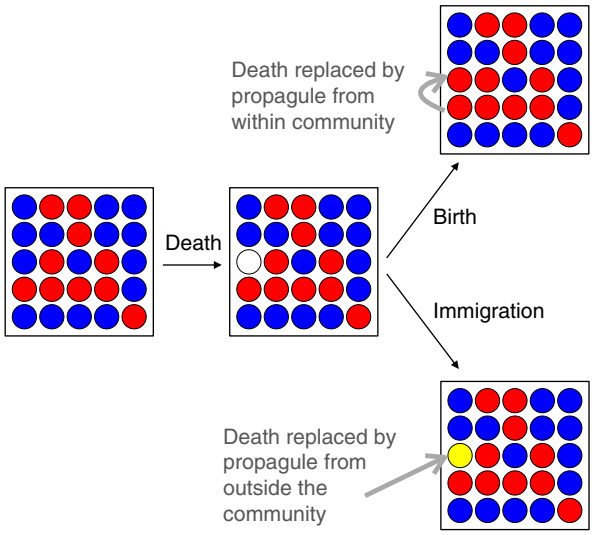

Figure 2 Graphical representation of Hubbell's (2001) Unified Neutral Theory of Biodiversity and Biogeography. In the model community (depicted as two species: red and blue, with dots corresponding to individual organisms) death occurs at random and is replaced either by a birth event (the parent chosen at random from within the community) or an immigration event (a propagule arrives from outside the community) which could introduce a new species to the community as indicated by the yellow individual. The dynamics of the metacommunity are similar except the process of immigration is replaced by the process of speciation.

equilibrium. This equilibrium is 'dynamic' because while the number of species may remain constant, the actual identities of species on an island is predicted to change as new species arrive and replace others going extinct.

This theory was most famously tested by Simberloff and Wilson (1970) in an experiment in which Simberloff defaunated mangrove islands of all their arthropod occupants and observed the colonization process. In accordance with MacArthur and Wilson's equilibrium theory, the number of species increased over time until species number reached an equilibrium level.

While the theory of island biogeography (MacArthur and Wilson, 1967) was originally developed explicitly for islands, it has seen broad applications in other systems. Researchers have applied the idea of balancing immigration and extinction to continuous landscapes by supposing that local communities can be approximated as island-like systems and receive immigrants from the surrounding landscape, now treated as a separate 'mainland,' much the same way as islands receive immigrants from actually separate mainlands (Hubbell, 2001; Leibold *et al.*, 2004).

Researchers have also identified exceptions to and shortcomings of MacArthur and Wilson's theory. One particularly interesting exception occurs when equilibrium cannot be achieved due to shifting landscapes. Brown (1971) identified such 'non-equilibrial' communities in the mountaintop refugia of the great basin (mountaintops here are equivalent to islands of montane habitat) where changing climate since the last glacial maximum cutoff dispersal routes for montane-adapted mammals, thus the current dispersal potential for these mammals does not match the current conditions and so their observed diversity is out of equilibrium compared to theoretical predictions.

The equilibrium theory of MacArthur and Wilson (1967) also ignored the speciation process, which can be critical in the assembly of island biotas (Gillespie, 2004; Losos, 2009; Losos and Schluter, 2000). Speciation adds to the species richness of an island in a similar way as immigration does, but speciation can be independent from the source pool of potential species colonists (Losos, 2009; Losos and Schluter, 2000). Losos and Schluter (2000) showed that speciation drastically changes the shape of the SAR, increasing the rate of species accumulation with area.

The Unified Neutral Theory of Biodiversity and Biogeography

Hubbell (2001) was inspired by the challenge of incorporating speciation into the theory of MacArthur and Wilson (1967) and in turn spurred a new renaissance in theory development in ecology and biogeography. Hubbell's (2001) Unified Neutral Theory of Biodiversity and Biogeography (**Figure 2**) assumes a local community functions like an island but in addition to immigration from the surrounding metacommunity, speciation can add species richness. Hubbell's additional inclusion of an explicit demographic process or birth and death enabled him to also predict the actual abundances of

species in a community leading to new predictions to be tested with data. Hubbell (2001) made the controversial assumption that all individuals across all species have equal probabilities of birth and death or giving rise to a new species. This assumption of 'neutrality' received substantial criticism because it refuted the historically central role of species differences (i.e., niches) in determining species composition and abundance (Hutchinson, 1959; Leibold, 1995). However, the Unified Neutral Theory of Biodiversity and Biogeography predicted the species abundance distribution (SAD) of many communities surprisingly well, leading to ongoing research as to what mechanisms, niche or neutral, underlie the patterns of diversity, rarity, and commonness we observe in nature (Rosindell *et al.*, 2011).

Brown (1995) and Maurer (1999) each proposed kindred niche-based theories of species richness and abundance through geographic space. Both built from the *n*-dimensional niche concept of Hutchinson (1959) which assumes that each species' fitness is limited by a unique set of environmental constraints. Brown (1995) and Maurer (1999) observed that such constraints should vary in space and thus a species cannot be equally abundant everywhere, but instead will experience areas of high and low population density.

The Maximum Entropy Theory of Ecology

One alternative to the mechanistic views put forward by neutral theory (Hubbell, 2001) and its niche-based counter arguments (e.g., Brown, 1995; Maurer, 1999) is the view that patterns in biodiversity may arise not because of uniquely biological mechanisms but simply the statistical properties of large aggregations of things (Preston, 1950; Nekola and Brown, 2007; Harte, 2011). Nekola and Brown (2007) showed that the diversity patterns of many systems completely removed from biology (e.g., cars in parking lots) follow patterns that can be well described by ecological theories, implying that the mechanisms put forward by these theories may not be uniquely biological. This line of thinking builds off the idea that if any generalities are to be found in biodiversity, the cause of these generalities must not be one prevailing biological mechanism, as a plethora of documented mechanisms have been recorded across the vast array of earth's ecosystems, but instead emerge in spite of that diversity of locally relevant mechanisms (Preston, 1950; Rosenzweig, 1998). This thinking is best formalized in the application of principles from statistical physics in ecology and biogeography. Harte (2011) put forward the maximum entropy theory of ecology (METE) which is able to accurately predict the SAD and the SAR, all while making no assumptions about the processes by which species enter a community, reproduce, and die. Harte achieves this by using the principle of maximum information entropy (Jaynes, 1982) which seeks to predict metrics (such as the SAD) given state variables (such as the total number of species and the total number of individuals) in a system. This is the same principle that can be applied to ideal gasses to derive predictions of their behavior (Jaynes, 1957).

Among other predictions, METE predicts the shape of the SAR with great accuracy compared to data (Harte *et al.*, 2009). In fact, METE predicts that all SARs should follow the same form across systems, which is simply a function of the ratio of the number of species to number of individuals in the systems. This reduction of a seemingly intractable diversity of patterns (i.e., all the variety of shapes and rates of SARs) to one simple rule is known as a scale collapse in that multiple observations from across scales collapse into one pattern when the salient variables are considered.

The theories we have thus far considered concern themselves with the geography of species richness and abundance. They seek to explain observed patterns of diversity, commonness, and rarity using simple mechanistic assumptions (such as balanced immigration and extinction) or in fact reject the mechanism all together and seek to explain observed patterns as statistical inevitabilities of large aggregations of things.

Theories of Geographic Range Size and Geographic Gradients

So far, the theories discussed have focused on the geographic distribution of species richness and abundance. Another central focus of theoretical biogeography is the distribution of species themselves – that is where in space do species live and how can we predict the properties of that spatial distribution (referred to as the geographic range)? A central focus through the development of biogeographic theory has been the study of the size of geographic ranges and how this predictably changes according to the geographic position of the range. The size and geography of ranges has implications for both the accumulation of species in space (the SAR) and the geographic pattern of species richness.

The average size of a species' geographic range is not constant across geographic space. Species ranges tend to be smaller in the tropics and at lower elevation (Stevens, 1989, 1992; Brown, 1995). This observation was formalized by Stevens (1989) who named the patterns 'Rapoport's rule' after earlier work by Rapoport (1982). However, why this pattern is so consistently observed still eludes explanation. One leading hypothesis was put forward by Janzen (1967) who argued that because the tropics are more climatically stable, species should evolve narrower climatic tolerances and thus their smaller range size naturally follows. A complementary hypothesis posits that species interactions are more intense in the tropics (Pianka, 1966) which could constrain species to the geographic region in which they have coevolved strategies for dealing with competitors, predators, and mutualists (Thompson, 2005).

The architecture of geographic ranges also bears on the shape of the SAR. Intuitively, more small ranges should yield a steeper SAR. Storch *et al.* (2012) developed this intuition into another form of SAR scale collapse, showing that after accounting for the mean geographic range size of a clade, its constituent SARs collapse onto a single curve.

The fact that geographic ranges are smaller in the tropics is also related to the latitudinal diversity gradient; there are more species in the tropics than in temperate regions (Pianka, 1966). Smaller geographic ranges in the tropics should intuitively lead to higher diversity, especially higher β-diversity (i.e., greater turnover in species composition across space). Whether β-diversity is indeed higher in the tropics is still under active

debate (Kraft *et al.*, 2011; Qian *et al.*, 2013) but the higher overall diversity is undeniable (Pianka, 1966). Thus, whether the higher diversity is the cause or consequence of smaller geographic ranges in the tropics also warrants further study.

Theories of biogeography address the spatial distribution of richness and abundance, both through considering the dynamics of assemblages of species as in the equilibrium theory of island biogeography (MacArthur and Wilson, 1967), and by trying to understand patterns in the geographic ranges of species and their consequences. Much research remains until we can fully understand how general biogeographic patterns (such as the SAR) emerge and whether these are the result of simple but pervasive biological mechanisms (e.g., those posited by Hubbell's (2001) neutral theory) or are in fact near statistical inevitabilities (Harte, 2011). Understanding whether geographic range patterns are the cause or consequence of species diversity patterns also remains a fruitful area for future theoretical development.

Biogeography, Evolutionary Theories in

MJ Hickerson, City College of New York, New York, NY, USA; City University of New York and the Graduate Center, New York, NY, USA; and American Museum of Natural History, Division of Vertebrate Zoology, New York, NY, USA

Introduction

One of the most commonly invoked yet persistently controversial causal mechanisms underlying the formation of new species is allopatric divergence. This is thought to occur with landscape reconfiguration and/or climate change that fracture species ranges into multiple isolated refugia divided by newly formed zones of unsuitable habitat. Over time, the lack of dispersal between formerly continuous populations results in the emergence of new sister populations or species (Ford *et al.*, 1949; Mayr, 1954; Cracraft, 1974; Lande, 1980; Losos and Glor, 2003). When this process of allopatric speciation is driven by reconfigurations of the landscape such as the separation of continents by plate tectonics, the uplift of mountains, the emergence of an Isthmus, desertification, or the formation of a large river, it is referred to as vicariance in the parlance of biogeography. Moreover, it has been seen as a mechanism of central importance because it can potentially subdivide whole communities of co-distributed species into co-distributed species-pairs, with these large-scale events potentially multiplying substantial portions of preexisting levels of biodiversity (Cunningham and Collins, 1994; Lessios, 1998; Bacon *et al.*, 2015).

This idea was perhaps first articulated by Alexander von Humbolt where he argued that if the separation of continents occurred after the development of living organisms, we should find similarities between animals on the opposing coastlines of such continents (von Humboldt and Bonpland, 1807). This idea was later more fully developed by Joseph D. Hooker who argued that the present-day distribution of plants in the southern hemisphere is the remains of a historically more widespread flora that was broken up by geological and climatic processes. Although he proposed that mechanisms causing community-wide allopatric isolation and diversification involved land-bridges between continents that have subsequently subsided (Hooker, 1853), an accumulation of observational evidence led to more general formalization of a theory of vicariance. For example, in the early twentieth century David Starr Jordan brought together such evidence from an array of geographic contexts to argue that the emergence of geographical barriers were the dominant drivers of speciation (Jordan, 1905, 1908), and this general idea has been long since supported by modern geological and climatic evidence (Moss and Wilson, 1998). Not only has vicariance been long considered to be important drivers of biological diversification across much of the tree of life (Rosen, 1978; Mayden, 1988; Cracraft, 1982; Joseph *et al.*, 1995; Riddle *et al.*, 2000; Gamble *et al.*, 2008), there has even been strong arguments in favor of advocating this mode of speciation to be an a priori assumption or null model (Wiley, 1988) leading to biased inference (Briggs, 2009).

As simple and indisputable as this may seem, an alternative hypothesis of allopatric speciation involving dispersal over preexisting areas followed by isolation and speciation also has old roots (Ortmann, 1902; Darlington, 1938; Adamson, 1932). This idea has seen a resurgence and many of the more recent emerging examples come from oceanic islands lacking in histories with connections to a mainland continent (de Queiroz, 2005; McCartney *et al.*, 2000; Winkworth *et al.*, 1999), as well as larger islands with ancient mainland connections such as Madagascar and New Zealand (McGlone, 2005; Yoder and Nowak, 2006).

As the debate about which of the two processes underlie the Earth's biodiversity continues (Wiens and Donoghue, 2004; Zink *et al.*, 2000; Bowen *et al.*, 2013), in parallel a number of different methodological advances have emerged that have the potential to more rigorously evaluate competing biogeographic scenarios given genetic data that is becoming increasingly sampled at the scale of partial genomes and multiple individuals across each extant species.

Ancestral Area Reconstructions

Traditionally, research and methodology to infer and reconstruct the ranges of species within a phylogenetic context have relied on pattern-based nonstatistical approaches such as parsimony and cladistic biogeography (Morrone and Carpenter, 1994; Donoghue and Moore, 2003). Only recently have inferences based on statistical frameworks such as maximum likelihood and Bayesian approaches been used to test alternative geographical hypotheses of diversification (Ronquist and Sanmartín, 2011). Such model-based parametric methods make inference using time-calibrated phylogenies under various models such as Dispersal–Vicariance analysis (Ronquist, 1997), Dispersal–Extinction–Cladogenesis (Ree and Smith, 2008), and ones that model the ancestor–descendant range evolution based on stochastic dispersal, vicariance and local extinction along all nodes and tips of a phylogeny (Goldberg *et al.*, 2011; Webb and Ree, 2012; Landis *et al.*, 2013; Matzke, 2014). These flexible methods allow the incorporation of spatial and temporal information as constraints, such as from fossils, sea levels changes, climate shifts, and continental drift (Clark *et al.*, 2008; Mao *et al.*, 2012; Meseguer *et al.*, 2015). Other advances include the incorporation of changes in speciation rates, sympatric speciation, instantaneous long distance founder speciation from ghost taxa, as well as being able to accommodate classical vicariance.

While these methods have provided opportunities to test biogeographical hypotheses with greater complexity, this comes with a cost of requiring more data. Although fossils can provide information for dating biogeographic events, they are often insufficient for resolving the geographical range evolution at ancient nodes in the phylogeny. Irregardless, integrating multiple sources of information such as ecological species distribution models (SDMs) can yield well resolved biogeographic histories given well-resolved phylogenies across

a diverse range of taxa and timescales (Meseguer *et al.*, 2015; Matzke, 2014).

Despite these advances, such model-based inferences all rely on the correct inference of a phylogenetic tree. However, two notable advances for phylogenetics have made this aspect of the inference much improved. First, there is the recent ability to generate data from hundreds or even thousands of places in the genome with the advent of new DNA sequencing technologies (Brito and Edwards, 2009). Secondly, phylogenetic models have recently incorporated theory from population genetics such as the coalescent, which accommodates the stochasticity across unlinked gene trees and ancestral polymorphism (Edwards, 2009). Indeed, with this new perspective, there becomes a clear link between historical geographic demography, the speciation process, and the history of phylogenetic relations, such that one could combine these types of inference within a global framework to reconstruct biogeographic history.

Inference of Biogeographic Histories with Nonspatial Population Genetic Models

Ancestral area reconstruction allows inference of the geographic mode of diversification by estimating the ancestor–descendant range evolution along all nodes and tips of a phylogeny, yet this type of inference is most powerful and reliable across the most recent nodes of divergence. Moreover, using coalescent-based models and population genetic data, one can obtain highly resolved inference of complex geographic histories of isolation, colonization, and/or admixture (Ortego *et al.*, 2015; Veeramah and Hammer, 2014). Leveraging the greater inferential power of these complex historical demographic models with substantially greater amounts of genomic data will increasingly play a role in understanding the geographic component of diversification (Edwards *et al.*, 2015).

Not only can coalescent models be used to test various hypotheses within lineages or species with greater amounts of inferential complexity being achieved with greater amounts of data (Excoffier *et al.*, 2013) or by integrating across various approaches (Metcalf *et al.*, 2014), these approaches also allow testing traditional biogeographic hypotheses such as vicariance and colonization. For example, if one adds effective size change under the often used *Isolation and Migration* model (Hey and Nielsen, 2004), this additional parameter directly relates to the demography of colonization by small founder populations (Hey, 2005) or conversely a vicariant history where an ancestral species is more evenly split into daughter species (Locke *et al.*, 2011). As is the case for methods for ancestral area reconstruction, these coalescent model-based strategies for testing classical biogeographic hypotheses can be aided by integrating with other approaches such as ecological species distribution modeling (Lacey Knowles and Alvarado-Serrano, 2010; Carnaval *et al.*, 2009; **Figure 1**).

Another strategy for improved statistical strength and achieving a better understanding of how regional climate and landscape change can shape the geographic history of speciation across a whole assemblage within the context of these classical hypotheses of vicariance and colonization is to deploy population genetic splitting models within a coalescent-based

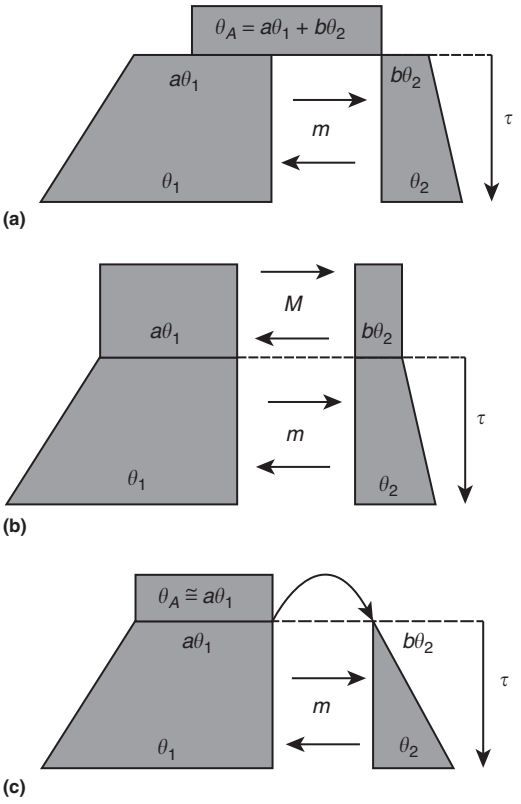

Figure 1 Models of classical vicariance (a), soft vicariance (b), and colonization (c). In (a), an ancestral population is split into two descendent sister population at time τ before the present. The vicariance time or colonization time is τ whereas $\theta = 4\,N\mu$ with N being the effective population size and μ being the per gene per generation mutation rate. The relative effective population sizes of the two sister populations is scaled by a and b at different time periods. In (b), M, the number of ancestral migrants per generation connects the two ancestral sister populations until it becomes reduced to m at time τ in the past. In (c), a small number of individuals from the ancestral population colonizes the descendent population at time τ and grows exponentially until the present ($\tau = 0$).

multispecies hierarchical Bayesian model (Hickerson *et al.*, 2006). In this case, the relative frequency of models of founder colonization versus cyclical isolation and admixture can be quantified across a whole assemblage of co-distributed sister species pairs by estimating hyperparameters that describe the magnitude of demographic expansion that is associated with colonization across species under the hierarchical model that allows species-specific parameters to independently vary across taxa (Hickerson and Meyer, 2008; Ilves *et al.*, 2010).

Although this type of inferential framework can be complex, it has so far been achieved using the simulation-based approximate Bayesian computation (Sunnåker *et al.*, 2013) such that probabilities of various complex models of island and continental colonization can be compared while allowing for the variance associated with the coalescent (Patiño *et al.*, 2015). When deployed on a large regional scale, this approach can elucidate the relative importance of colonization and vicariance in the speciation process across more than hundred avian taxon-pairs that span the Andes mountains, and several large river drainages. In the former case, mountain building appears

to have largely split preexisting ancestral populations consistent with vicariance, whereas in the latter case the inference suggests dispersal over preexisting river barriers followed by isolation and divergence across the rivers (Smith *et al.*, 2014).

Similar comparative studies looking at large numbers of taxon-pairs have also focused on the classic great American biotic interchange that joined North and South America before the Pleistocene (Webb, 2006). While such comparative inferences can illuminate the process of community assembly and colonization of terrestrial taxa from one continent to another (Cody *et al.*, 2010; Diamond, 1975), they can also shed light on processes underlying vicariance with respect to marine taxa that were split by the rising land bridge (Lessios, 2008). This classic biogeographic setting raising the paradox that estimating the timing of events rely on assumptions of DNA mutation rates, which are in turn obtained from estimates that are made by oftentimes controversial geologic dating such as the rise of the Central American Isthmus (Ho *et al.*, 2015). Moreover such large-scale comparative studies estimating DNA mutation rates (Knowlton and Weigt, 1998), or timing of events related to the great American biotic interchange (Bacon *et al.*, 2015) can suffer from substantial bias if a coalescent model is not used (Marko *et al.*, 2015; Hickerson *et al.*, 2003; Charlesworth, 2010), and if there are biases in data inclusion (Lessios, 2015). Moreover, many such comparative studies are provisional because they rely on the easily obtained single-locus mitochondrial DNA in animals and chloroplast DNA in plants. Encouragingly, multispecies coalescent models for sub-genomic scale data are starting to be developed for co-expansion models (Xue and Hickerson, 2015) that could be used to detect the magnitude of divergence through colonization and it is likely that they could be extended to different geographic models of speciation and divergence while accommodating the surge in partial genome data now obtainable from a wide array of nonmodel taxa (Ekblom and Galindo, 2011).

Inference of Biogeographic Histories with Spatial Population Genetic Models

The success in the aforementioned population genetic approaches to estimate historical demographic parameters relevant to biogeographic history such as colonization times and population expansion magnitude and timing all ignore information about geographic space. Although there is a long history of a set of methods referred to as *landscape genetics* that spatially explicitly relate geographical features such as altitude, topography, and ground cover, on patterns of genetic variation and structure (Manel *et al.*, 2003), these typically ignore landscape history and population history with respect to patterns of genetic variation, and thereby ignore the stochasticity and time-dependency of drift, mutation, and selection with respect to the landscape. However, of these, nonmodel-based methods have still proven to be useful for making inferences of geographical history of species. For example, one of the most common of such methods is to calculate the heterozygosity over space and make inferences of geographical origins of range expansion based on this value's expected negative correlation with the age of populations (Pierce *et al.*, 2014; Deshpande *et al.*, 2009). Alternatively, patterns in the comparisons between geographic and genetic distance are also common ways in which spatial and genetic information is used to infer the geographic origins of population expansions (Ramachandran *et al.*, 2005).

On the other hand, there is a set of emerging methods that are both spatial and incorporate explicit genetic historical models. One such commonly used method does not parameterize historical demographic history, yet uses diffusion models to infer the history of a sampled gene genealogy over both space and time (Lemey *et al.*, 2010). This versatile method uses a Bayesian statistical approach to infer continuous diffusion of the sampled genealogy using random walk models while simultaneously reconstructing the evolutionary history in time from a genetic sample. This results in the ability to trace the geographic origins of the sampled gene genealogy itself, which can be especially useful for tracking the historical spread of viruses (Kühnert *et al.*, 2011; Kuzmina *et al.*, 2013), plant genera (Terra-Araujo *et al.*, 2015), origins of biological invasions (Pfenninger *et al.*, 2014; Eme *et al.*, 2013), and even the geographic spread of language families (Bouckaert *et al.*, 2012). While this method is normally deployed on single gene datasets, which are typically most useful for the geographic inference of infectious diseases (Pybus *et al.*, 2012), they can be extended to make inferences based on a multilocus species tree (Nylinder *et al.*, 2014).

However, these methods typically make inference without parameterizing the geographic distribution of populations or population densities in continuous space. Although the standard way to model genetic data retrospectively using coalescent theory is routine under a set of discrete demes (Beerli and Felsenstein, 2001; Wakeley, 2001), modeling this process in a spatially continuous context has been quite challenging due to several technical problems (Felsenstein, 1975; Barton *et al.*, 2010, 2013). One solution has been to discretize continuous space into a two dimensional grid in order to implement simulation-based methods to reconstruct the spatial and temporal dynamics of population history. One commonly used framework is to spatially explicitly couple SDMs (Elith and Leathwick, 2009), demographic and population genetic models in order to capture the spatiotemporal and geographic dynamic of species divergence. The general idea is to first combine geo-references observations of species occurrence with environmental estimates to *predict* the expected range of a species at the present as well as at different times in the past (Waltari and Hickerson, 2012; Gavin *et al.*, 2014; Alvarado-Serrano and Knowles, 2014). These models are then converted into demographic models with deme-specific carrying capacities and migration potentials that are then used to define spatiotemporal demographic histories that generate patterns of genetic variation under coalescent models. Such integrated frameworks can then use patterns of observed genetic variation to test competing spatiotemporal hypotheses of colonization and divergence histories (Brown and Knowles, 2012). This general approach has been used to understand the relative likelihood of colonization versus vicariance driven divergence in at the timescale of the late Pleistocene in both plants and animals (Cornille *et al.*, 2013; Hung *et al.*, 2013) as well as understanding the spatial dynamics of invasive colonization at recent timescales (Estoup *et al.*, 2010). Although simulation-based ABC inference uses genetic summary statistics for

comparison between simulated and observed data to approximate a series of model probabilities, these metrics typically contain no spatial or geographical information. Encouragingly, new summary statistics that jointly use genetic and geographical information have recently been developed and have been shown to potentially improve the ability to discriminate among different complex geological histories of species divergence and colonization (Alvarado-Serrano and Hickerson, 2015), especially when aided by *Random Forest* discrimination algorithms (Pudlo *et al.*, 2015), a technique retooled from machine learning.

Discretized spatial models have been helpful, yet there are computational inefficiencies that lead to only enabling spatial inference across relatively shallow historical times. Fortunately, these shallower historical times can be relevant with regards to understanding the geographical history of recent species divergences, and there are new techniques for inferring the geographic origins of colonization and range expansion that do not require extensive simulation experiments (Peter and Slatkin, 2015).

Furthermore, there has been steadily growing theoretical work in spatially explicit coalescent models in one (Wilkins and Wakeley, 2002) and two dimensions (Limic and Sturm, 2006; Barton *et al.*, 2002). While these set of models do not discretize space into a grid, they often make various simplifying assumptions. One strategy that looks promising is to allow for local extinction and recolonization dynamics to obtain a spatially explicit model that may converge to fit real datasets even while implementing a torus on the edges of the geographical space (Barton *et al.*, 2010, 2013). On the scale of the geographic history within a species, genetic data can now be simulated efficiently under this spatially explicit model (Kelleher *et al.*, 2013, 2014), such that an approximate Bayesian computation framework could be built to use these simulation techniques for parameter estimation.

As the number of geographic models from which to better understand the spatial history of new species formation grows in number and complexity which can then better inform how the spatial histories of species can be shaped by future climate and landscape changes (Yannic *et al.*, 2013). By improving biogeographic investigations of species histories by integrating genetic data with independent information, researchers will better understand how the interacting processes of geographic isolation and long-distance dispersal drive regional patterns of biodiversity. Furthermore, greater availability of not only fossils but fossil DNA will continue to shed light on how isolation and the ability to disperse have both shaped regional patterns of speciation and extinction (Mann *et al.*, 2015).

Biogeography, History of

MV Lomolino, College of Environmental Science and Forestry, Syracuse, NY, USA

Glossary

Biogeography The study of geographic variation in all characteristics of life – from genetic, anatomical, physiological and demographic differences among geographic populations, to the diversity, distinctiveness, and differences in composition, and key processes of biological communities, ecosystems, and entire, regional biotas.

Buffon's Law Different regions of the globe, even those with similar environmental characteristics, are inhabited by distinct assemblages of plants and animals.

Continental drift The movement of the portions of the Earth's crust that comprise the continents.

First Law of Geography The very general tendency for the similarity among characteristics of particular areas to decline as the distance between those areas increase (synonymous with spatial auto-correlation).

Plate tectonics The general theory, inclusive of continental drift, of the origin, movement, and destructions of Earth's continental and oceanic plates.

Introduction

Put in its simplest terms, *biogeography* is the geography of life. Traditionally it was defined in more limited terms as 'the study of geographic distributions of organisms.' A thorough review of the historical development of this field, and its descendant disciplines – evolution and ecology, however, provides a more accurate understanding of biogeography as one of the most holistic and foundational of the biological sciences (Lomolino *et al.*, 2016; see also resources of the International Biogeography Society www.biogeography.org).

As we shall see, the historical development of biogeography has roots deep within the development of human civilizations and, indeed, may reach far into the early, evolutionary history of our own species when its aboriginal populations adapted to and simultaneously were modified by variation in environmental conditions as they migrated across this planet. Throughout its long history, biogeography like most sciences has progressed – not as an orderly, sequential accumulation of facts and advances in our understanding of the natural world, but more like the complex geological development of the Earth and the evolutionary development of its species. That is, biogeography developed from a complex interplay between empiricism and theory in fits and starts – a reticulating phylogeny of pattern description and conceptual advances marked by periods of discovery and innovations, and diversification and division among sub disciplines, alternating with periods of synthesis and reintegration (see Lomolino and Brown, 2009 for a review of the 'reticulating phylogeny' of island biogeography theory). Given this long and complex, albeit genuinely fascinating and singularly instructive history, a comprehensive account of the development of biogeography is far beyond the limited scope of any one article. Instead, my purpose here is to provide an overview of the key empirical discoveries and conceptual advances of the discipline, with special emphasis on the antiquity of some of its central ideas from the local knowledge of early civilizations to the globalization of that knowledge, and from the early articulations of its fundamental principles during the seventeenth through nineteenth centuries to the theoretical revolutions of the twentieth century.

Aboriginal Knowledge

Given the seemingly meteoric rise of humanity from its modest origins some 200 000 years ago to ultimately become the Earth's dominant species and ecosystem engineer, the idea that we too have been molded by a variety of environments across the planet is often met with much skepticism. Yet archaeologists and anthropologists continue to provide incontrovertible evidence that the physical and physiological characteristics of our species has borne and, to a real albeit less pronounced degree, continues to bear the imprint of the regular variation in environments and pervasive pressures of natural selection. Survival in the face of competition, predation, parasitism, and other struggles for existence not only altered the shape and stature of individuals, but also put a premium on accumulating knowledge on patterns in variation in local environments: locations of food plants and game, of water and natural shelters, and trends in variation in temperature and other climatic conditions as early humans migrated across their then limited ranges. Those living in areas of sharp environmental gradients, in particular populations inhabiting coastal/shoreline environments or those of montane regions with their tightly packed elevational gradients of diverse habitats, are likely to have been especially aware of and keen to adapt to the geography of nature.

Survival of these aboriginal populations may also have required exploration – a means of hedging bets against the frequent waning and collapse in local resources (whether due to natural causes or to overexploitation by their own populations). The overall impact of these and other forces were the expansion, drifting, and migration of the ranges of these local populations to other regions, climatic zones, and ecological realms (likely including many transitions from a terrestrial to

coastal and then to oceanic existence). As each population expanded its range, their collective knowledge continued to expand along with it, now to the point that their knowledge of the geography of nature expanded from the level of local habitats to the variation across a range of habitats within their region.

By 100 000 years ago, these forces of man and of nature drove the expansions of modern humans out of Africa, and by 50 000 years ago they had established populations across the coastal regions of Arabia and southern Asia, through Indonesia and onto Australia. By 30 000 years ago, human populations had colonized most of Europe and central Asia, had reached eastern Siberia, and were perched on the Beringian land bridge prior to their rapid advance into the New World. Yet, while these expanding branches of the human species across the globe demonstrated remarkable capacities for adapting to local and regional habitats and climates, their knowledge base likely remained regional – i.e., at the scales of environments they encountered and as independent and often isolated populations. It was likely that they identified the best local sites for game or fish, that the stature of plants varied with elevation, that temperatures cooled as they climbed local mountain ranges or dove deeper below the ocean's surface; that the numbers and diversity of food plants or game or fish varied along these same gradients and was higher in larger habitats or larger pools of water. Thus, some of the principal patterns and fundamental principles of biogeography – that place matters; that environments and life forms varied in a regular manner across local geographic gradients (here, the gradients of elevation, depth, and size or area of the habitat) was ancient knowledge, essential to the survival and geographic expansion of Earth's dominant species (for an interesting discussion of ancient knowledge and the origin of myths and legends, see Vitaliano, 2007). Establishment of the foundations of biogeography as a genuine science, however, would require much more than local knowledge of many hundreds if not thousands of independent populations of our species. It would require a fundamental expansion in the scale of this knowledge – a globalization of observations on the natural world that could only come from world explorations and integration of their many marvelous discoveries to establish the central patterns and fundamental, unifying principles of biogeography.

The Geography of Nature from Regional to Global Scales

By 10 000 years ago, human populations had colonized nearly all reaches of the globe save for the most isolated oceanic islands and the frozen lands of Antarctica. Globalization of knowledge on the geography of the natural world, however, would await the Age of Explorations by Europeans, which began some 500 years ago. Although the principal mission of these voyages across the seas and to distant lands were not scientific, they often included a naturalist whose specimens and narrative accounts of exotic plants and animals became grist for those seeking a broader understanding of how life varied across the globe. Many of these early naturalists were driven by a quest to serve the Creator – to understand the marvelous menagerie of life he placed across the globe, each local fauna and flora being perfectly adapted to the local conditions and surviving since the time of Creation until their discovery by the faithful explorers (Linnaeus, 1781; see also Browne, 1983; Lomolino *et al.*, 2016, Chapter 2).

By the eighteenth century, naturalists and museums had amassed a burgeoning collection of accounts and specimens from distant lands; but how to make sense of this massive and seemingly disarticulated collection? That mission – to develop a systematic description of life, was the life's work of many naturalists of those days, but none more accomplished than Carolus Linnaeus (1707–1778), who developed the system of binomial nomenclature that we continue to use today as a tool for ordering the ever-expanding lists of life forms inhabiting the planet. But making sense of this massive accumulation of knowledge on what we now call 'biological diversity' required far more than a system for cataloging species: it required a set of principles on how to assemble such knowledge into a coherent theory on the distributions, diversity, and distinctiveness of life across the planet.

Fundamental Principles of Modern Biogeography

Principles fundamental to biogeography are, of course, also fundamental to geography. As restated by Waldo Tobler, *The First Law of Geography* holds that "*everything is related to everything else, but near things are more related than distant things*" (Tobler, 1970). This principle of spatial auto-correlation is, in essence, a codification and generalization of earlier observations of aboriginal peoples, discussed above. A related, and at least as fundamental a pattern in the geography of nature is the other aboriginal knowledge of the distinctiveness of place – that environmental conditions vary in a regular manner from place to place – along the geographic gradients referred to above (distance from coastline and elevation above or depth below sea surface). This highly nonrandom spatial variation in environments forms the geographic template for natural selection and other forces that shape the geography of life across the planet.

That the distinctiveness of place applied to the world's biotas – i.e., at regional to global scales, however, was not established until the revelations of the Age of European Explorations. Thus, during the eighteenth century, European naturalists advanced what would become biogeography's most fundamental pattern, *Buffon's Law* (Buffon and Comte de, 1761). This principle was named in homage to Linnaeus' contemporary – Georges Louis Leclerc Comte de Buffon (1701–1788), whose studies of both extant and fossil animals (in particular mammals of the New and Old World tropics) revealed that different regions, even those with similar environmental conditions, are inhabited by different species.

Subsequent generations of explorer naturalists during the eighteenth and nineteenth centuries would establish the generality of Buffon's Law to plants and other animal taxa beside mammals, and to other climates and environments outside of the tropics. These confirmations of Buffon's Law simultaneously challenged Naturalists of Europe and elsewhere to explain how a world whose climates, land forms and ocean basins, and species were assumed to be fixed and

immutable could have achieved their current distributions and diversity. Buffon's explanation was one that challenged the concept of world stasis espoused by Linnaeus and dictated by established doctrine of the eighteenth century. Instead, Buffon asserted that life forms became established in a region of the higher latitudes of the Northern Hemisphere during an ancient period of global warming, and they then migrated southward into successive regions of the New and Old Worlds, becoming modified (in Buffon's terms, 'advanced' or 'degenerated') during these migrations. By advancing a theory that allowed both Earth's climates and its species to change, Buffon explained the distinctiveness and the similarities among regional to global biotas.

Thus, the geography of life provided insights that proved foundational for revolutions in science – revolutions that would establish, not only biogeography, but evolutionary biology as well. During the nineteenth century, Charles Darwin (1809–1882) and Alfred Russel Wallace (1823–1813) would be so struck by spatial variation and geographic distinctiveness of biotas (in particular, that of the Galapagos

Figure 1 Alexander von Humboldt's *Tableau physique des Andes et pays voisins*, published first in 1807, continues to serve as a classic exemplar in visualizing the geography of nature as a means of exploring the forces influencing the distributions and diversification of life across the planet (see von Humboldt and Bonpland, 2009).

Islands, and those of Indonesia, respectively) that they independently advanced the theory of evolution by natural selection – their theory explaining not only the distinctiveness of each assemblage of species, but trends in similarity among assemblages as well. They had each read the narratives of Alexander von Humboldt (1852) and were fascinated by his accounts of discovery in the Canary Islands and across the New World tropics of Amazonia, and by his essays on plant geography (Humboldt and Bonpland, 2009) where he described in meticulous but inspiring detail the geographic variation of plants and the suite of environmental factors that affect their distributions (e.g., see Humboldt's classic, schematic 'map' of biotic and environmental variation along the slopes of Mount Chimborazo, Ecuador – **Figure 1**; see also Humboldt and Bonpland, 2009). Darwin's and Wallace's explanations for the patterns in the geography of life across archipelagoes and across the planet (see **Figure 2**) were based on the mutability of species and the pervasive force of natural selection, but also on the assumption that – because the Earth and its land forms and ocean basins were fixed, species must colonize distant regions by dispersal. Darwin was one of the strongest proponents of long-distance dispersal, but not without opposition. Joseph Dalton Hooker (1817–1911) was a contemporary, frequent correspondent and admirer of Darwin, but nonetheless one of his greatest challengers on the question of long-distance dispersal. Instead, Hooker (1866/1867) proposed that distributions of, and the similarity among distant biotas (in particular those of the southern hemisphere) can be attributed to the effects of great climatic and oceanic upheavals that broke up the once continuous flora that had spread across continuous tracts of land at an earlier period. Rather than suggesting that entire continents could raft across the globe (a hypothesis that at that time must have seemed fanciful science fiction), Hooker (1844–1860, 1859, 1866/1867) and his supporters (referred to as 'extentionists') suggested that the relative elevations of land and sea had shifted – at one time, sea levels dropped to expose trans-oceanic land bridges that allowed dispersal of plants and animals among the now isolated southern landmasses.

Removal of the final underpinnings of the doctrine of the fixity of the Earth – its climate, species, and land forms and ocean basins, would require more than a century of research and integration of insight from an expanding variety of disciplines including biogeography, paleontology, ecology, oceanography, and geology (in particular, marine geology). During the latter decades of the nineteenth century and early twentieth century, scientists – most notably Antonio Snider-Pelligrini (1802–1885) (Snider-Pelligrini, 1859) and Alfred Lothar Wegener (1880–1930), had commented on the apparent fit of the continents across the Atlantic Ocean, inferring from this that the continents may have once been connected at an earlier time in Earth's history and the evolutionary history of its species. Wegener (1912), in particular, developed a comprehensive theory of *continental drift* which included a reconstruction of earlier positions and patterns of subsequent separation of the continents, along with the potential forces that could drive the movement of entire landmasses. Wegener's theory also included speculations on the impacts of all this on the world's biotas, both past and present.

Wegener's theory was soundly rejected by the established scientific community, and it wasn't until some two to three decades after his death that the geological data – especially that on bathymetry and its relationship to tectonic activity – provided incontrovertible evidence for the reality of continental

Figure 2 Alfred Russel Wallace developed the first, global-scale visualization of the distinctiveness and differentiation among the world's regional biotas, each region and subregion developing their distinct assemblage of species by evolutionary divergence, while the similarity in biotas among regions reflects the influence of biotic mixing via long-distance dispersal across existing barriers or ancient, but now submerged land bridges (Wallace, 1876).

drift, eventually leading to the more comprehensive theory of *plate tectonics* was generally accepted. While dispersal, natural selection, and evolution accounted for many patterns of distribution and diversity of life, many other patterns could not be explained without considering patterns in the origin, movement, and destruction of the Earth's tectonic plates. Although evidence for Hooker's proposed mechanism for connecting now isolated biotas – trans-oceanic land bridges – never surfaced, the more general premise of his theory of the geographic dynamics of southern biotas is now recognized as the foundations of vicariance biogeography.

During the latter decades of the twentieth century, scientists from an ever-widening breadth of disciplines would continue to advance our understanding of the dynamics in the Earth – its land forms and ocean basins, its climatic and environmental conditions, and the forces of dispersal, vicariance, and natural selection and other processes that have influenced evolutionary divergence among regional populations. The myriad of marvelous patterns in the distributions and distinctiveness of life – the mysteries of what we now call biodiversity throughout the geological record, can now be explained by applying the principles and tools of the perhaps singularly holistic and integrative body of theory that now comprises modern biogeography.

Biogeography, Human

A Harcourt, University of California, Davis, CA, USA

African Origins

The earliest *Homo sapiens* bones so far found came from sediments dated to a little under two hundred thousand years old in Ethiopia (McDougall *et al.*, 2005). Indeed most of the hominin line (humans and our ancestors excluding the apes), originated in Africa (Klein, 2009). For instance, all *Australopithecus* species, the immediate ancestor of *Homo*, are African.

That 'so far' in the first sentence is crucial. Anthropologists, archeologists, and paleontologists are always discovering earlier evidence. At the end of the nineteenth century, the earliest find of something that looked roughly human happened to be in Java; and so, at the time, scientists argued that the human line originated in Asia – with 'Java Man', eventually named *Homo erectus*. In fact, Erectus was perhaps the first hominin to expand its range outside of Africa – nearly two million years ago.

The evolutionary tree of human ancestry in **Figure 1** is one of several possible, because considerable debate surrounds the details. For instance, was *H. erectus* only Eurasian, or was it just the Eurasian form of *Homo. ergaster* of Africa? Indeed, are *H. ergaster* and *H. erectus* different species? The leader of the famous Dmanisi cave excavations in Georgia, David Lordkipanidze, thinks not. He argues that the substantial variation among the five *H. erectus* crania of approximately the same age found at this one site indicates that one variable species existed across Africa and Eurasia about two million years ago, not the two or even three often suggested (Lordkipanidze *et al.*, 2013).

The figure shows six species of the genus *Homo*. Some writers use the word 'human' to mean any of these species – *Homo habilis*, *H.ergaster*, *H.erectus*, and so on. Here, the term 'human' is used to mean only *Homo sapiens*.

Out of Africa

The human species initially left Africa about one hundred and twenty-five thousand years ago, as indicated by bones and stone tools of that date in southeast Arabia (Armitage *et al.*, 2011). However, the next oldest well-established indications of humans outside Africa are from about sixty thousand years ago, again in the Middle East. The first human diaspora failed. But the second was a roaring success (Oppenheimer, 2003).

Claims exist of diasporas earlier than sixty thousand years ago. One is based on seventy-thousand-year-old stone tools in southern India (Petraglia *et al.*, 2010). The problem is that nobody has yet found bones associated with the tools. That means that we cannot be sure who made the tools. Neanderthal is the obvious candidate, given the age and nature of the tools. But nobody has yet found Neanderthal remains closer than Turkmenistan, two thousand kilometers from southern India. Another claim is based on teeth from maybe more than 80 000 years ago in southern China (Liu *et al.*, 2015). This latter exciting find is too recent, though, yet to be widely accepted. Clearly, many puzzles in human evolution and hence historical biogeography remain to be solved.

By forty-five to forty thousand years ago, humans had reached Australia. Again, claims exist of an earlier arrival at about 60 000 years ago, as judged by dating of stone artifacts there, which could have been made by only humans. A major problem with that date though, is that it comes not from the artifacts themselves, but from the sediments in which the stone artifacts were found, but without clear signs that the artifacts did not in fact sink down from younger into older layers of sediment (O'Connell and Allen, 2004).

By the time early humans were in Australia, they were also in eastern Asia and much of Europe. Human presence over Eurasia is hardly surprising, given the lack of sea barriers to movement on the continent. However, to get to Australia humans would have had to cross a minimum of one hundred kilometers of open sea from either New Guinea or East Timor. That barrier might explain why Australia had to wait another forty thousand years for the next arrivals – Asians, who brought the dingo with them.

Some writers describe our spread across the Old World as rapid. But even if humans left Africa fifty thousand years ago, five thousand years to cover the twelve thousand kilometers to Australia is two to three kilometers a year, or a bit over five meters a day. That sort of speed indicates that we need to think of human movement across the world not as a migration, but as a population expanding and moving ameba-like across the world (**Figure 2**).

Humans left Africa as the northern hemisphere was heading toward the peak of the last ice age. The European ice cap finally extended down to the Midlands in Britain and to northern Germany in now mainland Europe. Not surprisingly, humans had to wait until the end of the ice age about ten thousand years ago and for the retreat of the ice cap, to enter Scandinavia.

However, humans were in north central Siberia a little over thirty thousand years ago, which is almost at the peak of the last ice age. We know this from the famous Yana Rhinoceros Horn site on the Arctic coast of central northern Siberia (Pitulko *et al.*, 2004). How could humans have lived there then if they could not get into Scandinavia until twenty thousand years later? It turns out that the Eurasian ice cap extended from Britain to only about half way across northern Russia. Farther east, the climate was too dry, it seems, for massive amounts of ice to form.

There humans stayed for fifteen thousand years or so, blocked from movement east by the massive North American ice sheet. In western North America this barrier extended from southern Alaska down to northern Washington. In the east it reached south as far as New York. Central Park there still carries signs of the three hundred meters of ice that once covered it. It is full of boulders dropped by the ice sheet, and the Park's bedrock still show the north-south scars from the boulder and stone laden ice scraping over it.

The last ice age reached its peak about twenty thousand years ago. Ice ages end rapidly, and by sixteen thousand years ago, the North American ice sheet had retreated enough for humans to start moving east from Siberia into the Americas. What is now the Bering Strait was then dry land. In effect, the water that made up the northern ice sheets came from the sea, which twenty thousand years ago was one hundred and twenty meters lower than it is now. The Bering Strait then was seventy meters above sea level.

Once again, humans appear to have moved fast. Just five hundred years after leaving Siberia – maybe sixteen thousand years ago – humans were in central Texas (Waters *et al.*, 2011). Less than a thousand years after that, those early migrants had reached southern Chile. We know that from the famous Monte Verde site (Dillehay *et al.*, 2008). The site is famous because it provides the earliest evidence of humans in South America. It is also notorious because of the sometimes harshly expressed disagreements with the finding that it was older than the oldest so-called Clovis sites in North America.

Archeologists recognize the Clovis culture by its elegantly crafted stone spear and arrow blades. They particularly characterize it by the smooth groove at the base of the blades,

presumably for slotting the blade into a shaft. The Clovis culture lasted for a few hundred years around thirteen thousand years ago. Archeologists used to consider it to be the culture of the first humans into the Americas. However, the firm dating in the 1980s of Monte Verde at nearly fifteen thousand years old, in other words nearly two thousand years older than any Clovis artifacts means that for thirty years now, we know that Clovis cannot have been the first culture in the Americas.

Routes Out of Africa

Central Texas, site of the earliest evidence yet of humans in the Americas, is half way across North America. The presence of humans here and at Monte Verde raises the issue of the routes followed by the earliest arriving humans in any part of the world. Did the immediate ancestors of the two-hundred-thousand-year-old first human in Ethiopia live in Ethiopia? Or did they move there from somewhere else in Africa? Did the emigrants from Africa who eventually peopled the rest of the world go across the south end of the Red Sea (properly the Reed Sea), or the north end? Were the first Americans immigrants from Siberia, or did they come across the Atlantic from western Europe – the 'Solutrean hypothesis' for the peopling of the Americas, refuted by the most recent genetic evidence (Rasmussen *et al.*, 2014). Did the Monte Verdeans arrive in southern Chile after crossing the southern end of the Andes from Argentina, as some argue, or did they come all the way down the coast from Alaska?

Early humans could well have taken a mostly coastal route in their expansion across the world. Along all the seashores of the world – Africa, Asia, the Americas, Australia – one can find immense mounds of shellfish, often mostly oyster shells, one hundred meters or more long, tens of meters wide, and up to five meters high. Trees grow on some of the mounds. The advantage of shellfish is not only that they are highly nutritious but also that they are easy to harvest. Even children can, with little effort collect a full meal of them.

A coastal expansion across the world means that modern-day archeologists interested in the details of the route need to be trained scuba divers, especially if their interest is the Old World. That is because at the time, sea levels were already tens of meters lower than now, if not yet at the one hundred and twenty meters lower than the ice age's peak.

Central Texas is of course not on the coast. It is, though, south of the so-called 'ice-free corridor' that appeared maybe fourteen thousand years ago as the ice sheet covering North America melted. The corridor was just east of the Rocky Mountains in roughly today's Alberta and Montana. It separated the Cordilleran ice sheet to the west from the far larger Laurentide ice sheet that extended all the way to Greenland. The corridor raises the question of whether the early Texans, and other early Americans, came down the coast to south of the ice sheets and then moved inland, or whether they expanded through the ice-free corridor into the center of North America and spread out from there?

The very earliest Americans must have moved down the coast, because before the corridor opened they had arrived in both Texas in southern North America, and in Monte Verde in southern South America. For maybe hundreds of years after the corridor opened, a coastal route for all the early North American immigrants, maybe even the Clovis culture, seems likely. The edges of retreating ice sheets are for several kilometers out a sodden, flooded terrain of boulders and rubble. Every now and again, so-called katabatic winds reaching a hundred kilometers or more an hour sweep off the ice. The ice-free corridor would have been one and a half thousand kilometers of appallingly cold, barren wasteland, and as yet no good evidence exists to indicate that the earliest Americans used the corridor.

The Americas were the last of the major continents to be peopled. But not the last continent, and not the last land. The last places were oceanic islands, especially the Pacific islands (Kirch, 2000). Humans reached the western Pacific islands, the Solomons east of New Guinea for example, maybe thirty thousand years ago. And there the human expansion across the Pacific got stuck for the next twenty-five thousand years. Substantial ocean-going boats were the requirement for further conquest of the Pacific, and those the islanders did not design and build until maybe five thousand years ago.

A particular form of pottery, Lapita pottery, shows that humans reached the mid-Pacific islands, Fiji for example, maybe four thousand years ago. Two thousand years later, humans had reached most of the Pacific islands. These voyages of settlement are extraordinary. Hundreds, even thousands, of kilometers of ocean crossed. Days, weeks, months maybe, with no sight of land. New Zealand was the last major landmass that humans reached – just seven hundred years ago.

Many boats must have foundered during the spread across the Pacific; so vast are the distances. As just one example, the Maoris of New Zealand came originally not from the closest landmass, Australia, but from the Cook Islands, over two thousand kilometers away. Genetic studies indicate that the entire present-day Maori population might have descended from just seventy female ancestors (Murray-McIntosh *et al.*, 1998).

Madagascar's first immigrants too might have come not from the closest continent, Africa, just four hundred kilometers away, but from Indonesia, specifically southeast Borneo (Razafindrazaka *et al.*, 2010). In a straight line, Borneo is three thousand kilometers from Madagascar. Both genetics and linguistics confirm this extraordinary migration. Maybe at about the same time, two thousand years ago, or maybe five hundred years later, Africans immigrated. One reason to think that the Borneans got to Madagascar before the Africans is that Malagasy, the language of Madagascar, is in effect a Bornean language. Five hundred years ago, the French arrived. And the island continent now is a mix of Indonesian, African, and French cultural influences.

How Do We Know?

Disparate scientific disciplines contribute to the discipline of human biogeography – genetics, archeology, and linguistics.

Because genetic differences accumulate over time, the level of genetic diversity in a population or region can indicate age; and as already indicated, Africa has the greatest diversity (Cann *et al.*, 1987, Cavalli-Sforza, 2000). Some studies indicate twice

as much genetic diversity there as in any other major world region. The concept of an African 'race' is clearly biologically untenable.

Immigration can also augment the genetic diversity of a population. Nowadays, big cities are immensely variable genetically because of immigration. However, immigration is not why Africa is so genetically varied. People have certainly immigrated into Africa. But Africa has more of its own genes than has any other continent. Indeed, all other continents' genetic profiles are essentially subsets of the African genetic profile. Any human population lacks many of the genes of other continents, but no regional population lacks African genes. No other way exists for such a genetic pattern than an origin in sub-Saharan Africa. Another reason for the drop in diversity away from Africa is that as humans dispersed, only a subset of each population moved on (Amos and Hoffman, 2010). 'Genetic bottleneck' is the jargon term for such a process.

The drop in genetic diversity from the source population is very evident with the peopling of the Americas from Siberia. Among Siberians, one can find all of the three major blood groups. But among Native Americans of North and especially South America, the O blood group is in the vast majority. Over eighty percent of Native North Americans are O. Ninety-nine percent of native South Americans, Amerindians, are O. Not only that, but native Americans and Beringians have a form of gene that nobody else in the world has (Schroeder *et al.*, 2007). Only one way exists for such a pattern. The vast majority of native Americans descended from a small number of Siberian immigrants.

And where did the Siberians come from? Genes indicate certainly eastern Asia, but also central Russia, and also western Europe. That last origin comes from a surprise recent find (Raghavan *et al.*, 2014). So if humans expanded along coasts in their first movement out of Africa, we clearly subsequently migrated along inland routes.

Where We are Influences What We are

Skin color is an obvious example, if a divisive one, of people in different environments differing anatomically, indeed physiologically, because individuals with certain traits do better in certain environment than do individuals without those traits. Oddly enough, even Darwin was wrong on skin color. He could not see how it matched the environment (Darwin, 1871, p. 174). But it does. People from the tropics tend to be darker than people whose ancestors came from outside the tropics.

The reason is that tropical peoples' skin has in its surface layers more melanocytes. By blocking and scattering the passage of light, the melanocytes help prevent sunburn, in other words, damage to the surface layer of skin cells. More crucially, the melanocytes filter out ultraviolet light by both absorbing and scattering it. That prevents the rays from penetrating deeper into the skin, and so prevents the ultraviolet from destroying vitamin B9 in any blood circulating near the skin (Jablonski and Chaplin, 2002). Vitamin B9, also known as folate or folic acid, has a variety of vital jobs in the human body. One is in the production of red blood cells. Another crucial part it plays is in the development of the fetus' spinal cord and brain.

So why do we not all have dark skin and why do females not have darker skin than do males? The answer is that UV light stimulates the production in our skin of vitamin D, crucial for healthy bones via its effect on the body's metabolism of calcium, among other elements. Too little sun, and a diet without vitamin D supplements, and children develop rickets. Strictly dressed Moslem women in northern latitudes can also suffer.

Yet the palest people are not those the farthest north. Arctic people are darker than western Europeans. It turns out that the Arctic peoples' traditional diet, heavy in fish and meat, is high in vitamin D. Until recently that was not true of western Europeans. Their diet was largely cereals, and cereals are unusually low in vitamin D (Khan, 2010). A main reason we do not see rickets in western European populations nowadays is that the major producers of bread and cereals add large amounts of supplemental vitamin D.

Many other aspects of our physiology and anatomy differ between regions (Harcourt, 2012, 2015). The lengths of our limbs and the shape of our bodies differ. For instance, Africans tend to be longer and thinner than Europeans and certainly Arctic people. A likely reason is that long, thin bodies lose heat more easily than do short, squat ones. Africans are better than Europeans at retaining salt when they sweat. Why? Probably because salt is in shorter supply in Africa than it is in Europe, so weathered are the rocks and soils of Africa.

But all these anatomical and physiological differences between people from different regions are in many textbooks of biological anthropology. A topic rarely found in any of the textbooks is the question of why in biogeographical terms, the tropics are more culturally diverse than are higher latitudes.

Geography and Cultural Diversity

The latitudinal gradient in diversity of plant and animal taxa is well known. Human cultures show a similar pattern, with a far greater density of cultures in tropical latitudes than outside them (Harcourt, 2012, 2015). Take Ecuador and Britain: travelers could hear twenty-three indigenous languages as they voyaged across Ecuador; they would hear no more than twelve in Britain. South America is two-thirds the area of North America, but one can hear fifty percent more languages in South America than in North America, nearly five hundred as against a little over three hundred (Lewis, 2009; **Figure 3**). The author terms these latitudinal contrasts in diversity (whether biological or cultural) the 'Forster effect,' after Johann Forster, the biologist on James Cook's second voyage around the world, who was one of the earliest biologists to remark on it (Harcourt, 2012, 2015).

Current winning arguments to explain the Forster effect in non-human species include the idea that rates of taxonomic diversification are higher in lower latitudes (Brown, 2014), and that life has had more time to diversify in large areas of the lower latitudes (Fine, 2015). After all, just twenty thousand years ago, much of northern Europe and America looked like Greenland currently does.

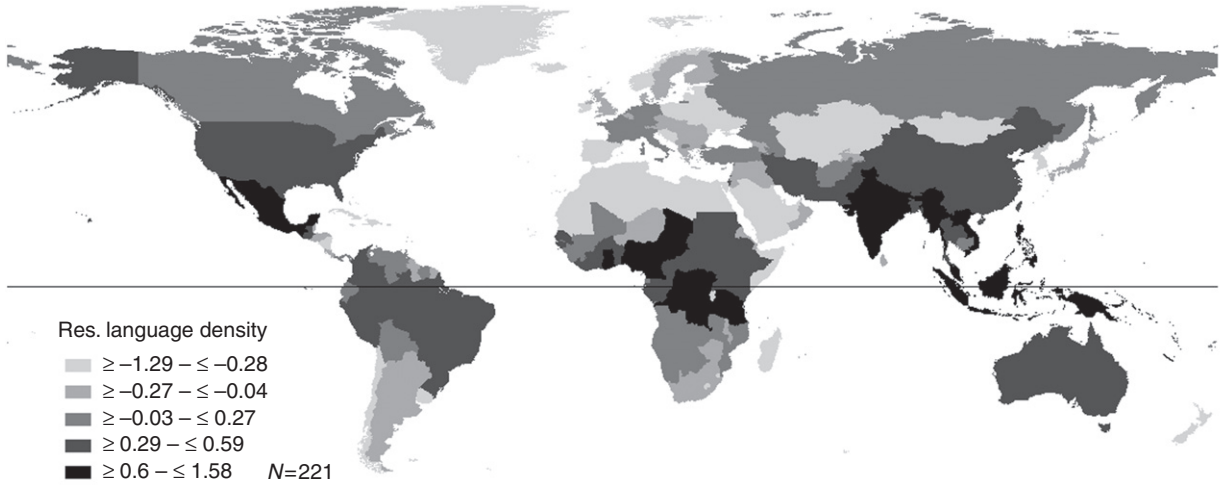

Figure 3 Density of languages per country in relation to the number expected given the area of the country. Map from www.ethnologue.com.

These ideas do not seem to work so well for human cultures. That is because humans arrived at roughly the same time in both tropical and temperate regions in first the Old World outside of Africa, and subsequently in the New World (Harcourt, 2012, Ch. 2). Indeed, as mentioned previously, one of the current earliest reported dates of arrival outside of Africa, a minimum of 80 000 years ago, is not in the tropics, but in temperate southeastern China (Liu *et al.*, 2015). And yet temperate China does not have more cultures than do tropical regions to the south. Nor does it have more than does the Amazon, where humans did not arrive until about 15 000 years ago. Add the likelihood that in the last ice age, Africa's and Asia's forests, which are large regions of high linguistic diversity now (Harcourt, 2012, Ch. 5), were reduced then to remnants (Jablonski, 1998; Hamilton and Taylor, 1991; Harcourt, 2012, Ch. 2), and there too human cultures might not have had much longer to diversify than have American cultures. Nevertheless, lack of time to diversify could partly explain New Zealand's paucity of native cultures. The original Maoris arrived less than a thousand years ago.

Of the many explanations offered for the Forster effect (Lomolino *et al.*, 2010, Ch. 15), one seems nicely to explain the distribution of cultures (Harcourt, 2012, 2015). Part of the explanation is based on the fact that the average size of a tropical culture's geographic range is smaller than that of a culture from higher latitudes. The same is true for many plant and animal species. To give an example for human cultures, the Guato and Bororo people of Brazil each range over less than seven thousand square kilometers. Compare that to the seventy thousand square kilometers of the MacKenzie Inuit of the Canadian Northwest Territory. In brief, more cultures pack into an area of a given size in the tropics than they do at higher latitudes.

An explanation for the fact of small geographic ranges in the tropics is the high productivity of the tropics. That high productivity means that a culture with a large enough population to survive over millennia can exist in a smaller area in the tropics than outside the tropics. Warmth and water produce an abundance of plants and animals, in other words an abundance of food. And crucially, where there is water, that abundance is available year-round in the tropics. That is why so many temperate bird species go to the tropics in the temperate winter. If cultures can survive in small geographic ranges, then more cultures can pack into a region.

The same productivity argument could explain the high diversity of Native American cultures on the Gulf Coast compared to farther north, and the west coast of the United States compared to inland. In both cases, the coastal environment is richer than the inland one. Compare, for example, California's highly productive Central Valley with neighboring Nevada's near-desert.

High tropical productivity alone cannot explain New Guinea's extraordinary density of cultures, the highest in the world. To understand this, we must turn to topography. Eastern New Guinea is in essence a mountain chain cut by deep ravines. Almost every major ridge has its own culture. Difficulty of movement, then, can prevent amalgamation of cultures, and promote diversity of them. Hence, we see a high diversity of cultures in the lower reaches of the Himalayas and the Karakorams.

New Guinea cultures are notoriously warlike and xenophobic. Does mere xenophobia, then, prevent mixing and hence cause diversity? Maybe, but if so, we need to ask which came first, the cultural diversity (resulting from geographic barriers), or the xenophobia.

In Europe, twenty-two of thirty-three boundaries between genetically distinct populations are obvious geographic barriers. A sea separates the French and English. A mountain range, the Alps, separates France from Italy. It looks as if geography might be separating cultures. However, thousands of ships and airplanes cross the English Channel every year, and have done for decades. Thousands of cars, buses, trains pass through Alpine tunnels every year. Soldiers have criss-crossed Europe for centuries, and soldiers are not famously celibate.

On the other hand, either side of these geographic boundaries and in nine of the remaining eleven cases where no geographic barrier exists, the genetically different populations speak a different language or dialect (Barbujani and Sokal, 1990). In other words, it looks as if indeed language

could be a barrier to cohabitation as is, in the case of animals, inability to understand or be stimulated by another species' courting behavior.

To conclude, the great cultural diversity of humankind seems to have been shaped in part by some of the same biogeographical influences as have shaped the diversity of other animals and also plants. Biogeographically, humans are in some important ways just another species.

Glossary

Allopatry Occurring in nonoverlapping geographic areas.
Biodiversity feedback A process by which species arising in areas of high biodiversity colonize areas on the periphery. The peripheral colonizers subsequently spawn new species that recolonize the original area and further increase diversity in the centers of origin.
Endemic Native species that is confined to a certain geographic region, often a biogeographic province.
Peripatric Occurring in a peripheral geographic area.
Phylogeography The study of the geographic distribution of individuals and their associated gene genealogies to infer historical processes responsible for contemporary distributions.
Relictual A remnant species that inhabits only a fraction of its historical geographic range, often because of environmental change.
Sympatry Occurring within the same geographic area such that frequent encounters are likely.

Introduction

Marine biogeographic provinces, based on distinct floras and faunas, have been recognized for over 150 years (Forbes, 1859). These provinces represent parts of the world that host unique biotas, both areas of recent evolutionary innovation and refuges of ancient lineages that persist today. Although impenetrable barriers are relatively uncommon in the sea, boundaries between these provinces are frequently associated with continents, sharp ecological gradients, or vast expanses of open ocean. Three observations by Forbes (1859) still guide the field of marine biogeography today: (1) each zoogeographic province is an area where new lineages arise and tend to mix with emigrants from other provinces; (2) each species is created only once and individuals tend to expand their range from their place of origin; and (3) to be understood, provinces, like species, must be traced back to their origin in the past.

The first global characterization of marine biogeographic provinces was compiled in the pioneering volume *Tiergeographie des Meeres* (Ekman, 1935), later updated and translated into *Zoogeography of the Sea* (Ekman, 1953). Therein, Sven Ekman described a series of large regions and subregions, including the continental shelf, tropical, temperate, and polar waters, their separation by zoogeographic barriers, and their endemism. Briggs (1974) divided the continental shelves into a series of large biogeographic regions that, in turn, contained smaller biogeographic provinces, each defined on the basis of endemism. This work established the now-accepted practice of defining biogeographic provinces on the basis of 10% endemism at the species level within published species inventories, most frequently fishes or well-known invertebrate groups such as mollusks. A central theme was that the greater the proportion of endemic biota, the greater the evolutionary significance of the province (Briggs, 1974).

Marine biogeography has seen a recent reevaluation in the face of considerable research over the past few decades (reviewed by Briggs and Bowen, 2012). Although there are debates about the definitions and boundaries, here we follow previous work and define the biogeographic provinces as shallow (<200 m) marine regions with at least 10% endemism (Briggs, 1974). In many provinces, data on endemism remain unavailable, or incomplete with only the most widely studied taxa (typically fishes) defining the boundaries. Recent works, including new studies from remote locations, and particularly phylogeographic approaches, have revealed genetic subdivisions within and between species that modify or redefine the various divisions (Avise, 2000). Notably, detailed phylogenetic comparisons of warm temperate and tropical biota are erasing the earlier artificial separation of these regions into different zoogeographic regions. As a result, marine biogeographic provinces have been realigned recently (Briggs and Bowen, 2012), and we follow this treatment below in defining marine biogeographic provinces.

Marine Biogeographic Barriers

The world's oceans are all connected, and have been for a very long time. While a few vertebrates have achieved circumglobal distributions (Gaither *et al.*, 2015), most marine species are constrained to a much smaller range, often defined by the edges of biogeographic provinces. In a continuous transglobal medium, what constitutes these boundaries? The most obvious barriers are geographic. Africa moved north into Eurasia about 11–18 million years ago (MYA), closing the Tethys Sea and creating an impenetrable barrier between the Indo-Pacific and Atlantic-Mediterranean systems (**Figure 1**). Occasionally tropical (or warm-temperate) marine species are able to colonize between the Indo-Pacific and Atlantic by going around southern Africa. This is especially possible at the end of each glacial epoch, when the cold water (Benguela) upwelling attenuates and a warm water corridor opens around southern Africa (Peeters *et al.*, 2004).

 doi:10.1016/B978-0-12-800049-6.00120-7

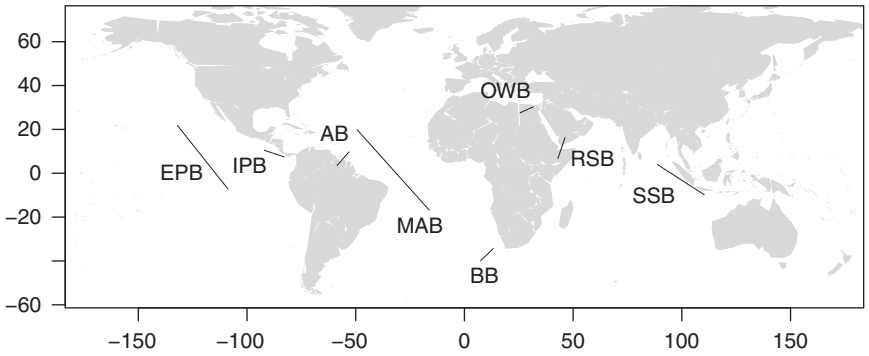

Figure 1 Map depicting the eight major marine biogeographical barriers: the East Pacific Barrier (EPB), the Isthmus of Panama Barrier (IPB), the Amazon Barrier (AB), the Mid-Atlantic Barrier (MAB), the Benguela Barrier (BB), the Old World Barrier (OWB), the Red Sea Barrier (RSB), and the Sunda Shelf Barrier (SSB) (Rocha *et al.*, 2007).

Another major geographic barrier is the Isthmus of Panama. An equatorial current flowed from the Pacific into the proto-Caribbean until about 6 MYA, followed by an impenetrable land barrier about 3 MYA. Many evolutionary studies have benefitted from this natural laboratory, with sister species on each side of Central America (Lessios, 2008). Notably, mankind has cut canals through both of these barriers, with few colonists crossing the (mostly freshwater) Panama Canal, but many species moving from the Red Sea into the Mediterranean Sea through the Suez Canal (Golani *et al.*, 2007).

An especially interesting land barrier is the Sunda Shelf (Indo-Pacific) barrier between the Indian and Pacific Oceans (**Figure 1**). This barrier only exists during glacial periods, when sea level drops over 100 m and exposes a nearly complete land bridge between Asia and Australia. The presence of an intermittent barrier, on ~100 000 year cycle, has allowed some species to diverge into sister species, while in other cases the Pacific and Indian Ocean cohorts reconnect and interbreed or hyrbidize (Gaither and Rocha, 2013; Hobbs *et al.*, 2009).

Open ocean is another major barrier, with the largest being the East Pacific Barrier between central Pacific islands (Hawaii and Polynesia) and the eastern Pacific, about 4000 km. Darwin (1872) labeled this an impenetrable barrier to nearshore organisms, and that view is supported by much taxonomy. However, recent phylogeographic studies have demonstrated that some organisms can make this crossing with sufficient regularity to maintain species integrity (Lessios and Robertson, 2006).

Freshwater outflows can also be barriers in the marine realm, with the Amazon River being the best-studied example (Floeter *et al.*, 2008). This enormous outflow cleaves the tropical West Atlantic into Caribbean and Brazilian Provinces, and many sister species have formed as a result (Briggs and Bowen, 2013). One interesting facet of this barrier is that it applies primarily to reef organisms. The nutrient-rich waters of the Amazon feed vast sponge beds under the freshwater Amazon plume, so for species that occupy sponge habitat, no barrier exists (Rocha *et al.*, 2002).

Marine Biogeography and Evolution

For many decades, evolutionary biologists have debated whether speciation is different in the sea. Most marine fauna have a pelagic larval stage that can stay in the water for days to months. This makes possible extensive dispersal and gene flow across thousands of kilometers, preventing allopatric speciation except on the largest scale between ocean basins (e.g., Iacchei *et al.*, 2015). However, shallow marine habitats can be very heterogeneous, offering many habitats and niches that provide opportunities for specialization and speciation along ecological boundaries (Bird *et al.*, 2012). Hawaiian limpets, for example, have evolved into three species in sympatry, after a rare colonization event from Japan about 5 MYA (Bird *et al.*, 2011). These limpets faced different selection pressures in the high, middle, and low intertidal, and adaptive divergence has produced three species in response to these differing ecological conditions (Bird, 2011). The emerging consensus is that speciation in the sea follows the same processes as terrestrial and freshwater biota, but on different scales of isolation, dispersal, and ecological divergence (Bowen *et al.*, 2013).

A central debate in marine evolution is about the role of biodiversity hotspots, such as the Caribbean Sea and the Coral Triangle (between Indonesia, New Guinea, and the Philippines). Do these hotspots serve as evolutionary incubators (centers of speciation) that export new species, or do they acquire species that arose elsewhere (centers of accumulation)? Recent evidence indicates that the hotspots are centers of origin (Briggs, 2003; Cowman and Bellwood, 2013). However, isolated peripheral provinces, including Hawaiian and the Red Sea, are centers of endemism and may export species as well (Eble *et al.*, 2015). Hence both areas of high endemism and areas of high biodiversity are important for evolutionary processes, with peripheral provinces producing new species primarily through allopatry, and hotspots producing more species in sympatry, with divergences along ecological lines (Briggs, 2005).

Plate Tectonics and Marine Evolution

The surface of Earth is divided into submerged oceanic plates and the thicker continental plates, all in continuous motion driven by flow in the underlying mantle. At several points in Earth's recent history (Cenozoic Era, 66 MY), tectonic changes have prompted revolutions in the distribution of marine life.

Here we provide three examples of how geology has altered the marine biogeographic history.

1. *The movement of a biodiversity hotspot*. For much of the Cenozoic Era, the Tethys Sea provided a continuous belt of warm water around the globe. This global connectivity ceased as Africa moved north into Eurasia about 18 MYA. As the connection between Atlantic-Mediterranean and Indian Ocean biospheres was severed, the center of highest tropical diversity moved east, from the Mediterranean-Indian region to the current hotspot in the Coral Triangle (Bellwood and Wainwright, 2002). About 5 MYA the Coral Triangle began exporting biodiversity (center of origin) that now accounts for an estimated 60% of global diversity in some fish groups (Briggs, 2003; Cowman and Bellwood, 2013).
2. *The trans-Arctic interchange*. Up until about 3.5 MYA, the Bering Strait and Arctic ice cap provided an impenetrable barrier between the North Pacific and North Atlantic oceans. With the opening of this barrier by warming and rising sea levels, a massive exchange of marine biota occurred, primarily from the high diversity North Pacific into the depauperate North Atlantic. Vermeij (1991) documented 265 mollusks invading the Atlantic, with only 24 moving in the opposite direction. Important fish groups such a salmon (family Salmonidae) and sculpins (family Cottidae) colonized into the Atlantic, while the cods (family Gadidae) may have moved the other way. This trans-Arctic passage closed with the return of Pleistocene sea ice, but Vermeij and Roopnarine (2008) warn that the Atlantic-Pacific interchange could resume by year 2050 under current climate predictions.
3. *The Isthmus of Panama*. The last vestige of the circumtropical Tethys Sea was eliminated about 3 MYA with the rise of the Isthmus of Panama. As noted above, this land bridge effectively divided a continuous tropical marine fauna into Caribbean and East Pacific cohorts (Lessios, 2008).

Marine Biogeographic Provinces of the World

Biogeographic provinces provide a broad overview of marine biodiversity, but of course this vast array of life is subdivided into smaller ecosystems and communities. For example, Spalding *et al.* (2007) divide coastal biodiversity into 232 ecoregions as a suitable framework for marine conservation measures. Likewise, within provinces there can be concordant genetic breaks among many species (Avise, 1992; Carpenter *et al.*, 2011; Toonen *et al.*, 2011) that indicate shared limits to dispersal among divergent taxa at a scale finer than the biogeographic provinces on which we focus here. Finally, there are a variety of unique ecosystems with communities that may exceed the 10% endemism criterion, but are beyond the scope of this article. Here we provide three examples of such unique ecosystems before moving into our survey of the shallow coastal marine biogeographic provinces of the world.

1. *Marine Lakes*. Marine lakes form when inland depressions in fractured karst (limestone) become flooded by rising sea level. There are roughly 200 marine lakes known, with most located in Vietnam, Palau, and Indonesia. Although these lakes remain connected to the sea through fissures or small tunnels, they typically have greatly reduced tidal influence, high rainfall and other freshwater inputs, and shelter from coastal winds. Combined, these factors reduce mixing and increase vertical stratification (Hamner and Hamner, 1998), and in turn, result in marine lakes being isolated and different enough from nearby ocean environments that they develop a suite of unique species separated from coastal congeners for many thousands of years (Dawson and Jacobs, 2001; Dawson, 2005).
2. *Hydrothermal vents*. These fissures in the Earth's crust, occurring at mid-ocean ridges and other volcanic hotspots, produce chemical-rich seawater that can exceed 400 °C. In the lightless environment below 1000 m, hydrothermal vents support chemosynthetic microbes that are the basis for one of the strangest ecosystems on earth, with highly specialized shrimps, clams, snails, and giant tube worms. Thermal vents are probably as old as the oceans (~4000 MY; Elkins-Tanton, 2011), and have been proposed as the origin of life on Earth (Wächterhäuser, 1990). However, phylogenetic studies show that the fauna are much more recent (<100 MYA) and some are derived from shallow marine species <20 MYA (Van Dover *et al.*, 2002). Six biogeographic provinces are recognized for thermal vent fauna, occurring on the scale of ocean basins: Western Pacific, Northeast Pacific, East Pacific Rise (30° N to 30° S), Azores, Mid-Atlantic Ridge, and Central Indian Ocean (Van Dover *et al.*, 2002). Further exploration may reveal additional faunal provinces. A biogeography of the deep sea has recently been proposed (Watling *et al.*, 2013), and we refer interested readers there for additional information.
3. *Whale Falls*. Carcasses of dead cetaceans (whales, dolphins, and porpoises) fall to the deep seafloor to create a highly localized ecosystem fueled by decomposition (Goffredi *et al.*, 2004). Such communities, called whale falls, are typically found at depths greater than 1000 m and can persist for decades, during which they provide a hard surface for invertebrate colonization as well as a source of sulfides from the microbial decay of organic compounds contained in the whale bones (Bennett *et al.*, 1994). These whale fall communities can provide stepping stones for the dispersal of deep sea hydrothermal vent species (Feldman *et al.*, 1998).

Our focus here is on shallow coastal seas, and following Briggs and Bowen (2012), we define the following biogeographic provinces for shallow (<200 m) marine habitats across the globe (**Figures 2** and **3**).

Warm Regions (Tropical and Warm-Temperate Waters)

Eastern Atlantic Region

Lusitania

This province encompasses the warm-temperate waters from the southern end of the English Channel down to southern Morocco and eastward to include the Mediterranean

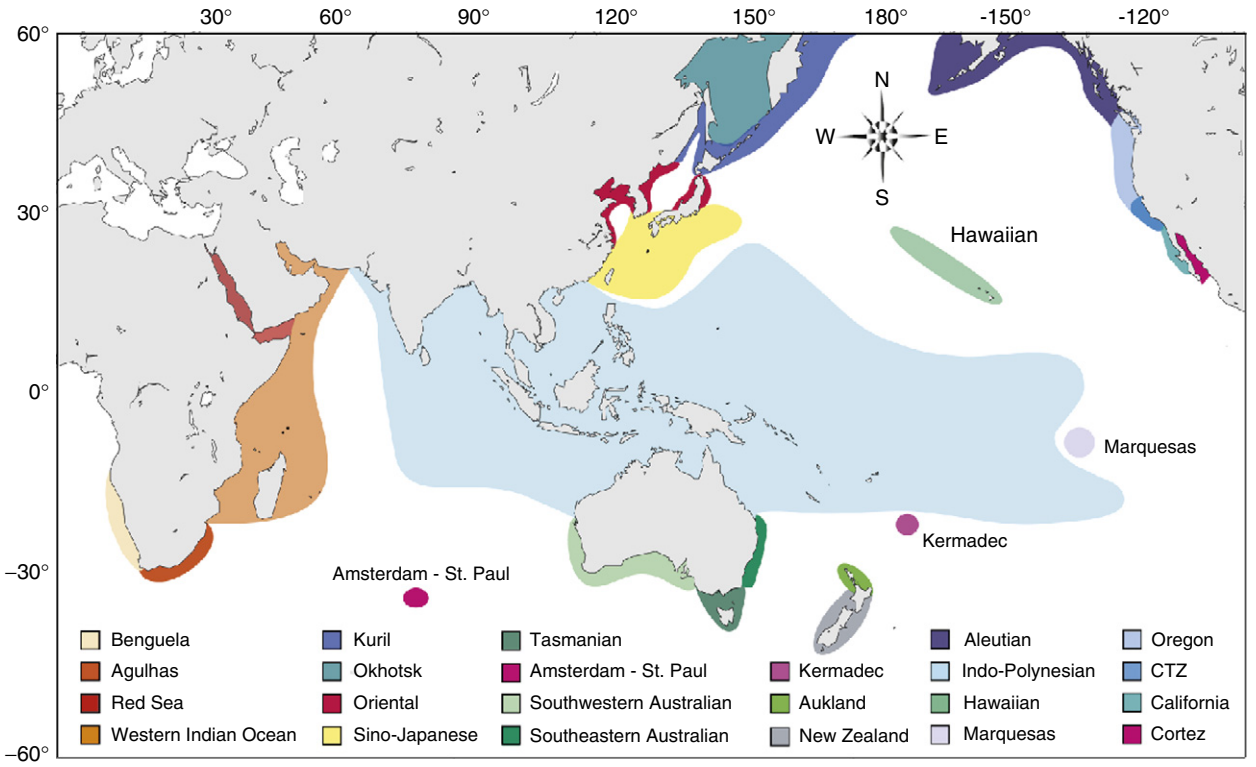

Figure 2 Map of the Indo-West Pacific Provinces. Each province is identified by a distinct color as shown in the key below the map. In general, the key lists provinces from West to East and from North to South. One province from the subantarctic region (Macquarie) and one of the New Zealand–Australian region provinces (Antipodes) are outside of the range of this map and are not shown.

(with 28% endemism) as well as the Azores, Madeira, and the Canary Islands. Although Briggs and Bowen (2012) place this province with the warm-temperate provinces on the basis of a prevalence of warm water fishes, Almada *et al.* (2013) have subsequently argued that the Macaronesian archipelagos are highly distinct from the mainland coasts of the Lusitanian Province, and these should not be grouped together.

Black Sea

This subtropical sea has a Mediterranean climate but is located in the temperate zone. It contains a mixture of relictual species mixed with more recent Mediterranean and freshwater invaders as well as a suite of alien species.

Caspian Sea

This is the largest enclosed body of water in the world, sometimes classified as the world's largest lake. Indigenous brackish water species (and genera) form the basis of the high endemism with the remainder of species drawn largely from the Mediterranean, freshwater, or Arctic biota.

Aral Sea

This 5.5 MY old sea is technically an endorheic lake (lacking an outflow), lying between Kazakhstan and Uzbekistan. Formerly the fourth largest lake on the planet, Soviet irrigation projects diverted inputs in the 1960s, and by 2007 only 10% of the 68 000 km^2 remained (Filippov and Riedel, 2009). The catastrophic decline in area has led some to label this as 'one of the planet's worst environmental disasters' (Daily Telegraph, 2010). The Aral Sea has been subject to rapid environmental changes throughout its entire history, leading some researchers to question the estimates of endemicity for this disappearing province (Filippov and Riedel, 2009).

Tropical Eastern Atlantic

Extending from southern Morocco south to Angola, and including the offshore islands of the Cape Verdes, São Tomé, and Principe, the Tropical Eastern Atlantic is characterized by a narrow continental shelf and seasonally strong upwelling. The waters are typically stratified with warm, turbid, lower salinity water (due to high river inputs) above cool nutrient-rich water, separated by a strong thermocline at about 100 ft (30 m). Although diversity is lower in comparison to the Tropical Western Atlantic, endemism is about 30% and this region is highly productive, ranking as one of the most important fishing zones in the world (Spalding *et al.*, 2007).

Benguela

Along the western coasts of Namibia and South Africa, this warm-temperate province is strongly influenced by the intense upwelling of cold nutrient-rich waters from ~200–300 m. The Benguela current results in a general equatorward flow of cooler water into the South Atlantic gyre. This nutrient-rich water is ~30–65 times more productive per unit area than the average global ocean. There remains some debate about whether the Namib, Namaqua, and Southwestern Cape bioregions each represent discrete biogeographic provinces or subregions (Lombard *et al.*, 2004), but with the boundaries

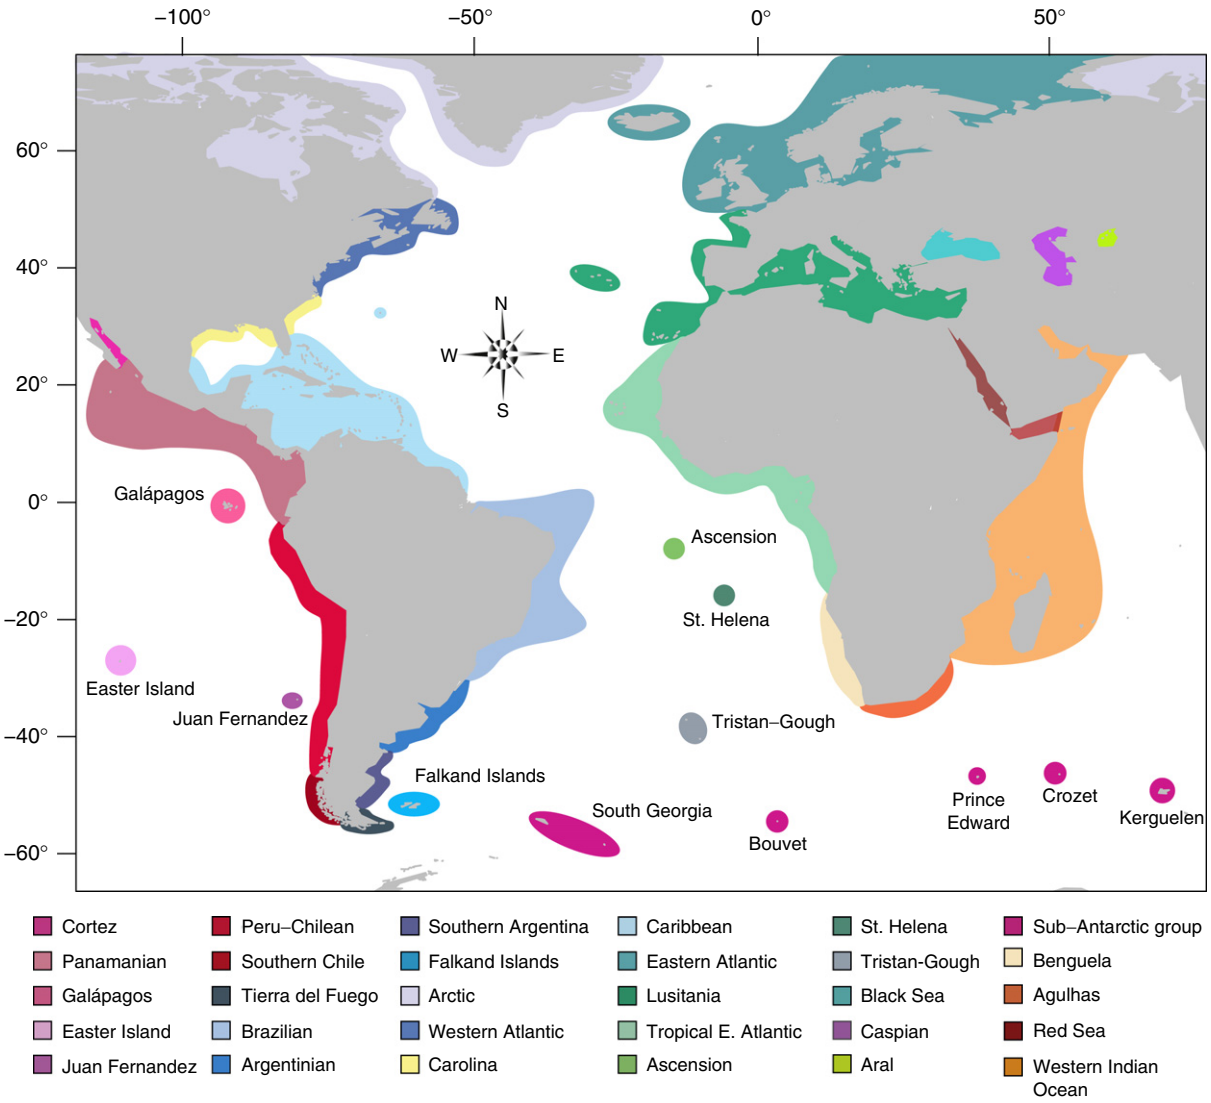

Figure 3 Map of the Atlantic and East Pacific Provinces. Each province is identified by a distinct color as shown in the key below the map. In general, the key lists provinces from West to East and from North to South. The Antarctic Province is outside the range of the map and is not shown here.

reported in Briggs and Bowen (2012) this province contains about 12% endemic species. The Cape of Good Hope forms the dividing line between the warm-temperate Benguela Province and the Agulhas Province (below) in the Indo-Pacific.

St. Helena

Located 4000 km east of Brazil, and 2000 km west of Africa, this is one of the most remote islands in the world, in the middle of a large expanse of deep ocean. St. Helena was an important haven for ships transiting from Asia to Europe during the age of sail (1500–1800s). With more than 400 species of endemic birds and plants, the terrestrial biodiversity is matched by high endemism of marine fishes and invertebrates (13%). St. Helena has nearly equal taxonomic affinities with the marine fauna of Brazil (16%) and the Tropical Eastern Atlantic (15%) (Floeter *et al.*, 2008).

Ascension

Located 1300 km northwest of St. Helena, Ascension Island lies 1600 km from the coast of Africa and 2250 km from the coast of South America. In contrast to the faunal affiliations of St. Helena, Ascension is more similar to the Brazilian province (29% shared species) than the Tropical Eastern Atlantic (6% shared species), with 11% endemic species.

Tristan–Gough

Located 2400 km from southern Africa, and 3400 km from South American, the Tristan–Gough volcanic hotspot includes four small islands, the largest of which are Tristan da Cunha and Gough. Lying more than 1800 km from the nearest land (Bouvet Island), and 2000 km from the nearest inhabited island (St. Helena) the archipelago of Tristan da Cunha is recognized as the most remote inhabited location on the planet. Formally designated as a UNESCO World Heritage Site, Gough

Island is considered one of the least disrupted ecosystems on Earth, and is home to a suite of endemic and endangered terrestrial and marine species.

Western Atlantic Region

Carolina

Located along the southeast United States and adjacent Mexico, this province includes two distinct regions isolated by the Florida Peninsula: one in the northern Gulf of Mexico, and the other along the Atlantic coast of North America. This region is sometimes regarded as a transition zone between the temperate Virginian province and tropical Caribbean province (e.g., Freeman *et al.*, 2007). Opisthobranchs (sea slugs and their relatives) show high endemism in the Atlantic section of this province (García and Bertsch, 2009), and numerous phylogeographic studies highlight genetic partitions between the two sections of this province (Avise, 1992).

Caribbean

Encompassing all the Western Atlantic tropics north of the Amazon River, this province extends from Bermuda and Cape Canaveral, Florida to northern Brazil. The Caribbean hosts the most extensive coral reefs in the Atlantic and is the hotspot for tropical Atlantic biodiversity. Endemism is high in reef fishes (33%, Floeter *et al.*, 2008), decapod crustaceans (32%, Boschi, 2000), and corals (37%, Veron, 2000). Much of the tropical fauna elsewhere in the Atlantic is derived from this province (Briggs and Bowen, 2013).

Brazilian

Extending from the Amazon River to Santa Catarina in southern Brazil, this province includes the offshore islands of Atol das Rocas, Fernando de Noronha, St. Paul's Rocks, and Trindade (Floeter *et al.*, 2008). Between the Brazilian and Caribbean provinces, the northeastern coast of South America from the Orinoco and Amazon rivers is characterized by soft bottoms and turbid waters, the Amazon barrier to dispersal of reef biota (Rocha, 2003). Despite this barrier, the Brazilian fauna is mostly derived from the Caribbean fauna, with 10.5% endemism in fishes (Floeter *et al.*, 2008), 12.5% in decapod crustaceans (Coelho *et al.*, 2008), and 25% in corals (Veron, 2000).

Argentinian

This province extends from Santa Catarina, Brazil to the Valdez Peninsula, Argentina. The northern boundary marks the transition from tropical reef fauna to warm-temperate fauna and sandy beaches, with rocky formations largely restricted to Mar del Plata and Valdes Peninsula. Invertebrate groups including mollusks and crustaceans show high diversity in this region that has yet to be properly documented. Although creation of a regional Ocean Biogeographic Information System (OBIS) node in the area has increased knowledge, this region is still identified as a major knowledge gap in marine biodiversity (Miloslavich *et al.*, 2011).

Western Pacific Region

Sino-Japanese

This warm-temperate province runs from the tip of the Korean Peninsula more-or-less directly across to the port city of Hamada, Japan and then on the oceanic side of Japan from Cape Inubō in the Chiba Prefecture, south to just before the start of the Ryukyu Archipelago. Along the coast of China the exact boundaries are unknown because the distribution patterns of marine species are not fully described (at least in Western literature); however, based on sea surface temperature, this province probably starts around Shanghai and extends south to Hong Kong. Much of the Island of Taiwan shows strong affinity to this warm-temperate region of the coast, although the southeastern portion is entirely tropical due to the influence of the Kuroshio Current.

Kermadec

The Kermadecs are a subtropical volcanic island arc only $\sim 33\ km^2$ in total area, located halfway between New Zealand's North Island and Tonga. Recognition of the distinct terrestrial and marine biota resulted in New Zealand declaring the islands a nature reserve in 1937. Although not many endemic fishes have been described, rates of endemism among invertebrates are exceedingly high, with gastropods, bivalves and bryozoans all in the area of 70% (Griffiths *et al.*, 2009).

Auckland

Circling the northern tip of North Island, New Zealand, this province shares a history and many species with the next two provinces (Waters *et al.*, 2007). There is believed to be a considerable endemic component to this region, but no published estimates currently exist for marine fishes or invertebrates. In the absence of detailed surveys, we follow Briggs (1995) and recognize this province, but highlight the need for systematic surveys of endemism for this region.

Southeastern Australian

Located on the eastern coast of Australia from Sandy Cape, north of Brisbane down to around Green Cape, roughly halfway between Sydney and Melbourne, this warm province is limited to the south by cold water in the Bass Strait between Victoria and Tasmania. The combination of cold water and warm water currents in this region limits dispersal of species and appears to have contributed to rapid and repeated speciation (Ayre *et al.*, 2009; Puritz *et al.*, 2012). With extremely high endemism of about 85% in shore fishes and over 60% in the benthic community, this region is also noteworthy as having the highest levels of endemism on the planet for macroalgae (Phillips, 2001).

Southwestern Australian

Extending around the southern coast of Australia from Shark Bay, Western Australia to Cape Jaffa, roughly halfway between Adelaide and Melbourne, this large and diverse province is home to extensive fringing reefs and offshore islands, with biodiversity that exceeds the Great Barrier Reef. Estimates of endemism range as high as 85% for shore fishes, 95% for mollusks, and 90% for echinoderms. The southern extent of

this province is likewise limited by the cooler waters around Victoria.

Agulhas

The Agulhas province wraps around the tip of southern Africa from the Cape of Good Hope northward to roughly Cape Vidal, South Africa. The mixing of the warm Agulhas and the cold Benguela currents dominates the oceanographic regime. The input of upwelling nutrients increases the productivity of this region and, combined with the influence of the two opposing current systems, creates a unique environment with a suite of endemic fishes, soft corals, and other invertebrates estimated at about 33% (Griffiths *et al.*, 2010).

Tropical Indo-West Pacific Region

Western Indian Ocean

From roughly the border of South Africa, ranging north to Arabian Sea and Persian Gulf, and including Madagascar, and the offshore island groups of the Seychelles and Comoros, this region contains about 14% endemic fishes. Although the Indian Ocean has around 25% endemic fishes, the separation of the Western Indian Ocean and Red Sea Provinces leaves too little endemism for the remainder of the Indian Ocean to be distinguished from the Western Pacific. For this reason, most of the Indian Ocean is affiliated with the central-West Pacific in the Indo-Polynesian Province (below).

Amsterdam–St. Paul

Île Amsterdam and the neighboring Île Saint-Paul are small, volcanic islands in the central southern Indian Ocean, roughly equidistant from Australia, South Africa, and Antarctica. This highly isolated habitat serves as an important breeding and nursery grounds for Subantarctic Fur Seals, Southern Elephant Seals, and Rockhopper Penguins.

Red Sea

The Red Sea is connected to the Gulf of Aden (northwestern Indian Ocean) through the narrow ($\sim$18 km) and shallow (137 m) Strait of Bab al Mandab. It is the world's northernmost tropical sea, lying between two strips of arid (desert and semi-desert) land, and is consistently the most saline (range 35–41 ppt) and warmest (range 21–34 °C) of tropical seas. Estimates of endemism for the Red Sea (including adjacent Gulf of Aden) are about 14% for fishes, 10% for crustaceans, and 7% for mollusks (DiBattista *et al.*, 2015a). Characterization of regional biodiversity is complicated by a lack of surveys along the African coast from Eritrea through Somalia, a situation that is unlikely to change in the foreseeable future. The unique communities of the Red Sea appear to be a result of the combined effects of turbulent geologic history, unusual environmental conditions, and physical isolation (DiBattista *et al.*, 2015b).

Indo-Polynesian

The largest biogeographic province in the world extends across half the planet, from the Arabian Gulf to the Tuamotu Archipelago in the central South Pacific. Latitudinally, the province begins at the northern tip of the Ryukyu Archipelago (Japan), extends south to Sandy Cape on the east coast and Shark Bay on the west coast of Australia. Genetic surveys of dispersive reef organisms are consistent with the boundaries of this enormous province, likely because dispersal between Australia and the Tuamotus requires no deep water passage further than $\sim$800 km (Schultz *et al.*, 2008). This continuity of shallow habitat is considered the primary factor shaping the cohesiveness of the Indo-Polynesian Province (Briggs and Bowen, 2012). However hierarchical clustering of reef fishes, based on presence/absence data, indicates additional subdivisions within this broad biogeographic region (Kulbicki *et al.*, 2013).

Hawaiian

Despite the cohesion of the Indo-Polynesian province across nearly half the globe, there are three isolated provinces along the eastern edge with high rates of endemism; Hawaii, Marquesas, and Easter Island. The volcanic Hawaiian Islands rise steeply from the deep seafloor of the central North Pacific to provide hundreds of square kilometers of shallow-water reef habitat in the middle of a vast expanse of deep ocean. The Hawaiian biota is primarily derived from Indo-Pacific ancestors (Kay and Palumbi, 1987), and recent work demonstrates that this province both imports and exports species through a process called biodiversity feedback (Bowen *et al.*, 2013). Endemism is uniformly high: about 15% of seaweeds, 18% of stony corals, 24% of annelids, 20% of echinoderms, 26% of mollusks, 38% of crustaceans, and 25% of reef fishes are endemic to the Hawaiian Archipelago (Kay and Palumbi, 1987; Randall, 2007). The reef fauna of Hawaii illustrates the impact of larval dispersal on community composition (Selkoe and Toonen, 2011). Many reef fishes with shorter pelagic larval durations (PLDs) of 10–40 days are absent or poorly represented here. There are no native shallow-water snappers (genus *Lutjanus*), only one native grouper (family Serranidae), and no clownfishes (genus *Amphiprion*). In contrast, the moray eels (family Muraenidae) with PLDs $>$80 days, and surgeonfishes (family Acanthuridae) with PLDs $>$50 days, are well-represented in Hawaii (Randall, 2007). Adjacent Johnston Atoll (865 km southwest) is included in this province due to strong taxonomic affinities, and it is believed to be both an outpost of Hawaiian fauna and a biogeographic gateway into the archipelago (Gosline, 1955; Timmers *et al.*, 2011; Skillings *et al.*, 2014).

Marquesas

Located in French Polynesia (South Pacific), these volcanic islands lie 1370 km northeast of Tahiti and 4500 km west of South America. This area is characterized by strong upwelling of nutrient-rich water that results in cooler temperatures, higher productivity, and less coral cover than typical South Pacific islands. The Southern Equatorial Current flowing westerly past the Marquesas may diminish colonization or gene flow from the Indo-Polynesian province, a finding reinforced by phylogeographic studies (Gaither *et al.*, 2010; Szabo *et al.*, 2014; Fernandez-Silva *et al.*, 2015). This unusual environment results in a relatively high endemism for reef fishes (11.6%).

Easter Island

Located 3700 km from the coast of Chile and 1900 km from Pitcairn Island, this is another isolated volcanic island on the outskirts of the vast Indo-Polynesian Province. Easter Island lacks protective barrier reefs, but hosts diverse coral reefs and 22% endemic reef fishes (Randall and Cea, 2010). Interestingly, Isla Salas y Gómez, 500 km east of Easter Island (~3200 km west of the Chilean mainland) has a more typical Indo-Pacific fish community and is considered an isolated outpost of the broad Indo-Polynesian Province rather than grouping with adjacent Easter Island (Parin, 1994).

Eastern Pacific Region

California

Located between Los Angeles, California and Magdalena Bay, Mexico, this province was recently revised due to the recognition of a broad transition zone in faunal composition from Point Conception south to Los Angeles (Burton, 1998; Dawson, 2001). Endemism was estimated previously at about 33% for fishes and 21% for mollusks, but these may be overestimates given that the boundary is moved and the province now covers less area.

Cortez

The Gulf of California, also known as the Sea of Cortez, is the body of water that separates the Baja California Peninsula from the Mexican mainland. The Gulf has existed for about 5 MY and has a rich diversity of island, coastal, and estuarine habitats. Although endemism is just over 10% for fishes, some have argued this province may be among the most diverse on the planet for micro-invertebrates and parasites (Campos *et al.*, 2009) which are not currently considered in these endemism counts.

Panamanian

This province extends along the coastal margin from the mouth of the Gulf of California south to the Gulf of Guayaquil, on the border between Ecuador and Peru. Endemism is about 49% for fishes (Robertson and Cramer, 2009) and 38% for decapods (Boschi, 2000). Offshore islands (with the exception of the Galápagos below) generally show affinity to the broader Panamanian province among the shore fishes, including the Revillagigedo Islands with 8.0% endemism, Clipperton with 5.8%, Malpelo with 2.5%, and Cocos with 4.6% (Robertson and Cramer, 2009). Thus, these offshore islands are all considered outposts of the Panamanian Province.

Galápagos

The only offshore archipelago in the East Pacific with sufficient endemism to be recognized as a distinct biogeographic province, the Galápagos Islands have 13.6% endemism for shore fishes (McCosker and Rosenblatt, 2010) and 16% for decapods (Boschi, 2000). This province is famed for the endemic species that inspired Darwin's (1872) theory of evolution by natural selection. Although the Galápagos straddle the equator, the Humboldt Current brings cold waters and frequent rains to the islands, except during El Niño events every 3–7 years.

Peru–Chilean

Including most of the western coast of South America, this warm-temperate province extends from the Gulf of Guayaquil to near the Taitao Peninsula (Chile) with roughly 13% endemism. Spanning over 35° latitude, there are few generalizations to be made about the climate and habitat throughout this range, other than the influence of the cold Humboldt Current along this coastline. This consistent current coupled with nearly continuous habitat along the coast results in a homogenous fish fauna along the western coast of South America. The Humboldt Current System is the most productive fishing area on the planet, with roughly 20% of the global catch coming from this region. During El Niño events, warm water moves east across the Pacific and suppresses upwelling, which leads to fish stock crashes and cascading ecological and economic impacts.

Juan Fernández

This province consists of three volcanic islands 650 km west of Valparaiso, Chile. Despite being over 2500 km from the nearest Pacific Island (Isla Salas y Gómez), both shore fishes and decapods show a stronger affiliation to the southwest Pacific than to the closer coast of Chile (Pequeño and Sáez, 2000), and endemism is estimated at about 25%.

Cool Regions (Cold-Temperate and Polar Waters): Cold-Temperate and Polar Northern Hemisphere

Eastern North Pacific Region

Aleutian

The 1900 km Aleutian Islands form the boundary between the Bering Sea and the North Pacific. This province stretches from the Pribilof Islands north of Aleutians (representing the southern limit of winter pack ice) to the northern tip of Vancouver Island (Horn *et al.*, 2006). Summer daylight can reach up to 20 h, leading to extensive algal blooms, while winter daylight can be restricted to 5 h with extremely limited productivity. Although fish endemism is sufficient for recognition of the province, endemism of the invertebrate fauna is particularly high, with 24% reported for decapods (Valentine, 1967) and 23% for mollusks (Boschi, 2000).

Oregon

This province extends from Vancouver Island south to a transition zone with the California Province. Recent surveys of the Californian fishes and invertebrates demonstrate that geographic endpoints of their ranges are variable and many more species cross Pt. Conception than end at this long-recognized biogeographic boundary (Burton, 1998; Dawson, 2001). If the Province were to terminate at Monterey Bay, endemism would be only about 2% in the decapods and shore fishes. In contrast, if the cold water California Transition Zone biota is included, the endemism level reaches the 10% cutoff for recognition as a distinct province. These data justify the formal recognition of the California Transition Zone, within the Oregon Province, from Monterey Bay south to Los Angeles, where the warm-temperate Californian Province begins.

Western North Pacific Region

Oriental

This province is discontinuous and includes three segments: the nearshore waters of the Yellow Sea, the southwestern portion of the mainland coast of the Sea of Japan, and shallow waters around northern Honshu Island, Japan. The first two segments are broken by the tip of the Korean Peninsula, which falls within the Sino-Japanese Province (defined above). This region is characterized by turbid, cool, highly productive waters, and patterns of endemism in this area are probably the result of a complex geological history with periodic isolation during glacial stages and subsequent recolonization as outlined below.

Kuril

A faunal break at the Tsugaru Strait, between the islands of Honshu and Hokkaido, marks the beginning of the Kuril Province, both along the outer coast of Japan, and within the northern Sea of Japan. This narrow province excludes the Okhotsk Sea (see below) but extends along the volcanic Kuril Island chain, and the eastern coast of the Kamchatka Peninsula ending at the northern end of Olyutorsky Bay in the Bering Sea. The two southern-most islands are of disputed ownership between Japan and Russia, in part because the region is among the most productive in the North Pacific. With expansive kelp forests, and their associated fish and invertebrate communities, exploitation by both marine mammals and humans is extensive.

Okhotsk

Confined to the Sea of Okhotsk, this province stands apart from the adjacent waters despite the lack of apparent barriers today. Although now continuous with the North Pacific through the Kuril Islands, and with the Sea of Japan around Sakhalin Island, phylogeographic studies conclude that the Sea of Okhotsk was isolated during periods of low sea level (Liu *et al.*, 2007). There are no recent taxonomic evaluations of this province, but high endemism in ascidians, pycnogonids (sea spiders), and fishes has been reported (Briggs, 1974).

Western Atlantic Region

There are conflicting opinions about the biogeographic provinces in this region. The region extends from the Strait of Belle Isle (or Labrador Straits) in Eastern Canada south to Cape Hatteras, North Carolina, with disagreement primarily focused on the biota found between Cape Hatteras, and Cape Cod, Massachusetts, often called the 'Middle Atlantic Seaboard.' Large numbers of tropical and warm-temperate species colonize during the summer months, resulting in many authors aligning this region with the Carolina Province to the south. These recruits typically disappear during winter, and the predominance of boreal species, combined with very low endemism led Briggs (1974) to argue that the Middle Atlantic Seaboard clearly belongs to the Boreal region. We follow that designation here, but recognize this remains a topic of debate. Using these boundaries gives estimates of 19% endemism among shore fishes, and 21% for opisthobranch gastropods.

Eastern Atlantic Region

This region runs from the Norwegian archipelago of Svalbard (formerly Spitsbergen) and Novaya Zemlya ringing the Barents Sea to the southern entrance of the English Channel. Iceland, the volcanic Faroe Islands and the Baltic Sea fall within this province. As the world's largest estuarine area, the Baltic Sea has been recognized previously as a distinct province (Golikov *et al.*, 1990), but this designation is not justified on the basis of endemism. Likewise, the unusual biotic mixture of Iceland has been a subject of debate, but with the exception of a few recognized subspecies, the island lacks endemics, and so falls within the Eastern Atlantic Boreal region. Based on these boundaries, the region contains about 20%–25% endemism for fish and invertebrate taxa. The richest biota occurs here on the eastern side of the North Atlantic, with more than 50% of transatlantic species originating from the North Pacific within the past 3.5 MY (Vermeij, 2005).

Arctic Region

The present glacial regime of the Arctic region dates to about 2.9–2.4 MYA (Mudelsee and Raymo, 2005). This relatively recent origin results in about 25% endemism overall, but very few endemics at higher taxonomic levels, particularly in comparison to the much older Antarctic. A notable exception is the narwhal, *Monodon monoceros*, which has a relictual Arctic distribution (Jefferson *et al.*, 1993). Phylogeographic analyses of Arctic charr (*Salvelinus alpinus*) indicate a recent recolonization following the last glacial retreat ($\sim$20 000 years ago, Brunner *et al.*, 2001). Although the cold Arctic region has traditionally been divided into a number of separate provinces, recent works find an essentially homogeneous biota lacking the regional endemism or phylogeographic structure to support such divisions. The polar cod (*Boreogadus saida*) is a regional indicator species based on the studies of Cohen *et al.* (1990) because it extends to all parts of this region but not into any of the cold-temperate regions.

Cool Regions (Cold-Temperate and Polar Waters): Cold-Temperate and Polar Southern Hemisphere

South American Region

This region was previously united in a single Magellan Province spread from Chiloé Island (Isla Grande de Chiloé) in southern Chile on the Pacific side to Río de la Plata at the Argentina/Uruguay border on the Atlantic side (Briggs, 1974). This designation was based on the shore fish fauna of the region, which show no indication of provincial endemism (Sielfeld and Vargas, 1999). Recent surveys, however, find very high endemism rates for invertebrates in southern Chile, Tierra del Fuego, southern Argentina, and the Falkland Islands that justify the designation of four distinct provinces within the South American region (Griffiths *et al.*, 2009).

Southern Chile

This province now begins at Península de Taitao in the Aysén region of Chile. Although previous surveys report no evidence

of provincial endemism, 109 marine shore fish species occur only within the waters of Chile according to FishBase (2004), and four additional marine endemic species have been described since then for a current total of ~113 fish species (Living National Treasures, 2015). Likewise, the molluskan fauna of the Chilean coast show a sharp increase in diversity above 42° S latitude (around Ancud), and most of these species do not penetrate the Atlantic side of South America, resulting in sufficient endemism to recognize a distinct Southern Chile Province.

Tierra del Fuego

At the southern tip of the South America, this rocky outcrop results from the formation of the Andes combined with the repeated Pleistocene glaciation. Known for some of the finest trout fishing in the world, with sea-run brown trout often exceeding 9 kg, this productive cold province is isolated from the Antarctic fauna, and distinct from the cold-temperate provinces to either side.

Southern Argentina

Beginning at the Valdez Peninsula, Argentina, this region is characterized by cool, moderately productive waters but does not extend up as far as the original Magellan Province. Unlike the shore fish fauna of Chile, the waters of Argentina are home to only four endemic species (Living National Treasures, 2015; Sielfeld and Vargas, 1999). In contrast, there is very little overlap between the Pacific and Atlantic polychaete and anemone faunas (Haussermann and Forsterra, 2005). Boschi and Gavio (2005) found ~35% endemism among decapod crustaceans on the Pacific side and ~18% on the Atlantic.

Falkland Islands (Islas Malvinas)

Located about 300 miles off the southern Patagonian coast, this archipelago lies essentially on the boundary of the subantarctic oceanic and tundra climate zones. With strong ties to the Patagonian biota, the islands are home to numerous endemic freshwater fish of the genus *Galaxias*. There are only two marine endemic fishes, but the endemism rate of invertebrates is sufficient to merit provincial status (Griffiths *et al.*, 2009).

New Zealand–Australian Region

Tasmania

An island state of the Commonwealth of Australia, Tasmania is located 240 km south of the Australian continent. Located in the infamous 'Roaring Forties' westerly winds that encircle the southern hemisphere, the island is surrounded by the Indian and Pacific Oceans and separated from mainland Australia by the Bass Strait. Geographically and genetically isolated by the combination of distance, strong currents and mixed climates, the island is well-known for unique terrestrial and marine biota. The boundaries of this province are still the subject of some debate, however. Briggs (1995) argues that it extends to the Victoria coast of Australia, but Griffiths *et al.* (2009) report endemism rates for only the island of Tasmania. Regardless, even if percent endemism were reduced by half, this province would still be distinct and recognized for its unique biota.

New Zealand

Located 1500 km east of Australia and 1000 km south of New Caledonia, Fiji and Tonga, islands in this group have been isolated for some 80 MY, leading to the highly distinct and endemic biota. The cool and productive waters are home to nearly half of the world's cetaceans, and large numbers of fur seals, sea birds, and penguins. Like Tasmania, New Zealand has very high rates of endemism for all marine invertebrate classes, possibly as high as 85% (MacDiarmid and Patuawa, 2010). There remains some question about whether the warm-temperate zone along the north coast between Auckland and East Cape contains sufficient endemism for recognition of a separate province (Briggs and Bowen, 2012). Judging simply by number of endemic species, New Zealand is the hotspot of the Southern Ocean, closely followed by Tasmania (although this order may well change with the proposed revision of boundaries).

Antipodes

A series of volcanic islands in the subantarctic waters south of New Zealand, this province consists of the Auckland, Antipodes, Campbell, and Bounty Islands. Characterized by steep rocky cliffs and sharp drop-offs, the fish fauna of these islands is not well known, but the molluskan fauna appears to be of sufficient endemism for designation as a province (Griffiths *et al.*, 2009). Dell (1962) reported molluskan endemism rates of 16% for the Aucklands, 23% for the Bounties, and 23% for the Snares, and asked if all these island groups should be separate provinces, a question which has yet to be answered.

Subantarctic Region

The biota of this region are highly distinctive owing to four historical factors: (1) persistence of a small ancestral group of Mesozoic and early Cenozoic taxa, (2) geographical isolation produced by the opening of Drake Passage, (3) extinction of many early Tertiary warm-temperate species, and (4) invasions of the region by cold-temperate species from the North Pacific. The result is six distinct provinces (Briggs and Bowen, 2012).

South Georgia

South Georgia and the South Sandwich Isles rise steeply from the sea bed roughly 1400 km to the southeast of the Falkland Islands. At the far southern latitude of 55° S, the area receives only about 1000 h of sunlight per year, which limits photosynthetic productivity, but not biodiversity. Hogg *et al.* (2011) conclude that South Georgia Island hosts greater biodiversity than the Galápagos Islands. Although seawater temperatures typically range from 0 to 4 °C throughout the year, the islands are far enough from the pole that the waters typically remain ice-free, with the exception of icebergs. The marine invertebrate classes surveyed to date have high endemism, and up to 34% of the shore fishes may be endemic (Briggs, 1974).

Bouvet

Bouvet Island (Bouvetøya) is a subantarctic volcanic territory administered by Norway. Lying 2200 km southwest of South Africa and 1700 km north of Queen Maud Land, Antarctica, this uninhabited island is more than 90% glacier and has been

a nature reserve since 1971. Although not as well surveyed as the South Georgia Province, the Bouvet Province has a very distinct fauna with over 50% endemism in gastropods (Griffiths *et al.*, 2009).

Crozet

The Crozet Islands (Archipel Crozet) are a French Overseas Territory consisting of a subantarctic volcanic archipelago in the southern Indian Ocean that formed about 50 MYA. With high precipitation (2000–3000 mm per year) and winds in excess of 100 km h^{-1} for ~100 days each year, these islands are uninhabited except for the research station Alfred Faure on Île de la Possession. A nature reserve since 1938, this archipelago was previously considered part of the Kerguelen Province, but now merits assignment to a separate province based on high endemism among marine invertebrates (Griffiths *et al.*, 2009).

Prince Edward

The Prince Edward Islands (Prince Edward and Marion) are located 1750 km southeast of the South African mainland. Declared a Special Nature Reserve by South Africa in 2003, they are uninhabited except for a South African research station on Marion Island. This province is recognized on the basis of high endemism among marine invertebrates surveyed to date, but detailed biotic surveys are lacking.

Kerguelen

The Kerguelen Islands (Archipel des Kerguelen), also known as the Desolation Islands, are part of the French Southern and Antarctic Lands with some 300 small islands spread across a few hundred kilometers. This volcanic archipelago emerged from the ocean ~35 MYA, although no eruption has been recorded since discovery of the islands in 1772. Home to a permanent research station, endemism of this biota is among the best known of the region, with roughly 60%–70% endemism among shore fishes, mollusks, and ascidians (Primo and Vázquez, 2007). This province probably should include the nearby Heard Island and McDonald Islands, but detailed biodiversity surveys are lacking.

Macquarie

Technically part of Tasmania, and a Tasmanian State Reserve since 1978, Macquarie Island lies roughly halfway between New Zealand and Antarctica. The island is located where the Australian tectonic plate meets the Pacific plate, and is the only place in the Pacific Ocean where rocks from the Earth's mantle are actively exposed at sea level. With taxonomic affinities to New Zealand, provincial status is based on over 60% molluskan endemism (Dell, 1964).

Antarctic Region

By comparison to the Arctic biota, the fauna of the Antarctic region is quite old. Contemporary conditions began about 24 MYA with the formation of the major ice sheet. This province includes all of the waters and island groups surrounding the continent out to the 1 °C February isotherm. Levels of endemism among mollusks, decapods, ascidians, sponges, polychaetes, and shore fishes range from about 42% to 88%, but there seems no support for provincial endemism within the region (Griffiths *et al.*, 2009). This degree of endemism is not surprising given over 20 MY of isolation, but it is noteworthy that there is also an extremely high rate of generic endemism in the region (75% of continental shelf and upper slope fishes; Eastman, 2005). Phylogeographic studies are consistent with lack of provincial subdivision, with little to no structure in a half dozen species surveyed across this vast region to date.

Conclusions

Considerable diversity, endemism, and new biogeographic provinces have been revealed by the suite of studies conducted since Briggs (1995), and more remain to be discovered. These provinces can serve conservation and management goals by highlighting the areas of unique biodiversity across the globe. We argue that in setting conservation priorities for these coastal areas of the globe, it seems reasonable to first consider those locations that are contributing species and augmenting diversity (i.e., the centers of origin). From these centers, new lineages spread and bring diversity and biological innovation (Vermeij, 2005). Newly colonized areas can then spawn new species and further increase diversity in the centers of origin through a process termed *biodiversity feedback* (Bowen *et al.*, 2013). These biodiversity centers include the Coral Triangle in the Indo-Pacific, the Caribbean Province in the Western Atlantic, the North Pacific Region, and the Antarctic Region including the surrounding halo of small island provinces. Endemism in the cold Southern Ocean tends to be greater than similarly sized provinces in the Northern Hemisphere. Efforts to conserve biodiversity hotspots have largely focused on the tropics (Krug *et al.*, 2009), but it is not the tropics as a whole that merit prioritization. Many temperate and cold water hotspots offer equally rich biological treasures for conservation that have been undervalued to date (Hogg *et al.*, 2011).

Acknowledgments

We thank Steve Karl, the Karl lab, and current and past members of the ToBo Lab for discussion and inspiration. This is contribution number 1641 from HIMB.

Glossary

Assemblage A collection of species that exist in a given habitat.
Biogeographic pattern A distribution of biotic diversity that is nonrandom with respect to space and/or environmental factors.
Community See Assemblage.
Composition The identity and relative abundance of taxa in a sample, assemblage, or community.
Dispersal The distance and rate at which an organism can travel, either passively or actively.
Diversity The richness and abundance of taxa.
Microorganisms/microbes Organisms with sizes <0.5 mm and masses $<10^{-5}$ g including Archaea, Bacteria, viruses, fungi, and other small Eukaryotes.
Population All individuals of a single taxon within an area.
Richness The number of taxa in a sample, assemblage, or community.
Selection The process allowing the proliferation of organisms that are relatively better adapted to external environmental conditions.
Taxon A group into which related organisms are classified based on a relatedness cutoff.
Taxon resolution The level of genetic variation of the taxa considered.
Trait A quantitative or qualitative characteristic of an organism.

Introduction

What is Microbial Biogeography?

Microbial biogeography is the study of the distribution of microorganisms across space and time. Microbes are generally defined as those organisms with sizes <0.5 mm and masses $<10^{-5}$ g foremost consisting of all members of the domains Archaea and Bacteria, but also including some fungi and other small Eukaryotes, as well as viruses. Since microbes constitute the vast majority of biodiversity on Earth and are critical components of ecosystem processes such as decomposition, nutrient and mineral cycling, and parasitism, there is much interest in understanding how this diversity is organized in nature. Recent advances in molecular genetic methodologies have allowed the culture-independent identification of organisms that cannot be differentiated visually, thus enabling the large-scale characterization of microbial diversity directly from the environment. Microbial biogeography reveals: where microorganisms live, why they live there, and in what abundance. It also aims to provide insight into the underlying ecological and evolutionary mechanisms that generate, maintain, and hinder microbial biodiversity, thereby facilitating predictions of where certain microorganisms can survive and how they will respond to changing environmental conditions.

Microbes are increasingly recognized as exhibiting distribution patterns similar to those of macroorganisms (Section Evidence for Microbial Biogeography). For example, microbes generally follow well-established biogeographic patterns such as the distance–decay relationship (Section Distance–decay) and taxa–area relationship (Section Temporal Changes). This was initially unexpected given some of the general disparities between microorganisms and macroorganisms, such as their size (μm vs. m), time between generations (min vs. years), population size (millions vs. hundreds of individuals), and hypothesized dispersibility (global vs. local). These similar distribution patterns instead support the concept of some 'universal' processes influencing all biodiversity.

However, important differences between biogeographic patterns for microorganisms and macroorganisms do exist, and likely result from differences in the relative importance of underlying ecological and evolutionary processes (Section Ecological and Evolutionary Mechanisms). For example, dispersal (i.e., the movement of an organism across space and time) is a key process responsible for the distribution and diversity of both microbes and larger organisms. Microbes can presumably disperse across much greater distances and at much greater rates than macroorganisms due to their larger population sizes and ability to withstand adverse conditions as well as travel in a variety of ways (e.g., through the atmosphere, via water currents, and on or in other organisms). This may explain why some microbial species exist at complementary latitudes in both hemispheres (e.g., marine bacteria; Amend *et al.*, 2013) while larger animals like polar bears and penguins are often restricted to just one pole (although there are notable exceptions, such as humpback whales and certain seabirds such as terns, which can be found at both poles).

The ability to study biogeography for microbes in the same way as larger organisms is complicated by the fact that species concepts are unclear for most microorganisms and can differ substantially from those for animals and plants. The primary reason for this is that the majority of microorganisms reproduce asexually (e.g., all members of the domains Bacteria and Archaea), with genetic diversity originating via mutations and direct genetic exchange mechanisms among sometimes distantly related organisms (e.g., horizontal gene transfer). Boundaries between species-level taxa and mechanisms of speciation are therefore obscured and cannot be based on the

degree of interbreeding (nor on morphology or other phenotypic traits due to size limitations) in the same way as classic species concepts. Even for microbes that are capable of sexual reproduction (exclusively fungi and other small Eukaryotes), species definitions and taxonomy can be problematic (e.g., due to a lack of resolution in morphological identification techniques; Foissner, 2006). Moreover, with the exception of cyanobacteria in stromatolites and some fossilized eukaryotic microbes, the vast majority of Bacteria and Archaea have no fossil record. Therefore, the extent to which current distributions are influenced by evolutionary history, geological history, and/or speciation (i.e., the 'historical' processes that broadly account for some biogeographic variation in some animals and plants) is particularly contentious and impractical for microbes. Despite these challenges, microbial biogeography is an active area of research, encouraging simultaneous advancements in microbial species concepts and evolution (e.g., Fraser *et al.*, 2009).

The Baas-Becking Hypothesis: The Birth of Microbial Biogeography

An important foundation of microbial biogeography is the Baas-Becking hypothesis, which states that for microorganisms, "everything is everywhere, [but] the environment selects" (Baas-Becking, 1934). The assertion that 'everything is everywhere' implies that the dispersibility and abundance of microorganisms allows them to maneuver on a global scale despite adverse geologic and environmental features. The claim that 'the environment selects' implies that current environmental conditions are solely responsible for distinct microbial populations or communities at local scales. In other words, as long as the environment is ecologically appropriate for a microorganism's growth, geological barriers and past events are irrelevant (O'Malley, 2007).

The Baas-Becking hypothesis elicits two predictions: (1) similar environments in different locations should harbor similar microbial communities and (2) all microbial taxa should be found everywhere, albeit at varying abundances. It has not been possible to test these predictions until relatively recently due to the lack of suitable methodologies for collecting and identifying the vast diversity of microbial taxa present in environmental samples. As a result, the empirical evidence and conceptual theory for microbial biogeography significantly lags behind that of macroorganisms.

Molecular Genetics: Enabling Microbial Biogeography

Recent advances in molecular genetic methods have enabled global studies of microbial diversity necessary for testing the Baas-Becking hypothesis. Before these molecular genetic methods existed, microbial species were onerously identified using cultivation techniques and morphological classifications, which miss the vast majority of microbial taxa. Now cost-effective, high-throughput DNA sequencing allows genetic analysis of environmental samples directly without the need for cultivation. These methods have been an important development for microbial biogeography because they allow a much greater subset of microbial diversity to be classified at a higher taxonomic resolution compared to traditional observational techniques. In fact, results from these new genetic methods have challenged the findings from earlier morphological studies. Initially, morphological studies supported the second assertion of the Baas-Becking hypothesis by finding virtually all microbial species detected in diverse and widespread habitats, suggesting that microbes were indeed globally distributed (e.g., Finlay, 2002). However, findings over the past decade using molecular genetic methods have challenged this result (e.g., Foissner, 2006), on the grounds that morphological classifications are not adequate representations of genetically differentiated taxa.

With these modern molecular techniques, taxonomic classification of microbes from environmental samples is now typically defined by nucleotide sequence similarity in one or more genomic regions. The most commonly used taxonomic marker genes are the evolutionarily conserved rRNA genes: 16S for Bacteria and Archaea; 18S for fungi and other Eukaryotes. Taxa, or Operational Taxonomic Units (OTUs) are conventionally defined at a $\geq$97% similarity cutoff in the rRNA gene, and are operationally analogous to species or genus. In this way, the most abundant taxa in a single sample are identified, and microbial biogeography studies often compare the composition of these identified microbial taxa among multiple samples. It is important to note several caveats to this approach. First, because the majority of microbial taxa are rare, it is nearly impossible to exhaustively sample all microbial diversity in every sample (Sogin *et al.*, 2006). Additionally, conventional OTU definitions are somewhat arbitrary and investigations of sequences at higher resolutions (either with a higher cutoff or with different genes) allow identification of a greater amount of microbial diversity (Section Taxonomic resolution). Although the sequence similarity approach is imperfect (Fraser *et al.*, 2009), it provides a convenient and standardized working definition necessary for investigating microbial diversity despite challenges associated with a lack of accepted species concepts for microbes (Section What is Microbial Biogeography?).

Evidence for Microbial Biogeography

Due in part to the Baas-Becking assumption that 'everything is everywhere,' debate remains regarding the extent to which microbes display biogeographic patterns. This section reviews the current evidence for microbial biogeographic patterns, with a focus on free-living microbes. While the biogeography of viruses and host-associated microbes is also an active line of research, their survival and therefore biogeography in many cases depends on the biology and ecology of nonmicrobial host organisms, which are beyond the scope of this article (e.g., of the biogeography of host-associated microbes, see Costello *et al.*, 2009; Hoberg and Daniel, 2008; Mikheyev *et al.*, 2010).

Endemism

Endemism occurs when a species is restricted to a unique geographic location; it is one of the simplest demonstrations

of a biogeographic pattern. However, identifying microbial endemics is complicated by the high diversity of natural assemblages and the fact that this diversity is composed of thousands of extremely rare taxa (Sogin *et al.*, 2006). Although continually improving sequencing methods may provide more complete samplings of microbial biodiversity, it is still nearly impossible to not only detect all taxa present in a given sample, but also prove the absence of any given species, explaining why demonstrations of microbial endemism are relatively rare. Instead, significant genetic divergence among taxa in different geographical locations, or restriction of particular microbial clades to specific regions of the world, is used as evidence for microbial endemism. For example, Whitaker *et al.* (2003) demonstrated genetic differentiation among hyperthermophilic Archaea from geothermal hot springs on different continents. It is important to note that endemism is evidence that microbial communities can be isolated from each other due to dispersal limitation (e.g., Talbot *et al.*, 2014), thus contradicting the Baas-Becking hypothesis.

Distance–Decay

Biotic communities tend to be more similar the closer they are in space, producing a negative relationship between similarity in community composition and geographic distance (Nekola and White, 1999). This 'distance–decay relationship' is commonly observed for macroorganisms and can be due to multiple factors including dispersal limitation and spatial correlation of selective environmental variables (e.g., ecoclines). Distance–decay has been consistently observed for microbes across a range of taxonomic and spatial scales (e.g., Cho and Tiedje, 2000; Whitaker *et al.*, 2003; Green *et al.*, 2004; Horner-Devine *et al.*, 2004; Martiny *et al.*, 2011), making it some of the strongest evidence that microbes exhibit spatially structured distributions akin to larger organisms.

Taxa–Area

The 'taxa–area relationship' is the observed increase in species richness with increasing size of the area sampled (**Figure 1**). This relationship has been observed repeatedly in larger animals and plants and is attributed to larger sampling areas simply containing more types of habitats and microenvironments than smaller ones (Rosenzweig, 1995). Demonstrating this relationship for microbes is challenging due to the difficulty in exhaustively sampling microbial diversity in a given sample, let alone across increasingly larger areas. However, microbial communities appear to also show taxa–area relationships, especially in terrestrial environments (Green *et al.*, 2004; Horner-Devine *et al.*, 2004).

Temporal Changes

Nonrandom changes in microbial community composition and diversity over time – for example, seasonally or even daily – are increasingly recognized as an important biogeographic pattern for microbes. For example, microbial community composition in the English Channel exhibits robust and predicable seasonal dynamics (Caporaso *et al.*, 2012). This is facilitated by dormancy, a feature not seen in larger animals but thought to be a common strategy in some microbes, which allows taxa that are not adapted to current environmental conditions to persist in low abundance in a nonactive state. The composition of the active microbial community therefore fluctuates over time in response to changing conditions. This is known as the 'seed-bank hypothesis' (Lennon and Jones, 2011) and has implications for our understanding of ecological resilience and thresholds to change.

Moreover, some studies have found a positive relationship between the number of species and time (analogous to the taxa–area relationship; Section Taxa–Area), such that the number of species observed increases with the time span of observation. This is likely due to immigration as well as the inclusion of more varied conditions and has been observed in a range of taxonomic groups and ecosystems across many years (White *et al.*, 2006). In certain environments, such as the Mid-Atlantic Bight, time rather than space or environment is the primary driver of microbial community composition (Nelson *et al.*, 2008).

Latitudinal Gradients

It is well established that larger animals exhibit latitudinal gradients in species richness such that the greatest biodiversity exists in the tropics and decreases toward the poles. Many

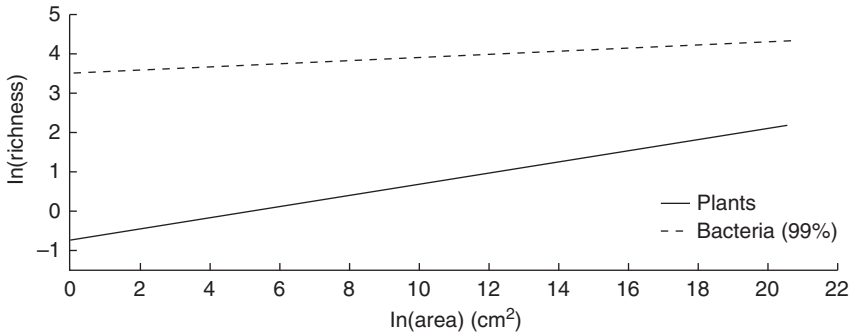

Figure 1 The taxa–area relationship for salt marsh organisms. Plants and bacteria both exhibited significant taxa–area relationships, but the *z*-value for plants ($z=0.103$) was significantly greater than that of bacteria ($z=0.040$). This may be due to factors such as lower taxonomic resolution, lower habitat specificity, and horizontal transfer of ecologically relevant genes for bacteria. Reproduced from Horner-Devine, M.C., Lage, M., Hughes, J.B., Bohannan, B.J.M., 2004. A taxa–area relationship for bacteria. Nature 432, 750–753.

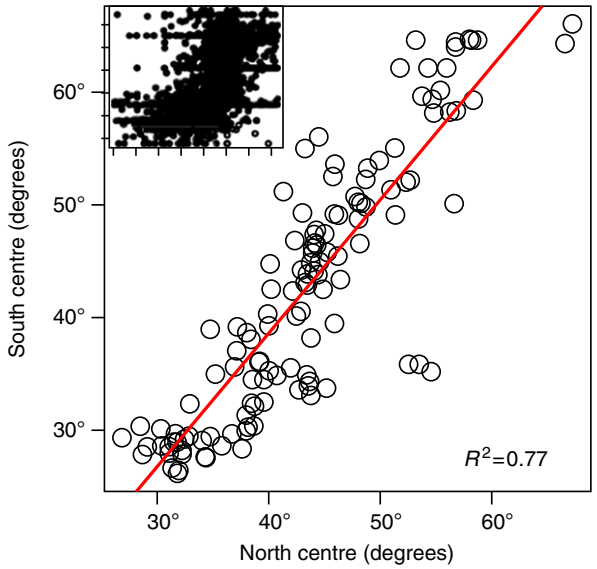

Figure 2 The northern OTU center location versus the southern OTU center location of marine bacteria, showing that marine bacterial distributions are complementary at opposite hemispheres. The correlation is strongest when considering only the wide-ranging OTUs (upper 99th percentile of the OTUs with the greatest latitudinal extent; $R^2=0.77$, $P<0.0001$). The inset figure shows all near-surface marine bacteria, illustrating how latitudinal complementarity diminishes as more narrowly distributed taxa are added ($R^2=0.33$, $P<0.0001$). Reproduced from Amend, A.S., Oliver, T.A., Amaral-Zettler, L.A., *et al.*, 2013. Macroecological patterns of marine bacteria on a global scale. Journal of Biogeography 40, 800–811.

hypotheses have been invoked to explain this general pattern (Rosenzweig, 1995; Hillebrand, 2004; Wiens *et al.*, 2010). However, it remains unresolved whether such a latitudinal pattern holds for microorganisms. Although gradients tend to weaken with decreasing animal size, implying that microbes should lack latitudinal richness gradients (Hillebrand, 2004), marine bacteria do show some evidence of a classic latitudinal gradient (Pommier *et al.*, 2007; Fuhrman *et al.*, 2008) and may also follow Rapoport's rule, as shown in **Figure 2** (Amend *et al.*, 2013). However, soil bacteria seem to have no relationship with latitude but instead a strong dependence on soil pH, which can vary greatly among soil samples (Fierer and Jackson, 2006). Thus, some environmental factors (e.g., soil acidity) may be strong enough to overwhelm latitudinal effects. Certain microbial populations have also been found at complementary latitudes in opposite hemispheres; for example, a study on marine surface bacteria showed not only a latitudinal gradient but also complementary distributions with similar populations at both poles (Amend *et al.*, 2013). These 'bipolar' (or 'anti-tropical') distributions are much more rare in macroorganisms as their dispersion on this large scale is limited by many factors, such as their larger body sizes (although there are exceptions, e.g., the humpback whale).

Elevation and Depth Gradients

Elevation gradients in composition are well established for macroorganisms, as dramatic changes in climate and therefore biota can occur with elevation over relatively short geographic distances. The gradients tend to exhibit either hump-shaped or monotonically decreasing relationships with elevation. In contrast, no consistent elevation patterns have emerged for microbes. For example, bacterial richness in the Rocky Mountains decreases from low to high elevations (Bryant *et al.*, 2008), while in the Andes there was no relation with elevation (Fierer *et al.*, 2011). Like elevation gradients, depth gradients in aquatic systems may arise from physical and chemical stratification. It is well recognized that microbial communities exhibit much more distinct variations with depth (see reviews by Martiny *et al.*, 2006; Lindström and Langenheder, 2011).

Ecological and Evolutionary Mechanisms

Microbial biogeographic studies to date have established that microbial communities exhibit nonrandom variability in space and time; moreover, these microbial distribution patterns are sometimes similar to those of larger organisms (Section Evidence for Microbial Biogeography). In this section, the possible underlying ecological and evolutionary processes producing these patterns are discussed. Existing evidence for their relative importance in driving microbial biogeography is also reviewed.

Framework

The Baas-Becking hypothesis (Section The Baas-Becking Hypothesis: The Birth of Microbial Biogeography) provided an important starting point for modern microbiologists to consider the driving forces of microbial distributions, namely 'dispersal' and 'selection.' However, a more comprehensive framework delineating all the possible mechanisms influencing microbial diversity in both time and space is currently being adopted (Martiny *et al.*, 2006; Hanson *et al.*, 2012). This framework takes into account biogeographic and evolutionary theory, dividing the processes influencing microbial biodiversity at all levels of taxonomic resolution into four main categories: selection, dispersal, drift, and mutation (**Figure 3**).

Selection includes all aspects of the contemporary environment such as abiotic variables (e.g., temperature, pH, nutrient availability) as well as the interactive effects of other organisms (e.g., competition, predation). Microbial taxa or genotypes that are best adapted to such external factors will survive and proliferate. This is the same concept as that implied by the 'environment selects' portion of the Baas-Becking statement. Dispersal refers to the distance and rate at which a microbe can travel, either passively or actively. Drift refers to stochastic changes in the composition of genes or communities that are facilitated by random demographic births and deaths. Finally, mutation covers the genetic basis of diversity and speciation in microbes, including horizontal gene transfer mechanisms. An earlier but related version of the framework (Martiny *et al.*, 2006) considers dispersal, drift, and mutation as part of the broader-level category of 'historical processes,' a term borrowed from traditional biogeography as typically applied to larger organisms.

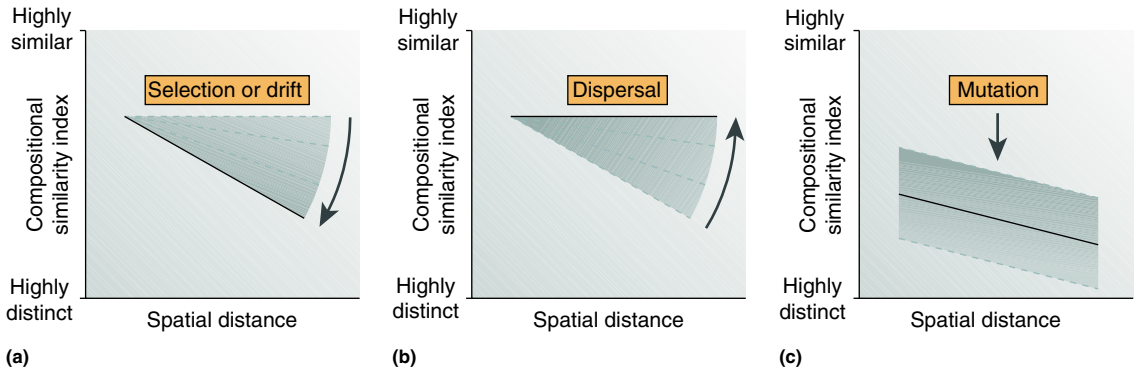

Figure 3 The effect of the four processes on the relationship between community similarity and spatial distance. (a) Selection and drift increase the strength of the distance–decay relationship (i.e., they steepen the slope). (b) Dispersal weakens the distance–decay relationship (i.e., it flattens the slope). (c) Mutation decreases the similarity between locations, regardless of the distance between them.

Relative Importance of Processes

Studies have confirmed that the process of selection (i.e., local environmental factors) greatly influences the composition of microbial communities in both space and time (reviewed in Hanson *et al.*, 2012). For example, numerous studies have linked spatial variation in microbial communities to variation in pH or salinity (e.g., Fierer and Jackson, 2006). Temporal variation in microbial communities also tends to be significantly correlated with seasonal variation in environmental variables such as temperature.

But what other mechanisms besides environmental selection can explain biogeographic patterns in microbial communities? The answer likely depends on determining the relative role of dispersal. Dispersal has the effect of mixing diversity across time and space, thus canceling out the influences of other processes (drift, mutation, and even selection) and weakening biogeographic variation. As for larger organisms, biogeographic variation may arise because not all taxa can disperse to or establish in all locations equally, an effect known as 'dispersal limitation.' The existence of dispersal limitation, even for some microbes, would partially falsify Baas-Becking's hypothesis.

However, measuring or tracking dispersal directly is difficult for most organisms, let alone those that are invisible to the human eye. For this reason, dispersal limitation for microbes is often indirectly inferred from the observed correlation between microbial community composition and geographic distance, after removing the influence of measured environmental factors (i.e., removing the effect of selection). When studies use this approach, many do find a correlation between microbial composition and geographic distance (Cho and Tiedje, 2000; Whitaker *et al.*, 2003; Martiny *et al.*, 2011), suggesting that microbial communities are not equally mixed by dispersal and are therefore dispersal limited. At the same time, other studies find no evidence for dispersal limitation in microorganisms (e.g., Finlay, 2002, and reviewed in Hanson *et al.*, 2012) and thus the debate over whether 'everything is everywhere' persists.

Consequently, a current line of research is to determine when and where dispersal limitation occurs for microorganisms. If dispersal limitation does exist for microbes, a subsequent area of research will be on whether additional processes (e.g., historical factors such as drift, local extinction, or past environmental legacy) play a role in microbial distributions and in what capacity.

Limitations and Outlook

Limitations

Spatial scales and temporal variations

The strength and existence of microbial biogeographic patterns are greatly dependent on spatial scales (Hanson *et al.*, 2012). This is likely because the ability of a microbe to disperse from one location to another decreases as spatial distance between those locations increases (Nekola and White, 1999). Therefore, the relative importance of the underlying processes (Section Relative Importance of Processes) varies with spatial scale. Additionally, dispersal limitation on very small spatial scales can cause significant community dissimilarities within certain habitats (e.g., biofilms and sediments; Martiny *et al.*, 2011), but with no effect on larger scales (i.e., their 16S rRNA genes are still globally distributed). Thus, characterizing biogeographic patterns at different spatial scales may inform the influence of microbial dispersal and other mechanisms controlling microbial distributions.

Temporal variations must also be considered when studying microbial biogeography. Recent studies have shown that microbial communities are highly dynamic in time and that seasonality is an important driver of microbial distributions (Section Temporal Changes). Moreover, biogeographic processes can have an inherent time component (e.g., dispersal rate) and thus the influence of these processes can be time dependent (Bell, 2010). Studies intending to characterize variation in microbial communities over space should therefore measure, control for, or at the very least, be interpreted in light of possible temporal variations.

Taxonomic resolution

The amount of variation detected within microbial communities is highly dependent on the level of taxonomic resolution used to define taxa (Hanson *et al.*, 2012). This is

determined by the sensitivity of the identification method, however for modern sequencing techniques (Section Molecular Genetics: Enabling Microbial Biogeography), taxonomic resolution can be arbitrarily defined by changing the sequence similarity cutoff value, for example. Low-resolution taxonomic definitions can combine taxa with different traits and evolutionary histories, blurring any variation in distribution as a result of those differences. Because broad-level taxonomic groups (e.g., genus or family level) tend to have wider distributions than narrower ones (e.g., species or subspecies/strain level), using broad taxonomic definitions may dilute biogeographic patterns and their underlying processes, for both microbes and macroorganisms (Martiny *et al.*, 2006; Hanson *et al.*, 2012).

Inferring process from pattern

Much evidence now exists demonstrating that microbes display a range of biogeographic patterns not unlike larger organisms (Section Evidence for Microbial Biogeography). However, using observational patterns to reveal the underlying ecological and evolutionary processes driving them (Section Ecological and Evolutionary Mechanisms) is problematic and prone to misinterpretation. This difficulty arises foremost because multiple mechanisms can combine to create the same pattern, and secondarily because instantaneous observations are insufficient for capturing this combination of processes occurring along a continuum of space and time. Mechanistic experiments to manipulate community assembly and dispersal under controlled conditions are needed to directly test the influence of each of the four hypothesized processes (Section Framework; Hanson *et al.*, 2012).

Applications and Significance

The motivation for studying microbial biogeography extends beyond deciphering the distribution of microbial biodiversity across the globe. Because microbes exist in every known habitat on Earth and are key players in ecosystem dynamics, including nutrient cycling and parasitism, studies of their diversity in space and time are finding an increasingly wide range of applications, some of which are described below.

Anticipating responses to environmental change

Under changing conditions microbes can adapt, move, die, or go dormant. How resilient are microbial communities to these scenarios? Microbial biogeography can help address this question by elucidating the factors controlling microbial distributions and abundances. For example, defining the range limits and dispersal abilities of different microbes can enable prediction of if and how microorganisms will adapt to changing environments. Likewise, identifying the factors correlated with microbial community composition and the 'microbial seed bank' (Section Temporal Changes) are first-steps toward understanding how whole microbial communities, and their activities, may shift under environmental change.

Improving human well-being and sustainability

Microbes are not only key components in the functioning of all ecosystems, but are also intimately involved in human health in a multitude of ways. Indeed, we think of microbes as pathogens and parasites, but a rapidly expanding field of research has discovered the importance of 'friendly' bacteria living in and on larger organisms, including humans. Applications of microbial biogeography to the study of the human 'microbiome' (e.g., Costello *et al.*, 2009) have been integral in understanding how these microbial communities protect against pathogens as well as how they are involved in many aspects of human health from obesity to autism to gastrointestinal disorders.

Microbial biogeography, as a framework for understanding microbial diversity generally, is also valuable for understanding the role of microbes in nearly every aspect of modern human society where microorganisms are involved. This includes agriculture, food production and spoilage, bioremediation, bioterrorism, wastewater treatment, and alternative energy production. For example, biogeography has been applied to the bioremediation of oil spills by oil-degrading microbes (Valentine *et al.*, 2012). It has even been applied to wine grape cultivation. Bokulich *et al.* (2014) discovered biogeographic patterns in grape-associated bacteria according to grape variety and regional climatic factors across viticulture zones, demonstrating how microbial biogeography of agricultural commodities may be used to enhance quality characteristics and economic value.

Underexplored extreme environments

Microorganisms are known for their capacity to exist and thrive in extreme conditions considered to be inhospitable to larger organisms. This includes high salinity, pressure, and temperature environments; low-energy systems; and toxic, acidic, or radioactive conditions. 'Extremophiles' grow directly in these conditions, while other microbes may simply evade these stressors by forming spores or entering states of low-metabolic dormancy (Lennon and Jones, 2011). Nonetheless, extreme microbial habitats are interesting targets for studying the limits and origins of life, and are also valuable models for understanding fundamental controls over microbial diversity and biogeography (e.g., Whitaker *et al.*, 2003).

Microbial biogeography may also be useful for providing insight into biodiversity in underexplored and difficult-to-access extreme environments, such as the deep biosphere and outer space. For example, panspermia (i.e., the distribution of life throughout outer space via comets, asteroids, and meteoroids) relies on microbes being able to travel and survive through the harsh space environment (e.g., vacuum conditions, extreme temperatures). Microbial biogeography on Earth can provide clues as to candidate microbes for panspermia and life on other planets. For instance, microbes can exhibit latitudinal dependencies such as the Rapoport effect (Section Latitudinal Gradients), which dictates that organisms living near the equator are found within smaller latitude ranges than those living near the poles. Thus more widespread, higher-latitude microorganisms can likely tolerate a wider range of climates, and therefore may also be capable of inhabiting otherwise lifeless Earth-like planets with uncertain environmental conditions.

Biogeography of Arthropods

RG Gillespie, University of California, Berkeley, CA, USA

Biogeography, the study of the distribution of organisms in space and time, frequently focuses on circumstances leading to these distributions, and consequently on ecological and/or historical factors that have played a role. The discipline integrates information across fields of evolutionary biology, ecology, geology, and geography: Selection within a given environment, in concert with isolation that might be achieved through geological or ecological events imposed on the organism, or the activities of the organism itself, have all acted at some level to mold ancient and recent distributions. The complexities of these interactions in leading to patterns of biotic distribution have been of interest to biologists since the time of Wallace and Darwin and before. However, it was only toward the end of the twentieth century that understanding of plate tectonics, and the development of cladistic approaches, transformed biogeography from being largely descriptive, to become a rigorous science. Over the last few decades and into the twenty-first century, biogeography has progressed significantly as a science alongside developments in the associated disciplines mentioned above. The goal of this article is to underscore the role and interplay of different factors in shaping biogeographic studies in arthropods. The author chose specific examples to highlight each of these factors; these are examples only and no attempt is made to be comprehensive – the literature is massive.

Age of Arthropods – Insights From Fossils

Arthropods are an ancient group, dating back far before the origin of many birds and mammals (Giribet and Edgecombe, 2013; **Figure 1**). While much of what we infer regarding biogeography is – necessarily – based on extant distributions, fossils have provided some intriguing insights about the biogeographic origins of certain lineages (Grimaldi and Engel, 2005); amber deposits, which date back to 230 million year old (a nematoceran fly and two mites), provide particularly detailed information on the morphology of arthropods, and sometimes even carry ecological information (Schmidt *et al.*, 2012). Cambrian marine communities were dominated by arthropods, including trilobites, with much diversity illustrated by the Cambrian Burgess Shale of British Columbia (Briggs, 2015). Using multiple molecular datasets with fossil calibrations, current data suggest a Cambro–Ordovician colonization of land of different arthropod lineages ($\sim$510–471 mya) that occurred at about the same time as land plants (Rota-Stabelli *et al.*, 2013). Further diversification is thought to have started in the Silurian–Devonian, and has been linked to the rise of the angiosperms, for example, in phytophagous beetles (McKenna and Farrell, 2006). Likewise in ants, which have existed on Earth for $\geq$100 million years, specimens became common in the fossil record in the Eocene (LaPolla *et al.*, 2013). Here again, the diversification has been linked to the rise of angiosperm-dominated forests and their correspondingly more complex leaf-litter layers (Moreau *et al.*, 2006; Wilson and Hölldobler, 2005). However, at least in beetles, it has recently been suggested that the rapid increases in diversity through certain periods might rather be due to little extinction (Smith and Marcot, 2015). In any case, arthropods are ancient, and their history has been shaped by geological and climatological processes from ancient times to the present.

Geological Movements in Arthropod Biogeography

In terms of biogeography, some of the most interesting ancient patterns are associated with the break-up of Gondwana, which imposed isolation on previously connected biotas. The separation began at the beginning of the Jurassic (about 184 Mya), with the eastern part (Antarctica, Madagascar, India, and Australia) separating from Africa and the western part (South America) moving away from Africa as the South Atlantic Ocean opened, beginning about 130 Mya. Subsequently, the section that included what is now India–Madagascar–Seychelles broke off, and Australia (and later New Zealand) began to separate from Antarctica about 80 Mya. The Indian plate collided with Asia about 45 Mya, and South America separated from Antarctica about 30 Mya.

North America and Europe were connected until the Atlantic Ocean opened about 70 mya. Close phylogenetic relations between various insect groups in eastern North America and Europe are evidence of the past unity. Thus, a number of representatives of Collembola, Hemiptera, Homoptera, Coleoptera, Diptera, and Hymenoptera show this pattern (Noonan, 1988). Among spiders, the mygalomorph spider genera *Antrodiaetus* and *Atypoides* (Antrodiaetidae) show a disjunct Holarctic distribution in which trans-Beringian and trans-Atlantic routes appear to account for the present-day distribution in Japan and North America (Hendrixson and Bond, 2007).

In the same way, the stepwise break-up of Gondwana has led to disjunctions between organisms from Andean South America, Australia, New Zealand, and Madagascar. For example, relationships among the Plecoptera suborders – Antarctoperlaria and Arctoperlaria – has been linked to the break-up of Pangaea into Laurasia and Gondwanaland; then when Gondwana broke up, the ranges of the suborder Antarctoperlaria and its families became disjunct, with distinct representatives on each of the distant landmasses (Zwick, 2009). Relationships among basal lineages of scarab beetles can be explained by the break-up of Gondwana (Kim and Farrell, 2015; **Figure 2**). Gondwanaland Moths (Lepidoptera: Palaephatidae) are limited to Chile, Argentina and Australia. Diversification of insects across the Gondwana landscape has frequently been associated with plant associations. Thus, among bugs, members of the family Peloridiidae (Hemiptera) show a classic Gondwana distribution: Australia, New Zealand, and southern South America. They are associated

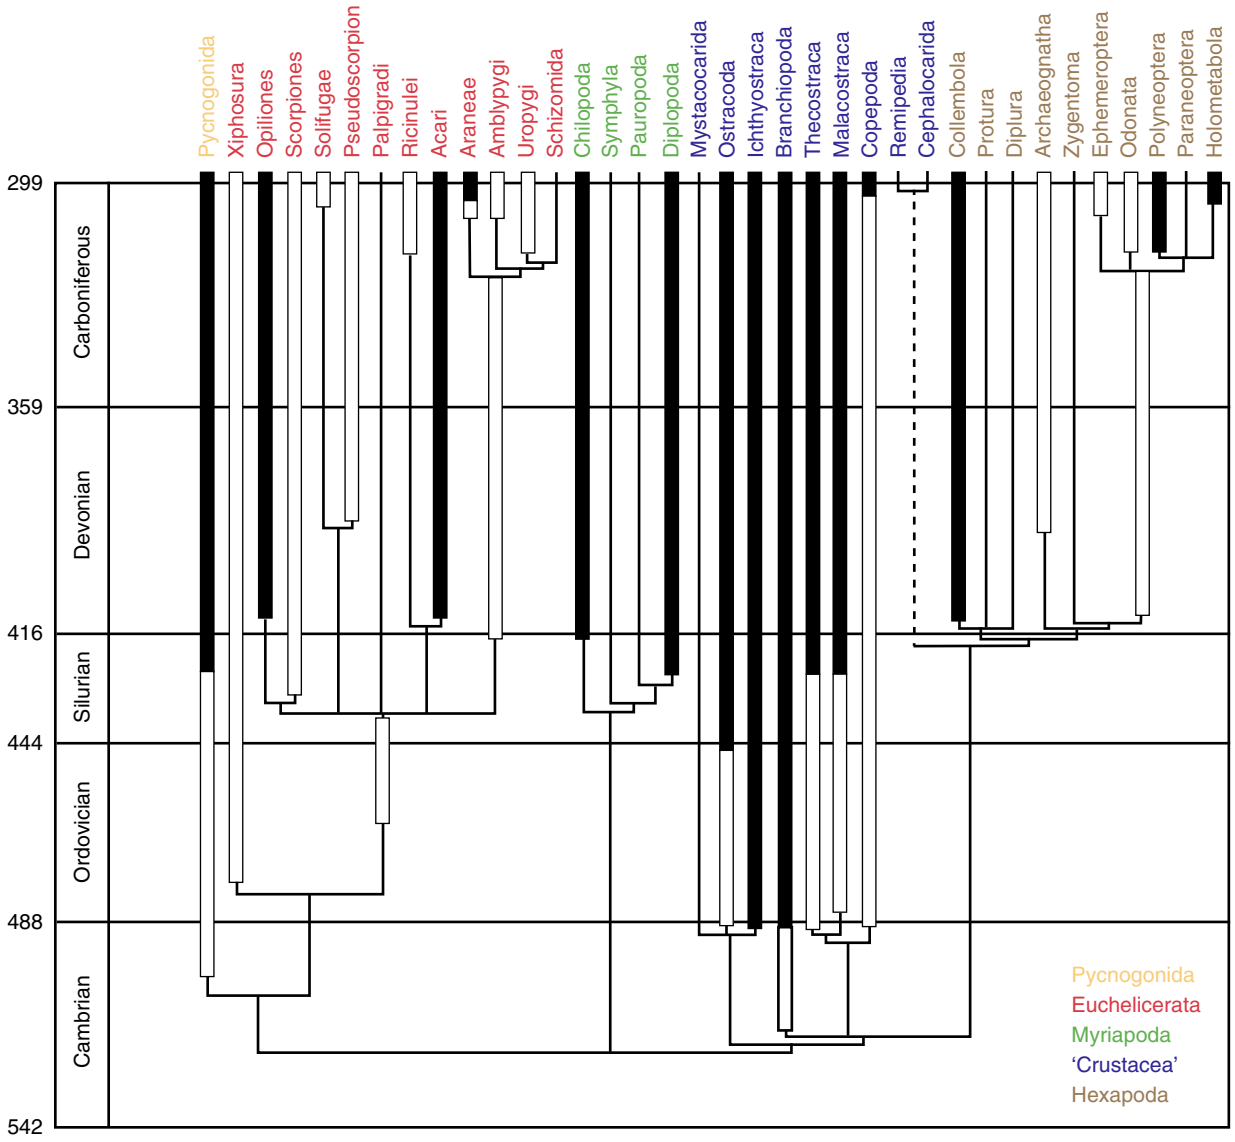

Figure 1 Relationships between living arthropod lineages with paleontological calibration (Giribet and Edgecombe, 2013). Molecular dating and paleontological inference have been used to place the origin of the Hexapoda in the Cambian. Solid bars indicate unambiguous fossils assigned to the crown group; open bars indicate the presence of fossils assigned to the stem group.

with moss in *Nothofagus* (southern beech) forests and probably feed on the moss (Burckhardt, 2009). *Araucaria* beetle herbivores also share Gondwanan distributions with their host: Divergence between the Australian and the South American *Araucaria*-feeding taxa occurred around the Cretaceous/Paleocene (Sequeira and Farrell, 2001). A number of spider lineages have also been shown to reflect the geologic history of continental movement, in particular several mygalomorphs (Ayoub *et al.*, 2007) and an ancient lineage of pelican spiders (Wood *et al.*, 2013). Gondwanan affinities are also found in non-spider arachnids. For example, opilionids show a relationship between Sri Lanka–Australia–New Zealand (Giribet *et al.*, 2012).

There are also examples from other parts of the world where insects and spiders are clearly associated with the geological history of the region, for example, in southeast Asia, where the complex history of the region has played a major role in fostering diversification (Lohman *et al.*, 2011).

On a somewhat more recent timescale, North America has proven particularly intriguing for examining biogeographic hypotheses. The Baja California peninsula has a complex geological history having undergone latitudinal and longitudinal displacements along the northwest to southeast peninsula starting approximately 15 million years ago with more recent events associated with the formation of islands and seaways (Dolby *et al.*, 2015). Deep divergence has been found between the spider *Homalonychus selenopoides* on the east side of the Colorado River and its congener *Homalonychus theologus* on the west side of the river including the Baja California Peninsula (Crews and Hedin, 2006). In the same way, the

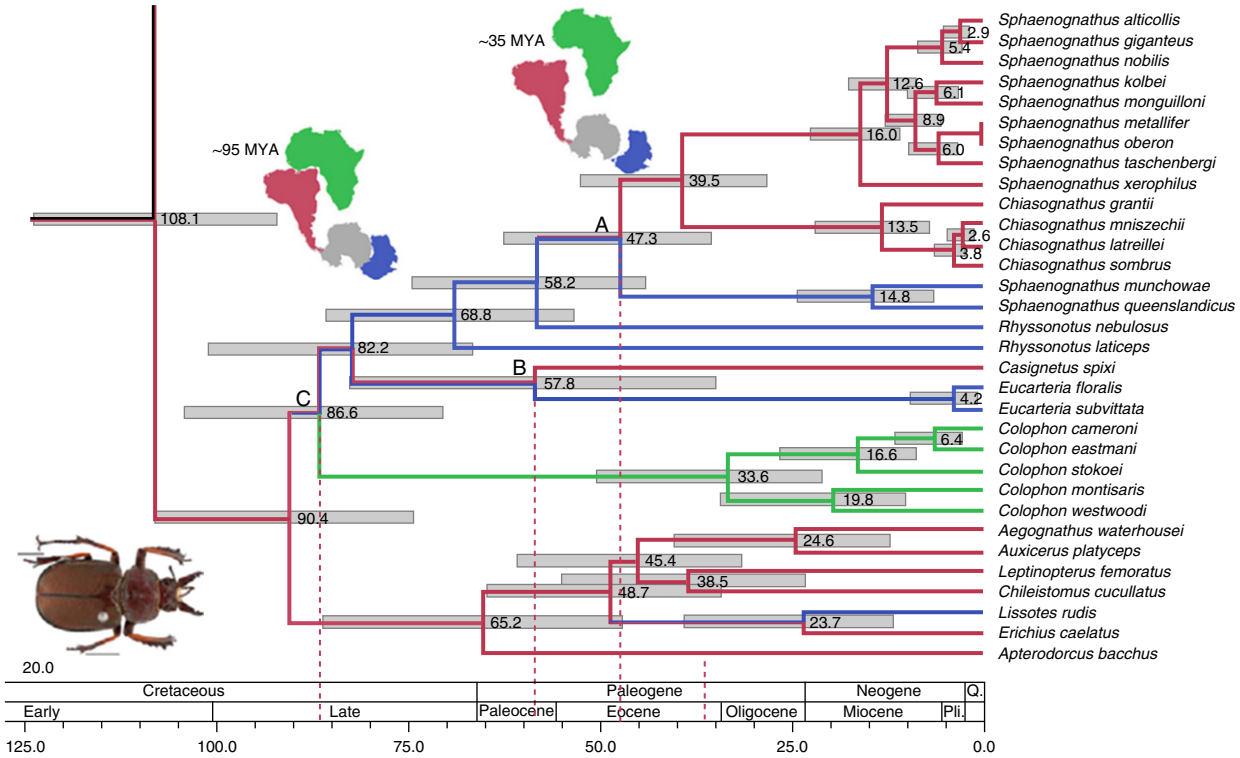

Figure 2 Stag beetles (Lucanidae) are one of the earliest branching scarab lineages. The split between many of the lineages are largely concordant with the pattern of continental break-up of the super-continent Gondwana. Colored branches indicate Neotropical (red), Australasian (blue), and Afrotropical (green). Reproduced from Kim, S.I., Farrell, B.D., 2015. Phylogeny of world stag beetles (Coleoptera: Lucanidae) reveals a Gondwanan origin of Darwin's stag beetle. Molecular Phylogenetics and Evolution 86, 35–48.

islands of the Western Mediterranean are continental fragments of the eastern Iberian Peninsula dating to about 30 Mya; among many different arthropod groups, including beetles (Condamine *et al.*, 2013) and spiders (Bidegaray-Batista and Arnedo, 2011) molecular data suggests that diversification has been driven by the separation of the landmasses.

Climate can operate as an isolating mechanism in a similar manner to that of geology. Thus, for example, the aridification of Australia has led to relict populations in remnant patches of rainforest in the north east (Bell *et al.*, 2007) and around other isolated patches of the continent (Rix and Harvey, 2012; Figure 3).

Dispersal and Colonization

Besides the role of geology and climate in providing barriers, and imposing isolation through vicariance, dispersal between landmasses has also played a major role in shaping biogeographic patterns among arthropods. Thus, dispersal characteristics of colonists are clearly important, not only in predicting which species colonize an area, but also in the process of diversification. Aerial dispersal occurs primarily through flight in insects, and ballooning on silk threads in spiders. The ability for aerial dispersal, and the loss of that ability, plays a key role in biogeographic patterns in arthropods. Coupled with this, the tendency of some insects, in particular Lepidoptera and Orthoptera, to migrate can facilitate the potential for movement and colonization (Danthanarayana, 2012). Certain insects, such as migratory locusts and some dragonflies, can reach very high densities, which can lead to mass emigration events. However, regular migrations are found in certain Lepidoptera, for example, the painted lady and the red admiral undergo seasonal migration as do monarch butterflies.

Among araneomorph spiders and some caterpillars, dispersal is by ballooning, in which a strand of silk, usually let out by an immature, is caught in the wind and the animal is carried off (Bell *et al.*, 2005); as a result of this behavior, certain spiders have been found to be among the first and most persistent colonists on mangrove islands in the Florida Bay (Simberloff and Wilson, 1969).

However, in terms of biogeographic pattern, much work has focused on loss of dispersal. For arthropods with nondirectional dispersal strategies and that colonize isolated habitats, selection will tend to act against individuals that disperse because their nondirectional dispersal – such as ballooning spiders and Lepidoptera larvae – will result in their loss from the gene pool (Gillespie *et al.*, 2012). Dispersal ability may also be lost if not required and its maintenance demands energy.

Dispersal through vectors, such as on the fur or feathers of larger animals, may play a role in allowing insects to colonize remote areas, and rafts of vegetation or ice, have clearly also been important in transporting arthropods to such sites.

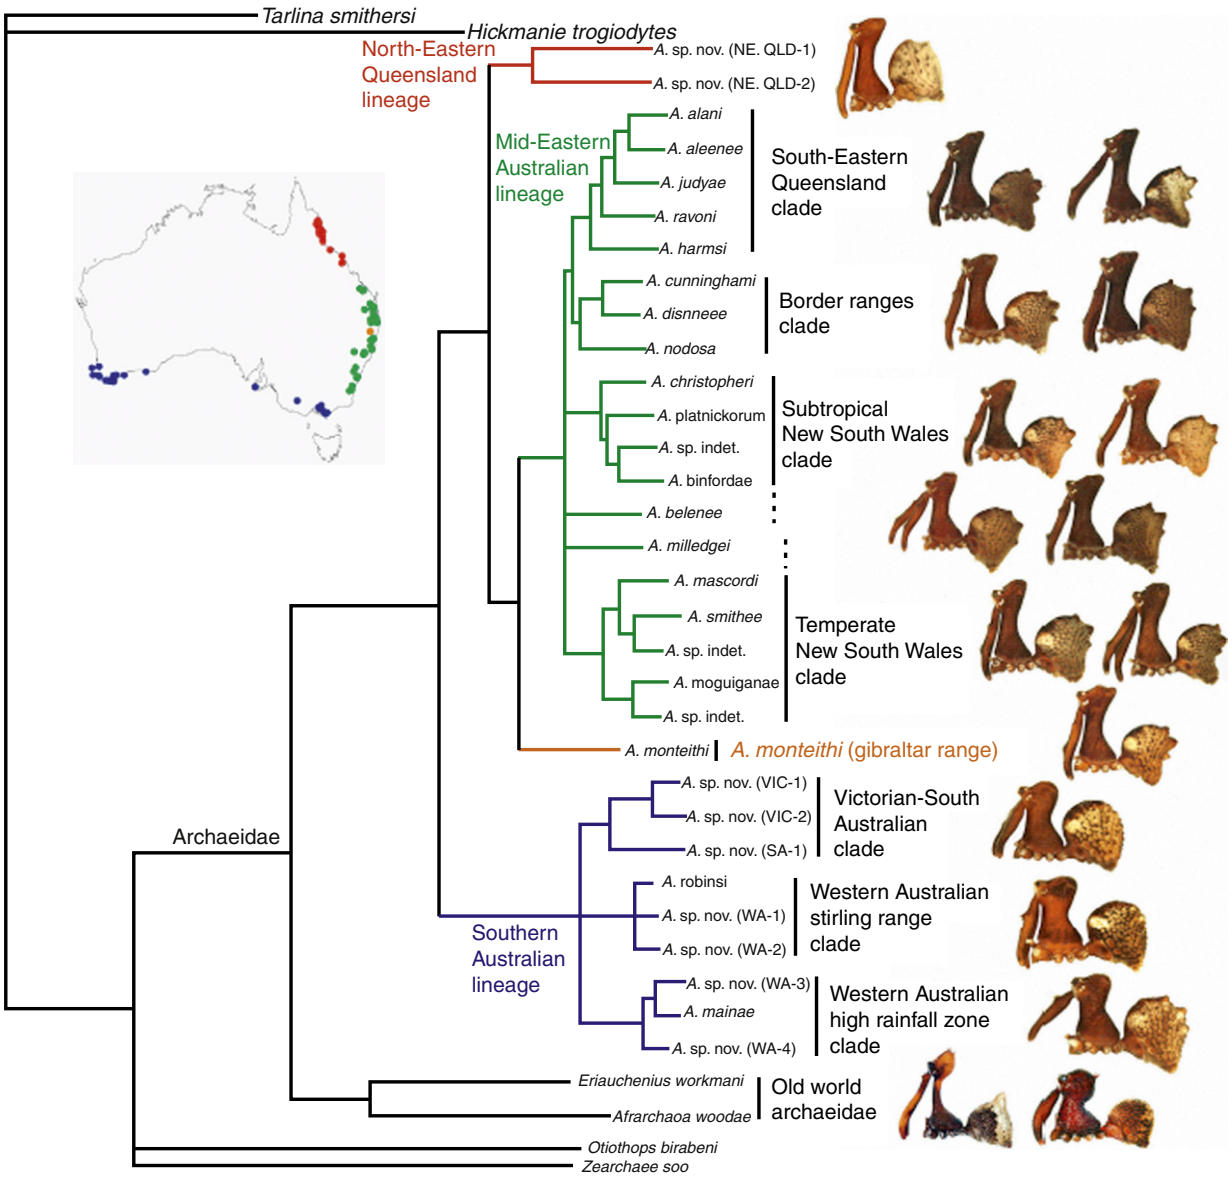

Figure 3 Phylogeny and historical biogeography of assassin spiders (Araneae: Archaeidae) in the Australian mesic zone suggesting Miocene speciation within Tertiary refugia. Major Australian lineages and regional clades are shown according to their distribution as are lateral profile images of representative taxa (Rix and Harvey, 2012).

Biogeography of Interactions

Interactions play a key role in shaping biogeographical patterns, though it is often difficult to infer ecological interactions from fossil data. However, there are exceptions. Evidence of herbivory in arthropods is first shown in the Early Devonian within early detritivore-based terrestrial ecosystems (Labandeira and Currano, 2013). This early herbivory is characterized by two pulses: one during the Early Devonian and a second, more extensive one commencing at the Mississippian–Pennsylvanian boundary. Pollination dates from the late Paleozoic, although the mid-Mesozoic strategy of pollination was replaced in the mid-Cretaceous with current patterns, initially generalist, with subsequent specialization in the Late Cretaceous and Paleogene.

Considering modern lineages, pollinators have long been considered to play a role as selective agents in shaping floral traits, though determining the way in which they might have influenced angiosperm diversification has been more difficult. While studies that combine phylogenies with pollinator data have highlighted the frequency of pollinator-driven diversification, the specific role that pollinators play in potentially driving diversification is still not clear (van der Niet and Johnson, 2012). The fig–fig wasp system is well known for the tight association between the plants and their pollinating wasps (Agaonidae, Chalcidoidea) with which they appear to have approximately codiversified. Moreover, multiple additional groups of non-pollinating chalcids have colonized figs independently with most of the non-pollinators being gall inducers or inquilines; diversification of the wasps has tracked

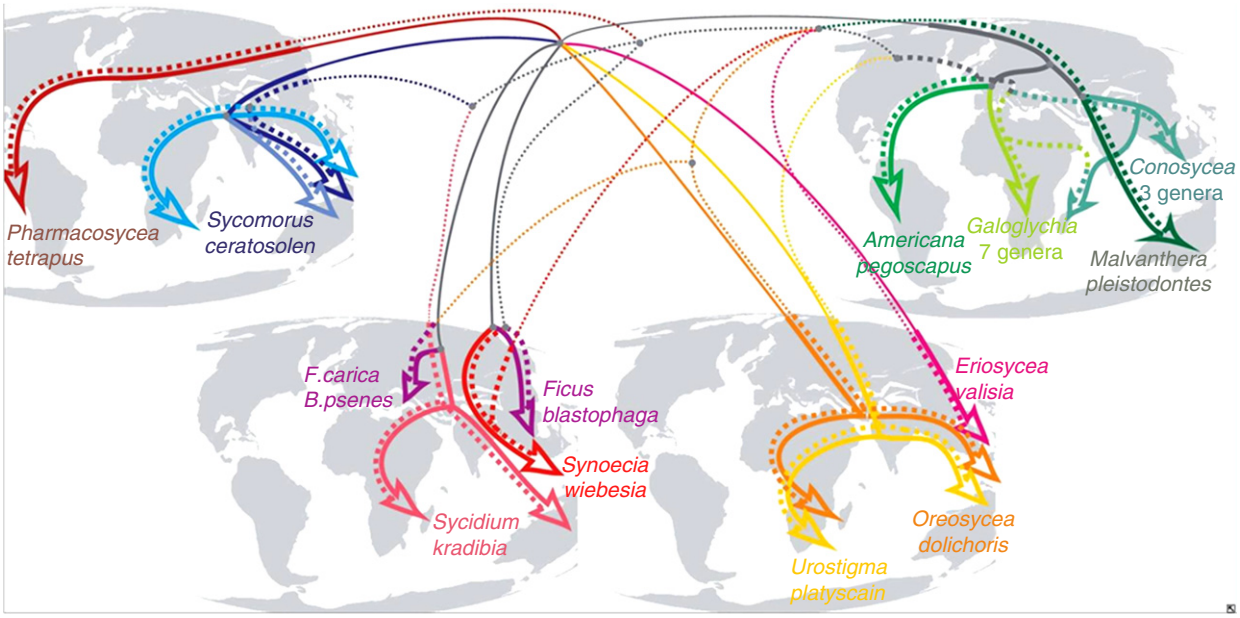

Figure 4 Hypothetical biogeographical scenario of mutualism diversification (presented on 4 different maps for clarity). Solid arrows: figs; dashed arrows: wasps (Cruaud *et al.*, 2012). It appears that the major lineages of both figs and pollinators split during the Tertiary and then spread southward through the evergreen woodland and tropical forest belts of Eurasia.

that of the host plants and associated pollinators, with similar ages and synchronous colonization events between fig trees, pollinator wasps and non-pollinating wasps (Sycophaginae) (Cruaud *et al.*, 2011, 2012; **Figure 4**).

The role of host associations for taxa that have colonized remote islands has been particularly enigmatic. Thus, when a member of a tightly coevolved pair first arrives on a remote island, it is likely that its immediate partner is absent; yet coevolved complexes of pathogens and their vectors, and plants and their pollinators, still exist on these islands, so how is this achieved? Recent work on patterns of codiversification and host association in an obligate pollination mutualism – that between the plant family Phyllanthaceae and the moth genus *Epicephala* on different Pacific archipelagoes, and comparing patterns here with those on the western Pacific Rim (the evolutionary source of both plant and insect) – has shown that not only have the insects and plants reached some of the most remote islands of Oceania, but the mutualism is maintained (Hembry *et al.*, 2013). This raises intriguing questions of how colonization occurs on remote islands and what constrains it, and the extent to which the interaction itself can drive population differentiation.

Island Biogeography

Islands have traditionally been considered to be any relatively small body of land completely surrounded by water. However, their primary biological characteristic, isolation from a source of colonists, is common to many situations on continents where a piece of land is surrounded by dramatically different habitat. As a result, ideas developed for true islands are frequently applicable to similar continental system. One of the best-known effects of insularization is its influence on species diversity, which has been modeled as a balance between immigration and extinction, equilibrium between these depending on the size of the island and the distance from the source of colonists (MacArthur and Wilson, 1967). Empirical support for the model came from a classic study using arthropods on islands of the Florida Keys (Simberloff and Wilson, 1970). Spiders provide one of the classic natural experiments in support of the model: After a 1996 hurricane in the Bahamas, every lizard and web spider originally found on the exposed islands was gone. However, recolonization was rapid and in 1 year, the number of species was the same as before the hurricane struck and equilibrium was recovered quickly, just as it was for Simberloff and Wilson's mangrove arthropods. Interestingly, the same pattern was found again after Hurricane Floyd in l999 in which spiders were eliminated from a more northerly group of islands (Schoener and Spiller, 2006).

Dispersal versus Vicariance: Islands can be divided into two major types – continental and oceanic. Continental islands generally form by breaking off as a fragment from the source. In these, the ecological space will initially be filled as a consequence of connection to the source of colonists prior to insularization (Gillespie and Roderick, 2002). Species numbers will decrease following fragmentation through the process of relaxation. If these islands become more isolated, species will eventually arise through relictualization with the formation of 'paleo-endemics' through vicariance, such as the various Gondwana lineages described above. In contrast, oceanic islands, by definition, have never been in contact with the source of colonists and have abundant 'empty' ecological niche space. On these islands, species numbers will initially increase through immigration, the rate depending on the degree of isolation. If isolation persists, over time species arrive through dispersal and species formation will result in

'neo-endemics.' When isolation is extreme, the ecological space will gradually be filled through speciation (rather than immigration) and adaptive radiation of neo-endemics.

While the geological distinction between these island types is quite clear-cut, changes in island area, topography, and isolation have provided opportunities for subsequent dispersal to continental islands. New Zealand is prime example of a landmass that has been shaped by both ancient events, as revealed through the biogeography of Onychophora (Murienne *et al.*, 2014) and Cyphophthalmi (Boyer and Giribet, 2009; Giribet *et al.*, 2012) and more recent dispersal (Goldberg *et al.*, 2008). Likewise, while the ancient landmass of Madagascar has spider fauna that originates from Gondwana (Wood *et al.*, 2012), there are many colonizers that presumably arrived more recently via Cenozoic dispersal, and mostly from Africa (Yoder and Nowak, 2006).

Adaptive Radiation

Adaptive radiation has now been described for many different arthropod groups, invariably associated with an acceleration in diversification rate and some of the most rapid rates of diversification have been found among adaptive radiations of insects in the Hawaiian Islands (0.8–4.2 Myr^{-1}) (Mendelson and Shaw, 2005). However, recent work on ant-nest beetles (*Paussus*), which are intimately tied to a given ant host from which they exploit food and protection, show tremendous diversity, and some of the highest rates of diversification yet reported (Moore and Robertson, 2014).

In some situations, adaptive radiation is associated with novel hosts, with notable examples of key innovations coming in the form of plant defenses, which in turn can provide the conditions necessary for a herbivore or parasite to develop a trait that is resistant to the defense of the host, and can therefore diversify on to the host. This 'escape and radiate' hypothesis (Ehrlich and Raven, 1964) has now been implicated, at least broadly, in major radiations of herbivorous insects and plants (Winkler and Mitter, 2008). Symbiotic associations may also serve as key innovations, providing a means through which partners can exploit habitats unavailable to either partner alone. For example, microbial mutualists can present ecological opportunity and allow adaptive radiation of their insect hosts (Janson *et al.*, 2008). Moreover, interactions can enhance diversity, as shown in gall midge insects which symbiotically rely on fungus to break down plant material, and are 17 times more diverse than similar lineages without the symbiotic relationship (Joy, 2013).

Diversification within an adaptive radiation can occur as a result of ecological shifts, such as changes in habitat or diet. Recent illustrations of this have been provided by habitat switching in Hawaiian spiders (Gillespie, 2004), host switching by Hawaiian leafhoppers (Bennett and O'Grady, 2012), and gall midges on goldenrods (Stireman *et al.*, 2012), as well as the ant-nest beetles (Moore and Robertson, 2014) mentioned above. Alternatively, ecological associations may be maintained with divergence occurring in allopatry, as has been found in Hawaiian *Drosophila* (Magnacca and Price, 2015). Both elements appear to be involved in a given adaptive radiation, though the prevalence of ecological versus geographical shifts in driving proliferation varies across radiations. For example, across a radiation of hyperdiverse moths in Hawaii (*Hyposmocoma*, Cosmopterigidae), most adaptive differentiation appears to have occurred early in the radiation, with recent proliferation a result of geographical isolation (Haines *et al.*, 2014).

Range Expansion and Invasion

Climatic shifts can have a major effect on the distribution, abundance, and diversity of arthropods. Range expansion of North American *Parnassius* butterflies in the late Pleistocene has been associated with warming climate (Schoville and Roderick, 2009). For insects associated with plants, the climate can lead to expansion or contraction of their resource, with insect diversity being dictated by the availability of plants (Nyman *et al.*, 2012). However, the most dramatic recent examples of range expansion are linked to invasion, often associated with increased movement of humans. Arthropods have become increasingly recognized as important invaders with enormous potential for impact. This topic has been covered in a recent book (Simberloff, 2013).

Target Areas for Biogeographic Study – Oceanic and Continental Islands

Hawaiian Islands and French Polynesia

The Hawaiian archipelago (4000 km from the nearest continent, North America; 3200 km from nearest island group) exhibits extreme disharmony (only 50% of insect orders and 15% of known families represented in the native fauna, (Howarth and Mull, 1992)), coupled with extraordinarily high levels of endemism among all terrestrial arthropods, and numerous cases of adaptive radiation. The accentuation of disharmony through speciation is well illustrated in the moth genus *Eudonia*, which is represented by only one species in central Polynesia and eastern Melanesia (the presumed source), but by 18 species in the Society Islands, 13 in the Marquesas, and over 100 species in Hawaii. The microlepidopteran family Cosmopterigidae has only 180 species in North America (north of Mexico) and 388 in Australia, but has 85 endemic species in the Marquesas and over 350 in Hawaii (Gillespie and Roderick, 2002).

The source of colonists and mechanisms of dispersal have been studied and discussed extensively for many of these lineages, and general patterns are emerging (Gillespie *et al.*, 2012). For the Hawaiian Islands, taxa known for aerial dispersal abilities (birds and spiders in particular) have generally colonized from the east, in agreement with the direction of extreme storms. For other Hawaiian lineages, affinities with the north support the idea that insects feeding within seeds can show a pattern of colonization matching their plant hosts. In addition, some terrestrial taxa have likely reached remote islands through rafting, which appear to be most common for those associated with dead wood, leaf miners, wood borers, and other insects that inhabit plant debris, or those that attach their eggs to vegetation. Stepping-stone colonization may be

the major pattern of colonization for rafters. Thus, *Rhyncogonus* weevils occur on oceanic islands throughout the Pacific, and appear to have colonized archipelagoes in a sequential stepping-stone fashion (Gillespie *et al.*, 2008).

The Hawaiian Islands are characterized by some of the most remarkable examples of diversification in arthropods. Early and ground-breaking studies focused on *Drosophila* (O'Grady and Markow, 2012), and highlighted the importance of sexual selection in fostering the rampant proliferation of species. However, recent work highlights some major new lineages of insects, and the interplay between habitat, host, and geography is shaping diversification, as has been illustrated by leafhoppers (Bennett and O'Grady, 2012), planthoppers (Goodman *et al.*, 2012), cosmet moths (Haines *et al.*, 2014), and bark lice (Bess *et al.*, 2014), as well as *Drosophila* (Magnacca and Price, 2015).

Although a break in gene flow is clearly important for adaptive differentiation, hybridization, and genetic admixture resulting from previously separated populations coming back in contact, have increasingly been implicated in the generation of adaptive variation and functional novelty (Gillespie and Roderick, 2014; **Figure 5**). Though more work is needed, it is clear that genetic mixing and hybridization among recently diverged populations play a key role in fostering adaptive radiation, as has been suggested for spider lineages (Roderick *et al.*, 2012).

Caribbean

The Caribbean region is one of the most biogeographically complex island systems and knowledge of the arthropod diversity is still rather poorly known. Among vertebrate lineages, the islands have served as the setting for adaptive radiation among those with limited dispersal ability (Losos, 2010). Although studies to date have provided insights into how individual lineages have colonized and subsequently diversified within the island system, there are as yet no unifying principles to explain the origin and diversification of Caribbean taxa. Notable controversies include the source of colonists and the means by which they colonized the islands, and biogeographic patterns within lineages. A particular focus of debate has been the role of vicariance versus dispersal in shaping the Caribbean biota and the importance of a hypothesized landbridge ('GAARlandia') between South America and the Greater Antilles during the Eocene Oligocene transition (Iturralde-Vinent and MacPhee, 1999). Arthropods, because they can provide a fine scale resolution of biogeographic

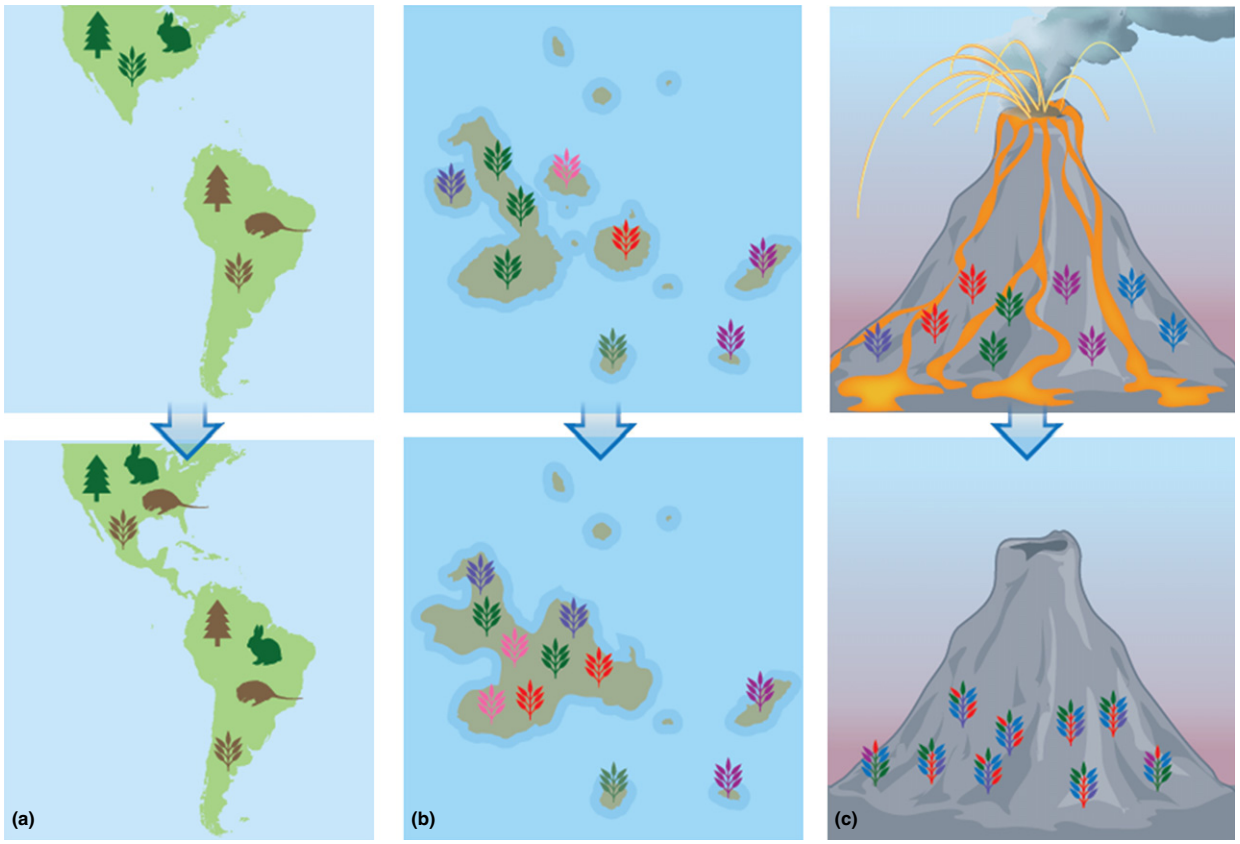

Figure 5 Isolation across scales of space and time. (a) On a multimillion-year timescale, distinct assemblages of biota form in isolation on different continents, and joining of the continents may lead to biotic exchange or species displacement. (b) On a millennial timescale, different species may evolve in isolation on different islands; connections between these islands can then result in a richer biological assemblage as newly formed species come together. (c) On a decadal timescale, populations may be isolated by recurrent events, such as volcanic eruptions; subsequent reconnection of these populations may result in new genetic combinations, a phenomenon that may also occur with invasive species. Reproduced with permission from Gillespie, R.G., Roderick, G.K., 2014. Evolution: Geology and climate drive diversification. Nature 509, 297–298.

patterns, are ideal candidates for elucidating the nature of these relationships. Thus, various arthropod lineages in the Caribbean provided a rich system for testing theories in cladistic biogeography (Liebherr, 1988). More recent studies have examined specific patterns of intra-island diversification and island–island vicariance, as has been demonstrated for *Amphiacusta* crickets (Oneal *et al.*, 2010) and *Drosophila* flies (Brisson *et al.*, 2006).

Colonization of the Caribbean has been examined for several groups, with spiders in the genera *Loxosceles* (Sicariidae) (Binford *et al.*, 2008) and *Selenops* (Selenopidae) (Crews and Gillespie, 2010), as well as butterflies (Matos-Maraví *et al.*, 2014), supporting the GAARlandia hypothesis in the colonization by the lineages of North from South America. In other groups, including *Centruroides* scorpions (Esposito, 2011) and swallowtail butterflies (Lewis *et al.*, 2015), biogeographic analysis could not reject the hypothesis of dispersal being the only route for colonization of the Caribbean.

Macaronesia

The arthropod diversity of the Azores has been studied intensively over recent years, though richness on the islands is rather low and many species are very rare (Terzopoulou *et al.*, 2015). In the Canary Islands, most of the arthropod work has focused on beetles, butterflies, *Drosophila*, cockroaches, bees, spiders, and mites (Juan *et al.*, 2000), with additional work on other lineages, including grasshoppers and mantids. This research has shown that most lineages have originated through dispersal from the nearby continent followed by *in situ* speciation, though the pattern of colonization is more complex than in Hawaii. Over evolutionary time *in situ* speciation comes to dominate over colonization as the source of new species. For example, the spider genus *Dysdera* includes three well-defined lineages; for the lineages that have proliferated, diversity has arisen largely *in situ* (Macias-Hernandez *et al.*, 2008). Molecular data indicates a slowing of the diversification over time, perhaps due to slower speciation or higher extinction rates.

Galapagos

The Galapagos, famed for the remarkable examples of evolution in action provided by Darwin's finches, has mostly been colonized from South American, though evidence from flightless *Galapaganus* weevils suggests a potential role for now sunken seamounts for their early evolution; patterns of diversification in the weevils are linked to volcanic activity together with habitat shifts (Sequeira *et al.*, 2008). A group of grasshoppers in the Galapagos shows affinities with the Old World, and may be a relict of a previously more widespread distribution or the result of long-distance, trans-Atlantic dispersal (Husemann *et al.*, 2015). A fascinating element that is emerging from studies of diversification of arthropods in the Galapagaos is the pattern of repeated evolution of similar ecotypes, as illustrated by wolf spiders (De Busschere *et al.*, 2012) and beetles (Hendrickx *et al.*, 2015) associated with extensive admixture, the latter contributing to diversification.

Target Areas for Biogeographic Study – Terrestrial Islands

Sky Islands

The environments of mountaintops are often quite different from the surrounding slopes, and can include cloud forests, alpine grasslands, herbfields, and paramo; these sites tend to be relictual fragments of previously more widespread habitats, isolated by changing climate (Watson, 2008). Perhaps the best-known sky islands, at least from a biological perspective, are the American Madrean 'sky islands' of southeastern Arizona and New Mexico. Here, striking phenotypic divergence has been found among populations of the jumping spider *Habronattus pugillis* (Masta, 2000), as well as scorpions (Hughes, 2011), and cerambycid (Smith and Farrell, 2005) and carabid (Ober and Connolly, 2015) beetles. Given that these habitats are only ca. 10 000 years old, diversification has been rapid.

Caves

Cave-adapted terrestrial arthropods are particularly common in beetles and spiders, though there are also some species of crickets, pseudoscorpions, amphipods, and isopods (Juan *et al.*, 2010). The two mechanisms proposed to explain speciation in caves are the 'climatic-relict' hypothesis, in which species become restricted to caves after extinction of the surface populations, and the 'adaptive-shift' hypotheses in which cave species are formed through adaptive parapatric divergence in the subterranean environment. In either case, the general pattern is of monophyly within cave populations, with large divergences between populations. However, in some situations, cave species may arise through a predisposition for hypogean living and a preference for dark habitats, as shown for Canary Island dysderid spiders (Arnedo *et al.*, 2008), cave-modified species of phalangodid harvestmen (Opiliones: Laniatores) (Hedin and Thomas, 2010), and Hawaiian *Schrankia* moths (Medeiros *et al.*, 2009), in all of which phylogenetic analysis reveals multiple switches between cave and epigean habitats.

Habitat Fragments

The process of fragmentation has resulted in insularization at many different scales across space and time. Fragmentation of Gondwana has been described above. On more recent time scales, many arthropods are restricted to sand dunes (Van Dam, 2013) or desert salt flats (Crews and Gillespie, 2014). These habitats were historically connected, and various different climatological events have been implicated in shaping the current relationships across the fragmented landscape.

On the young island of Hawaii, ongoing volcanic activity has created a dynamic mosaic of habitats of different age as large areas of forest are destroyed or fragmented when lava flows around them. Fragmentation on scales of hundreds of meters and over several hundred years can be sufficient for genetic differentiation of spider populations (Vandergast *et al.*, 2004), though – because of its transitory nature – this fragmentation is likely to be more important in maintaining

genetic diversity than in separation of populations (Roderick *et al.*, 2012). On larger spatial scales, distinct volcanoes represent geological gradients with independent histories of diversification and community assembly from recent to ancient ecosystems.

The Future of Research in Arthropod Biogeography

The field of biogeography is poised for a revolution as a result of huge amounts of genomic data that are becoming available through rapidly developing technologies that provide a wealth of information on functional genes, as well as an abundance of putative neutral markers. Applying these technologies to arthropods will provide a temporal framework of colonization or fragmentation of a lineage, associated demographic changes involved, relative population sizes, and other aspects that allow inference into the interplay between geologic and climatologic history, and the biology of arthropods.

Biogeography of Interactions

DH Hembry, University of California, Berkeley, CA, USA

Glossary

Antagonism Interactions in which members of one species benefit and members of the other lose fitness; examples include predation and parasitism.

Biotic interchange Event in which the biotas of two regions come in contact and organisms colonize one region from the other.

Coldspot (coevolution) Pair of interacting populations within a geographic mosaic of coevolution, between which coevolution is not occurring.

Commensalism Interaction in which members of one species benefit but the fitness of members of the other species is not affected.

Competition Interactions in which members of both species lose fitness as a result of their interaction. For example, two predator taxa which attack the same species may compete for their shared prey.

Free-living Interactions in which the physical contact between members of interacting species is relatively brief compared to symbiotic interactions.

Geographic mosaic theory of coevolution (GMTC) Theory describing how coevolution between two species varies among their different pairs of interacting populations.

Hotspot (coevolution) Pair of interacting populations within a geographic mosaic of coevolution, between which coevolution is occurring.

Modular Networks broken into weakly connected subnetworks, or modules.

Mutualism Interaction in which the interacting members of both species benefit; may include interactions such as pollination and seed dispersal.

Nested Networks consisting of both a core of generalist species and asymmetric specialist species who interact with these generalists.

Symbiotic Interactions in which members of one species spend much or all of their life cycle in close physical proximity or intimacy to the tissues of a host.

Interactions between different taxa can be studied in a biogeographic context in the same manner as individual taxa can. Ecologists and evolutionary biologists classify species interactions according to the fitness benefit and loss to individuals of the species involved in them. 'Mutualisms' are interactions in which the interacting members of both species benefit; these may include interactions such as pollination and seed dispersal. 'Antagonisms' are interactions in which members of one species benefit and members of the other lose fitness; common examples of antagonisms are predation and parasitism. 'Commensalisms' are interactions in which members of one species benefit but the fitness of members of the other species is not affected. Finally, 'competition' encompasses interactions in which members of both species lose fitness as a result of their interaction. For example, two predator taxa which attack the same species may compete for their shared prey. Mutualisms and antagonisms usually occur between trophic levels; competition occurs between members of the same trophic level, while commensalisms may occur within or between trophic levels.

Interactions are also classified by the degree to which they are 'symbiotic or free-living.' Symbiotic interactions are ones in which members of one species spend much or all of their life cycle in close physical proximity or intimacy to the tissues of a host. Free-living interactions are ones in which the physical contact between members of interacting species are much more brief. Some interactions combine aspects of symbiosis and free-living ecology. For instance, many herbivorous insects are highly symbiotic as larvae which live inside the tissues of their hosts, but their adults are more free-living and live outside the host.

Historical Biogeography of Interactions

Phylogenetic and paleontological studies indicate that some interactions seen in extant biotas can be conserved over macroevolutionary timescales, whereas other interactions no longer occur or are more recent in origin.

Reconstruction of Historical Biogeography of Intimate Associations

The two ways in which the historical biogeography of interactions can be ascertained are via fossils and via phylogeny-based methods. Fossils can indicate changes in interactions that have occurred. For instance, extant hummingbirds are restricted to the Americas, where they are important flower visitors – so much so that many distantly related lineages of plants have evolved to be pollinated by hummingbirds, and shifts to hummingbird pollination are implicated in plant speciation (e.g., Kay *et al.*, 2005). However, fossil hummingbirds are known from the Oligocene of central Europe (Mayr, 2004; Bochenski and Bochenski, 2008), indicating that some Old World plants were likely pollinated by hummingbirds, and may have coevolved with hummingbirds, in the Tertiary, even though no such plants exist today, and these particular interactions can be considered extinct.

For intimate interactions where specialization is very high at the species level, extreme phylogenetic conservatism can allow phylogenies and divergence time estimation to be used to understand historical biogeography. In many cases, the utility of these methods is to narrow down the range of

possible hypotheses for the evolution of the interactions between two lineages.

Phylogenetic studies of bark beetles feeding on *Araucaria* conifers in South America and Australasia (Coleoptera: Curculionidae: Scolytinae) suggest that beetles alive today are relicts of ancient beetle–*Araucaria*, associations. Long basal branches leading to these beetles in the phylogeny (Sequeira *et al.*, 2000) and molecular dating of divergence times (Sequeira and Farrell, 2001) indicate that these associations are very ancient, dating back probably to the late Cretaceous, when *Araucaria* were more widely distributed. The distribution of these associations today in Gondwanan landmasses and the molecular dating do not, however, distinguish between the hypotheses that the distribution of these interactions in South America and Australasia is due to vicariance following the breakup of Gondwana, or is due to dispersal between these continents once they had already separated. However, they do falsify the hypothesis that scolytine–*Araucaria* interactions are much more recent and dispersed among widely separated *Araucaria* populations on distant continents during the mid- or late Tertiary.

In other cases, phylogenetic information can reveal historical biogeographic processes that would otherwise be invisible. For instance, two sister genera of moths, *Parategeticula* and *Tegeticula*, are the only insects which pollinate yucca plants (Agavaceae: *Yucca*) in North America; these moth genera rely on the seeds of yuccas as food for their larvae. Phylogenetic analysis and divergence time estimation of *Tegeticula* and *Yucca* suggest that the former diversified much more recently than the latter, despite the obligate interaction between the two (Althoff *et al.*, 2012). One possible explanation is that *Yucca* initially codiversified with *Parategeticula*, but then *Tegeticula* spread across most *Yucca* species and in doing so displaced most *Parategeticula* populations. The five extant species of *Parategeticula* today are distributed primarily in the southern part of the range of *Yucca*, consistent with the argument that *Tegeticula* displaced the genus throughout much of its ancient range. Although these age estimates are not without error, they do suggest, interestingly, that different pollinator lineages may competitively interact, and possibly competitively exclude each other, over evolutionary timescales, with major implications for understanding coevolution between yuccas and their pollinating moths. Although the examples above come from parasitic interactions between herbivorous insects and their host plants, many other examples exist from animal hosts and their parasites (see Morand and Krasnov, 2010).

Competitive Exclusion/Extinction in the Evolution of Biotas

Competition between different clades, unfolding across a biogeographic template, is thought to be a major factor in the evolution of life, and the biogeography of this competition – which clades end up in which regions of the world, and how they interact when they come into secondary contact through episodes of 'biotic interchange' – has long been recognized as a major component of this (Vermeij, 1991). For instance, for most of the Tertiary, North and South America were isolated by ocean. As a result of the distinct geologic histories of the two continents (North America was frequently connected with Eurasia; South America was initially connected to Antarctica and other Gondwanan landmasses before becoming an island) and their isolation from each other, largely independent and phylogenetically distinct mammal faunas evolved on the two continents. When North and South America were joined by the formation of the Isthmus of Panama in the Pliocene, many mammal lineages migrated into each others' continents, leading to new competitive (and presumably also predatory) interactions. This event is referred to as the Great American Interchange. Like many other episodes of biotic interchange, the invasions were asymmetric: in the Pleistocene, 11% of North American mammal genera invaded the South, while 2% of South American genera invaded the North (Vermeij, 1991); similar asymmetries occurred in bird invasions (Smith and Klicka, 2010). This invasion was found to follow a higher rate of extinction of mammal genera in South as compared to North America during the Pliocene (Vermeij, 1991). In another well-demonstrated example, through the Tertiary, Indian and Pacific ocean marine invertebrate communities have had much higher predation and grazing intensity than do Atlantic ones, leading to regional differences in defensive traits among the two biotas (Vermeij, 1978).

These asymmetries in invasion and interaction intensity are often cited as evidence for competition in the assembly of biotas (Vermeij, 1991). Similarly, competition is often invoked as a factor governing diversification and extinction in adaptive radiation on islands. Different islands within the same archipelago may, by virtue of their age, size, or other characteristics, experience different effects of competition in the diversification and assembly of their biotas (Rabosky and Glor, 2010; Gillespie and Baldwin, 2009).

Biogeography of Interaction Loss, Gain, and Reassembly

A biogeographic approach can also be used to understand factors leading to the loss, gain, and reassembly of interactions. The colonization of a new region by a lineage may lead to the loss of old interactions or the gain of new ones. For example, in colonizing Madagascar from Africa, *Dalechampia* vines lost their associations with specialized resin-collecting bees and evolved to be pollinated by generalist pollen-feeding insects (Armbruster and Baldwin, 1998). The presumed difficulty of co-dispersal by specialized taxa is one reason that interactions on oceanic islands are often argued to be more generalized than their continental equivalents (Kaiser-Bunbury *et al.*, 2010; see below). The gain of new interactions can be difficult to assess via the fossil record or phylogenetic analysis, but it is frequently observed among invasive species. Introduced Japanese white-eyes (*Zosterops japonicus*) act as pollinators of endemic lobeliad plants (*Clermontia parviflora* and *Clermontia montis-loa*) in Hawaii (Aslan *et al.*, 2014). In the Society Islands of French Polynesia, the endemic gray-green fruit dove (*Ptilinopus purpuratus*) feeds on fruits of the invasive tree *Miconia calvescens* and is likely to be an important disperser of its seeds. In the same archipelago, two invasive birds of Old World origin, the red-vented bulbul (*Pycnonotus cafer*) and the silvereye (*Zosterops lateralis*), feed on fruits of, and may serve as important seed dispersers for, a diverse flora of introduced and invasive trees and shrubs from the New World and other areas outside the native range of these invasive birds

(Spotswood *et al.*, 2012). These examples, although recent and not necessarily yet leading to evolutionary changes, indicate the potential for novel interaction gain and loss following the colonization of new regions.

Interactions can also be maintained or reassembled despite colonization of a new region. For example, the only fungus-growing termites (Macrotermitinae) which have been able to colonize Madagascar from Africa are those which have vertical rather than horizontal transmission of their mutualistic fungi (*Termitomyces*; Nobre *et al.*, 2010). In other cases, interactions can be reassembled even when interacting species disperse separately. Leafflower trees (*Phyllanthus* s. l.: *Glochidion*) are found in continental regions of tropical and subtropical Asia and Australasia. They are pollinated by specialized leafflower moths in the genus *Epicephala*, which actively gather pollen from male flowers, transfer it to the stigmas of female flowers, and then lay eggs in the flowers' ovaries so that their larvae may consume a subset of the developing seeds (Kato *et al.*, 2003). Species-specificity between plant and moth is very high (Kawakita and Kato, 2006). However, dozens of endemic *Glochidion* species are known from the oceanic archipelagoes of Polynesia and Micronesia in the Pacific, some of which are >5000 km from the nearest continents. Co-dispersal is extremely unlikely because a *Glochidion* seed would require at least several years to grow into a mature plant, whereas an *Epicephala* larva would become an adult in a few weeks. However, despite this apparent barrier, *Epicephala* moths and *Glochidion* trees have independently colonized the remote Pacific and reassembled their interaction on each island where they are found today (Hembry *et al.*, 2012). Phylogenetic analysis indicates that not only have *Epicephala* been able to reassemble their interaction with *Glochidion* once, but that they have actually done so multiple times. There have been at least two independent colonizations, differing in age, of south-eastern Polynesian *Glochidion* by *Epicephala* (Hembry *et al.*, 2013a).

Ecological Biogeography of Interactions

Biologists have long remarked that just as different species and clades are found in different parts of the world, different interactions between these species and clades are also found in different parts of the world. However, quantifying these differences and searching for meaningful pattern in the biogeography of interactions has been more challenging.

Latitudinal Gradients in Interaction Types, Specialization, and Interaction Diversity

Since the beginnings of modern evolutionary ecology, it has been argued that major differences exist in patterns of interactions between the tropics and the temperate zones. The classic argument is that interactions in the tropics are more specialized than interactions in temperate or boreal zones (MacArthur, 1972; Janzen, 1973); a corollary is that biotic interactions are more important in the tropics than at higher latitudes (Dobzhansky, 1950; Fischer, 1960). Sometimes these hypotheses are thought to be linked with the well-demonstrated latitudinal diversity gradient, in which species richness increases with decreasing latitude. An ecosystem can pack in more species if each of them has a narrower ecological niche and interacts with a fewer number of other species. Consequently, understanding how biotic interactions and their specialization vary with geography is fundamental not only for understanding patterns of biodiversity and ecology, but to fundamental dimensions of biodiversity. Many estimates of the number of species depend heavily on assumptions about the degree of specialization of parasitic insects, mites, and nematodes and their animal or plant hosts (see Erwin, 1982 and Novotny *et al.*, 2002 for two famously contrasting views).

Objectively assessing patterns of specialization across geographic gradients is, however, hampered by the availability of comparable data from different regions of the world (Ollerton, 2012). As stated above, 'interactions' encompasses mutualism, antagonism, competition, and commensalism, and many of the best quantitative datasets are taxonomically and ecologically limited. Since the turn of the century, however, a number of groups of researchers have sought to empirically test the common assumption that tropical interactions are more specialized. These studies have primarily focused on terrestrial interactions between plants and their pollinators and seed dispersers, and plants and their insect herbivores. Some studies have found support for greater specialization in the tropics; these include plant–pollinator interactions generally (Olesen and Jordano, 2002; Trøjelsgaard and Olesen, 2013), hummingbird–plant interactions (Dalsgaard *et al.*, 2011), and host specificity in herbivorous Lepidoptera (moths and butterflies; Dyer *et al.*, 2007). In contrast, a recent large-scale review found evidence for the opposite pattern, that plant–pollinator and plant–seed disperser interactions are more specialized in the temperate zones than in the tropics (Schleuning *et al.*, 2012). Finally, other studies have suggested no important difference in specialization between the tropics and temperate zones for interactions such as plant–pollinator mutualisms (Ollerton and Cranmer, 2002), herbivorous insects and their host plants (Novotny *et al.*, 2006), and for niche breadth generally (Vázquez and Stevens, 2004). Biotic interactions appear to be stronger or more important on organisms' fitness in the tropics compared to in temperate zones (Schemske *et al.*, 2009), although this comparison is difficult to make quantitatively. Whether specialization is greater in the tropics than in temperate zones, and if so why, is likely to remain an area of active investigation.

Biogeography of Ecological Networks

One emerging area in understanding the ecological biogeography of interactions has been in examining geographic variation in ecological network structure. Ecological interactions within communities (such as food webs, plant–pollinator interactions, and seed–disperser interactions) can be envisioned as interaction networks, in which species that interact are connected via links. The specialization of species within these networks (above) is just one of many topological properties of these networks that may vary geographically. Like assessing geographic patterns of specialization in biotic interactions, this is a major area of recent growth and attention in interaction biogeography.

Cross-system comparisons have revealed that major, qualitative patterns in network structure often do not vary geographically among comparable interactions. For instance, plant–pollinator interactions are generally both 'nested' (consisting of a core of generalists and asymmetric specialists who interact with these generalists) and 'modular' (broken into weakly connected subnetworks, or modules), regardless of the region of the world in which they occur (Bascompte *et al.*, 2003; Olesen *et al.*, 2007). However, a number of studies have begun to assess differences in network structure across geographic regions. Network-level specialization (described above; Dalsgaard *et al.*, 2011; Schleuning *et al.*, 2012) is only one topological property that has been examined and it appears to vary geographically with latitude in pollination and seed-dispersal networks. Other studies on pollination networks have suggested that connectance is lower at high elevations, generalization increases at high latitudes and elevations, modularity increases toward the tropics, and specialization increases on oceanic islands (Olesen and Jordano, 2002; Trøjelsgaard and Olesen, 2013). In contrast, host–parasitoid networks do not show latitudinal patterns after sampling effects are controlled for (Morris *et al.*, 2014). Finally, geologic history – island age, which dictates the maximum possible age of the interaction network on that island – has effects on plant–pollinator network structure in the Canary Islands (Trøjelsgaard *et al.*, 2013; **Figure 1**). Some of these disparate findings, particularly within pollination networks, may be explained by differences in the metrics examined. Specialization can either take the form of asymmetric specialists which interact with generalists, or symmetric specialists which interact with other specialists (Guimarães *et al.*, 2006), and asymmetric specialization has been argued to be important in permitting the positive correlation between niche breadth and latitude (Vázquez and Stevens, 2004). To date, only a few studies have examined spatial variation in network structure, and this is likely to be a major area for future research in the biogeography of interactions.

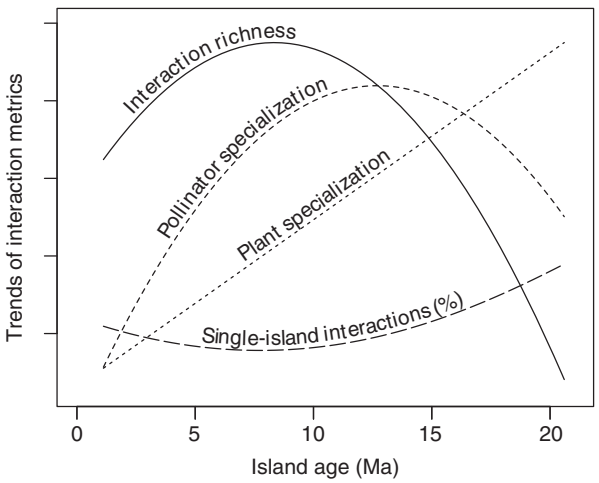

Figure 1 Summary of relationships found between structural properties of plant-pollinator networks (*y*-axis) and island age (*x*-axis), in the Canary Islands, reproduced from Trøjelsgaard, K., Báez, M., Espadaler, X., *et al.*, 2013. Island biogeography of mutualistic interaction networks. Journal of Biogeography 40, 2020–2031. All curves are normalized and *y*-axis values are omitted to show general trends. The different metrics (interaction richness, pollinator specialization, plant specialization, and proportion of interactions restricted to a single island) show differing trends with increasing island age.

Interactions on Islands

Biotic interactions on islands are typically thought to be more generalized than on continents (Carlquist, 1974; Kaiser-Bunbury *et al.*, 2010), although this interpretation has been rarely examined quantitatively and has been challenged by empirical analyses (Olesen and Jordano, 2002). Isolation of islands is thought to reduce successful colonization and establishment by new species in general and by specialists in particular, and the chance of extinction of any species once established on an island is also greater than in a comparable area on a continent (MacArthur and Wilson, 1967; Holt, 2010). These factors are thought to promote the prevalence of generalist species on islands, as well as the evolution of novel generalized interactions not seen on continents (lizards acting as pollinators and seed dispersers on islands being perhaps the most charismatic examples; Olesen and Valido, 2003). Specialized herbivorous insects certainly do exist on even very remote oceanic islands (either via colonization or *in situ* diversification; Hembry *et al.*, 2013b; Bennett and O'Grady, 2012); whether these assemblages are more or less specialized at the species level than on continents remain to be tested quantitatively. Interactions such as those hypothesized to have occurred between the endemic radiations of lobeliad plants and pollinating honeycreepers in Hawaii (Lammers and Freeman, 1986) suggest that given sufficient time and ecological opportunity, unique specialized mutualisms may be able to evolve even on remote oceanic islands.

Biogeography of Coevolution

Although often considered separately from the biogeography of interactions, much recent research in coevolution has focused on geographic variation in the evolution of interactions between different populations of two or more interacting species. Most investigators define coevolution as reciprocal natural selection between two or more species (Janzen, 1980; Thompson, 1994, 2005). The geographic mosaic theory of coevolution (GMTC; Thompson, 1994, 2005) postulates that coevolution between two species varies among their different pairs of populations. Some pairs of populations constitute coevolutionary 'hotspots,' where coevolution is actively occurring, whereas others constitute coevolutionary 'coldspots,' in which only one or neither species is evolving, and thus coevolution is not occurring. This spatial variation in coevolutionary outcomes arises as a result of abiotic selection gradients across the populations, differential gene flow between them, coevolution with different species (or different populations of the same species) among populations, or a combination of these processes.

Empirical tests of the GMTC have found that, as predicted by theory, interactions between two species often vary considerably in their traits and fitness outcomes for each species across their metapopulations. For example, the seeds of

lodgepole pines (*Pinus contorta*) in the Rocky Mountains of North America are fed upon by red squirrels (*Tamiasciurus hudsonicus*) but also by birds called red crossbills (*Loxia curvirostra* complex; Benkman, 1999; Benkman *et al.*, 2001; Edelaar and Benkman, 2006). In most parts of the Rockies, red squirrels are the most important predators of lodgepole seeds, so the cones evolve thick bases to avoid being easily gnawed off branches by squirrels. In isolated mountain ranges without squirrels (the South Hills and Albion Mountains in the US state of Idaho, and the Cypress Hills in the Canadian provinces of Alberta and Saskatchewan), crossbills are the most important predators of lodgepole seeds. Crossbills extract seeds from cones by prying apart scales with their bills while the cones are still attached to the trees. Instead of having thick bases, cones from these mountain ranges evolve thicker scales at the distal ends of their cones so that it is harder for crossbills to pry apart the scales. In these isolated mountain ranges, crossbills evolved deeper, shorter, and more curved bills which are more effective at extracting seeds from the cones available to them (Benkman *et al.*, 2001). Coevolution between crossbills and pines, in concert with both geographic isolation and the evolution of differences in their calls, has even driven these isolated crossbill populations to evolve into new species (Smith and Benkman, 2007). In this example, coevolution between pines and crossbills is actually promoting the speciation of crossbills in these outlying populations. Whether or not geographic isolation, in combination with coevolution, often promotes speciation is poorly understood and little studied, but may be an important future research area in the biogeography of interactions (Hembry *et al.*, 2014).

Overview

Studies of island biogeography are undergoing an invigorating transformation, from primarily ecological investigations founded in the equilibrium theory of MacArthur and Wilson (1967) toward a more general exploration of dynamic processes and patterns that span from generational to geological time (Whittaker *et al.*, 2008). By drawing on distributional, chronological, geological, and phylogenetic relationships among many kinds of data – for example, abundance, disparity, and diversity of alleles, species, and traits – this evolutionary biogeographical perspective (*sensu* Morrone, 2009, p. 1) aims to identify generalities in how ecological and evolutionary processes combine to produce current biogeographic patterns on diverse kinds of islands. While modified forms of the ecological equilibrium theory of island biogeography remain instrumental for investigating variations on extant patterns over short periods, the new general dynamic model links those ecological snapshots and thus animates the processes and patterns of change.

Theoretical Setting

The current theoretical transformation in island biogeography beckons integration of influential hypotheses that have grown up around islands. Relationships between species richness versus distance, distance-decay, and the classic species-area relationship (SAR; MacArthur and Wilson, 1967) – which embody processes such as migration, coupled with extirpation – may be united with evolutionary theories of bottlenecks, founder events, genetic drift, and founder-flush evolution that lead perhaps to peripatric speciation and punctuated equilibrium (Mayr, 1963; Gould and Eldredge, 1977). Evolutionary patterns emerging from ecological principles, such as the island rule, character displacement, adaptive radiation, reduced antipredator strategies, and decreased motility (e.g., Vermeij, 2004; Lomolino *et al.*, 2013) also should find their places within a general dynamic theory of island biogeography. In this article, we provide a brief overview of recent developments in ecological–evolutionary biogeographical research in diverse island situations.

Places and Players

Many kinds of places and organisms show patterns consistent with the aforementioned island theories: arthropods, lizards, and plants on oceanic islands, mammals on mountaintops, microbes in water holes, fishes and jellyfishes in lakes, and so on (**Figures 1** and **2**; Gillespie and Clague, 2009). This diversity emphasizes that island theory is not about a place alone, but rather the interactions between a place that has some level of isolation and a taxon (or many taxa) that shows the effects of that isolation. We explore these interactions using three of the most well-studied places that provide insular environments: islands, mountaintops, and lakes.

'True' Islands

Island theory has been inspired principally by studies of true islands, i.e., parcels of land completely surrounded by water. Their sometimes extreme isolation has led to exceptional biotas and earned them reputations as natural laboratories of evolution (Wagner and Funk, 1995; Losos and Ricklefs, 2009). The ecological–evolutionary dynamics of these, and other insular environments, are influenced by four key geographic characteristics: their mode of origin, isolation, size, and age (**Figure 3(e)**).

True islands are classified, coarsely, as continental or oceanic, based on their *geological origins*. Continental islands include fragments of continental crust or shelf that protrude above water; they may be connected to nearby mainland via land bridges during periods of lowered sea level. Oceanic islands instead have volcanic and/or tectonic origins and formed without connection to any mainland (Whittaker and Fernández-Palacios, 2007, p. 12). These differences influence the dominant processes structuring their biotas. Continental islands – fragments – begin with a substantial complement of mainland species, which after isolation are removed by extinction (or 'relaxation'; Simberloff, 1974), rapidly at first and at decreasing rates thereafter; the subset of species that persist may eventually become island endemics. In contrast, *de novo* oceanic islands begin devoid of life and must be colonized by species, added one-by-one into a newly formed landscape for evolution. The same place may be a different kind of island at different times; for example, a fragment may become a *de novo* island if stripped of its species (e.g., by submergence; Whittaker and Fernández-Palacios, 2007, p. 32). *De novo* islands, especially true oceanic islands, provide a theater for novel ecological and evolutionary diversification and some of nature's most striking adaptive radiations.

Once on an island, populations are subject to evolutionary dynamics that are determined in part by the *degree of isolation*. Islands that are close to the mainland – typically continental islands – will tend to be dominated by repeated colonization and extinction (MacArthur and Wilson, 1967) and influx of alleles from elsewhere. More isolated islands – usually oceanic islands – allow rare colonizers to escape the homogenizing influence of gene flow, thereby favoring the evolution of novel biotas (Losos and Ricklefs, 2009). There is, though, no single geographic distance that distinguishes islands with these

Figure 1 Some of the many species that inhabit islands. (a)–(c): Earthworm mice represent an adaptive radiation that is endemic to mountaintops in the Philippines. The radiation includes at least 50 species, at least 30 of which are restricted to Luzon Island. The species range from 15 to 220 g, including stout-bodied species that burrow through the soil to upright, gracile species that hop about on their hind legs along tiny trails. Up to seven species have been documented as occurring fully sympatrically on the 'sky islands' of northern Luzon. (a) = *Apomys musculus*; (b) = *Chrotomys whiteheadi*; (c) = *Rhynchomys soricoides*. (d)–(i): Representative Hawaiian *Tetragnatha* spiders showing three of four known ecomorphs of the spiny leg on older (Kauai, Oahu) and younger (Maui) islands; the taxa shown form different ecomorphs on the same island that are more closely related to each other than to the same ecomorph on different islands. (d) = *Tetragnatha kauaiensis*, Kauai; (e) = *Tetragnatha perreirai*, Oahu; (f) = *Tetragnatha pilosa*, Kauai; (g) = *Tetragnatha waikamoi*, Maui; (h) = *Tetragnatha kamakou*, Maui; (i) = *Tetragnatha quasimodo*, Maui. (j): Multiple subspecies of golden jellyfish, *Mastigias papua*, inhabit the coastal ocean and marine lakes in Palau. The ocean form (far left) is hypothesized to be similar to the ancestral medusae that colonized lakes after the Last Glacial Maximum and have since been evolving independently for between ~6000 and 15 000 years (second left to far right). (k)–(o): *Anolis* lizards have adaptively radiated on each of the four islands of the Greater Antilles: Cuba, Hispaniola, Puerto Rico, and Jamaica. Similar sets of microhabitat specialists with similar morphological adaptations (ecomorphs) have arisen on each island. All those shown evolved on Cuba: (k) = *Anolis alutaceus,* a grass-bush anole; (l) = *Anolis allisoni*, a trunk-crown anole; (m) = *Anolis mestrei*, a trunk-ground anole; (n) = *Anolis equestris*, a crown-giant anole; (o) = *Anolis angusticeps*, a twig anole.

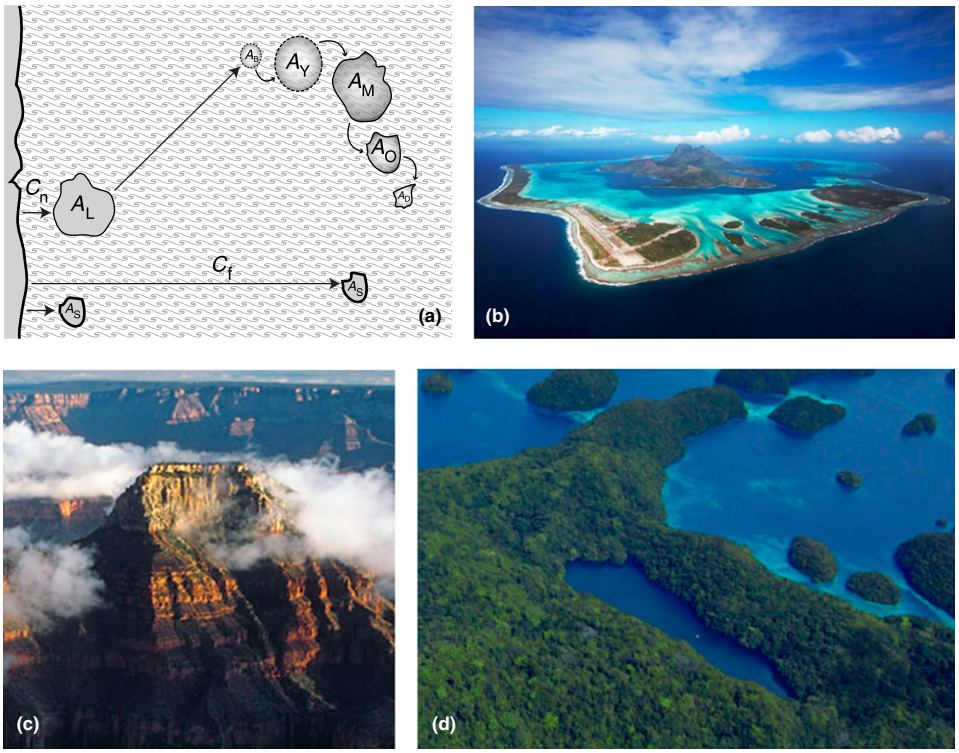

Figure 2 The geographic dimensions of islands, with some examples. (a) The basic geometric properties of islands: their colonization distance, $C_{(\text{near or far})}$, from the nearest mainland and their size which usually is measured as area, $A_{(\text{small or large})}$. These physical dimensions are considered to be causally related to biological characteristics of islands. For example, fewer species are able to travel – i.e., immigrate, I – to more distant islands; smaller area harbors fewer habitats and so fewer individuals, N, and fewer species, S; smaller populations in turn may elevate extinction rates, E; all rates may be species-specific. Intermediate islands may be stepping stones to more distant islands, and infrequently species endemic to islands may recolonize mainland areas. In the classical island biogeography theory of MacArthur and Wilson (1967), the basic physical dimensions are considered to be static and so the biological characteristics in equilibrium. However, the C and A of all islands change through time – for example, due to tectonic or volcanic activity, sea level change – with consequent impacts on I, N, S, and E. Thus, physical stasis and biological equilibrium may exist only as ecological 'snapshots' during a dynamic evolutionary history and future of islands, from birth $_B$, youth $_Y$, maturity $_M$, old-age $_O$, and toward death $_D$. (b) An oceanic island, Bora Bora; the land and reefs surrounding the extinct volcanic peak form gradually as the island subsides into the ocean. (c) A tabletop mountain, Arizona, also known as a mesa or tepui, which erodes through time. (d) A marine lake, 'Jellyfish Lake' in Palau, which formed, deepened, and increased in area after the Last Glacial Maximum as climate warmed, ice-caps melted, and sea level rose; since sea level stabilized ~6000 years before present, the lake has been getting shallower due to sedimentation. (b) http://www.louwphotography.com/South-Pacific/French-Polynesia/Bora-Bora/i-kPfDJT6/A, (c) http://blogs.mycentraljersey.com/arizonaexpedition/files/2013/07/Sky-Islands.jpg, (d) Christoph Gerigk.

effects. The greater a taxon's dispersal ability, the more geographically isolated an island must be to enter what MacArthur and Wilson (1967) called the "radiation zone", in which substantial biodiversity is generated within the island (or archipelago) from one or a few colonizing species (Gillespie and Baldwin, 2010).

The course of evolution in species following colonization of an insular environment is also influenced by *island size*. On small islands, species may undergo anagenetic speciation, evolving into a single new species and contributing to the exceptional endemism of the island biota without increasing species diversity on the island. On large islands, further within-island geographic or ecological separation of populations allows for cladogenesis, during which one species splits into two or more species. As with degrees of geographic isolation, the distinction between small versus large islands is relative, depending upon species' traits, particularly dispersal ability (Kisel and Barraclough, 2010). For example, the size threshold for cladogenesis is less than 100 km^2 for *Bulimulus* land snails on the Galápagos (Losos and Parent, 2010) but at least 3000 km^2 for Caribbean *Anolis* lizards (Losos and Schluter, 2000). Cladogenetic radiation can also occur at the scale of whole archipelagos, even if individual islands are below threshold sizes (Grant and Grant, 2010), because narrow straits separating islands can filter out potential migrants and thus resist gene flow. The ecological opportunities afforded by such islands can stimulate bursts of evolutionary radiation, which may decline through time as available opportunities are increasingly exploited (Mahler *et al.*, 2010).

These effects of origin, isolation, and size all take time to accrue; they may even change with time as the island itself changes (**Figure 3(e)**). Thus, the *age of an island* is the fourth major influence on ecological–evolutionary dynamics on islands. Incorporating island age into oceanic island biogeography is the major novel component in the new General Dynamic Model (GDM; Whittaker *et al.*, 2008). As the island

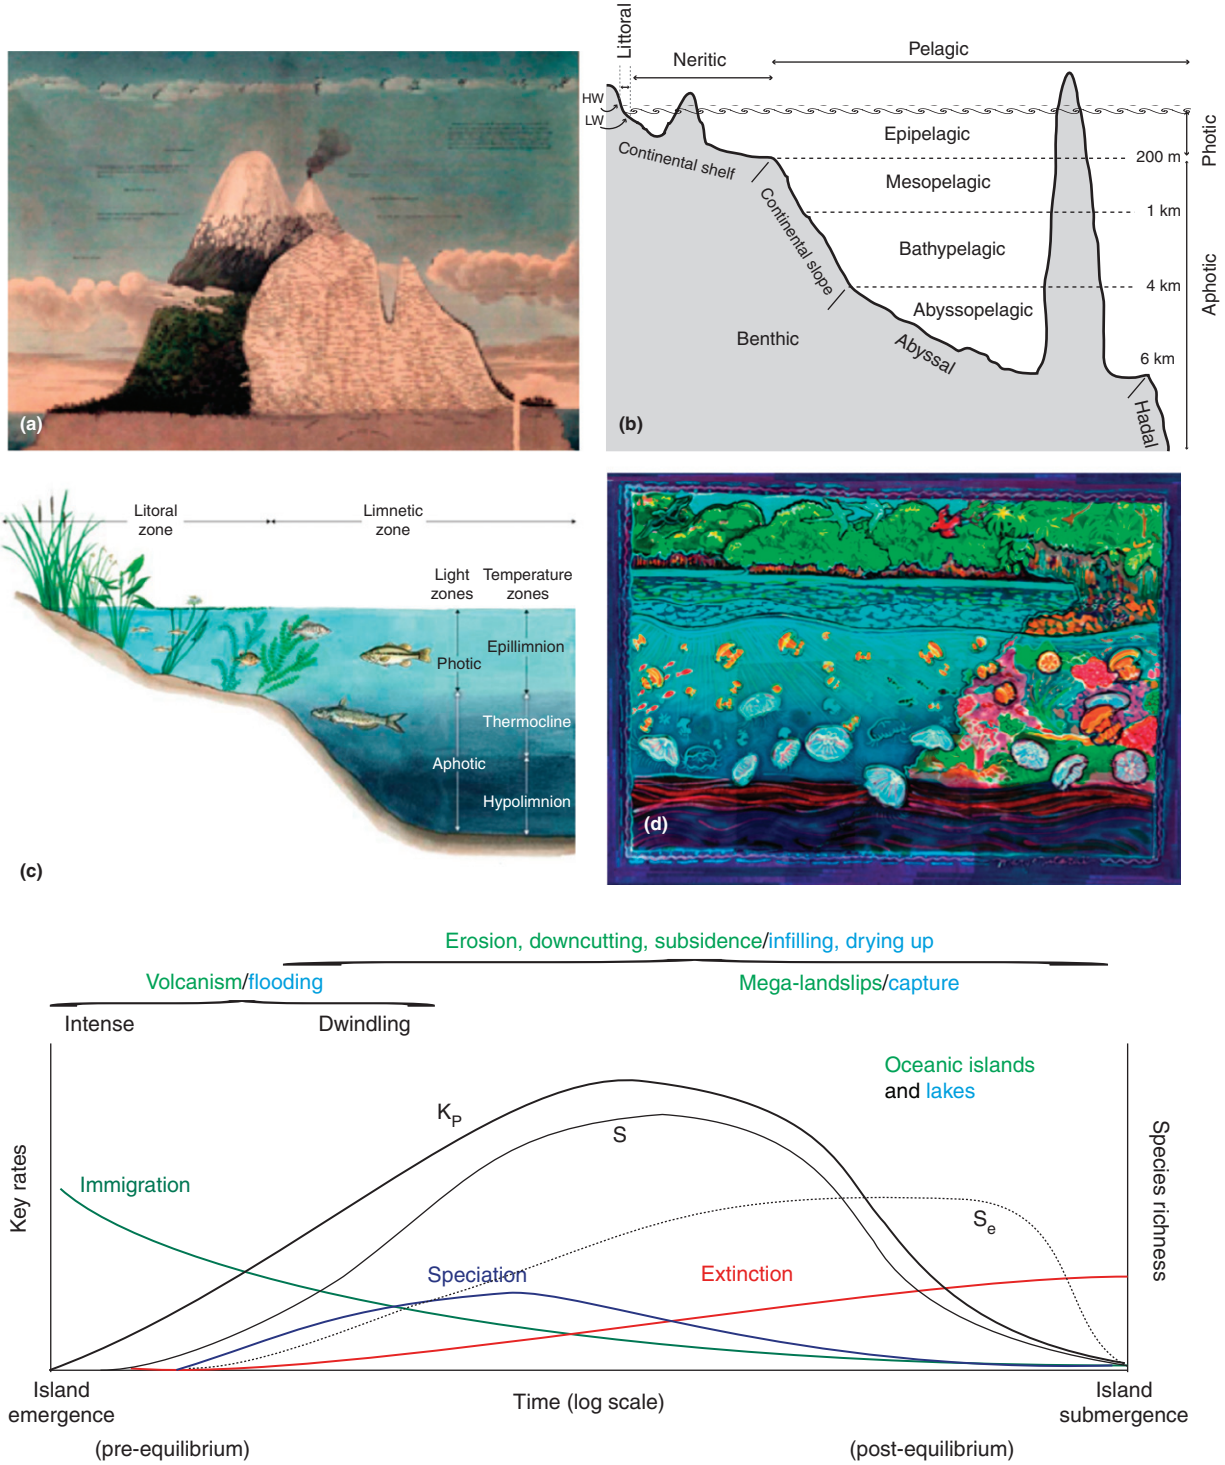

Figure 3 Environmental dimension of islands – horizontal and vertical zonation – and their interaction with time. (a) The classic description of altitudinal zonation of plants by Alexander von Humboldt. (b) Classification of islands by their positions in the sea, with continental or nearshore islands generally on a shallow shelf and distant oceanic islands rising from the ocean floor through multiple 'life zones' to the surface. HW, high water mark; LW, low water mark. (c) Freshwater lakes are similarly structured though typically on much smaller spatial scales, with nearshore littoral versus open-water limnetic regions, and depth zonation based on light, temperature, oxygen, and other factors that determine, and also maybe influenced by, the distributions of various organisms. (d) Marine lakes are structured in essentially the same manner as freshwater lakes, with horizontal and vertical zones being absent or present depending on the size and depth of the lake; the image shows rich eukaryotic life including jellyfishes in well-oxygenated illuminated surface-waters, above anoxic, cold, dark, chemically distinct bottom-waters inhabited by archaea. (e) Schematic of how the properties of islands may change through time according to the General Dynamic Model of oceanic islands; K_p – potential carrying capacity, S – species richness, S_e – endemic species richness (Whittaker *et al.*, 2008). (a) Chicago University Press. (c) http://imgarcade.com/1/lake-zones/. (d) Margo Vitarelli.

life span progresses and area, elevation, and topographic complexity increase, and environments change (e.g., Chadwick *et al.*, 1999), oceanic islands – specifically, those that form above geological 'hot spots' – shift from biotas composed primarily of immigrant species originating from older, nearby, islands, or from outside the archipelago, to those dominated by endemic species that diversified *in situ*. Islands that form along plate margins along subduction zones may persist much longer and grow to larger size, providing the opportunity for even greater speciation within the island or archipelago. The fates of islands and their biotas, though, may differ. Hot-spot islands will erode, subside, and their unique biotas disappear. Plate-margin islands more often will collide with, and become a permanent part of, the adjacent continent, which may reduce or provide new opportunities for the 'island' taxa.

The GDM provides a general framework linking the geological, geographical, ecological, and evolutionary dynamics of at least some 'life-stages' of many islands, especially oceanic islands. The geological time scale of the GDM, however, prohibits direct observation of evolutionary dynamics throughout a single island's life span. Moreover, generally poor fossil records on oceanic islands mean historical dynamics often cannot be documented retrospectively. Thus, most tests of the GDM depend on volcanic hot spot archipelagos – such as the Canaries, Galápagos, Lesser Antilles, and Hawaiian islands – that are composed of islands of widely varying age which can act as substitutes for different stages in the island life span. While some such studies find results consistent with predictions of the GDM, for example, that total and endemic species diversity should be a positive function of area and a hump-shaped function of island age, a number of exceptions suggest that not all archipelagoes follow the idealized GDM (**Figure 3 (e)**; Cameron *et al.*, 2013). Why islands, archipelagos, and lineages vary in their agreement with the GDM is a question ripe for both theoretical and empirical exploration. Fortunately, the occurrence of many archipelagos and islands around the world means that these natural laboratories often are replicated, providing opportunities to robustly test ecological–evolutionary hypotheses and to explore both the causes of shared patterns and also the reasons for unique outcomes.

Mountaintops

True islands have analogues in other terrestrial situations, including 'sky islands' and tepui. With increasing elevation, conditions tend to become cooler and wetter, often resulting in the presence of biological communities on mountaintops that are separated from each other by long distances and distinct communities living in warmer, drier conditions below.

That high elevation species often are composed of multiple separate populations isolated on various mountaintops was described first in Alexander von Humboldt's ground-breaking 1807 documentation of plant zonation on mountains in the Canary Islands and in the Ecuadorian Andes. That altitudinal 'life zones' or biomes exist sequentially up mountains was clarified by C. Hart Merriam in 1890, and the term 'sky island' was coined in the early 1950s and came into common usage by the 1990s (Warshall, 1995). Today, the term and concept of sky islands is applied broadly, to forested mountains in deserts, to the flat-topped steep-sided plateaus in northern South America called tepuis, to patches of cloud forest at the tops of the eastern arc mountains of Tanzania, and volcanic peaks in the Philippines; the term might also describe the tops of guyots and seamounts which are surrounded by deep ocean. As with true islands, the geological and biological history of each sky island greatly influences its species richness, level of endemism, and biological dynamics, and much variation in these and other factors is evident. However, because sky islands are connected by other terrestrial habitats through which at least some organisms can migrate, they have become known as 'habitat islands' rather than 'true islands' although these categories may have limited rhetorical value long term.

One of the first quantitative analyses of mountaintop biogeography employed extensive information from previous surveys of mammals on mountains in Utah and Nevada (Brown, 1971). As predicted for true islands, there was a strong correlation between mountaintop habitat island area and the number of species of small mammals that were montane specialists. However, there was no evidence for an effect of distance from a larger montane forested area – i.e., the degree of isolation from a montane analogue of 'mainland' was unimportant – indicating that modern mountaintop communities are fragments of formerly widespread communities that inhabited lower elevations in the western United States during the Last Glacial Maximum (LGM). That is, sky islands form the equivalent of continental shelf islands: in the absence of colonization, the biotas are gradually depleted by extinction, particularly on small sky islands where small populations are especially vulnerable. Moreover, sky islands may not be isolated in the same way as oceanic islands because surrounding lower elevations are inhabited by generalists such as bears and coyotes that often wander up to high elevations and may impact the dynamics of the small montane mammals and other organisms. The role of highly mobile organisms in modifying 'island' dynamics also has been emphasized for island-like marine habitats such as seamount-tops and reefs that are visited by itinerant sharks (Vermeij, 2004). It is now apparent that at least some colonization by some montane species probably has taken place since the LGM, offsetting relaxation in part. Conversely, studies of fossils show that the current absence of other species may be due to continued absence preceding the LGM rather than evidence of extinction since the LGM, as was initially assumed. While Brown's (1971) studies of sky islands of Utah and Nevada have become pivotal examples of nonequilibrial island dynamics and a model for investigations of other organisms on mountains in other parts of the world, subsequent research has shown that the development of current patterns was more complex than initially envisioned.

Nonequilibrial dynamics and long-term processes, especially evolution, as noted in the previous sections, are now some of the primary factors shaping new developments in island theory. Studies of mountaintops remain at the forefront of these developments, perhaps because they provide so many varied situations. For example, sky islands in North America provided a complex geographical and dynamic climatic landscape during the Pleistocene that may have promoted rapid speciation in *Melanoplus* crickets (Knowles, 2007). Tropical

mountain chains on continents and large islands provide situations in which speciation may contribute more to species richness than direct colonization, emphasizing that an evolutionary perspective on the dynamics of species richness is essential (Graham *et al.*, 2014). Furthermore, it becomes apparent that 'speciation' on islands can mean many things. For example, high elevation cloud forest on the Philippine island of Luzon supports at least 30 species of an endemic clade of 'earthworm mice' (which specialize in feeding on earthworms and other soft-bodied soil invertebrates) descended from an ancestral species that likely colonized lowland regions of the island about 8 million years ago. Speciation of the extant earthworm mice subsequently took one-to-several millions of years, and in some cases isolated mountaintops each host one of several closely related species indicating topographic isolation led to allopatric speciation, while in other cases a single sky island may host up to seven distantly related species in sympatry evincing multiple colonizations and character displacement in body size and feeding niche (Heaney *et al.*, 2016). These kinds of patterns have, in turn, led to recognition that the geological dynamics of mountain topography may change on timescales similar to those for the evolution of species. Thus, as in the GDM of oceanic island biogeography, the geological history of mountains is an essential component of conceptual models that attempt to describe long-term aspects of biodiversity on sky islands.

Lakes

Like islands and mountaintops, lakes come in a variety of sizes, shapes, types, and ages. Lakes are defined as depressions $\geq$2 ha filled with water – fresh, saline, or marine – that may persist for over 20 million years (Bengtsson and Herschy, 2012), although most are much shorter-lived. Lakes thus seem to offer similar potential for a range of ecological and evolutionary dynamics as evident on true islands and sky islands and represented in the GDM.

The majority of studies of lakes have been conducted in northern temperate freshwater systems which, like mountaintops, show mixed support for patterns predicted by equilibrium island theory. For example, meta-analyses indicate species richness increases with lake area (Arnott, 2009), probably as an effect of habitat heterogeneity, but a low effect size suggests that the lakes are not highly isolated. The slope of the SAR also is influenced by body size of the study taxa, which may be a proxy for dispersal ability, and thus the proximity of lakes influences patterns of connectivity and explains $\sim$20% of the variance in plankton community similarity. A similar percentage overlap in zooplankton community composition is explained by lake environment, presumably reflecting ecological filtering and natural selection (e.g., Arnott, 2009). Altogether, through time, the degree of isolation, the size of a lake, and the characteristics of the inhabitants each likely contribute to the formation – or lack thereof – of endemic populations, species, or species-flocks. Geologically young postglacial North American lakes may include only one or a couple of ecomorphs of sticklebacks (Schluter and McPhail, 1992), whereas ancient African Rift Lakes include many hundreds of species of cichlid fishes (e.g., Wagner *et al.*, 2014).

Some recent studies of tropical saline lakes have added a perspective from the underrepresented and by some metrics quite different marine realm (**Figure 1(d)**). Intriguingly, these marine lakes show many of the standard island patterns, but also share some of the increasingly common deviations from equilibrium theory. Modern marine lakes formed *de novo* after the LGM as rising sea levels forced water and propagules into low-lying inland valleys between $\sim$6000 and 15 000 years ago. Connections with the surrounding ocean 'mainland' still exist via underground tunnels and fissures, and the isolation of a lake likely is a function of interactions between the geographic and physical characteristics of a lake and the traits of potential colonists. Marine lakes show classical SAR and distance-richness curves in marine invertebrates, and the more isolated marine lakes harbor genetically isolated populations, subspecies, and species currently unknown elsewhere. However, phytoplankton have a flat or negative SAR, and population genetic and evolutionary analyses indicate nonequilibrial dynamics such as genetic drift during establishment and subsequent selection that generates novel morphologies and behaviors which change through time (Dawson and Hamner, 2005). Thus, populations in marine lakes show patterns reminiscent of common evolutionary trends in species inhabiting oceanic islands, including reduced swimming speed which mirrors reduced flight in birds and some insects, reduced size relative to ocean ancestors consistent with the 'island rule' (Lomolino *et al.*, 2013), and reduced coloration and vestigial morphology consistent with diminution of antipredatory devices associated with reduced predation in island settings (Vermeij, 2004). How such microevolution influences community processes through time and thus the form of the GDM currently is unclear.

Of special note, then, is that some lakes harbor rich sediment records that may allow direct tests of the GDM and evolutionary island theories. In lakes, dead or dormant organisms sink to the bottom where they may be preserved, and perhaps fossilized, in chronological sequence. By mining through these sediments, community composition, ancestral states, and anagenetic change can all be observed directly thus revealing actual evolutionary and biogeographic patterns through time, rather than relying on space-for-time substitutions using 'modern analogs.' For example, fossils in a Miocene lake reveal sequences of armor reduction in incumbent *Gasterosteus doryssus* sticklebacks, then invasion and replacement by a new highly-armored lineage which itself subsequently evolved reduced armor (Bell *et al.*, 2006; Hunt *et al.*, 2008). This paleontological succession parallels the biogeographic inference, from modern populations of *Gasterosteus aculeatus* (threespine stickleback), of multiple marine-to-freshwater colonization events and the *in situ* evolution of distinct ecomorphs including some with reduced armament (Schluter and McPhail, 1992; Schluter, 2000). Recent lake sediments also promise integration of ecological and evolutionary island biogeography through exploitation of seed banks and subfossils that permit 'resurrection' of putatively ancestral forms in modern experiments or paleogenomic analyses (Orsini *et al.*, 2013). Testing for repeated patterns in lake species, like repeated patterns in *Anolis* lizards and *Tetragnatha* spiders on true islands (Gillespie, 2004; Losos, 2009), will indicate the extent to which the ecological–evolutionary

characteristics of insular habitats are generalizable and therefore the possible explanatory power of the GDM in 'true' and other island situations.

Outlook

True islands, lakes, and mountaintops in some ways appear among the most different kinds of places. Yet they share key attributes such as clear bounds in space and through time, a degree of isolation, and oftentimes a simplified ecosystem; each may form *de novo* or by fragmentation (as may other kinds of islands). These 'natural experiments' will be invaluable to biogeography in the future, as in the past, because islands and island-like systems provide unparalleled opportunities for studying the many interacting mechanisms that influence ecological–evolutionary processes and determine general patterns of diversity. Islands and island-like systems also will be indispensible in providing numerous variations on those general themes that enable interactions to be deconstructed, reconfigured, and explored. In time, we suggest biogeography may distinguish places not in terms of whether they are true islands, mountaintops, or lakes, nor perhaps on the basis of their particular geographic location, nor the major branches of the tree of life to which they are home. Rather, biogeography will distinguish places to the extent they differ in a suite of ecological–evolutionary mechanisms (Figure 4) that shape the suite of organismal traits and ecosystem processes that are present at a particular place and time.

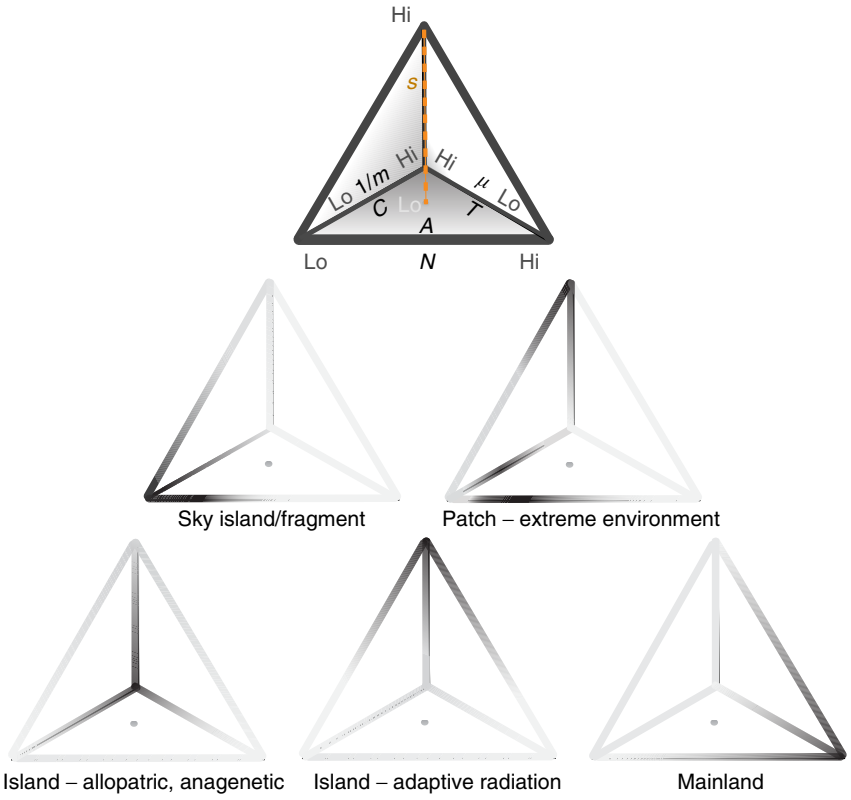

Figure 4 A conceptual diagram illustrating the biophysical nature of islands, island-like habitats, and mainland. 'Top'*:* A pyramidal volume represents interactions among the three key geographic characteristics of islands – colonization distance (*C*), area (*A*), and age (*T*, for time) – and the four principal mechanisms of evolution: migration (m), mutation (μ), genetic drift (a function of population size, *N*), and selection (s). The axes can be shaded to indicate the theoretical parameter spaces that describe various biogeographic situations. 'Middle row'*:* For example, patchy distributions may occur when habitats are recently isolated, as in the case of sky islands and continental islands, leading to small population size, ecological drift, and extirpations. Alternatively patches may result from extreme environments wherein strong natural selection counteracts modest levels of movement. In neither case has the habitat or population persisted sufficiently long to differentiate into an insular form. 'Bottom row'*:* Small islands that are remote, i.e., sufficiently distant to exceed the usual dispersal potential of a species, may harbor endemic species that evolve anagenetically in allopatry (or peripatry). Larger islands may foster adaptive radiations. The framework applies equally to true islands, mountaintops, and lakes, thus facilitating conceptual and quantitative comparisons among types of island. Note that an island may move through this parameter space with time, for example from a recently colonized island (left middle), through anagenetically evolving peripatric population (left bottom), to an adaptive radiation as the island size and habitat heterogeneity increases (center bottom).

Biogeography of Vertebrates

RM Brown, University of Kansas, Lawrence, KS, USA

Glossary

Adaptive radiation The evolution of ecological and phenotypic diversity within multiplying lineages, usually associated with the rapid production of high species diversity.

Ecological opportunity As organisms colonize new areas and encounter environments (islands, habitats) in which competitors or predators are absent, or in which new food resources can be exploited, novel adaptive processes can dive the evolution of new species as a response.

Gondwana The supercontinent, formerly composed of today's Africa, South America, India, Antarctica, Australia, Arabian peninsula, New Zealand, Madagascar, New Guinea, and other smaller landmasses.

Tetrapods The four-limbed vertebrates and descendants, including the living and extinct mammals, birds, amphibians, reptiles, and some extinct fishes.

Vicariance Passive divergence of evolutionary lineages, resulting from the formation of a barrier or geological processes; the splitting of formerly united species distributions via continental fragmentation and drift.

Biogeography is the study of the evolution of geographical distributions of organisms, a topic that has intrigued and bewildered theologians, philosophers, and biologists for thousands of years. We can trace the origins of biogeographical thought to early Greek philosophers like Plato (428–348 BC) and Aristotle (384–322 BC) and, eventually, to scholars like Linnaeus (1707–78) who first articulated theoretical concepts of the nature of species (*Essentialism* and *Typology*) and then logically asked why certain species occupied particular places. A century prior to the publication of Darwin's and Wallace's formulation of the idea of organismal evolution by natural selection (Darwin, 1859; Wallace, 1860), Georges-Louis Leclerc, Comte de Buffon (1707–88) clearly articulated the fundamental principles of natural selection but deliberately deemphasized their significance in light of societal and religious conventions of his day (sixteenth century Europe). Buffon observed distributions of extant organisms but also studied fossils, leading him to the inevitable conclusion that life changes with time, and varies geographically, often inhibited by physical barriers. Based on his observations, Buffon issued what has become known as Biogeography's First Principle (or 'Buffon's Law'), the idea that environmentally similar (but isolated) regions of Earth have distinct assemblages of animals. This simple observation, sometimes summarized as *The Uniqueness of Place* (Lomolino *et al.*, 2010), became so influential that, in large part, it spawned an Age of Exploration and more than a century of worldwide travel and discovery by several generations of European cartographers, mariners, botanists, and zoologists. Although the first generation of these explorers was primarily composed of botanists, or *Phytogeographers*, vertebrate zoologists soon joined their ranks and the field of *Zoogeography* (biogeography of animals) was born.

At the intersection of numerous physical sciences relating to both life and the geographical template on which it has evolved (Lomolino *et al.*, 2010), the field of biogeography addresses fundamental responses of life to the spatially variable biotic and abiotic environment. As the focus of many biogeographical hypotheses, physical barriers, environmental gradients, atmospheric and temperature extremes, seasonal, latitudinal and elevational variability, and interactions with other organisms are often key to understanding both the extent and limits of species distributions. On land, vertebrate animals respond in a wide variety of ways to environmental limiting factors, geographic barriers, and the presence of other species. The author's purpose here is to review a small subset of the many ways land vertebrates have responded – and continue to respond – to the geographic template. The author will discuss several bodies of work, which have influenced the development of the field in important ways. However, although biogeography might once have been viewed primarily as an historical science, it is now characterized by the melding of fundamental macroevolutionary and macroecological principles, their associated bodies of theory, schools of thought, and massive amounts of empirical data, now rigorously evaluated in an increasingly integrative, hypothesis-testing framework (Ladle *et al.*, 2015). Most of these biogeographical elements became so influential as a result of the careers, big ideas, and hard work of scores of individuals, working in disparate disciplines. Thus, students of biogeography necessarily must constructively gather information from a variety of sources to glimpse the 'big picture'; it is only relatively recently that textbooks with titles including the term '*Biogeography*' have been published (e.g., Lomolino *et al.*, 2010; this volume). To understand the discipline's foundational concepts, the reader is referred to these texts as a first reference, but then necessarily to the primary literature in geology, geography, earth history, phylogenetic systematics, ecology, and evolution.

The First Vertebrates

Vertebrates first appeared approximately 500 million years ago, during the Cambrian explosion. The first forms were fish-like jawless marine organisms with cartilaginous internal skeletons, and bony, plated, external armor; these were the Ostracaderms. True fish, with bony internal skeletons, and

eventually functional jaws, first evolved more than 450 million years ago in the Ordovician, becoming quite common in the Devonian. These early fish, the Gnathostomes, possessed moveable opposing jaws, teeth, paired appendages, and a modern vertebrate immune system. The development of an opposable and functional grasping jaw (derived from anterior gill support arches), and many additional associated feeding specializations, was a major advance that occurred in the Gnathostome fishes approximately 420 million years ago and allowed these organisms to exploit a broad array of feeding environments, and evolving into possibly as many as 65 000 to 75 000 species (Westneat *et al.*, 2005; Pough *et al.*, 2009), including the Chondrichthyes (cartilaginous fish) and Osteichthyes (bony fish) which are further divided into the Sarcopterygii (lobe finned fish) and Actinopterygii (ray finned fish) of today. The lobe finned fishes include fossil and extant lungfish and coelacanths that we are familiar with today, but it is a pair of fossil taxa, *Eusthenopteron* and *Panderichthys*, that appears most closely related to the series' early tetrapods (e.g., *Tiktaalik*, *Acanthostega*, *Ichthyostega*, *Tulerpeton*; 390–360 mya) that made the evolutionary transition from an entirely aquatic lifestyle to an at least partially terrestrial, weight bearing, upright land vertebrate (Radinsky, 1987; Laurin, 2010).

Vertebrates invaded land at about 350 million years ago, giving rise to many forms we know from extant lineages and extinct fossils; possibly as many as 70 000 vertebrate species have been formally characterized (with tens of thousands more implied by trace fossils and other evidence). The next 10 million years was a period of major evolutionary radiations of amphibians, giving rise to two large groups, the large and robust labyrinthodonts and their slender, delicate relatives, the lepospondyls. Much of the initial Carboniferous and Permian fossil amphibian diversity went extinct at the end of the Permian (although a few lineages survived into the Triassic and one into the Jurassic), and a variety of hypotheses exist to explain how these dominant and diverse forms are related to the amphibians of today (the Lissamphibia: frogs, salamanders, and caecilians; Duellman and Trueb, 1994; Marjanović and Laurin, 2007; Sigurdsen and Green, 2011). Approximately 50 million years later, a lineage of labyrinthodonts evolved the amniotic egg and the ability to reproduce away from water. Together with the evolution of flexible scales composed of keratin, early reptiles were equipped to invade the interior of landmasses, arid environments (Laurin and Reisz, 1997).

Because of the timing of their initial diversification on land, terrestrial vertebrate diversification was initially impacted by the breakup of Pangaea and Gondwana (**Figure 1**), processes that resulted in isolation and unique early radiations of land vertebrates on individual landmasses. At 213 million years ago, the Triassic–Jurassic extinction event resulted in the loss of the labyrinthodont amphibians and most marine reptiles, leaving the majority of terrestrial vertebrate lineages limited to dinosaurs, who subsequently radiated evolutionarily into many of the vacant niches left empty following these extinction events.

As landmasses moved farther and farther apart, their vertebrate faunas became increasingly distinct taxonomically, and biogeographic patterns can be related to habitat types and paleoclimates to the extent that these can be reconstructed. The assumption that early vicariance, or cladogenetic divergence as a result of geological processes (splitting of formerly united species distributions via continental fragmentation and drift) primarily explained dinosaur distributions (Sampson *et al.*, 1998) was challenged by Sereno (1999), who suggested that local extinction and dispersal may have been major 'controls' of dinosaur land distribution, bringing into question the issue of whether a truly cosmopolitan dinosaur fauna ever existed. However, Upchurch *et al.* (2002) demonstrated that major vicariant divisions of dinosaur fauna were all a result of (1) the separation of Asia from Pangaea in the Early–Mid Jurassic; (2) the fragmentation of North America from Gondwana; (3) the separation of Australia (formerly eastern Gondwana) from Africa + South America (western Gondwana); and (4) the fragmentation of Africa from South America during the Early–Mid Cretaceous. Meanwhile, the signature of intercontinental dispersal and subsequent diversification becomes apparent in the fossil record and numerous examples of dinosaur dispersal have been documented (Rowe *et al.*, 2011; De Queiroz, 2014).

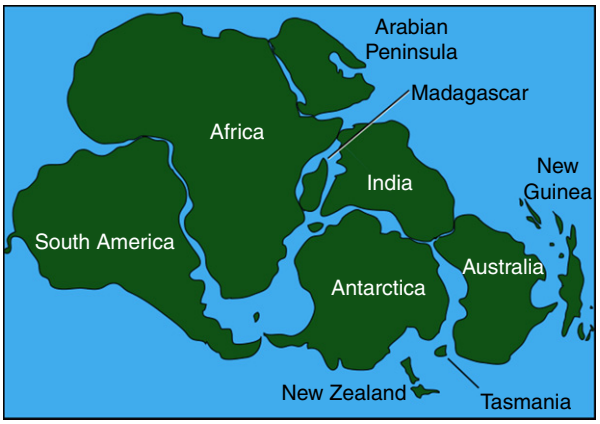

Figure 1 The breakup of the supercontinent Gondwana, 200–180 million years ago, with the outlines of today's major landmasses indicated. Adapted in part from Chatterjee, S., Goswami, A., Scotese, C.R., 2013. The longest voyage: Tectonic, magmatic, and paleoclimatic evolution of the Indian plate during its northward flight from Gondwana to Asia. Gondwana Research 23, 238–267.

Following the Cretaceous–Tertiary (K–T) asteroid impact at 66 mya, the loss of two-thirds of all Earth's diversity, and the extinction of all non-avian dinosaur diversity, a small group of terrestrial vertebrates (small mammals, birds, reptiles, amphibians) remained. In the absence of dinosaur and Mesozoic reptile dominance, birds and mammals soon flourished and occupied the majority of terrestrial niche space. The Paleogene (66–23 mya) marked a period characterized by the onset of many classic terrestrial mammal evolutionary radiations and biogeographic range expansions, presumably in response to the ecological opportunity presented by widespread extinctions of the dinosaurs. These include the sudden and prolific diversification of many clades of today: whales, bats, horses, and primates (Alroy, 1999). Extinctions were selective in some clades in particular areas. For example, marsupials largely disappeared from North America, and Laurasian

multituberculate mammals (a large group that had survived the previous 120 million years) went extinct, as did southern hemisphere Gondwanatherian mammals. Chiropterans, marsupials, and Cetartiodactyla (whales and even-toed ungulates), in contrast, may have diversified and expanded their global distributions in response to the K–T extinction (Bininda-Emonds *et al.*, 2007).

Plate Tectonics, Continental Drift, and the Paleotransport of Vertebrates

As discussed above, plate tectonics, rift formations, and the breakup of Pangaea, Laurasia, and Gondwana (**Figure 1**) had profound impacts on the distribution of a wide variety of early land vertebrate lineages. These tectonic events initially structured vertebrate assemblages, rendering land vertebrate species pools unique and identifiable on a continental scale. For example, as the southern continents successively fragmented, the taxonomically and biogeographically unique faunas became isolated and developed their own faunistic identities as a result of millions of years of isolation coupled with *in situ* evolution and faunal exchanges facilitated by plate collisions and landmass accretions. *Mesosaurus*, for example, was one of the first aquatic reptiles inferred to be a coastal habitat specialist, documented in fossil beds of southern Africa and eastern South America. Part of the celebrated '*Glossopteris*' floral/faunal assemblage, including *Lystrosaurus* (with an Indian, African, and Antarctica distribution) and *Cynognathus* (distributed in South America and Africa), the group has been cited as direct evidence in support of the hypothesis that the southern continents were once joined and that Gondwanan vicariance led to the primary patterns of geographical distribution in terrestrial vertebrates (Laurin, 2010).

Phylogenetic analyses of extant taxa have also been used to provide inference into the question of continental fragmentation and drift as a major initial causal factor for understanding land vertebrate distributions. The lungfishes (Lepidosireniformes) of South America, Africa, and Australia might appear to be an ideal group with a classic Gondwanan distribution; however, recent fossil evidence suggests that this group was formerly widely distributed, with a modern day distribution resulting from widespread extinction subsequent to the breakup of the supercontinents. Despite the many reinterpretations of previously assumed Gondwanan land vertebrate distributions, paleotransport of vertebrates on drifting continental fragments continues to be inferred in modern phylogeny-aided biogeographical inference and involving younger time scales (Bossuyt and Milinkovitch, 2001; Bossuyt *et al.*, 2006; Gamble *et al.*, 2008; Blackburn *et al.*, 2010; Siler *et al.*, 2012; Brown *et al.*, 2016). In a recent review and 'event-based' biogeographic analysis, Sanmartin and Ronquist (2004) demonstrated the surprising result that animals more closely followed order-of-Gondwanan landmass fragmentation predictions than did plants. Other single-taxon analyses have uncovered the apparent result of pure Gondwanan vicariance as a result of the tectonic fragmentation of former supercontinents. For example, Turner (2004) interpreted a phylogenetic analysis and documented distributions of crocodyliform taxa (notably, including both fossil and extant taxa) as evidence for pure Gondwana fragmentation affecting the primary diversification of a major class of vertebrates during the Mid to Late Cretaceous (see also Gamble *et al.*, 2008, for a similar example in geckos).

Vicariance and Dispersal: Theory versus Data

The influential biogeographer Léon Croizat is noted for his unwavering faith in the idea that most of the Earth's disjunct distributions could be explained by the breakup of former supercontinents, leading to isolation, divergence, and the formation of new lineages (vicariance). He famously summarized this with his dictum: "earth and life evolve together" (Croizat, 1962). Motivated and inspired by some of the Planet's most celebrated disjunct distributions, Croizat made major advances in Panbiogeography as he strove to explain shared patterns of endemism and provincialism. How could closely related taxa (species, genera, families) come to occupy separate and isolated geographical ranges on landmasses on either side of the world's major ocean basins? Operating in the absence of rigorous phylogenetic methods or today's sophisticated and time-calibrated estimates of evolutionary relationships, but with an appreciation of the emerging understanding of plate tectonics, Croizat was led to the conclusion that disjunct distributions were the direct evidence of vicariance. Focusing on patterns of endemism and disjunction shared by many unrelated organisms with a simple procedure he termed 'track analysis,' designed to summarize these instances of shared disjunctions, Croizat was convinced that virtually all groups of terrestrial plants and animals arrived at their current distribution by paleotransport on the fragments of former supercontinents. At the time, the standardization of a formal, repeatable method for analyzing distributions was novel and represented a substantial advance over the descriptive and taxon-by-taxon, idiosyncratic biogeographical studies that preceded. Croizat's work also heavily influenced the development of the school of Vicariance Biogeography (Nelson, 1973; Nelson and Platnick, 1981), a dominant perspective in the field for more than 30 years. According to this philosophical perspective, dispersal was virtually dismissed as exceedingly rare or improbable, barely considered except in passing, with the study of dispersal-related biology even ridiculed as being 'unscientific' and considered only by researchers who were prone to fantasy. In much the same way that we now look back at the period in the history of biogeography when workers inferred hypothetical landmasses (such as land bridges) on the basis of current day species distributions as overly simplistic and naively misdirected, an emerging mainstream of biogeographers similarly view Croizat's Panbiogeography and the Vicariance Biogeography school as an interesting but peculiar period in the history of the discipline. In retrospect, how could we possibly have dismissed the possibility (and ignored the evidence) that organisms do naturally disperse long distances, even across massive geographical barriers such as mountain ranges, deserts, and oceans (de Queiroz, 2005; Gillespie *et al.*, 2012)? As Lomolino *et al.* (2010) discuss, the period during which these ideas had mass appeal (1960s through 1980s) marks a time of great sociological and philosophical debate in systematics: a time

in which the impact of many novel contributions was somewhat diminished by strong, domineering personalities, who aggressively pursued winning in debate in order to promote their beliefs. Vertebrates, especially those embodying relative dispersal ability – amphibians, flightless birds, freshwater fish, etc., – figured heavily into this heated discussion.

Patterns: Endemism, Provincialism, Cosmopolitanism, and Disjunct Distributions

The search for explanations of biogeographic patterns – emergent properties of species distributions – inspired the first true biogeographers and contributed directly to the conception of evolution by natural selection (Darwin, 1859; Wallace, 1860, 1876, 1881). As the nineteenth century drew to a close and the newly acquired species distribution data from the age of exploration became available, vertebrate biologists noted a series of conspicuous shared patterns of species distributions. The 'Father of Biogeography,' A. R. Wallace, and noted vertebrate naturalist P. L. Sclater, are generally credited with having defined the major terrestrial biogeographical regions or 'realms' of the planet, among many other distribution patterns (Wallace, 1860, 1876; Sclater, 1858). Chief among these were the recognition of vertebrate endemism, biogeographical provincialism (or regionalism), and range disjunctions, all at varieties of scale.

The discovery and recognition of mammal, bird, amphibian, and reptile species with geographical distributions limited to a particular landmass like a small island (and not occurring anywhere else on Earth) is compelling evidence for the importance of historical events (such as colonization of a far away island by a vertebrate species) and the contribution of isolation to the processes of speciation. For example, the observation that the primate species the Red Slow Loris (*Loris tardigradus*) occurs only on Sri Lanka, that Melanesian Forest Frogs (genus *Cornufer*) are largely endemic and confined to islands of the Southwest Pacific, or that kangaroos and wallabies (marsupial mammals of the family Macropodidae) are limited primarily to the Australian continent, are all examples of the way in which varying taxonomic levels exhibit endemism at different scales. These examples contrast strongly with the nearly worldwide distribution of bats (order Chiroptera), a true case of cosmopolitanism in a terrestrial vertebrate species.

When many species or even an entire biota are influenced by such historical events, the resulting concordant patterns of endemism are often referred to as *biogeographical provincialism* or *regionalism*. Patterns of endemism are concentrated nonrandomly and usually are associated with particular areas. This co-occurrence of many endemic forms is sometimes also associated with particular biotic characteristics. Provincialism is a pattern that informs biogeographers about the significance of geographic barriers and their impact on numerous related and unrelated species. To return to the examples provided above, biogeographic provinces have been defined by isolation of biotas on islands (Bossuyt *et al.*, 2006). As a result of isolation, 12 named primate species or subspecies are endemic to the island of Sri Lanka, for example, and occur nowhere else on Earth (Nekaris and de Silva Wijeyeratne, 2009). Similarly, 95 + % of amphibians native to the Southwest Pacific's island archipelagos (the Solomon Islands, the Bismarcks, Admiralties, and Fiji) are endemic to those landmasses (AmphibiaWeb, 2015) and 90 + % of Australian mammals exhibit concordant distributions, primarily endemic to this landmass (Nowak, 1999).

Empirical Insights into the Biology of Long-Distance Vertebrate Dispersal

Well-known disjunct distributions in which vertebrate geographical ranges are discontinuous and usually divided by a substantial geographical barrier have inspired some of the most conceptually intriguing biogeographical studies and the discipline's most fervent debates. At the heart of these heated debates have been two basic alternate biogeographical hypotheses, namely the interpretation of biotic disjunctions as necessarily the result of ancient vicariance versus the possibility that these patterns lend support for the hypothesis of recent dispersal (e.g., Yoder and Nowak, 2006; Sanmartin and Ronquist, 2004). A third possibility in some systems, the interpretation of a formerly more widespread distribution, followed by extinction of populations or species in intermediate areas, has been invoked in terrestrial vertebrates exhibiting disjunct distributions on continents where climate change associated with glacial retreats caused shifts in major habitat types (e.g., mesic versus xeric forests; Nielson *et al.*, 2001).

The mechanisms of dispersal over marine barriers vary, and some authors have emphasized organismal or ecological traits that render certain vertebrates more prone to active or passive transport (Carlquist, 1965, 1966). For vertebrates capable of surviving exposure to salt water and sun, dispersal is achieved by simply floating and traveling passively with currents (Gerlach *et al.*, 2006). For land vertebrates of low relative dispersal ability and salt tolerance like nonvolant mammals, amphibians, or freshwater fish, the common assumption is the transport of animals on natural flotsam associated with strong storms. These include floating islands (large portions of river banks that have broken free, and floated out to sea), mats of vegetation, and/or log jams and tangled masses of tree trunks, which are often discharged from river mouths following flooding on land (King, 1962; Krause *et al.*, 1997). The occurrence of floating debris fields, coupled to the discharge of large amounts of freshwater, can create stratified freshwater 'lenses' (layers) of freshwater that form above denser salt water, and create temporary freshwater currents – all of which may favor the transport of salt-intolerance terrestrial vertebrates. Such mechanisms have been either directly observed (Censky *et al.*, 1998) or inferred by testing predictions with storm track data, localized flow patterns in the vicinity of river deltas, information from prevailing ocean currents, and phylogeographic data (Measey *et al.*, 2007; Bell *et al.*, 2015). The key to understanding the plausibility and importance of these supposedly rare or 'improbable' events is the simple fact that even seemingly unlikely phenomena may become easier for us to consider when their 'occasional' successful occurrence is multiplied by many millions of years (De Queiroz, 2014).

Several developments have contributed over the last three decades to the unraveling of the dominance of the Vicariance Biogeography paradigm; most of these directly involve

empirical studies of dispersal involving iconic land vertebrates (e.g., Townsend *et al.*, 2011). First, several of the most ardent promoters of this perspective have retired, moved on to other areas of research, or softened their perspectives. Additionally, the development of modern model-based molecular phylogenetic analysis has changed our understanding of the evolutionary relationships of most vertebrate clades, either radically by turning evolutionary trees on their head (e.g., squamate reptiles; Townsend *et al.*, 2004; Losos *et al.*, 2012), or by demonstrating widespread convergent evolution and repeated evolution of vertebrate body form (such as repeated evolution of elongate, limb-reduced/absent snake-like lizards), which misled previous morphological trait-based studies (Reeder *et al.*, 2015). Third, biologists have developed a better understanding of how vertebrates of seemingly low relative dispersal ability actually do achieve overseas dispersal (Carlquist, 1966; McDowall, 2002). Finally, as calibrated molecular divergence date estimation has become more reliable due to advances in methods and collection of large robust multilocus datasets, many vertebrate groups of apparent, ancient Gondwanan origin have simply turned out to be too young. In these instances where disjunct groups on either side of an ocean basin are many millions of years younger than the dated fragmentation of the landmasses in question, an explanation of vicariance becomes intractable.

One such clear case is illustrated by estimation of the split between Old World and New World monkeys. For a vicariance explanation to account for the distribution of these African and American taxa, the divergence between the clades would have to approximate the final separation of Africa and South America (~110 mya). One recent time-calibrated phylogenetic analysis dated their divergence at somewhere between 50 and 26 mya (Springer, 2012), meaning that the ancestors of New World monkeys (now about 55 species) crossed the Atlantic at about 40 mya, much too late to permit the former vicariance scenario.

Ratite birds (the Rheas and Tinamous of the Americas, the Ostriches of Africa, the Emus and Cassowarys of Australasia, and the Kiwis and extinct Moas of New Zealand) are a classic and often invoked case of diversification via vicariance (Cracraft, 1974). Their phylogenetic relationships (a monophyletic clade), the preponderance of flightlessness in most species, and their distributions on separate southern isolated Gondwanan landmasses, has been invoked as a classic case of diversification necessarily resulting from continental-scale vicariance (Craw *et al.*, 1999). Dispersal via powered flight in contrast was comfortably discounted due to the clade's tendency toward large bulky bodies and the inability of extant species to fly. At the center of these assumptions were the giant extinct Moas of New Zealand, which vicariance biogeographers confidently pointed out could not possibly have reached New Zealand by any means other than overland colonization when this island was still connected to Australia and Antarctica. However, a recent phylogenetic analysis using a massive genomic dataset recently has resulted in a major rearrangement of the group's family tree. Together with a analysis of ancestral evolutionary state reconstruction Phillips *et al.* (2010) estimated that flightlessness actually might not have been the ancestral condition in this group, leading to a revised interpretation of multiple recent losses of flight in individual lineages. This opens the door to the very real possibility that the ancestors of these iconic large-bodied flightless birds may have, in fact, dispersed to some of their current locations via powered flight over open oceans – after which they subsequently evolved large body sizes and lost the ability to fly. The case emphasizes the importance of evaluating alternate evolutionary hypotheses in conjunction with biogeographical studies. And, just because many ratite birds are large and flightless today does not necessarily mean that their ancestors were giants, incapable of flight. And once these seemingly 'self-evident' constraints are relaxed (i.e., giant flightless Moas 'obviously' could not have flown to New Zealand), biogeographers can consider the alternate explanations (in this case, dispersal) for ratite Gondwanan distributions previously assumed to have resulted from pure vicariance (Craw *et al.*, 1999; Phillips *et al.*, 2010; De Queiroz, 2014).

Another frequently invoked case of Gondwanan vicariance is the classic case of more than 1600 freshwater cichlid fishes inhabiting southern portions on a number of continents. Because of their distribution and an early branching pattern mirroring the order of fragmentation of Gondwanan landmasses, cichlid fish have been widely accepted as a group, whose distribution arose from Gondwanan vicariance, starting at 135 mya. Friedman *et al.* (2013) presented a combined but independent paleontological and molecular-clock estimate for the time of the clade's origin that soundly rejected the assumed Gondwanan vicariance scenario in cichlid fishes. In this case, both stratigraphic distribution of fossils and the age inferred from a robust time-calibrated analysis of DNA sequence divergences both agreed on a Paleocene (65–57 mya) origin of the group, suggesting a primary role for dispersal in generating the observed distribution of cichlid fish. Although the case of cichlid fish left some questions unanswered (the Friedman *et al.*, 2013, analysis did not include fossil taxa), ichthyologists generally agree that the Rainbowfishes, the Gobies, and the Killifishes are most likely all pure Gondwanan in origin.

Yoder and Nowak (2006) reviewed the entire terrestrial flora and fauna of Madagascar, a celebrated and spectacularly isolated landmass, formerly tucked into the heart of Gondwana (**Figure 1**), and often cited as a prime example of a biota derived from pure vicariance, preventing exchange with African fauna following the separation of the island from this continent 135–125 million years ago. Reviewing all available molecular divergence data the authors concluded that the vast majority of the fauna – including freshwater fish and amphibians with their presumed low relative dispersal abilities – was derived from descendants of more recent (Cenozoic) transoceanic dispersal events from Africa.

Many similar and well-studied vertebrate groups, once widely accepted as clear cases of Gondwanan or Pangaean vicariance by virtue of their modern distributions and presumed poor dispersal abilities, have likewise failed to stand the test of molecular phylogenetics and modern divergence date estimation (Rowe *et al.*, 2010; Townsend *et al.*, 2011; Friedman *et al.*, 2013). Summarizing many of these studies, De Queiroz (2014), with reference to Croizat's dictum, stated: "Earth and life evolve together—except when they don't."

With time and new advances, biogeographers have come to routinely embrace necessarily more sophisticated analytical approaches and much more pluralistic interpretations.

However, the influence of Panbiogeography and Vicariance Biogeography is still felt in curious ways. For example, only recently have probabilistic modeling methods for biogeographic inference been developed with explicit parameters that model long-distance dispersal to a novel area (such as a distant island, not previously or currently occupied by the clade of interest; Ree and Smith, 2008; Matzke, 2013a,b). The assumption is that this methodological shortcoming may be an historical and sociological artifact, dating back to a time when mention of the word 'dispersal' would earn a young biogeographer a swift and public rebuke from a siliverback member of the Vicariance Biogeography school.

Biogeographic Barriers, Interchanges, Gradients, and Filter Zones: Stepping Stones, Conduits, and Corridors

Biogeographic barriers, as discussed above, inspired the scholarship that resulted in the birth of the field and the first articulation of biogeography's first principles (Wallace, 1860). The inferred barriers themselves vary in assumed permeability, from the absolute apparent turnover characterized by Wallace's Line (Huxley, 1868) to the various biogeographic lines that divide the major realms of the planet (Wallace, 1860, 1876; Sclater, 1858). The universality of absolute biogeographic lines has been discussed at length (Mayr, 1944; Simpson, 1977) and is tempered with a wide variety of exceptions (Esselstyn *et al.*, 2010; Lohman *et al.*, 2011; Brown *et al.*, 2013).

The permeability of biogeographic barriers has been studied at length, mostly in the context as the concept was originally defined: impenetrable barriers across which land vertebrate dispersal is limited by marine channels (e.g., freshwater fish or amphibians, believed to be wholly incapable of dispersal over salt water). For example, Esselstyn *et al.* (2010) analyzed taxonomic and phylogenetic evidence for all terrestrial vertebrates with ranges abutting either side of the northern end of Wallace's Line (i.e., Huxley's Modification of Wallace's Line; **Figure 2**) and argued that the immediate area (Palawan Island, and smaller landmasses to the north and south of this elongate corridor) more accurately meets the definition of a biogeographic filter zone and not an absolute biogeographic line or barrier. Classic biogeographic filter or 'transition' zones have been defined by linear island chains such as the Lesser Sunda islands of eastern Indonesia, or the Alaskan Aleutian island chain, stretching between distinct biogeographic provinces (Kricher, 2011; Lomolino *et al.*, 2010). In such systems, as the number of faunal elements from one end of the chain declines successively with distance form the source, the influence and origin of inferred elements from the opposing region increase (**Figure 3**; Carlquist, 1965; Lomolino *et al.*, 2010). Filter zones, whether island chains or matrices of suitable habitat surrounded by inhospitable habitat (such as the 'Sky

Figure 2 The Australasian faunal interchange zone is home to the most celebrated biogeographic lines (funal turnover zones or biogeographic barriers) on the Planet. Wallace's Line, as originally conceived (Wallace, 1860) illustrates the faunal turnover that occurs at the eastern edge of the continental Asian landmass, Sunda Shelf (light blue shading, left). This feature corresponds to the land that was exposed during Pleistocene periods of lowered sea levels. This biogeographic boundary is now recognized as the area of transition between Asian fauna and that of Wallacea, the transitional faunal zone that separates Asian from Australian fauna. Lydekker's Line is the equivalent feature on the Australian Sahul Shelf (light blue shading, right), and Weber's Line represents the geographic point of equivalency or balance between Asian and Australian faunas. Adapted from Mayr, E., 1944. Wallace's Line in the light of recent zoogeographic studies. The Quarterly Review of Biology 19, 1–14; Simpson, G.G., 1977. Too many lines; the limits of the Oriental and Australian zoogeographic regions. Proceedings of the American Philosophical Society 121, 107–120.

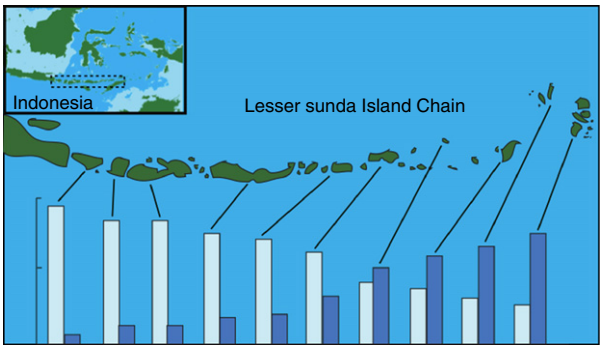

Figure 3 A terrestrial biogeographic filter zone is formed by areas of suitable habitat (such as dry land), separated or surrounded by an inhospitable matrix (sea water). The fauna of the Lesser Sunda islands of Indonesia (inset) illustrate the concept well: a chain of small landmasses separated by ocean channels, with the dispersal abilities of species demonstrated by their successful colonization of more and more distant islands. With dispersal from both ends of the chain of islands contributing to each island's fauna, the proportion of Asian species (light blue) nearly balances that of Australian species (dark blue) on midway through the chain. Adapted from Carlquist, S., 1965. Island Life. Garden City, NY: Natural History Press.

Figure 4 An example of an adaptive radiation in frogs from an island archipelago. Narrow-mouth frogs (genus *Kaloula*) have been characterized as an adaptive radiation, which began as their ancestors invaded an island archipelago (Blackburn *et al.*, 2013). From an inferred terrestrial mainland Asian habitat generalist, the Philippine *Kaloula* evolved into small, ephemeral pool breeding montane species ((a) *Kaloula walteri*), large-bodied open habitat burrowing species ((b) *Kaloula picta*), delicate scansorial shrub-breeding species ((c) *Kaloula conjuncta*), and tree-hole cavity dwelling taxa ((d) *Kaloula kalingensis*). Photographs by the author.

Islands' of the Madrean Archipelago; Manthey and Moyle, 2015) selectively illustrate the variation in relative dispersal abilities of the various taxonomic groups and the degree to which environmental filtering strongly structures community assembly along edges of biogeographic transition zones (Sommer *et al.*, 2014).

Other biogeographic island chains have been viewed as dispersal conduits or suitable habitat corridors, possibly allowing 'stepping stones' dispersal or 'island hopping' from one region to another (Carlquist, 1966). Dispersal conduits between continents and island archipelagos have been identified in empirical studies. For example, Diamond and Gilpin (1983) and Brown and Guttman (2002) (see also Brown and Siler, 2013) identified multiple chains of islands, which have facilitated faunal exchange of amphibians, reptiles, birds, and mammals between the mainland Southeast Asian continent and adjacent island archipelagos (see also Taylor, 1928; Inger, 1954). Comparative biogeographic analyses indicate that these series of terrestrial stepping stones have served as the primary source for mainland colonization of oceanic archipelagos (Brown and Siler, 2013; Brown *et al.*, 2013). The conservation significance of stepping stones and corridors of suitable habitat patches have been broadly discussed in insular terrestrial systems in terms of their importance for long-distance vertebrate dispersal – especially in light of species distributional shifts anticipated under climate warming scenarios as species track suitable habitats (Saura *et al.*, 2014).

Insular Extremes: Spectacular Vertebrates of Isolated Islands and Extraordinary Vertebrate Radiations in Island Archipelagos

Studies of vertebrate island biogeography have involved some of the planet's most interesting and unique forms of life. Three primary phenomena make this so. First, as previously discussed, the inferred origins of vertebrates on Earth's most isolated landmasses capture the imagination of evolutionary biologists and beg for an historical explanation that is inherently interesting – whether an ancient vicariance scenario or an inference of a spectacularly long-distance dispersal event.

Second, because of extreme isolation and the unique environments of islands, island vertebrates have evolved in many cases into bizarre forms, with phenotypic novelty accentuated and exaggerated by millions of years under unique selective regimes. Celebrated examples include island gigantism in tortoises, birds, and shrews, and at the other end of the spectrum, miniaturization in formerly large-bodied lineages like mammoths. Other examples of the 'Island Syndrome' involve inferences such as the secondary loss of flight in numerous lineages of birds after having arrived on islands, or other novel differences in life history, reproduction, demography, or behavior of island populations as compared to closely related species on the mainland (Adler and Levins, 1994).

Third, the uniquely replicated environments and at times unutilized resources (i.e., simplified food webs lacking top predators) of insular systems appear to have had an extraordinary impact on the process of diversification in vertebrates of island archipelagos. A disproportionate portion of the Earth's well-studied and truly spectacular adaptive radiations are found in islands or island-like archipelagos, and include highly celebrated clades, such as Darwin's finches in the Galapagos (Grant and Grant, 2008), the Hawaiian honeycreepers (Lerner *et al.*, 2011), New World direct-developing frogs (Heinicke *et al.*, 2008), the mantelid frogs of Madagascar (Vieites *et al.*, 2009), the great cichlid fish radiations of African rift valley lakes (Turner, 2007), lizards of the genus *Anolis* (Losos *et al.*, 1998; Mahler *et al.*, 2010), and the markedly diverse rodents,

narrow-mouth frogs, and forest frogs of the Philippines (Jansa *et al.*, 2006; Blackburn *et al.*, 2013; Brown *et al.*, 2015; **Figure 4**).

As such, it should be no surprise that islands not only spawn the big radiations, but they also inspire the big ideas. The geographic setting for much of our current speciation theory was the island archipelagos of the Pacific (Darwin, 1859; Wallace, 1860; Mayr, 1942), and some of evolution and ecology's most conceptually compelling, classic ideas were first conceived through the study of organisms on islands. These include topics such as equilibrium biogeography theory (Macarthur and Wilson, 1963), community assembly rules (Macarthur and Levins, 1967), adaptive radiation (Glor, 2010), ecological opportunity (Mahler *et al.*, 2010), evolution of supertramps (Toussaint *et al.*, 2013), taxon cycles (Wilson, 1961), and the Earth's great speciators (Diamond *et al.*, 1976; Moyle *et al.*, 2009). The importance of insular systems for development of conceptual models of processes of evolutionary biology cannot be over-emphasized (Vences *et al.*, 2009; R. Brown *et al.*, 2013; J. Brown *et al.*, 2014), and the study of land vertebrate biogeography historically has provided the inspiration behind the study of the Earth's most iconic island systems.

Future Prospects

The study of land vertebrate biogeography is at a crossroads, suggesting a synthetic paradigm shift has already begun with the availability of genomic data, the conceptual merging of traditions of historical versus ecological biogeography, and dampening of oscillations of a philosophical pendulum characterizing a history of debate between vicariance versus dispersalist perspectives. Although among the major branches of the Tree of Life the biodiversity of land vertebrates is comparatively well known, their distributions are less well documented, and an alarmingly large proportion of our understanding of mammal, bird, amphibian, and reptile distributional limits are approximations based on centuries-old, undocumented, or unverified observational data. This creates a challenge of great urgency for biogeographers charged with biotic inventories, surveys, and greatly needed follow-up surveys, and represents a major conservation concern in the face of species distributional shifts anticipated as a result of climate and other environmental change. Nevertheless, modern trends in the field of biogeography indicate that increasingly multidisciplinary approaches, massive integrative datasets, extensive collaboration, and increasingly global coordination and cooperation – where once competition prevailed – are becoming standard practice in the research programs of most vertebrate biogeographers. Because, relative to other groups, vertebrates are so well studied, with many aspects of their phenotype, genotype, and ecological characteristics understood by biologists, land vertebrates promise to serve as the model for biogeographers interested in studying integrated organismal biology through the application of multiple data streams.

Environmental Dynamics Affecting Evolutionary Processes and Biogeographic Patterns

Biogeographic patterns, as we observe them today are driven by current environmental settings interacting with influences from past abiotic environments as well as the characteristics and evolutionary history of current and ancient biotas (Ricklefs, 2004, 2006). The abiotic environment selects for certain biotic characteristics (traits), which enable species to utilize the prevailing environmental conditions in a certain habitat. The evolution of specific morphological, physiological, and behavioral traits enables species to occur even under environmental conditions, which are hostile for most other species (e.g., succulent or xeromorph leaf structures as an adaptation to perpetually dry conditions). Assuming that abiotic environmental conditions are the major shaping force of species' characteristics, species which co-occur in a certain habitat should evolve similar characteristics to cope with the prevalent environmental conditions (Osborn, 1902). In other words, environmental selection should enhance trait similarity among co-occurring species. Prominent examples for trait similarity are the independent evolution of giant rosette plants in tropical alpine environments, for example, on Hawaii, the Canary Islands, and in tropical alpine ecosystems of South America and Africa, or the vicariant evolution of succulence in Cactaceae in North and South America and Euphorbiaceae in Africa, Europe, and Asia. Indeed, biomes of the world can be characterized by species characteristics which evolved independently in different phylogenetic groups (Schroeder, 1998, e.g., giant rosette plants **Figure 1**), i.e., biome-specific traits such as xeromorphic leaves in Mediterranean ecosystems from the Chaparral in California, the Macchia in the Mediterranean basin, and the Fynbos in South Africa, are found in very different geographic regions of the world but under comparable abiotic environmental conditions (De Micco and Aronne, 2012). Thus, convergent traits selected for by similar

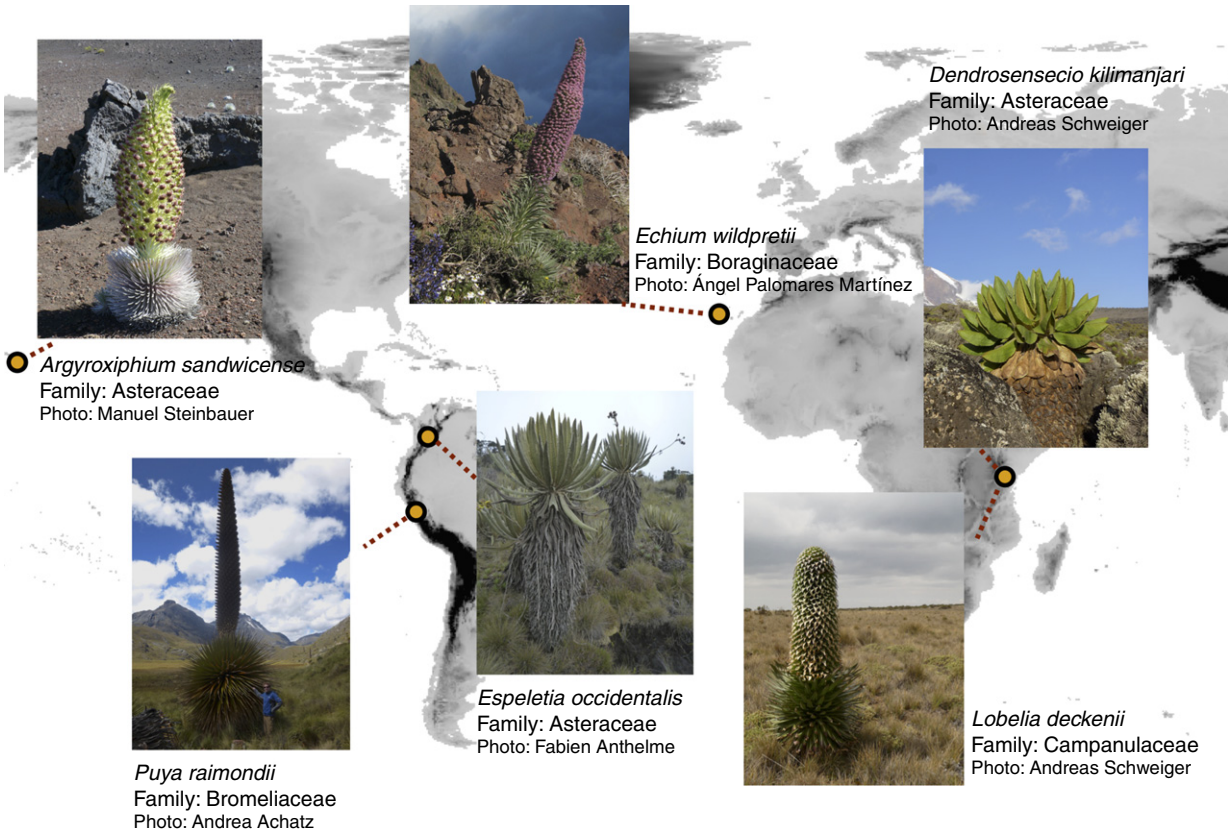

Figure 1 Giant rosette plants have independently evolved as adaptation to environmental conditions in (sub-)tropical high-elevation ecosystems.

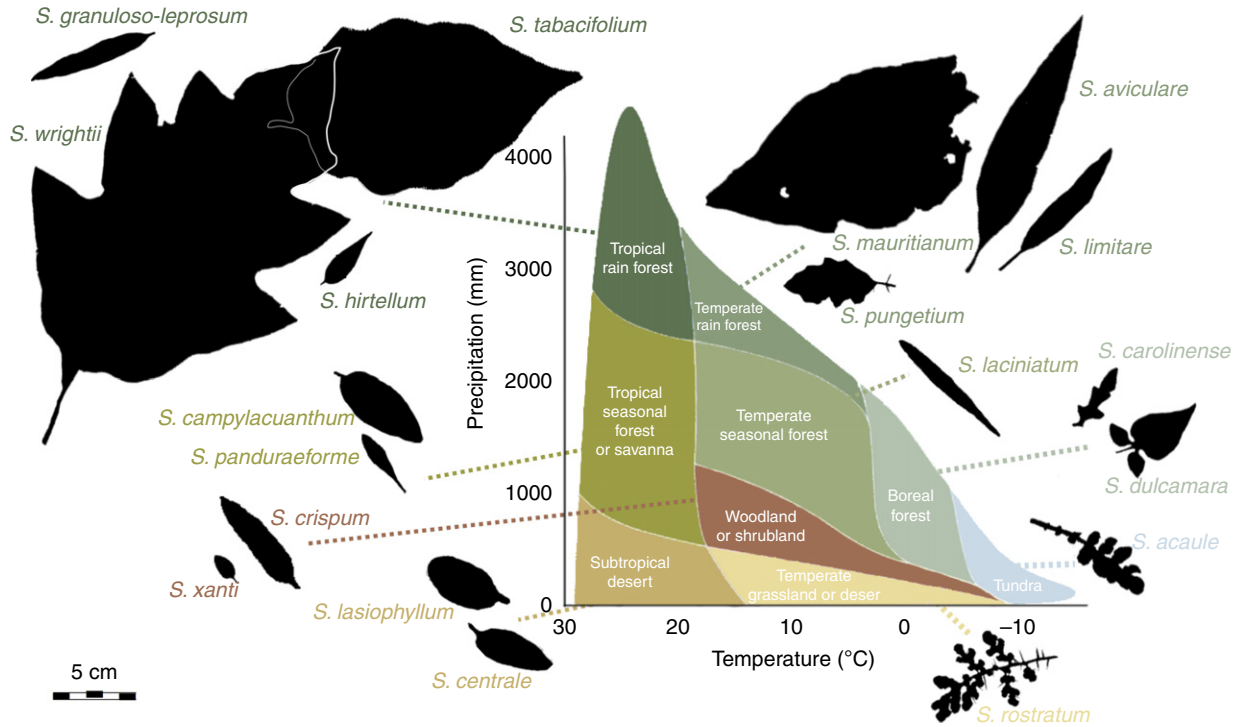

Figure 2 Leaf size and shape of closely related species (all genus *Solanum*) change as adaptations to environmental characteristics (illustrated here using the biome-classification proposed by Whittaker (1975)). Leaves were scanned from herbarium records.

environmental conditions are an impressive demonstration of the influence of environmental conditions on species characteristics. On the other hand, different environmental conditions in the different biomes of the world can lead to a high variety of morphological traits in closely related species (see Figure 2 for the genus *Solanum*, Solanaceae).

Although abiotic environmental conditions seem to shape large-scale patterns of species characteristics, interactions between species co-occurring in the same environment have to be assumed to be of similar importance for species trait evolution. In theory, two coexisting but very similar species inhabiting the same habitat should rapidly diverge or face extinction by competitive exclusion (Begon *et al.*, 2006). Thus, competition between similarly equipped species for the same resources has to be seen as an opposing force to environmental selection (MacArthur and Levins, 1967). Indeed, there are a number of examples of trait divergence in co-occurring species (e.g., *character displacement*, Brown and Wilson, 1956; Beans, 2014).

Character displacement driven by competition is, however, only one among many biotic mechanisms driven by the coevolution of species. Examples of species interactions affecting evolutionary processes include a variety of predator–prey or herbivore–plant interactions including the loss of herbivore defense mechanisms under the absence of herbivores on islands (Bowen and Van Vuren, 1997; Irl *et al.*, 2014). Species interactions and coevolution are suggested to be themselves strong drivers of evolutionary dynamics (*Red Queen* phenomenon, Van Valen, 1973).

Besides antagonistic interactions shaping species trait evolution, synergistic (mutualistic) interactions strongly affect the evolution of traits among coevolving species. These synergistic interactions among species were underestimated in the past but are nowadays believed to be a major shaping force of species trait evolution (Guimarães *et al.*, 2011). One of the most prominent examples of mutualistic interactions driving trait evolution of interacting species are the numerous very specific pollinator–plant interactions which are known for numerous orchid species (e.g., with orchid bees *Euglossini*, Roubik and Hansen, 2004). Coevolution driven by mutualistic interactions may results in visible spatial patterns of biotic organization like the *devil's gardens* in the Amazonian rainforest where ants living inside one specific tree (*Duroia hirsute*) kill all competitive vegetation in the surrounding, resulting in distinct clear cut patches in the otherwise dense tropical rainforests (Frederickson *et al.*, 2005).

In summary, environmental conditions in combination with synergistic and antagonistic biotic interactions shape evolutionary dynamics and biogeographic patterns. However, these evolutionary process and the resulting patterns are strongly influenced by the geographical context, which changes with time. Particularly plate tectonics as well as geomorphological events may alter geographic isolation and leaves its legacy in current distributions and characteristics of biota (Gillespie and Roderick, 2014). In addition, prevalent abiotic conditions of a certain environment are not temporally stable but vary strongly over time, especially on time scales that are relevant for evolutionary processes (Fernández-Palacios *et al.*, 2011). Thus, ecosystems have to be considered as complex adaptive systems, in which the current spatial arrangement of biotic elements (i.e., species) and their characteristics are the result of nonlinear system dynamics affected by

past environmental conditions and the ecological response to these conditions (Gell-Mann, 1994; Levin, 1998). Thus, causal drivers for current patterns of species distribution and trait characteristics may have time lags spanning from decades (Aggemyr and Cousins, 2012) to even millions of years (Kissling *et al.*, 2012).

Mechanisms, Structures and Scale Dependence of Biogeographic Patterns

Biogeographic patterns have fascinated scientists since the time of the early naturalists such as Alexander von Humboldt, but general interest of humans in these ecological patterns likely dates back several thousand years to the early human hunters and gatherers (Lomolino, 2001). Numerous ecological patterns were described since then at various spatial scales ranging from local patterns such as the above-mentioned devil's gardens to global patterns such as the latitudinal gradient of biodiversity. However, the description of biogeographic patterns is just the first step to understand the underlying, often invisible ecological processes driving the observable patterns. The understanding of processes causing biogeographic patterns is one of the most fundamental aims of ecologists and evolutionary biologists (Rosenzweig, 1995).

Processes driving ecosystem functioning which then result in observable biogeographic patterns strongly vary on temporal and spatial scale. It has long been suggested that procesess driving small-scale patterns act fast whereas processes driving large-scale patterns act over longer time periods (Brooks, 1988). Under this notion, biogeographic patterns emerging at continental scales can be adequately explained by long-term evolutionary processes such as speciation and extinction whereas patterns emerging at the community level can be best explained by short-term ecological processes or assembly rules acting at the population level (Cracraft, 1994). Biogeographic patterns and the underlying ecological processes have been studied for decades on distinct spatial and temporal scales without considering cross-scale interactions. However, ecological systems are complex with feedbacks between different hierarchical levels of organization and patterns emerging at the observed scale may be the result of mechanisms operating at different, unobserved scales (Levin, 1992; Gaston, 2000; see **Figure 3**). The importance of cross-scale interactions of ecological processes to understand biogeographic patterns across scales and, thus, whole ecosystem functioning are now increasingly recoginzed (c.f. Gunderson and Holling, 2002; Murphy *et al.*, 2007) but the study of cross-scale interactions is still underrepresented in ecological research.

Besides the overwhelming range of spatial and temporal scales on which ecological systems are observable, the scale of organisms themselves is impressive. Organismic body mass spans more orders of magnitude than the scale differences between the earth and the entire galaxy (from small microorganisms with 10^{-13} g to large plant species (10^{8} g), West and Brown, 2005). The scale of observation, thus, plays a crucial role when identfing biotic patterns and underlying explanations (Gaston, 2000). In addition, grain of observation and size of the study area may strongly influence observations (Rosenzweig, 1995; Steinbauer *et al.*, 2012). To sum it with Hutchinson's words, *"The concepts of scale and pattern are ineluctably intertwined"* (Levin, 1992).

Fundamental Evolutionary Patterns in Biogeography

Evolutionary processes drive fundamental biogeographic patterns on various organizational scales ranging from patterns in body sizes, for example, Bergmann's rule (i.e., an increase in body size with decreasing latitude), the distribution of life forms such as the latitude–elevation relationship of alpine treelines (Körner, 2012) or spatial patterns in species range sizes, for example, Rapoport's rule (i.e., increase of range size with decreasing latitude) and Stevens' rule (i.e., increase of elevational range with elevation, Stevens, 1992) to spatial

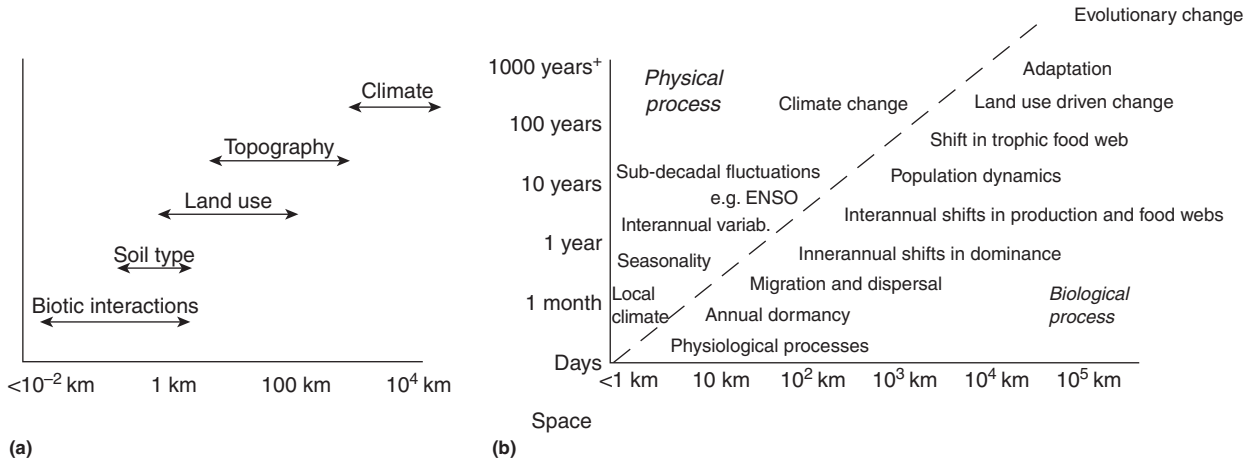

Figure 3 Schematic illustration suggested for processes and drivers operating at different spatial and temporal scales (a) adapted from Levin, D. A., 2003. patterns in the structure of whole communities (i.e., species richness) such as the latitudinal diversity gradient (i.e., an increase of species richness toward the equator, Mittelbach *et al.*, 2007) and the elevational diversity gradient (i.e., an often complex pattern of species richness and elevation; Sanders and Rahbek, 2012). The following text and corresponding **Table 1** highlight some of the most prominent biogeographic patterns. None of the discussed causal mechanisms are uncontroversial. We classify the patterns according to their geographic origin into patterns based on latitude, elevation as well as island-specific phenomena as well as according to the affected biotic traits: species richness, morphology, and geography (including species dispersion and isolation).

Latitudinal Patterns

Latitude might be considered the single most prominent environmental gradient for species-related biogeographic patterns found on this planet. Indeed, a variety of theories exist that describe how species diversity, body size and body coloration, range size, or life forms vary with latitude. However, in many cases the mechanistic processes lying behind this latitudinal effect on the features of life are still unclear, leading to controversial and sometimes also contradicting explanations (Steinbauer, 2013). In the following we present some of the most noteworthy latitudinal patterns.

In our current world, most species are found in the tropics, while species richness decreases toward the poles. This phenomenon – already observed by Charles Darwin and Alfred Russel Wallace – has been termed the latitudinal diversity gradient (Mittelbach *et al.*, 2007) and is a general biogeographic pattern throughout a wide range of taxa (Hillebrand, 2004). Initially a high climatic stability in the tropics when compared to temperate regions has been suggested to enhance diversification (Wallace, 1878) either by higher specialization (Janzen, 1967) or coevolution (Schemske *et al.*, 2009) of tropical species, leading to the observable latitudinal gradient in species richness. However, empirical evidence of considerable climatic fluctuations in tropical regions challenges these hypotheses about the underlying environmental drivers of this biogeographic pattern (Mittelbach *et al.*, 2007). Not climate stability but rather climatic similarity to past environmental conditions has been proposed as an alternative explanation (Fine and Ree, 2006). The ancestors of current biota evolved under much warmer conditions than today. The adaptations to prehistoric warmer environments are suggested to be phylogenetically conservative (niche conservatism). As a consequence more species survived in the warm tropical climates whereas prehistoric climatic cooling in the higher latitudes lead to higher species extinctions and, thus, to lower species diversity (Wiens *et al.*, 2010). Another alternative explanation for this prominent biogeographic pattern is the increased availability of energy and thus, resources in the tropics compared to higher latitude which might enable the coexistence of more-individuals in tropical regions (Evans *et al.*, 2008), speed up evolutionary dynamics (Allen and Gillooly, 2006), or set a higher carrying capacity for species (Rabosky, 2014). Many of these explanations are not mutually exclusive, but the ongoing discussion shows the complexity when inferring processes responsible for observable patterns.

Morphological traits of species show distinctive changes along latitudinal gradients including species body size, size of species extremities, and species coloration. One of the most prominent, latitudinal patterns related to species morphology is an increase of body size with increasing latitude, named *Bergmann's rule* (Bergmann, 1847). In contrast to the latitudinal diversity gradient with many competing mechanistic explanations, this latitudinal pattern is related to species thermoregulation. The proposed reason is based on the simple biophysical assumption that larger animals have smaller surface-to-volume ratios than small ones and thus, require less energy for thermoregulation (McNab, 1971). This pattern is, however, only true for endotherms, for example, birds (Meiri and Dayan, 2003) and mammals (Ashton *et al.*, 2000), whereas ectotherms show unclear body size patterns, which either confirm or contradict this pattern or show no relation at all along latitudinal/elevational gradients (Shelomi, 2012).

The energy balance of ectotherms is strongly linked to body coloration (*thermal melanism hypothesis*, Clusella-Trullas *et al.*, 2007) which in turn is linked to body size (e.g., Schweiger and Beierkuhnlein, 2015 for Carabids). Thus, interactions of two thermoregulative, morphological traits varying with latitude, namely body size and coloration, may be one explanation for the inconclusive latitudinal patterns of body size in ectotherms. Thermoregulatory control mechanisms are also assumed to drive the increase of species extremities with decreasing latitude, which is observable, for example, for foxes (Genus *Vulpes*) or hares (Genus *Lepus*) and conceptualized in *Allen's rule*. Changes in body size, length of extremities, or coloration are not only observable along latitudinal but also elevational gradients, where thermoregulation is equally important.

The observed pattern that species' range size increases toward the poles has been termed *Rapoport's rule* (Stevens, 1989; Gaston *et al.*, 1998). There are indications that Rapoport's rule is restricted to the Northern Hemisphere (Rohde, 1996; Ruggiero and Werenkraut, 2007). However, the generality of this biogeographic pattern is highly controversial and still bears a lot of discussion.

Besides species latitudinal ranges, species elevational ranges have the tendency to change along latitude which is conceptualized in *Janzen's rule*. In 1967, Daniel Janzen hypothesized that elevational ranges of species (as a proxy of their thermal tolerance) increase from the tropics toward the poles (Janzen, 1967). He attributed this phenomenon to increasing seasonality along the latitudinal gradient. Because tropical species experience only little temperature variation throughout the year, it is advantageous for them to specialize their niche, i.e., develop small thermal amplitudes. In contrast, species at higher latitudes experiences a wide range of temperatures at any given location owing to the seasonal climate. For these species it is therefore necessary to develop a wide thermal niche in order to persist. As a consequence of higher species packing per unit elevation (or area), this seasonality-driven mechanism is used to explain hotspots of species richness in the tropics compared to higher latitudes. Support for this pattern has been found for ectotherms (Ghalambor *et al.*, 2006) and interestingly for vertebrates (McCain, 2009a), although recent findings suggest that seasonality dependence is altered by the species' life stage and physiology (Sheldon *et al.*, 2015).

Table 1 Selected spatial biogeographic patterns, important explanations, and controversies. References are not necessarily the authors first describing a pattern but often key reviews or summaries

		Name	*Pattern*	*Reference*	*Explanations*	*Discussions*
Latitude	Species richness	Latitudinal diversity gradient	Species richness decreases with latitude	Mittelbach *et al.* (2007), Fine (2015)	Climatic stability (Wallace, 1878) Diversity begets diversification (Van Valen, 1973; Gillooly *et al.*, 2004) Environmental fluctuations (Janzen, 1967) Niche conservatism (Wiens and Donoghue, 2004) More-individuals hypothesis (Wright, 1983; Evans *et al.*, 2008) Metabolic theory of ecology (Brown *et al.*, 2004) Species carrying capacity/energy (Rabosky, 2014)	Different nonexclusive explanations (Mittelbach *et al.*, 2007; Kraft *et al.*, 2011; Steinbauer, 2013; Harmon and Harrison, 2015)
	Species morphology	Bergmann's rule	Body size increases with latitude	McNab (1971)	Optimal surface-to-volumes ratio for thermoregulation (Bergmann, 1847) Dispersal capacity – energy relation (Blackburn and Hawkins, 2004)	Restricted to endotherms, ectotherms show unclear pattern (Mousseau, 1997)
		Allen's rule	Appendage increase with temperature	Allen (1877)	Thermoregulation	Many exceptions and little empirical support (Nudds and Oswald, 2007)
		Color related patterns	Yellow intensification of pollen with UV radiation Increasingly light-colored ectotherms with temperature	Stevenson (1985), Clusella-Trullas *et al.* (2007), Flenley (2011)	Yellow colors protect DNA from UV radiation induced mutations (Flenley, 2011) Thermoregulation in ectotherms (Clusella-Trullas *et al.*, 2007; Schweiger and Beierkuhnlein, 2015)	Colors often adapted to avoid visual detection or may serve other purposes
	Species geography	Rapoport's rule	Species' range size increases with latitude	Stevens (1989), Gaston *et al.* (1998)	Increase in niche width with latitude due to climatic fluctuations (Janzen, 1967; Stevens, 1989) More competition in species rich communities (Brown, 1995)	Only Pale- and Nearctic phenomenon (Rohde, 1996; Ruggiero and Werenkraut, 2007)
		Janzen's rule	Elevational range of species decreases toward the equator	Janzen (1967)	Increasing seasonality toward the poles results in larger thermal amplitude for a given high latitude species compared to tropics	Some ectotherm lineages show this pattern (Ghalambor *et al.*, 2006), unresolved for plants
		Alpine treeline	Subtropical double-maxima in upper limit of the arboreal growth form	Körner (2012)	Common isotherm seasonal mean temperature of 6 °C (Körner and Paulsen, 2004)	Islands show only a single maximum (Irl *et al.*, 2015)
Elevation	Species richness	Elevational richness gradient	Species richness peaks at mid elevations	Sanders and Rahbek (2012)	Mid domain effect/range overlap (Colwell *et al.*, 2004)	Lack of knowledge (McCain, 2009b), Likely no single

Table 1 Continued

		Name	*Pattern*	*Reference*	*Explanations*	*Discussions*
					Species-area relationship (Rosenzweig, 1995) Warm and wet climates (McCain, 2009b) Species interactions (Anthelme and Dangles, 2012)	mechanism (Pau *et al.*, 2012; Sanders and Rahbek, 2012)
	Species geography	Stevens' rule	Increase of species' ranges with elevation	Stevens (1992)	See Rapoport's rule	
		Mountain endemism	High percentages of endemic species on mountaintops	Steinbauer *et al.* (2012)	Isolation enhances speciation (Sky islands; Steinbauer *et al.*, 2013; Antonelli, 2015) Lower climate change velocity in mountains supports species survival (Sandel *et al.*, 2011)	Isolation not always increasing with elevation
Islands	Species morphology	Island rule (Island dwarfism/ gigantism)	Small animals colonizing islands tend to become larger, while large ones tend to become smaller	Lomolino *et al.* (2013), Carlquist (1967)	Absence of large predators on islands may support larger body sizes of smaller species (missing selection) Limited resource availability may select for small individuals	Clade-specific pattern, not general rule (Meiri *et al.*, 2008)
		Island woodiness	Herbaceous lineages evolve woody life forms on islands	Carlquist (1974), Lomolino *et al.* (2013)	Adaptation to low seasonality/frost (Carlquist, 1974)	Mechanism not really understood
	Species geography	Loss of dispersal ability after establishment on isolated islands	Species lose dispersal ability after establishing on islands	Darwin (1859), Carlquist (1967), Carlquist (1974)	High dispersal capacity enhances chance of being swept off the island (Carlquist, 1967; Gillespie *et al.*, 2012)	Lavergne *et al.* (2004), Vazacová and Münzbergová (2014)
		Shifts in plant reproduction	Species change plant reproduction after establishing on islands		Adaptation to low seasonality/frost (Carlquist, 1974) Adaptation to missing herbivores	
		Progression rule	Biota colonize younger islands after older islands	Funk and Wagner (1995), Roderick and Gillespie (1998)	Newly formed islands colonized from older existing ones (see e.g., Bess *et al.*, 2013) Priority effects promote early arriving species (Fukami, 2015)	Exceptions (Gohli *et al.*, 2015) and colonization history often more complex (Macías-Hernández *et al.*, 2013)
		Taxon cycle	Repeated range expansions and contractions of lineages in the order of 10^6 years, taxa initially colonize coastal habitats, but later adapt to highland conditions	Wilson (1959), Ricklefs and Bermingham (2002)	Coevolution with enemies of pests (Ricklefs and Bermingham, 2002)	Causal mechanisms under debate

Another, in the historical context of biogeography very prominent latitudinal pattern tackles the upper elevational range limit of tree species, which strongly decreases toward the poles. The *alpine treeline* is the fundamental limit of the arboreal growth form (arguably the most dominating life form in Earth's vegetation) and marks the transition from tree-dominated vegetation to treeless alpine scrub or grassland (Holtmeier, 2009; Körner, 2012). The alpine treeline demonstrates a nontypical latitudinal pattern, expressing its maximum elevation in the subtropics of the Northern (Miehe *et al.*, 2007) and Southern Hemisphere (Hoch and Körner, 2005) both around 4800–4900 m a.s.l. From the subtropical double-maxima, treeline elevation decreases toward the poles but also toward the equator (Hermes, 1955; Troll, 1961). In contrast, due to lower seasonality and cloud-induced lower solar radiation, treeline elevation on islands shows only a single maximum near the equator (Irl *et al.*, 2015). The treeline is formed by a wide range of different tree species (deciduous, coniferous, evergreen broadleaved) but a uniform thermal limit (seasonal mean temperature of approx. 6 °C, Körner and Paulsen, 2004) has been suggested for the treelines worldwide, which is independent of phylogenetic relationships, trait evolution, and biogeographic features and thus, might present a general explanation for this global, biogeographic pattern (Körner, 2012).

Elevational Patterns

In many respects elevation can be considered as the vertical representation of the (horizontal) latitudinal gradient (Lomolino, 2001). Thus, many concepts that apply to latitude have been transferred or adapted to elevational gradients. Elevational gradients are fundamental in shaping Earth's current species richness and have substantially contributed to the evolution of Earth's outstanding diversity of species and life forms. However, as is the case for latitude, elevation integrates a wide range of environmental features (e.g., temperature, precipitation, solar radiation, cloudiness, atmospheric pressure, etc.), making it quite difficult (and often impossible) to determine the actual underlying drivers and mechanisms.

Similar to the latitudinal patterns in species richness, the number of co-occurring species also shows distinct changes along elevational gradients. Species richness tends, in general, to show a mid-elevation maximum, even if a decline in species richness with elevation was assumed until the 1990s (McCain, 2009b; Karger *et al.*, 2011). In addition, the isolation of high elevation ecosystems is assumed to cause island-like situations leading to high ratios of unique endemic species ('islands in the sky,' Steinbauer *et al.*, 2012, 2013). Protection from high UV radiation may cause more yellow pollen at high elevations (Flenley, 2011) and more generally, any change in the environment along elevational gradients may result in characteristic trait compositions (like the common decrease in growth height in ecotypes of one species with elevation).

Species ranges sizes also change along elevational gradients – conceptualized in *Stevens' rule* (Stevens, 1992). Stevens' rule can be seen as an extension of Rapoport's rule to elevational gradients (i.e., a thermal gradient comparable to the latitudinal gradient). Stevens' rule has been documented for a wide range of taxa such as butterflies in the USA (Fleishman *et al.*, 1998) or orchids on the island of La Réunion (Jacquemyn *et al.*, 2007). Similar to Rapoport's rule, support for Stevens' rule is fragmental and the generality of this rule is debated.

Island-Specific Phenomena

Islands are considered nature's 'test tubes' (Losos and Ricklefs, 2009), acting as model systems for the development of a wide array of fundamental theories in ecology, biogeography and evolution (e.g., Darwin, 1859; Wallace, 1880; MacArthur and Wilson, 1967; Whittaker *et al.*, 2008). In addition, islands play an important role in the conservation of global biodiversity, not because of their exceptional species richness (Kreft *et al.*, 2008) but owing to their high degree of endemism (Kier *et al.*, 2009). Due to island-specific features such as small area, isolation and genetic impoverishment, islands are particularly vulnerable to land use change (Caujape-Castells *et al.*, 2010), invasive species (Kueffer *et al.*, 2010), and climate change (Harter *et al.*, 2015). For these reasons, the evolutionary patterns found on islands deserve a special focus, as we would like to demonstrate in the following.

Islands are ecosystems surrounded by a matrix inhospitable for terrestrial biota (Whittaker and Fernández-Palacios, 2007). Particularly studies on volcanic oceanic islands have stimulated the development of novel theories and concepts which have been successfully transferred to other systems such as inland lakes, caves, coral reefs, habitat fragments, or continental mountain systems. In the following, we would like to present and discuss four important features related to the geography and morphology of island taxa: island dwarfism and gigantism, island woodiness, dispersal capacity loss of island species, and the taxon cycle.

One of the most striking patterns related to the morphology of island animals is the island dwarfism and gigantism. The body size of island species (esp. animal species) typically becomes much larger or smaller than the body size of their closest relative on the continent, ultimately reaching an optimum size dependent on island-specific features (Lomolino, 1985; Lomolino *et al.*, 2012). This phenomenon has been observed in a wide range of different taxa (non-volant mammals, bats, passerine birds, snakes, and turtles, Lomolino, 1985). Both features are often referred to as the *island rule* (Van Valen, 1973; Lomolino, 1985). The island rule is particularly pronounced in paleo-endemic species, highlighting the evolutionary effect of time being isolated from potential predators and competitors (Lomolino *et al.*, 2013). However, recent studies indicate that the island rule is only clade-specific and not a general rule, if phylogenetic measures are applied (Meiri *et al.*, 2008).

Whereas animals are likely to get either smaller or larger on islands, plant species tend to get woody. The phenomenon is conceptualized under the term *island woodiness*. Shrubby or tree-like growth forms often characterize endemic plant species on oceanic islands, although they originate from herbaceous lineages (Carlquist, 1974). The phenomenon of island woodiness (or secondary woodiness) has been widely observed in many different genera throughout many oceanic island archipelagos, for example, the genera *Rumex* and *Sonchus* on the Canary Islands, *Echium* on the Canary Islands, Madeira, and

the Cape Verdes (Lens *et al.*, 2013), *Opuntia* and *Scalesia* on the Galapagos Islands (Hamann, 2001), the silversword alliance of Hawaii (Baldwin, 1997), or in the genus *Dendroseris* (or 'tree lettuces') of the Juan Fernández Islands (Moreira-Muñoz *et al.*, 2014). The common explanation for this ecological pattern is strongly related to the environmental conditions that characterize oceanic islands. Due to the low seasonality on oceanic islands adaptations to winter frost are not a competitive advantage. Thus, plants face an evolutionary advantage if they do not dieback or cease photosynthetic activity during parts of the year to avoid frost but rather produce biomass throughout the whole year. Thereby, woody plant tissue is advantageous because the initial high investment into the assimilation of carbon results in stable and durable structures with competitive advantages over herbaceous and especially annual species (Carlquist, 1974).

Besides the distinct effects of island features on plant and animal morphology, it also limits the dispersal ability of island endemic species. Long-distance dispersal often associated with nonstandard events (e.g., storms, oceanic rafts, etc.) is a prerequisite for biota to colonize oceanic islands in the first place (Heleno and Vargas, 2015). However, poor dispersal ability is a characteristic feature of endemic species on oceanic islands (Carlquist, 1974). Flightless birds, for example, the dodo of the Mascarenes (Livezey, 1993) and many species of the avifauna of New Zealand (Duncan and Blackburn, 2004), or poor dispersing plant species (Carlquist, 1967) are typical examples. Several explanations have been presented arguing why endemics are poor dispersers. On a spatially restricted island surrounded by an unfavorable environment the production of dispersal agents (diaspores) with high dispersal capacity would result in most passively dispersed diaspores landing in the ocean (Carlquist, 1967). Thus, the production of high dispersal diaspores is not a successful strategy for the proliferation of a species, resulting in disadvantages in terms of energy and competition. Further, long-term climatic stability on islands was suggested as one reason why good dispersal capacity is not a necessary trait for survival, when compared to more dynamic continental systems (Cody and Overton, 1996).

The *taxon cycle* (Wilson, 1959) is one of the key models implementing changes on evolutionary rates in an island biogeographical context. This conceptual idea initially used to explain patterns of diversity in ants on islands, suggests that the ant species successfully colonizing islands in Melanesia tend to be generalists adapted to marginal open habitats (Wilson, 1959). With time these generalist species tend to shift from marginal to forest habitats due to adaptation and specialization (Wilson, 1959). Extinction in the marginal habitats paves the way for a new wave of generalist colonizers (Pigot *et al.*, 2012). The cycle is suggested to reoccur about every 10^6 years (Ricklefs and Bermingham, 2002). Similar patterns have been observed for a wide range of taxa, for example, passerine birds (Jønsson *et al.*, 2014), the West Indian avifauna (Ricklefs and Cox, 1972) and Melanesian ants (Economo and Sarnat, 2012) but also North American highland fishes (Hoagstrom *et al.*, 2014) or freshwater decapods shrimps (Cook *et al.*, 2008) which strengthens the generality of this ecological process. Acknowledging differences in isolation of habitats within islands or continental landscapes in dependence of the environmental context (Steinbauer *et al.*, 2013), the taxon cycle seems to be not just an idiosyncrasy of oceanic islands but might be a general ecological process affecting biodiversity patterns on a global scale. New species successfully establishing in a landscape are likely preadapted to ecosystems also available in a larger context. With time those species may shift habitat (and specialization) utilizing the ecological opportunities provided by the ecosystems that are less inhabited because they are unique (or highly isolated) in a larger spatial context.

Conclusion

Biogeographic patterns, which can be observed in our current world, are the result of ecological (abiotic and biotic) processes interacting among various temporal and spatial scales. These cross-scale interactions of ecological processes have to be taken into account when studying biogeographic patterns and their underlying ecological driving forces. However, research on biogeographic patterns is up to now strongly restricted to certain temporal and spatial scales but hardly accounts for cross-scale interactions, which limits the full understanding of the relevant ecological processes leading to the expression of biogeographic patterns. Furthermore, the observation of biogeographic patterns itself is strongly scale dependent, which additionally blurs a general understanding of ecosystem functioning. Modern analytical methods in combination with the increasing availability and unification of observational data from various scales ranging from *in situ* field investigations up to earth observation via satellites bear the potential to overcome these scale-dependent problems and explicitly focus on cross-scale interactions among ecological processes and patterns. Another promising approach might be the investigation of scale-independent patterns (fractals) which can be frequently observed for geophysical structures (e.g., shorelines) but are understudied in ecology.

Bird Flight Origins

A Feduccia, University of North Carolina, Chapel Hill, NC, USA

Glossary

Airfoil A structure with curved surfaces designed to give the most favorable ratio of lift to drag in flight, used as the basic form of the wings, fins, and most aircraft.

Arboreal Pertaining to animals living primarily in trees, from the Latin, *arboreus*, of trees.

Archaeopteryx Also known as the urvogel, an extinct primitive bird of the Late Jurassic Period, having numerous bird-like characteristics including flight feathers, but with reptilian features such as teeth and a long bony tail.

Archosaur Any reptile of the subclass Archosauria, including the dinosaurs, pterosaurs, and crocodilians, characterized by an antorbital fenestra and two pairs of openings in the temporal region of the skull.

Avian Relating to birds, or things so related is called avian.

Cursorial Adapted for running, as the feet and skeleton of ostriches, horses, etc.

Dromaeosaur Any of a group of small- to medium-sized carnivorous maniraptoran dinosaurs that flourished during the Cretaceous Period (146 to 66 million years ago). Generally agile, lightly built, and fast-running.

Feather The diverse, flat epidermal appendages growing from a bird's skin and forming its plumage, typically consisting of a partly hollow horny shaft fringed with vanes of barbs that produce individual airfoils in flight feathers or remiges. Feathers are generally divided into categories of flight feathers and body contour feathers which produce laminar flow in flight and insulation.

Glider A volant animal with varied flight surfaces, including feathered wings, skin flaps, etc., capable of gliding from a higher to lower level by the action of gravity.

Jurassic The period of geologic time known as the second period of the Age of Reptiles or Mesozoic, spanning (200 to 145 million years ago) during which dinosaurs diversified and the earliest birds are known.

Maniraptora The group of bird-like theropods known as 'hand snatchers' were a clade of coelurosaurian dinosaurs including the dromaeosaurs birds.

Microraptor A genus of small, very bird-like, four-winged glider paravians (possibly dromaeosaurids) with avian pennaceous flight feathers. Numerous well-preserved fossil specimens have been recovered from the Early Cretaceous, Liaoning, China.

Pterosaur The group of flying reptiles of the Mesozoic Era, characterized by leathery, bat-like wings. Early groups had teeth and a long tail, but through the Cretaceous Period the teeth and long tail were lost.

Remiges (singular remex) Any of the large flight feathers of a bird's wing. Used also to describe hind-limb flight feathers of newly discovered Jurassic and Early Cretaceous gliders of China.

Scansoriopterygid Scansoriopterygidae is a family of very small four-winged glider archosaurs close to the ancestry of birds, known from well-preserved fossils unearthed in the Middle Jurassic Daohugou fossil beds of China. The skeleton is primitive and lacks any dinosaurian features.

Tetrapteryx A term introduced by naturalist William Beebe in 1915, describing his view of a hypothetical ancestral proavian, a small arboreal glider with four wings. His predication has recently been confirmed by discovery of four-winged microraptors and scansoriopterids and other fossils from the Early Cretaceous and mid-Jurassic of China.

Thecodont The varied groups of fossil quadrupedal or partially bipedal reptiles of the Triassic and persisting into the Jurassic Periods, having an antorbital fenestra and teeth set in sockets, and ancestral to crocodilians, pterosaurs and all groups of dinosaurs, as well as birds.

Theropod The group of 'lizard-hipped' or saurischian dinosaurs characterized by being obligately bipedal, with a large balancing tail and short arms with a hand reduced to three digits, I, II, III; theropod literally means 'beast-footed.'

Urvogel German term for the earliest known bird *Archaeopteryx* of the Late Jurassic Period, of the Solnhofen Limestone, Bavaria, approximately 150 million years old. It was in many features a fairly typical bird, but exhibited definitive reptilian characteristics such as conical teeth and a long bony tail.

Volant Relating to, or characterized by, ability to glide or fly.

Introduction

The origin of bird flight has intrigued people and engendered debate since the discovery of the then earliest bird, the Late Jurassic German urvogel *Archaeopteryx* in the early 1860s. This well-preserved fossil, sometimes called the Rosetta Stone of evolution, was discovered when the debate on Darwin's theory of evolution by natural selection was at a peak, only two years after the publication in 1859 of *The Origin of Species*, and an animal linking two major groups of vertebrates, reptiles and birds, was not likely to be quietly cataloged and slid into some dusty museum drawer. The first skeletal specimen, known as the *London specimen*, was purchased by the British Museum and described by Richard Owen in 1863. In 1867, the most famous *Berlin specimen*, preserved in spread-wing pose, was acquired by the Germany's Humboldt museum where it resides today (Figure 1). Until today, a total of 12 skeletal specimens (one unstudied) and a single feather have been recovered from the Upper Jurassic Limestone of Bavaria, along with a spectacular array of fossils that provide the most comprehensive window

available on Late Jurassic life (Wellnhofer, 2008). New discoveries of similar fossils coeval or of slightly older age from China have added immensely to our knowledge of flight origins (Feduccia, 2012).

Although debate on bird origins was intense, Thomas Huxley, Darwin's ally, sometimes called Darwin's Bulldog, saw the urvogel more as a link between reptiles and birds, and emphasized the small Solnhofen dinosaur *Compsognathus* (**Figure 2**) as a definitive link to birds, particularly based on the hind-limb skeleton, but he was equally enthusiastic about an avian ancestor among either Ornithischian (e.g., *Iguanodon*) or theropodan (e.g., *Megalosaurus*, *Compsognathus*) dinosaurs (Feduccia, 2012). Since for Huxley, birds were vaguely derived from 'dinosaurs' or perhaps their archosaur antecedents (thecodonts), the origin of flight must have been, albeit mysteriously, occurred from the ground up, and he viewed the living flightless ratites (ostrich, rhea, emu, etc.) as intermediates leading to modern birds. Today, however, we know that all flightless birds, regardless of ancestry, are derived from flying ancestors and still exhibit numerous flight adaptations (De Beer, 1956).

Trees-Down versus Ground-Up Flight Genesis

In later editions of *Origin*, Darwin referred to *Archaeopteryx* as 'that strange secondary bird' in reference to its occurrence in the Jurassic Period, curiously de-emphasizing its importance in any dinosaurian nexus, and Huxley considered it an 'intercalary bird': "In certain particulars, the oldest known bird does exhibit a closer approximation to the reptilian structure than any modern bird…..The leg and foot, the pelvis, the shoulder-girdle, and the feathers…...are completely those of existing ordinary birds" (Huxley, 1868).

Archaeopteryx is a reasonably advanced avian, in profile and size an almost perfect superficial match for a modern magpie (*Pica pica*) or Australian pheasant cuckoo (*Centropus phasianus*) (Heinroth, 1923), so its relevance to bird flight can legitimately be questioned (**Figure 3**). *Archaeopteryx* falls in the middle of living birds statistically in important measures of wing function, as plotted in **Figure 4**, aspect ratio versus relative wing loading (Norberg, 1990), and in addition exhibits primary wing flight remiges with asymmetric vanes on the feathers, producing individual airfoils. Manfred Reichel's classic drawings of the urvogel in different life poses (Reichel, 1984) illustrate its possible diverse behaviors, terrestrial, trunk-climbing, and in full flight (**Figure 5**).

Huxley's 'dinosaurian' origin of birds model was initially accepted, but the publication of Heilmann's (1926) book

Figure 2 Skeleton of *Compsognathus*. Creative Commons. https://upload.wikimedia.org/wikipedia/commons/4/49/Compy.jpg.

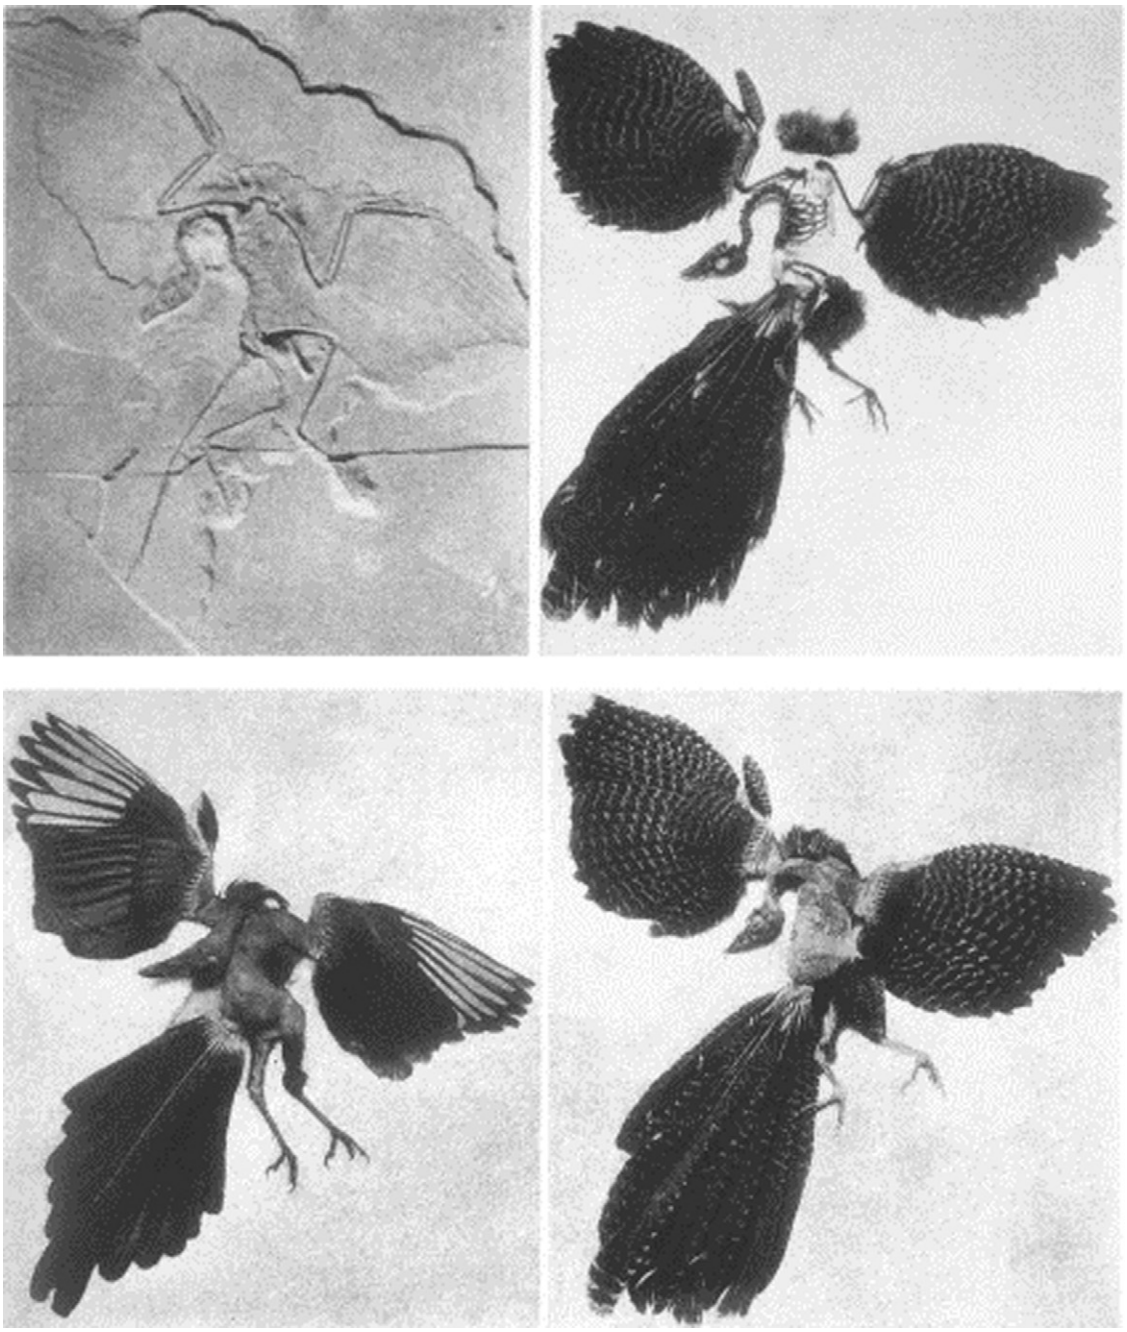

Figure 3 *Archaeopteryx* look-alikes. Upper left, the Berlin *Archaeopteryx*, compared with the Australian pheasant cuckoo (*Centropus phasianius*) (upper right), prepared brilliantly by Oskar Heinroth in 1923, in similar posture, showing the remarkable superficial similarity, including elliptical wings. However, the coucal is primarily terrestrial as indicated by its much flatter claws and distally frayed tail feathers and loosely constructed feathers of tail and wing. Below, similar comparisons of magpie (*Pica pica*) and the same coucal, showing similarity in profile. Magpies are equally at home on the ground or in trees. Reproduced from Heinroth, O., 1923. Die Flugel von Archaeopteryx. Journal für Ornithologie 71, 277–283; courtesy, Stefan Garthe for Journal für Ornithologie.

The Origin of Birds shifted focus to a group of primitive arboreal archosaurs then called 'thecodonts' (now more appropriately basal archosaurs), which are the more inclusive group of largely Triassic reptiles from which both groups of dinosaurs, pterosaurs, crocodilians, and birds are all ultimately derived. Heilmann thus favored a small tree-dwelling archosaur as the ancestor of birds, and thus favored a trees-down model for flight origin.

In the late 1960s, however, the debate was altered when Yale's John Ostrom discovered skeletons of a human-size Early Cretaceous dromaeosaurid theropod, *Deinonychus* (Figure 6), which exhibited innumerable bird skeletal features, including

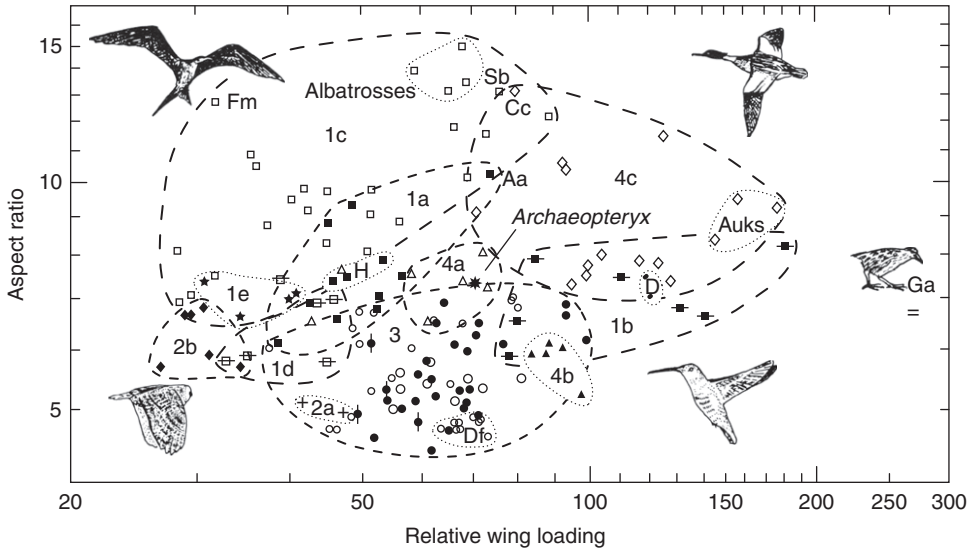

Figure 4 Aspect ratio vs. relative wing loading in various birds. The encircled foraging groups are defined solely by the similarity of flight and foraging modes, not by systematic affinity. Aa = *Apus apus* (swift); Cc = *Cygnus cygnus* (swan); D = diving petrels; Df = Darwin's finches; Fm = *Fregata maginificens* (frigatebird); Ga = *Gallirallus australis* (flightless New Zealand wood rail); H = swallows; Sb = S*ula basana* (bobby). Note particularly the position of the urvogel *Archaeopteryx.* Reproduced from Norberg, U.M.L., 2004. Bird flight. Proceedings of the 23rd International Ornithological Congress, pp. 921–935. Beijing: Current Zoology; courtesy, Ulla Lindhe Norberg.

a bird-like hand and wrist; the field would never be the same (Ostrom, 1969). Importantly, because this dromaeosaur and its kin like *Velociraptor* were thought to be entirely terrestrial (Chiappe, 1997), it rekindled the debate on flight origins, for Ostrom providing evidence that, somehow mysteriously, flight must have originated from the ground up (Ostrom, 1979). Most of these ideas date back to 1907 with an untenable running dinosaur model by Baron Franz Nopcsa (Nopcsa, 1907; **Figure 7(a)**). The problem, of course, was once aloft: where would the energy come from to keep the animal airborne? More recent models have used *Archaeopteryx* as a cursor, at early flight stages, being capable of takeoff from a running start, using already developed wings as a primary thrust generator (Burgers and Chiappe, 1999), but all ground-up models have been seriously challenged. Derek Yalden showed that *Archaeopteryx* and early birds are all arboreally adapted and have sharp claws highly recurved and adapted for trunk climbing, and match beautifully those of trunk-climbing birds and mammals (Yalden, 1985). All ground-up models have failed because of the architectural limitations of the pectoral apparatus of *Archaeopteryx* and putative avian ancestors, either theropod or archosaurian, which was incapable of a powerful, rapid upstroke of the wing. Another recent model by Dial (2003), called 'wing-assisted incline running' (or WAIR), uses the chukar partridge as a model. By this scenario, partridges (and presumably ancestral birds or their antecedents) vigorously beat their wings to run up steep or vertical substrates, even trees, and thus such birds could get off the ground. Yet, it is unclear what relevance this model might have to flight origins, and as noted above, early birds or any of their putative ancestors lacked the necessary pectoral anatomy for a strong, vigorous recovery stroke of the wing. Thus all ground-up models fail to explain flight origins in reasonable biomechanical terms, are 'gravity-resisted,' and have generally been discarded.

As with all these scenarios, Ostrom's main obstacle was how a bird could evolve elongate modern flight feathers and an avian wing if it were, as he saw it, first an earth-bound theropod dinosaur. He proposed a scenario whereby the flight feathers of protobirds elongated as insect traps and continued elongation until full wings and flight were achieved (**Figure 7(b)**). The other ground-up models noted above, rely on ancestors with a strong recovery stroke of the wing, absent in all putative avian ancestors, either dinosaurian or archosaurian (Feduccia, 2012). The Ostrom model has been highly criticized, no longer considered feasible; and along with more recent models now resides in the waste bin of theories that are biologically and biophysically unsound.

Mesozoic Experiments in Flight

During the Triassic and the preceding Permian, numerous, often bizarre, arboreal vertebrates experimented with the new aerial ecological zone for the first time. Notable among these Triassic archosaurs were *Longisquama* and *Sharovipterix* (**Figure 8**). *Longisquma* had elongate feather-like appendages (parafeathers) projecting from the upper mid-line of the back; it was probably a parachuter in butterfly profile, using its integumental appendages to break the fall. *Sharovipteryx* was a small gliding reptile, and has been reconstructed with various conformations of a leathery patagial gliding delta-wing, another early evolutionary experiment in the conquest of air. Among the menagerie of volant forms were numerous and anatomically varied gliding Triassic lizards including *Mecistotrachelos* from the late Triassic of Virginia, which like modern southeast Asian lizards of the genus *Draco*, glided on membranous wings supported by elongated ribs that could spread laterally to provide a gliding surface; and there are gliding

geckos and even parachuting tree frogs (*Rhacophorus*) and a gliding snake (*Chrysopelea*) of Southeast Asia. The first active fliers were the leathery winged pterosaurs of the Triassic, which evolved in great variety through the Cretaceous losing their long tails and teeth, and debate on the genesis of their flight closely paralleled the debate on bird flight, but now is known

to have originated, like that of birds, from the trees-down, via the arboreal model (**Figure 9**).

Patterns of botanical evolution during the Late Permian and the Triassic are relevant to the evolution of widespread experimentation with arboreality and with forms of flight among reptiles. Tall conifer forests emerged during this geological time span, and because angiosperms had yet to evolve, there were no vines or other similar plants. A somewhat similar but analogous situation exists today in the rainforests in Borneo where myriad gliding creatures have evolved. There are 30 or so gliding species in the rainforests of Borneo; these include four species of flying frogs, that use loose flaps of skin on their limbs as well as long web fingers to parachute. There are flying geckos that use webbed toes and flanges of skin on the legs and tail for gliding, and lizards that use their expanded rib cage for gliding; and even a ribbon-flat, paradise tree snake that flatten the body to propel for a distance of up to 30 meters (98 ft). These creatures are more aerodynamically agile than appreciated; the harlequin tree frog, for example, capable of 180-degree mid-air turns, and *Draco* lizards can make hundred-foot glides between trees, landing upright on tree trunks. Gliding mammals include flying lemurs (*Cynocephalus*) and 14 species of flying squirrels ranging in size from the 15 cm (6 in) pygmies to the red giant flying squirrel that can exceed one meter (3 ft) in length including the tail. In Amazonian rainforests, the only gliders are small squirrel monkeys that parachute from tree to tree while assuming the same flattened, spread eagle posture characteristic of all gliders; there are also Central American parachuting frogs. However, the diversity of Bornean forests is not there. One explanation is that the rainforests of Borneo, unlike those of the Amazon basin, Africa, or other similar regions, are dominated by giant dipterocarp trees, which fruit infrequently and unpredictably; this forces animals to expand the territory to be canvassed for food. Gliding offers an energetically cheap and efficient method of canopy travel for a variety of animals, relieving them of the long trip down to the ground and back up again. Also, the dipterocarp forests of Borneo are taller, have fewer lianas, and a more discontinuous canopy than Amazonian rainforests. In dense Amazonian rainforest canopies, gliding is more difficult and an organism can simply climb from tree to tree (Laman, 2000; Feduccia, 2012).

The Bornean rainforest suggests a possible general explanation for evolutionary experimentation in the aerial ecological zone during the Triassic, an evolutionary trend that produced not only the volant pterosaurs, but flying lizards, and strange experiments in flight such as the delta-winged *Sharovipteryx* and the butterfly-parachuter *Longisquama*.

Chinese Discoveries Refocus Debate

The urvogel *Archaeopteryx* was until recently the only Jurassic bird, and was the focus of almost all debate on the subject until the past few decades when the Lower Cretaceous Chinese Jehol Biota and equally well-preserved Jurassic deposits produced some equally significant fossils relevant to bird and flight origins (Zhou *et al.*, 2003). Among the most significant discoveries were fossils with both fore- and hind-limb wings (Zheng *et al.*, 2013), confirming the prediction by early naturalist William Beebe that modern avian flight was preceded by a four-winged stage which he called the *tetrapteryx* (**Figure 10**; Beebe, 1915).

Perhaps the most significant discovery was the very bird-like Early Cretaceous microraptors (*Microraptor* and allies, silhouette, **Figure 11**), four-winged gliders considered variously basal dromaeosaurs or early offshoots of the avian radiation. There are also Jurassic fossils variously considered troodontid

Figure 7 Illustrations showing the historically contrasting views on the origin of avian flight. (a) The ground-up or cursorial model. In this highly improbable model the early feathers would produce drag, which would have the undesired effect of slowing down the animal; then, once the animal was aloft, where would the energy come from to maintain flight? (b) An equally improbable scenario, John Ostrom's 'insect net model' which attempted to explain elongation of feathers in a non-flight context. (c) The trees-down or arboreal model illustrated by a trunk-climbing proavian (either a basal archosaur or a theropod) that began to jump from limb to limb, then parachute from trees, eventually beginning to glide as the angle of descent decreased from 45°. Gliding increased maneuverability and slowed landing. Following gliding, flapping would begin to prolong powered flight. The arboreal theory is intuitively facile, using high places or gravity as a source of power, converting potential energy into kinetic energy. (d) Illustration by Ulla Norberg illustrates the energetically least expensive manner to traverse a forest, by climbing and gliding. Panels (a) and (d): Adapted from Norberg, U.M., 1990. Vertebrate Flight. Berlin: Springer, courtesy Ulla Lindhe (Norberg)); (b) and (c): Reproduced from Chatterjee, S., 2015. The Rise of Birds. second ed. Baltimore, MD: Johns Hopkins Press; courtesy Sankar Chatterjee.

Figure 9 Bird and pterosaur flight origin went through a similar tortuous debate, but now the arboreal theory dominates paleobiological and ornithological thought. Here terrestrial locomotion in pterosaurs is shown above in Cretaceous *Pteranodon* (left) and *Pterodactylus* (right), and below, Jurassic *Rhamphorhynchus*, featuring teeth and long tail, later lost. In the center is H.G. Seeley's 1901 view of the basal, bipedal *Dimorphodon*, now disproved by finds of a uropatagium (skin stretching between hind limbs), quadrupedal tackways, and a specimen showing it was flat-footed. Kevin Padian in the 1980s erroneously revived Seeley's model with his view that pterosaurs were closely allied with theropods, which were obligately bipedal and therefore concluded that pterosaur flight originated from the ground up, now totally disproved. Silhouettes modified from Reichel, M., 1984. Dessins (1896–1984). Basel: Geological Institute of Basel University. Reproduced from Feduccia, A., 2012. Riddle of the Feathered Dragons. New Haven, CT: Yale University Press.

theropods or early birds, some, like the mid-Jurassic *Anchiornis*, with fully developed avian wings and a tetrapteryx flight bauplan. Forms such as the Jurassic four-winged glider scansoriopterids (Czerkas and Feduccia, 2014), originally described as coelurosaurs, stand at the base of the avian tree, and show very little in the way of theropod affinity. The recent discovery of a partially preserved fossil scansoriopterid named *Yi qi*, with feathers and a bat-like patagial flight membrane was an early evolutionary flight experiment, and adds additional mystery to the entire problem (Xu *et al.*, 2015). Many of these early Chinese fossils are often reconstructed erroneously as cursorial dinosaurs, but such a model is not tenable because the elongate hind-limb wing feathers would have been a hindrance in running and would have created detrimental drag for an animal preparing to take flight. Instead, all these animals were trunk-climbers, may have been parachuters or gliders at varied stages of development, and beautifully illustrate how the origin of flight may have occurred via the biophysically facile, 'gravity-assisted' arboreal model with wing-assisted climbing or WAC (Chatterjee and Templin, 2012; Chatterjee, 2015), as opposed to the improbable, 'gravity-resisted' cursorial model.

Conclusions

Ground-up or cursorial (from Latin *cursus*, running) theories for flight origin are historically based on the belief that birds are derived from earth-bound theropods, incapable of tree climbing (Chiappe, 1997). The varied versions of this model have all failed because if running or jumping were involved, any elongation of feathers would produce drag and therefore

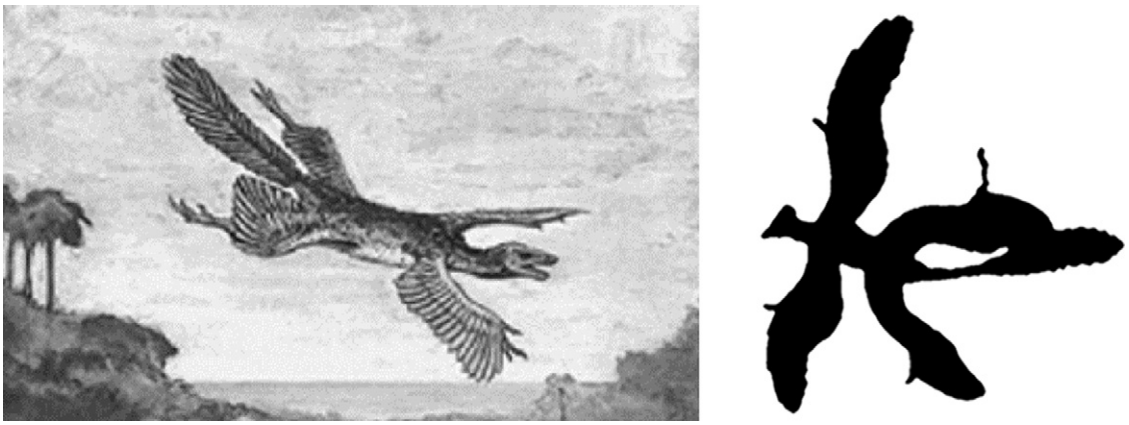

Figure 10 Beebe's (1915) hypothetical *tetrapteryx* stage in avian flight, remarkably confirmed in recent years by the discovery of microraptors, four-winged avian-like, basal dromaeosaurid gliders from the Jurassic and Lower Cretaceous of China. Silhouette of the Early Cretaceous four-wing glider *Microraptor* shown on the right in silhouette. Left: reproduced from Beebe, W., 1915. A tetrapteryx stage in the evolution of birds. slow down the organism while running, and hence the term 'gravity-resisted'. While paleontologists have in recent decades embraced the view that birds evolved from terrestrial maniraptoran dinosaurs typified by the dromaeosaur *Velociraptor*, and as noted some still hold the view that flight evolved from the biophysically improbable ground-up model, there is no reason that many of these maniraptorans could not have climbed trees (Zhou, 2004). Most early workers, however, favored evidence for a small, arboreal basal archosaur as the logical ancestor, with flight having evolved via the biomechanically facile trees-down model from small arboreal archosaurs (Norberg and Norberg, 1989), or even arboreal maniraptoran theropods, which may prove to be early avians (James and Pourtless, 2009). The simple trees-down 'gravity-assisted' model has been used without exception by myriad land vertebrates that have developed flight.

O. Able in 1911 suggested an extension of the arboreal hypothesis, that both dinosaurs and birds descended from tree-climbing archosaurs (Able, 1911), and a version of this idea has been carried into modern times by Zhonghe Zhou who has termed the new version the dinosaurian trees-down model for avian flight (Zhou, 2004). However, there is still dispute as to whether the Chinese Jurassic and Early Cretaceous four-winged gliders are true theropods or early avians (Feduccia, 2012), and the recently discovered scansoriopterids from the Middle Jurassic of China are close to suitable tree-dwelling, archosaurian ancestors for birds (Czerkas and Feduccia, 2014), but are devoid of any theropod skeletal characters.

Whatever the true ancestor is, the most reasonable explanation for the origin of flight, not only in birds, but in all other vertebrates, is the arboreal or trees-down model (Chatterjee and Templin, 2012; Chatterjee, 2015). The requisites for flight origin are small size, because without that restriction, no integumentary structures (such as feathers) will have any effect on breaking the fall; and high places, primarily trees. High places allow such animals to take advantage of the cheap energy provided by gravity (**Figure 4**). Not only the climbing adaptations of early birds but their possession of a hind toe (hallux) for perching indicate that

they were largely arboreal, and their possession of brain enlargement, particularly a highly developed cerebellum, acute visual sense, and neurosensory development for hearing and equilibrium (inner ear), all point to an arboreal setting. The arboreal theory for flight origins, unlike the cursorial theory, has the advantage of beginning to explain how all the microstages in flight origins were individually selected for, including the progression of arboreal jumping or leaping, parachuting, gliding, leading to maneuvering powered, flapping flight.

Glossary

Aves The class of vertebrate animals comprising all living species of birds.
Cretaceous The geological period lasting from 145 to 65 million years ago.
Divergence time The age (often denoted in million years ago) of time of evolutionary separation between two taxonomic units.
Eocene The geological epoch lasting from 56 to 34 million years ago.
Eocene–Oligocene extinction The geological transition encompassing the end of the Eocene and the beginning of the Oligocene period (34 million years ago) marked by large-scale faunal and floral extinction (that included most stem members of modern bird families).
Paleocene The geological epoch lasting from 65 to 56 million years ago.
Paleogene The geological period lasting from 65 to 23 million years ago, encompassing the Paleocene, Eocene, and Oligocene epochs.
Paraves The evolutionary lineage that contains all living and extinct birds and those maniraptoran dinosaurs that are immediate ancestors of birds. This lineage itself is comprised of two groups, one (Avialae) containing fossil and modern birds, and one (Deinonychosauria) containing dromaeosaur (including microraptors), and troodontid dinosaurs.
Phylogeny The reconstruction of the evolutionary history (relationships) of a group of species.
Radiation The increase in taxonomic biodiversity over a short period of time, involving rapid morphological evolution and new ecological exploitation.
Taxonomy The biological classification of a group of organisms/species.

General Introduction

Though birds are not better adapted to their environment than other animals, to human eyes they appear almost enviously so. Birds have perfected the art of flying and singing in more colorful ways than any other organism (Figure 1). Humans continue to be fascinated by the lush variety in bird behaviors, food capture, and their ability to thrive in almost any environment. Throughout human history, birds have played many important symbolic roles and served as inspiration for art. However, in today's time, birds are perhaps best suited as symbols of conservation and extinction. This article serves to introduce the reader to the general aspects of bird appearance (what anatomical features make a bird a bird), origins (what is the ancestor to birds?), phylogeny and timeline (when did the various types of living birds separate and diversify?), and the importance of birds to the welfare of humans. In order to provide a scientific framework to introduce these issues and better recognize current threats of extinction, these topics will be discussed through an evolutionary lens. To best appreciate the variation among the roughly 9500 living species of birds (Aves), it is useful to have an understanding of the humble origins among dinosaurs, followed by subsequent radiations into now extinct toothed birds, and later on, beaked birds. This journey addresses the questions of where and when birds evolved from reptilian ancestors, and how (the mechanisms through which) this was accomplished through evolutionary time. Once these questions are answered, the biodiversity of living birds is better understood as an immeasurable set of exemplary cases of specialization and ecological niche filling in evolution. With this vision, the importance of preserving birds for the future of humanity, existing knowledge gaps, and opportunities for research are highlighted briefly.

The Origin of Birds

Birds are commonly defined by a combination of powered flight ability and the possession of feathers and beak. Indeed, the combination of these three characteristics in the animal kingdom is found only in birds. To uncover evolutionary history through time, one must also consider the fossil record, i.e., evidence of once extinct organisms ancestral to living species. In this context, it can be seen that not all extinct

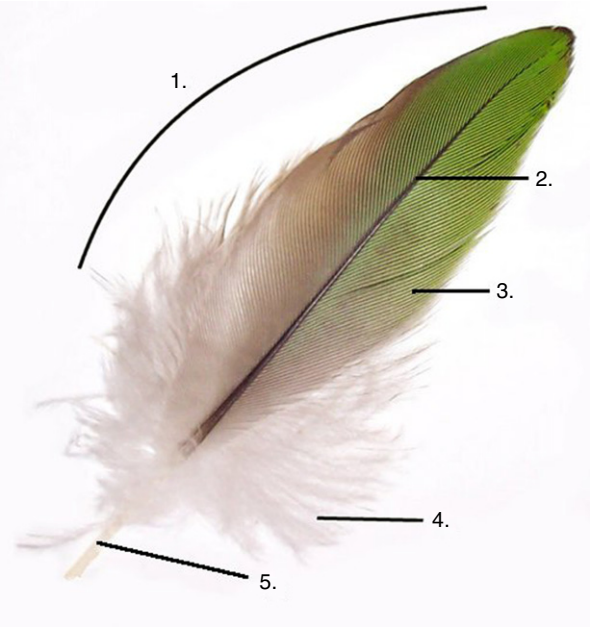

Figure 2 Parts of a feather. (a) vane, (b) rachis, (c) barb, (d) afterfeather, and (e) hollow shaft, calamus. https://en.wikipedia.org/wiki/Feather#/media/File:Parts_of_feather_modified.jpg.

Figure 3 Reconstructed skeleton of *Troodon* sp., a bird-like troodontid. Creative Commons. https://en.wikipedia.org/wiki/Troodontidae#/media/File:Troodon_Perot_Museum.jpg.

birds displayed the three 'bird' traits and that other extinct organisms, particularly dinosaurs, were the first to evolve feathers and additional anatomical traits once considered unique to birds, for example, the semilunate carpal wristbone and the wishbone-shaped furcula. The presence of lightweight feathers is so intricately tied to today's fluffy birds that it is hard to imagine that some of the more robust dinosaurs were also covered with feathers (**Figure 2**). The insight of some dinosaurs being feathered is relatively new, linked to many discoveries of exceptionally preserved fossils from China starting in the late 1990s and early twentieth century (Norell and Xu, 2005). Through these discoveries, research has concluded that feathers evolved originally for purposes other than flight (Prum and Brush, 2002), via a filamentous-pinnate-branching feather order (Clarke, 2013). Despite this ancient origin, modern flight feather anatomy remains a relatively recent phenomenon unique to birds (Feo *et al.*, 2015). Current analyses of comparative anatomy that have included the known varieties of feathered and non-feathered dinosaurs, modern and ancient birds, and other ancient reptile lineages, consistently show that birds are descendants of a particular lineage of dinosaurs, the maniraptorans (Smith *et al.*, 2015). This group of dinosaurs is one of several theropod (meat-eating) dinosaur lineages that also includes *Deinonychus* and *Velociraptor* (Dromaeosauridae) and the bird-like Troodontidae (**Figure 3**), and as a whole (a group termed Paraves) is a close cousin of *Tyrannosaurus rex*. Thus, based on current scientific consensus, birds are (living descendants of) dinosaurs.

A second consensus is appearing from the most recent comparisons of earliest bird fossils and dinosaurs: that of a muddled line between what is called a bird (avian dinosaur) and what is called a non-avian dinosaur. While this zone of evolutionary innovation is blurry and taxonomically confusing, it points out several interesting evolutionary phenomena that put the origin of birds into a sound framework: (1) birds never show close evolutionary relationships to primitive non-dinosaurian reptiles (Xu *et al.*, 2014; Smith *et al.*, 2015); (2) birds are an evolutionary outcome of continued miniaturization (decrease in body size) in a particular lineage of dinosaurs, the theropods, that already showed a tendency toward miniaturization (Turner *et al.*, 2007; Benson *et al.*, 2014; Lee *et al.*, 2014); (3) Paravian dinosaurs did not show size reduction in forelimb proportions, thus giving the first birds relatively long forelimbs (Puttick *et al.*, 2014), which promoted the evolution of flight; (4) rapid anatomical innovation occurred during the evolutionary period immediately following the origin of birds (Brusatte *et al.*, 2014); (5) many 'bird' traits are first observed in theropod dinosaurs (Makovicky and Zanno, 2011; Xu *et al.*, 2014); (6) the evolution of birds from dinosaurs is an evolutionary successful outcome from a time where several dinosaurs experimented with flight (Han *et al.*, 2014; Xu *et al.*, 2015). For example, microraptoran dinosaurs (**Figure 4**) close to the origin of birds had four instead of two wings (Xu *et al.*, 2003), using their long leg feathers as added flight devices. Gaps in our knowledge remain on the relative relationships of troodontids and microraptoran dinosaurs to birds (Xu *et al.*, 2014). Where they part of birds or closely related to them? Resolution of these issues is important because it answers what the first bird looked and behaved like (Godefroit *et al.*, 2013). Did birds evolve flight from gliding down trees like bats and other animals did, or by taking off from the ground? The answer is yet unclear.

Diversity of Extinct (Non-Modern) Birds

Immediately preceding the boom of Chinese feathered dinosaur finds, a similar renaissance took place in our understanding of the varieties of now extinct bird lineages that ultimately gave rise to modern birds (Chiappe and Dyke, 2002). These birds are generally distinguished from modern birds by having teeth, thus lacking a true beak. Several fossil lineages are known and intricately studied, and these include primitive weak-flying birds with long tailbones such as *Archaeopteryx* (currently 11 specimens known; Foth *et al.*, 2014) and *Jeholornis* (Zhou and Zhang, 2003). More advanced toothed birds include the short-tailed exquisite flying birds (Chiappe, 2007) and are represented by the well-known and abundantly found Confusiusornithids (Chiappe *et al.*, 2008), Enantiornithids, Ichthyornithids, and Hesperornithids, and numerous unique fossil genera (e.g., *Gansus*, *Apsaravis*, *Ambiortus*, *Patagopteryx*). While many of these distinct fossil bird groups have been known since the mid-1990s (Chiappe, 1995), the evolutionary tree of toothed birds is becoming better understood with each new fossil find. This conclusion applies particularly to the taxonomy of Enantiornithine birds, the ecological diversity of toothed birds not directly ancestral to modern birds, and the anatomical traits of those extinct toothed birds (Ornithurae) that ultimately gave rise to modern (living) birds.

Timing the Evolutionary History of Modern Birds

With so much detail laid out in the fossil record about the origin and early ecological diversification of toothed birds, it is surprising to see little to no direct evidence for the events leading up to the wholesale extinction of all toothed birds at the end of the Cretaceous period (Longrich *et al.*, 2011;), and in particular for the (reason for) survival of modern beaked birds Robertson *et al.*, 2004). The fossil record here is scant (e.g., Fountaine *et al.*, 2005; Brocklehurst *et al.*, 2012), and for this reason, genetics-based studies have provided particular insight where fossils alone have been less able to do so. One must keep in mind that molecular insights provide indirect evidence of (or reconstruct rather than show directly) evolutionary history in contrast to the fossil record. Thus, to reconstruct phylogenetic relationships and divergence times of the major groups of modern birds, collaboration among paleontologists and molecular biologists has been especially sought (e.g., Dyke and van Tuinen, 2004; van Tuinen *et al.*, 2006; Ericson *et al.*, 2006; Slack *et al.*, 2006; Jarvis *et al.*, 2014).

Few fossils point to the presence of modern birds in the Cretaceous. Although contentious, several fossil representatives of the waterfowl (duck) lineage Anseriformes are known from the latest Cretaceous (Clarke *et al.*, 2005; Kurochkin *et al.*, 2002) of South America and Asia. The next earliest fossil finds are from the earliest Paleocene, following the end-Cretaceous extinction event in New Zealand, and belong to the penguin lineage *Waimanu* (**Figure 5**, Sphenisciformes; Slack *et al.*, 2006). Combined with a phylogenetic framework for living birds, the molecular clock can be used to constrain the age of Anseriformes and Sphenisciformes according to their fossil record and infer ages of other phylogenetic divergences. Using this approach, many analyses have been performed, which yield a mid-Cretaceous initial divergence among modern birds (reviewed in van Tuinen, 2009) followed by either Cretaceous diversification of many distinct bird orders (e.g., Cooper and Penny, 1997; Paton *et al.*, 2002; Brown *et al.*, 2008; Brown and van Tuinen, 2011; Pacheco *et al.*, 2011), Cretaceous and Paleogene diversification depending on order (van Tuinen *et al.*, 2006; Pacheco *et al.*, 2011), or entirely Paleogene diversification of orders (Ericson *et al.*, 2006; Jarvis *et al.*, 2014). The disparity among these findings is likely a result of varying use of fossil priors and perhaps also saturation in molecular data (van Tuinen and Torres, 2015). More analyses testing these parameters will be forthcoming in the near future. Until then, it is plausible to assume a mid-late Cretaceous divergence among the primitive modern lineages Paleognathae and Neognathae (despite absence of Cretaceous fossil evidence for Paleognathae) that is inferred from fossil evidence of the age of the Ornithurine outgroup, of the age of Neognath birds, and the consistent observation of a distinct branch length (indicating strong phylogenetic support from unique molecular differences) at the base of Neognath and Neoavian birds. Furthermore, diversification of the majority of distinct birds orders is likely post-Cretaceous (uncertain for Anseriformes, Galliformes) and

Figure 6 The eagle is a Neognath and the moas are Paleognaths. Creative Commons. https://en.wikipedia.org/wiki/Evolution_of_birds#/media/File:Giant_Haasts_eagle_attacking_New_Zealand_moa.jpg. https://en.wikipedia.org/wiki/Evolution_of_birds#/media/File:Giant_Haasts_eagle_attacking_New_Zealand_moa.jpg.

for some may be an ecological response to Eocene–Oligocene extinction (van Tuinen *et al.*, 2006). These scenarios are consistent with the overall fossil record of modern birds and with major branch length patterns seen in various molecular datasets.

Phylogeny of Modern Birds

The timing of the divergences between the major lineages of modern birds is dependent on knowledge of the phylogenetic relationships among these lineages. Fortunately, much progress in phylogenetic reconstruction of the modern bird tree has recently been made through analysis of taxonomically large and character-rich datasets (reviews in Torres and van Tuinen, 2013; Jarvis *et al.*, 2014; Mayr, 2014). At its base, the group containing all modern birds consists of two distinct lineages, the Paleognathae (tinamous and ratites) and the Neognathae (all other birds) (**Figure 6**). Neognathae itself consists of two distinct lineages, the Galloanserae (waterfowl and gamefowl, **Figure 7**) and all remaining birds (20+ orders). This latter grouping contains the Neoavian birds, which appear to have rapidly diversified into all known ecological types observed today. The latest evidence from the fossil record and genetics concurs that the diversification of an ancestral Neoavian bird into today's songbirds, parrots, aquatic birds, raptors, shorebirds, and other distinct lineages happened in a matter of only a couple million years (Ericson *et al.*, 2006; Jarvis *et al.*, 2014; Mayr, 2014). Exciting recent genetic consensus is building on a separate origin of, on the one hand, a group containing pigeons and relatives united with flamingos and grebes and on the other hand a group containing all other neoavian birds. The separation of these two groupings of ecologically disparate birds implies massive ecological and anatomical convergence in the aquatic realm (Fain and Houde, 2004). Strong genetic evidence further exists for the independent acquisition of raptorial lifestyles (Ericson

Figure 7 A male specimen of Ceylon junglefowl (*Gallus lafayetti*), a representative of Galloanserae. Creative Commons. https://en.wikipedia.org/wiki/Galliformes#/media/File:Flickr_-_Rainbirder_-_Ceylon_Junglefowl_(Gallus_lafayetii)_Male.jpg.

et al., 2006; Jarvis *et al.*, 2014). Morphological analyses support some of these findings but complete agreement is still lacking. Also, phylogenetic results from multi-locus genetic studies are often sensitive to several parameters and a complete phylogenetic tree at the ordinal level is not yet statistically secure enough. More importantly, family-level and species-level genetic and morphological studies are still anticipated for many bird lineages, and thus a full modern bird tree of life is still several years away. Despite the lack of a fully resolved phylogeny for birds, the major outer branches have now been established. This framework will prove essential in the assessment of the evolutionary origins and ecological, behavioral, and geographical breadth seen among birds, but also in promoting the conservation of birds currently under threat.

Conclusion

With today's scientific knowledge about the evolution of birds, it is easy to get excited about them as lone survivors of the dinosaurs, to observe and study them as a large spectrum of variations around a theme involving flight, high metabolic rate, and numerous specializations in food capture. As visible and audible gems, birds too are ever-present facets of daily human life, providing humans easy access to food, inspiration, and admiration. For all these reasons, it is increasingly important that we recognize the current danger of losing many wonderfully unique birds to extinction. Some bird families show particular prevalence to being under threat yet funds for putting existing conservation plans in action are frequently lacking. Without immediate action, many threatened birds may soon be lost forever. Given projected future climate scenarios for the next 50 years, it is not unlikely that a considerable portion of bird diversity that originated through a rapid evolutionary radiation over a span of a couple million years, may go extinct at a much higher, indeed alarming, rate due to human-caused habitat loss and environmental change (e.g., Pimm *et al.*, 2014). For the sake of building upon an already sound scientific knowledge base and acknowledging the importance of birds to many aspects of humanity, new students of ornithology are fortunate to build a

career during a time where data gathering is needed more than ever, whether this involves studying live birds in the field or captivity, fossil birds in the rocks, or genetic aspects of birds and their parasites in the lab.

Cambrian Explosion: A Molecular Paleobiological Overview

L Parry and D Pisani, University of Bristol, Bristol, UK

Glossary

Bilateria Bilateria is the lineage of all animals except the sponges, jellyfishes, corals, comb jellies, and placozoans (the plated animal). Bilateria share a common ancestor (i.e., it is a clade) and it is characterized by a primitive bilaterally symmetrical body plan. That is, the bilaterian last common ancestor was bilaterally symmetrical.

BST Burgess Shale Type deposits. These are fossil deposits with exceptional preservation. Fossils are preserved in BST as carbonaceous compressions with or without mineralization of tissues such as guts and muscles.

Cambrian The first period of the Phanerozoic eon is called cambrian. The Cambrian spans the interval between 541 and 485 Mya. It is characterized by abundant fossil animals that can be unambiguously assigned to extant (living – not extinct) animal phyla.

Clade A group of species sharing a common ancestor is called clade.

Crown group Given any living lineage (say the placental mammals), the crown group includes all living members of that group, their last common ancestor, and all fossil members of the same group that descended from the same common ancestor.

Ediacaran This is the last period during the Neoproterozoic. The Ediacaran spans the interval between ~630 and 541 Mya. It is characterized by the emergence of macroscopic organisms in the fossil record, including animals.

Fossil biomarkers Chemical fossils extracted from sediments that may be specific to particular lineages of life and can constrain their origin in deep time in the absence of a fossil record.

Ga Billions of years ago. This acronym is used when defining a single point in time (e.g., 1.5 Ga).

Gya Billions of years ago. This acronym is used when defining a time interval (e.g., 1–1.5 Gya).

Ma Millions of years ago. This acronym is used when defining a single point in time (e.g., 541 Ma).

Metazoa A synonym for animals is called metazoa (sponges included).

Molecular clock An abstraction of the general observation that the number of differences in the genomes of two related species is a function to the time since they shared a common ancestor is called molecular clock.

Mya Millions of years ago. This acronym is used when defining a time interval (e.g., 541–520 Mya).

Relaxed Molecular Clock Methods These methods represent improvements over the Strict Clock Method (see below) and assume that the rate at which changes accumulate in the genomes of different species is lineage dependent. That is, each branch in a phylogenetic tree is assigned its own rate of change.

Stem group This group includes all taxa more closely related to an extant group than to any other extant groups, but that diverged from the extant group before the last common ancestor of the extant taxa was alive.

Strict Molecular Clock Method This was the first methodological implementation of the molecular clock. It assumed that the rate at which mutations accumulated in genomes was the same across all the species in the considered phylogeny.

Taphonomy The study of what happens between an organism death and its discovery as a fossil is called taphonomy. It includes the effects of decay and diagenesis.

Total group The Crown plus Stem group is called total group.

Trace fossils Behavioral fossils, such as burrows and borings, and feeding marks.

Introduction

Historically, the fossil record has been the principal source of information to understand animal evolution. Based on this information the Cambrian period (541–485 Mya), the first period in the Phanerozoic eon, has long been considered the cradle of animal life. More recently, the genomic record has also been used to study animal evolution and our current understanding of the origin and early evolution of animals is derived from a combined interpretation of the fossil and the genomic record of life (see Erwin *et al.*, 2011).

Herein a 'Molecular Paleobiological' overview of the Cambrian explosion and the origin of animals is provided that integrates molecular and fossil evidence to derive a

 doi:10.1016/B978-0-12-800049-6.00271-7

picture based on a critical interpretation of both sources of information.

The Cambrian Fossil Record

The base of the Cambrian (541 Ma) is defined by the synchronous first appearance of *Treptichnus pedum*, a trace fossil with probing vertical and horizontal movement representing the first evidence of extensive vertical movements within a substrate. Only Bilateria have the complex muscle systems and the turgid body necessary to vertically borrow within sediments in such a fashion, and *Treptichnus* is widely accepted to represent the first unambiguous evidence for the widespread existence of Bilateria in the fossil record. Recent experiments using extant animals showed that *Treptichnus* traces were most likely produced by a priapulid-like worm (Vannier *et al.*, 2010). Priapulida are a small extant animal phylum including only eight genera with an extensive Cambrian fossil record (Smith *et al.*, 2015). They have a distinctive body plan and together with the Arthropoda (e.g., insects, spiders, crustaceans, millipedes, and centipedes), the Nematoida (round and Gordian worms), the Loricifera, the Kinorhyncha (mud dragons), the Tardigrada (water bears), and the Onychophora (velvet worms) are members of one of the three major bilaterian clades: the Ecdysozoa. Accordingly, *Treptichnus* indicates that the first two major splits in the bilaterian tree of life (separating Deuterostomia, Lophotrochozoa, and Ecdysozoa – i.e., the three main bilaterian animal lineages) happened before the Cambrian. Consequently, also divergences between non-bilaterian animal lineages (sponges, the elusive placozoans (the plated animal), jellyfishes, corals, and comb jellies), that predated the separation between the Bilateria and their sister lineage (jellyfishes, corals, and most likely also comb jellies), must also have happened in the Precambrian (**Figure 1**). The conclusion is that while the

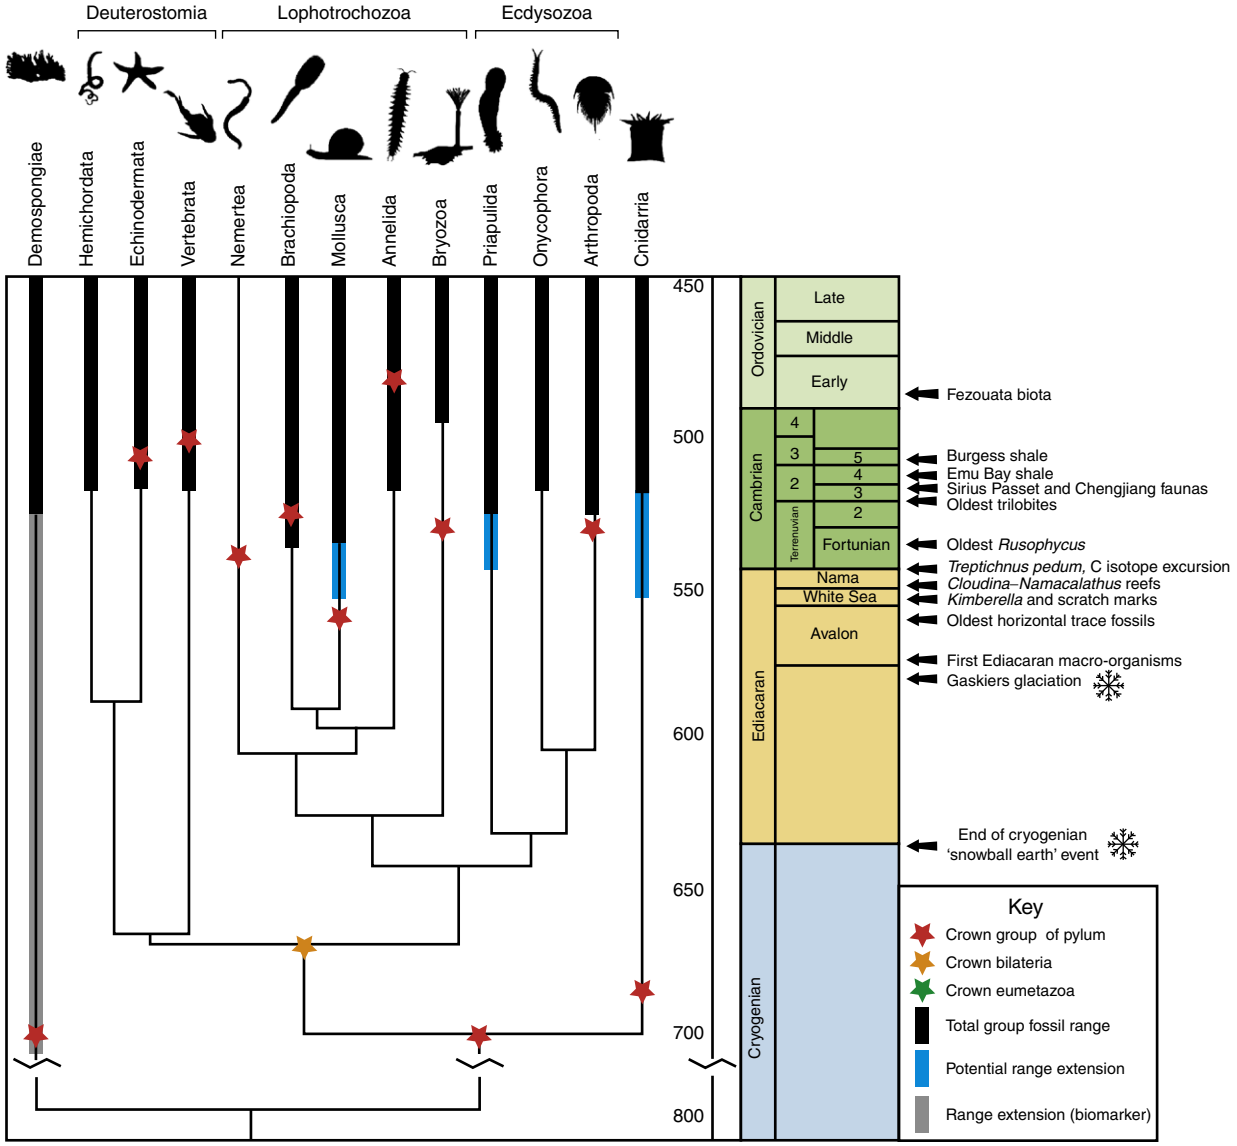

Figure 1 Molecular time tree of animal evolution after Erwin *et al.* (2011). Positions of key events on timescale to the right are approximate.

Cambrian has long been considered the cradle of animal life, fossil evidence now indicates the animal originated in the Precambrian. What is unclear is whether they originated deep in the Neoproterozoic (in the Cryogenian), or much more recently, after the last of the snowball earth event, in the Ediacaran. While animals origins might be as deep as 750 Ma (Erwin *et al.*, 2011; dos Reis *et al.*, 2015), the Cambrian still represents a crucial period in the history of animals, with the Cambrian explosion now being interpreted as the time when crown group animal lineages underwent their diversification (Erwin *et al.*, 2011). That is, the Cambrian is the time when lineages generally recognized as classes and in some cases phyla in the Linnaean hierarchy emerged.

The Cambrian fossil record is characterized by its famous 'weird wonders.' These are exceptionally well preserved fossils, from Burgess Shale type (BST) deposits that occur from Cambrian Stage 2 onwards, and include iconic species like *Anomalocaris*, *Halkieria*, and *Hallucigenia* (**Figure 3**). BST deposits also provide evidence of soft-bodied animal groups otherwise poorly known or unknown from the fossil record and place a minimum age on their origin. These include sipunculans (Huang *et al.*, 2004), tunicates (Chen *et al.*, 2003), hemichordate worms (Caron *et al.*, 2013), and chaetognaths (Vannier *et al.*, 2007). BST biotas are now known to be geographically and temporally widespread (**Figure 1**) and new localities are still being discovered (Caron *et al.*, 2014). Cambrian fossils from BST deposits, as well as the older 'small shelly fossils' (**Figure 3(f)**), and the more recently discovered small carbonaceous fossils (Butterfield and Harvey, 2012), represent exceptional windows into the early evolution of the extant animal phyla. Many Cambrian organisms belong to the stem groups of the extant phyla (for explanation, see **Figure 2** and Glossary), and consequently their morphology provides key information regarding the common ancestors of extant animal phyla, and the sequence of character transformations that led to the origin of their morphologies.

BST fossils are among the best-preserved invertebrates fossil known, and their importance for understanding animal evolution is undoubted. However, their evolutionary interpretation is not without controversies. For example, Conway Morris and Peel (1995) presented a revolutionary interpretation of *Halkieria* and used it to link the stem lineages of molluscs, annelids, and brachiopods. They proposed that *Halkieria evangelista* (**Figure 3**) was a stem-group brachiopod, advocating homology between the anterior and posterior shell and the shells of brachiopods. In this scheme annelids also evolved from a *Halkieria*-like animal, with the chaetae (bristles) of stem annelids (**Figure 3**) suggested as derived from the mineralized sclerites of halkieriids. However, the body plan and sclerite morphology of *Halkieria* has many similarities with aculiferan molluscs – chitons and their relatives (Vinther and Nielsen, 2005), and *Halkieria* is perhaps better explained as a stem aculiferan, phylogenetically predating the evolution of intermediate shell plates as seen in extant chitons (Vinther, 2015). Furthermore, the most primitive stem-group annelids have simple chaetae (Parry *et al.*, 2015), that are very different from the sclerites of halkieriids.

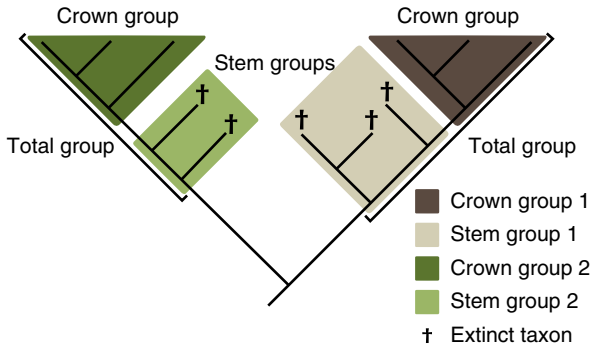

Figure 2 Graphical explanation of the stem-group, crown group, and total-group phylogenetic concepts.

Cambrian ecdysozoans have been extensively studied and include several unique extinct morphotypes, like the iconic Anomalocaridids (**Figure 3**), Cambrian apex predators with grasping frontal appendages and acute vision (Paterson *et al.*, 2011). Anomalocaridids are stem arthropods and provide evidence for the complexity of early animal ecosystems. *Tamisiocaris*, an anomalocaridid from Sirius Passet, has an appendage morphology indicative of filter feeding, but is well nested within this predatory lineage (Vinther *et al.*, 2014). The acquisition of a filter feeding ecology from a large-bodied predatory ancestor is known in modern animals (e.g., the whales) and *Tamisiocaris* thus indicates that familiar evolutionary trends and ecological phenomena known from well-understood animal lineages had been established as early as Cambrian Stage 2.

Investigations of the Cambrian ecdysozoan fossil record have uncovered candidate stem and crown group members of many of its constituent phyla. Such taxa include character combinations that can be useful to infer the morphology of the last common ecdysozoan ancestor. The long problematic *Hallucigenia* (**Figure 3**) has now been identified to belong in the onycophoran stem lineage. *Hallucigenia* has been shown to possess onycophoran like claws, but it possesses a foregut armature lined with a circlet of elements, pharyngeal teeth, and mouthparts similar to those of taxa like the priapulids (Smith and Caron, 2015). This would suggest that the last common ancestor of Ecdysozoa most likely had priapulid-like mouthparts.

Trilobites (**Figure 3**) are important Paleozoic euarthropods and first appear in Cambrian Series 2 (**Figure 1**; Liñán *et al.*, 2015). Despite their robust, mineralized skeletons, there is a lag between the origin of trilobites and their first appearance as fossils, mirroring general trends in the fossil record of animals. When trilobites first appear, they are already separated into distinct geographic faunas, suggesting a significant hidden evolutionary history (Lieberman, 2002).

It is now known that by the end of the Cambrian, all of the phyla with a mineralized skeleton must have existed. Subsequently, the Great Ordovician Biodiversification Event recorded a diversification of animals at taxonomic ranks below phylum level and also the increase of ecological phenomena like bioerosion (Servais *et al.*, 2010). The causes of the Cambrian explosion have been the subject of intense debate and range from biotic factors such as an intense predator–prey arms race to abiotic factors including the end of snowball Earth glaciations (Marshall, 2006). The role of oxygen has been particularly prominent in this discussion, and an increase in oxygen concentrations is often invoked as a driver for the

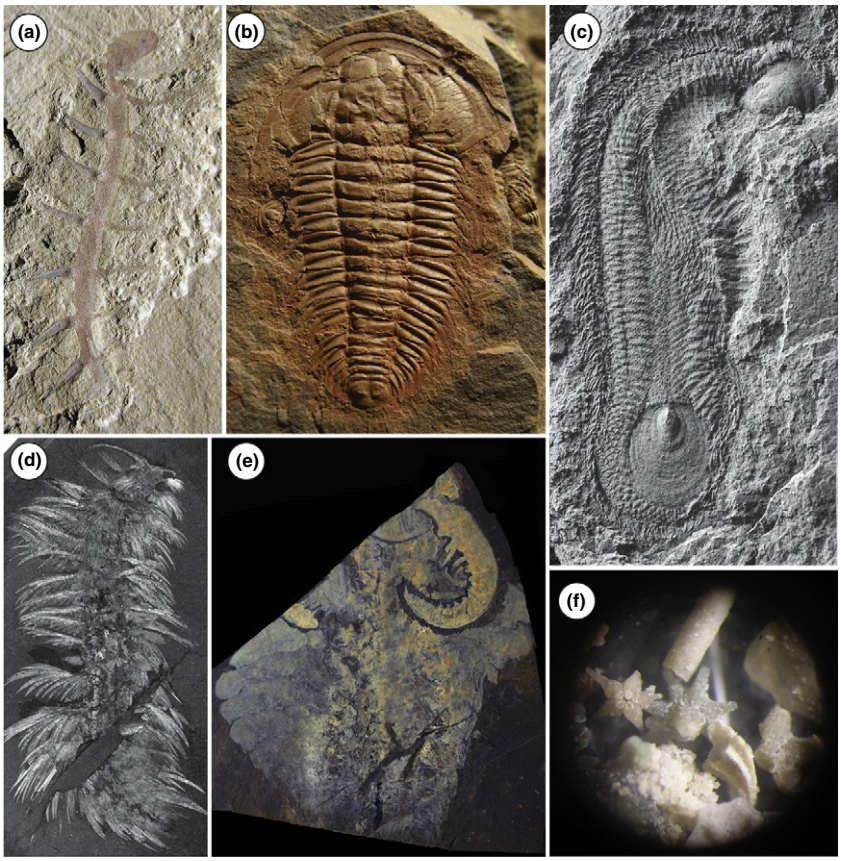

Figure 3 Cambrian fossils. (a) *Hallucigenia fortis*, a stem Onycophoran from the early Cambrian Maotianshan Shales; (b) *Redlichia takooensis* an early Cambrian trilobite from South Australia; (c) *Halkieria evangelista* an early Cambrian mollusc; (d) *Canadia spinosa*, from the middle Cambrian Burgess Shale; (e) *Anomalocaris canadens* from the middle Cambrian Burgess Shale; (f) Examples of small shelly fossils (SSFs).

origin of animals in the Neoproterozoic, for a review see Sperling *et al.* (2015).

While BSTs, small carbonaceous fossils, and the small shelly fossils offer important insights into the morphology of the earliest members of the major bilaterian lineages, Cambrian fossils are mute on the origins of animals and on the origin of the Bilateria, as these groups had a deeper (Precambrian) history. To attempt understanding the origin of animals we must thus look deeper to the Ediacaran fossil record and beyond.

The Ediacaran Record and the Origin of Animals

The Ediacaran (631–541 Mya) is the period preceding the Cambrian. Paleontological and genomic evidence suggests that minimally this is the period during which the deepest divergences within Bilateria and perhaps Metazoa took place (see above, Erwin *et al.*, 2011; dos Reis *et al.*, 2015).

When Darwin penned the origin of species, he lamented the absence of body fossils in strata older than the Cambrian (then part of the Silurian period) and consequently the lack of direct fossil evidence for the origin of animals. Darwin's disdain for the fossil record led him to assert that 'no organism wholly soft can be preserved.' Fortunately, this prediction proved to be false, and there is a wealth of soft-bodied fossils from Ediacaran rocks that document animal life before the Cambrian. When such sites were discovered, the belief that Precambrian rocks were barren led to the conclusion that the rocks, and consequently the fossils they preserve, could not possibly be from this time. This changed in 1958 with the discovery of *Charnia masoni* (Ford, 1958) in Charnwood forest in Leicestershire from unequivocally Precambrian sediments. Subsequently similar fossils, such as those from the Ediacara Hills in Australia, were later recognized to be Precambrian in age.

The oldest of the classic 'Ediacara biota' type macrofossils are known from the Avalon assemblage of Newfoundland, which appear a few million years after the Gaskiers glaciation (582–580 Mya). This assemblage contains many taxa of the rangeomorphs, a group to which *Charnia* belongs. The Avalon assemblage is then followed by the White Sea (~560–550 Mya) and Nama (~550–541 Mya) assemblages (Waggoner, 2003) that are characterized by distinct biotas with some taxonomic overlap. The White Sea assemblage is the most diverse while the Nama is significantly more taxonomically depauperate (Darroch *et al.*, 2015). The Ediacaran macrofossils were initially interpreted as relatives of extant taxa such as jellyfish and sea pens (Glaessner, 1984). Many of these interpretations were then overturned as they were based only on superficial similarity, see Antcliffe and Brasier (2007) for an

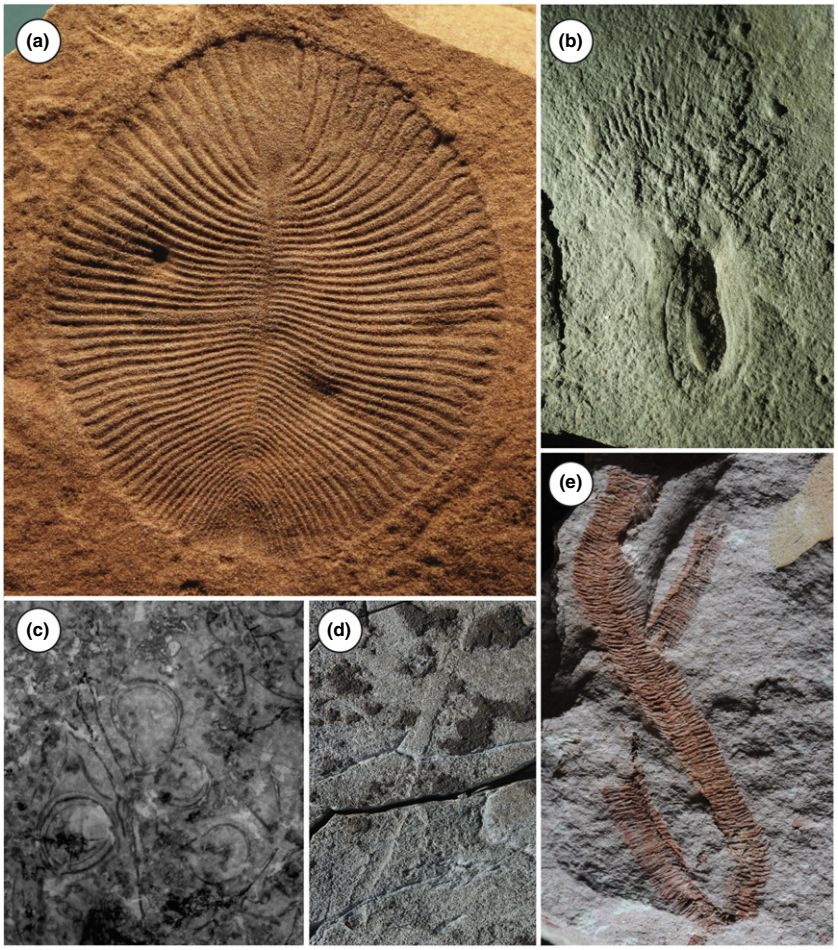

Figure 4 Ediacaran fossils. (a) *Dickinsonia costata*, Flinders Ranges, South Australia; (b) *Kimberella quadrata* from the Erginskaya formation; (c) *Cloudina sp.* from the late Ediacaran of Brazil; (d) Surface trail from the Mistaken Point Formation, Newfoundland; (e) *Corumbella werneri* a tubular cnidarian like body fossil from the late Ediacaran of Brazil.

example, leading to further reinterpretations of these fossils. Alternative interpretations have viewed these organisms as potentially belonging to every multicellular eukaryotic lineage, including a proposed independent and wholly extinct experiment in multicellularity known as the Vendobionta (Seilacher, 1992). While at least some ediacarans are considered metazoans, such as *Kimberella* and *Corumbella* (see below), the affinities of many Ediacaran organisms, like the rangeomorphs, are still unclear.

There is perhaps no Ediacaran fossil more iconic, or with a taxonomic history more tumultuous, than *Dickinsonia* (**Figure 4**), which has been considered a polychaete worm (Wade, 1972), a placozoan like animal (Sperling and Vinther, 2010), a lichen (Retallack, 1994), a cnidarian (Valentine, 1992), a protist (Seilacher *et al.*, 2003), and total group (see Glossary and **Figure 2**) Bilateria (Gold *et al.*, 2015). Due to the simple construction of these fossils, functional morphology and development may be helpful tools in determining their affinities. For example, if passive mechanisms for the formation of *Dickinsonia* feeding traces can be ruled out (Mcllroy *et al.*, 2009), *Dickinsonia* can be assumed to have been motile and muscular and consequently would have to be of a grade of organization higher than the sponges. Sperling and Vinther (2010) presented a more precise hypothesis for the affinities of *Dickinsonia* based on its mode of feeding. *Dickinsonia* fossils suggest that it was feeding with its ventral surface. This is because trace fossils with opposite relief to *Dickinsonia* fossils are generally associated with these fossils. This suggests that the whole ventral surface was digesting and absorbing organisms from the microbial mat over which *Dickinsonia* was crawling (Sperling and Vinther, 2010). Among extant taxa, feeding with the ventral surface is a phenomenon restricted to placozoans, hence the suggestion of a possible close affinity between these taxa. It is plausible that other enigmatic Ediacaran organisms fed through their external body surface as well, given that organisms like the rangeomorphs lack evidence for a mouth or gut and have a high surface area to volume ratio (Laflamme *et al.*, 2009).

From an evolutionary perspective, perhaps the most important among the Ediacaran fossils are *Kimberella* (Fedonkin and Waggoner, 1997) and annulated tubular fossils like *Corumbella werneri* (Pacheco *et al.*, 2015). *Kimberella* is generally interpreted as a total group mollusc, also because some *Kimberella* fossils have been found in association with scratching traces on microbial mats compatible with a radula-like feeding apparatus. *Corumbella werneri* shares ultrastructural similarities with both extant coronate scyphozoans (the

'crown' jellyfish – phylum Cnidaria) and the extinct conulariids (Pacheco *et al.*, 2015), potentially bridging the morphological gap between these putatively closely related groups (Van Iten *et al.*, 2006). Fossils like *Corumbella* may be the oldest animal body fossils, and if it that was the case they would extend the evidence for the existence of Cnidarians (*Corumbella*) and perhaps Bilateria (*Kimberella*) to ~550 Ma and ~558 Ma, respectively.

The ecology of the Ediacaran was different in several crucial respects to that of the Phanerozoic. Substrates were dominated by microbial matgrounds which give way to Phanerozoic style mixgrounds across the Ediacaran–Cambrian transition (Buatois *et al.*, 2014). Trace fossil diversity is limited to horizontal grazing trails and burrows (Mángano and Buatois, 2014) as well as horizontal (**Figure 4**) and vertical structures attributed to cnidarian grade animals (Liu *et al.*, 2010; Menon *et al.*, 2013). The marked difference between Ediacaran and Cambrian trace fossil assemblages highlights the fact that although motile animals were certainly present in the Ediacaran, the diversification of bilaterian clades close to the Precambrian–Cambrian boundary changed the taxonomic make up of marine communities, the geochemical environment of the substrate (with the onset of bioturbation), and the ecological interactions between organisms. While the matground environments typical of the Ediacaran do persist into the early Cambrian, the Ediacaran macroorganisms are conspicuously absent (Buatois *et al.*, 2014). This suggests that their disappearance is not the closure of a taphonomic window due to the demise of matgrounds, but instead represents a faunal turnover or mass extinction which is also supported by studies of late Ediacaran diversity and geochemistry (Darroch *et al.*, 2015).

Biomarker Evidence for a Pre-Ediacaran Origin of Animals

While there are no animal-like body and trace fossils older than ~600 Ma, fossil biomarker extends the possible existence of sponges deeper into the Cryogenian but not earlier than the late Tonian, maximally to 713 Ma (Love *et al.*, 2009). 24-isopropylcholestane has been suggested as a biomarker for Demospongiae, which is the largest of the four lineages of extant sponges (Love *et al.*, 2009), see **Figure 1**. The veracity of sponge biomarkers has been recently challenged (Antcliffe, 2013) and successfully defended (Love and Summons, 2015). The biomarker record demands a substantial gap in the sponge body fossil record, of approximately 240 Ma (Sperling *et al.*, 2010). However, early sponges might have been no more complex than simple colonies of unicellular eukaryotes that might have been difficult to fossilize as multicellular aggregates. Interestingly, the biomarker records allow for a substantial reconciliation of the molecular divergence times of the evolution of animals, and the fossil record.

Evidence from the Genomic Record

Our understanding of animal evolution has been revolutionized by the increasing application of molecular sequence data to unraveling animal phylogeny. Old concepts like Articulata (a clade of arthropods and annelids) have found little support from molecular systematics and have been replaced with Lophotrochozoa (a clade of animals with a trochophore larva or a lophophore), and Ecdysozoa (the clade of the animals that molt their cuticle). The fossil record lends support to these concepts, with fossils known that share characters with both Onycophorans, Arthropods, and Priapulida within Ecdysozoa (e.g., *Hallucigenia* – see above), and fossils that highlight the similarity between molluscs, brachiopods, and annelids (Butterfield, 1990; Conway Morris and Peel, 1995).

The relationship between molecular divergence time estimates and the Cambrian explosion have a checkered history, with early studies recovering divergence dates for both the origin of animals and of the major split within Metazoa in the Mesoproterozoic (~1.5–1 Gya – e.g., Wray *et al.*, 1996). However, such studies used simplistic assumption about the molecular evolutionary process, and practices that had been strongly stigmatized in subsequent papers. Notable among these was Graur and Martin (2004): 'Reading the entrails of chickens: molecular timescales of evolution and the illusion of precision,' that single handedly put to rest 20 years of dubious molecular clock studies. Recent studies using recently developed (relaxed) molecular clock methods and multiple calibrations have recovered dates more congruent with the fossil record (e.g., dos Reis *et al.*, 2015; Erwin *et al.*, 2011; Parfrey *et al.*, 2011). Erwin *et al.* (2011) found that deep divergences in the animal tree of life occurred in the Precambrian, but less than 800 Ma – i.e., animals are not older than the Cryogenian or the late Tonian, while the diversification of the crown groups of the animal phyla occurred within or just before the Cambrian (**Figure 1**). This confirms the Cambrian explosion was a real evolutionary event; even if it did not correspond with the origin of animals. There are caveats to interpreting such studies, however, as uncertainties in the internal phylogeny of clades render it uncertain whether or not the crown node has been properly bracketed, such as in annelids (Parry *et al.*, 2014). Further on a more recent study by dos Reis *et al.* (2015) have exposed the sensitivity of such analyses to calibration and have questioned the precision that is achievable in molecular clock analyses deep in the animal tree of life (dos Reis *et al.*, 2015). While studies such as (dos Reis *et al.*, 2015) are welcome and represent important sanity checks, it is interesting to note that they confirmed a possible maximal age for the origin of animals not deeper than the Cryogenian, and diversification of the animal phyla close to the Cambrian or within the Cambrian. That is, the study of dos Reis *et al.* (2015) confirmed a Neoproterozoic (<800 Ma), rather than Mesoproterozoic (~1.5 Ga) origin of animals and the Cambrian radiation of the crown members of the animal phyla.

Conclusions

Both the fossil record and molecular divergence times support a significant diversification of animals close to the Precambrian–Cambrian boundary. From this perspective the Cambrian explosion has to be considered a real evolutionary event, rather then a mere increase in fossil abundances. The Cambrian fossil record documents the early history of numerous bilaterian phyla

but provides no information on the origin of the groups deeper in the animal tree. To gain information about the origin of lineages that diverged closer to the root of the animal tree we have to look at the Precambrian record and at the genomic record. Sponges are the earliest diverging animals (Pisani *et al.*, 2015) and are known from Precambrian (Cryogenian) fossil biomarkers and cnidarians are known from the Ediacaran, broadly in line with the predictions of molecular divergence times. Overall, we can conclude that there is a reasonable agreement between molecules and the fossil record, and that what we could call a 'Molecular Paleobiological Approach' is allowing a congruent picture for the origin and early evolution of animals to emerge, even if convergence of independent lines of evidence is not quite there yet. We are however hopeful that further paleontological explorations and improvement in molecular clock methods will in the next decades lead to a complete understanding of the origin and early evolution of animals.

Glossary

Calvin–Benson Cycle Series of chemical reactions that constitute the light-independent phase of photosynthesis; occur in the chloroplasts; and use CO_2, H_2O, and ATP/NADH to produce glucose.

Enabler Trait of an organism which facilitates the evolution of another trait.

Epiphytism Plant life strategy involving growing on the surface of another plant.

Molecular dating Technique used to date biological events based on the number of changes accumulated in DNA molecules, calibrated with absolute time data from the fossil record.

Monophyletic A group of organisms consisting of all the descendants of a single ancestral species.

Photorespiratory cycle Series of energetically costly reactions which recycle the three carbon product that results from the oxygenation reaction of RuBisCO.

Photosystem Protein complexes which facilitate the conversion of light energy into chemical reducing power during photosynthesis.

Phylogeny The study of the patterns of branching of populations of organisms into subpopulations or new species.

Stomata Pores found in the epidermis of plants through which exchanges with the atmosphere occur.

It is remarkable that almost all assimilation of inorganic carbon into food chains around the world is performed by a single enzyme, ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco; Raven, 2013). This enzyme is used by all photosynthetic organisms for the fixation of atmospheric CO_2 in the Calvin–Benson cycle, which constitutes the light-independent phase of photosynthesis. Despite this quasi-universality, the enzyme seems rather poorly suited for the current conditions of Earth (Tcherkez *et al.*, 2006). Rubisco is estimated to have evolved more than 2.7 billion years ago (Nisbet *et al.*, 2007), on a version of planet Earth that was very different. The atmosphere of this time was extremely rich in CO_2 and almost devoid of O_2 (Kasting, 1993). Rubisco happened to evolve with a propensity to confuse the O_2 and CO_2 substrates, two featureless molecules (Tcherkez *et al.*, 2006). This was not problematic in the O_2-free environment of Rubisco early history and was consequently not counter-selected. However, O_2 became very abundant in the atmosphere following the expansion of photosynthetic organisms some 2.4 billion years and CO_2 levels continuously decreased during Earth's history (Bekker *et al.*, 2004; Kaufman and Xiao, 2003). The emergence of an atmosphere where O_2 is more abundant than CO_2 revealed the flaws of Rubisco to natural selection (Sage, 1999; Christin and Osborne, 2013). When O_2 is abundant, it will be incorporated in a significant proportion of Rubisco reactions. The products of O_2 fixation by Rubisco are toxic and need to be recycled by the photorespiratory cycle (Ogren, 1984). This cycle consumes energy to release CO_2, and can therefore be considered a wasteful process. In total, up to 29% of light energy is dedicated to photorespiration in the current atmosphere (Skillman, 2008), which strongly decreases plant productivity in conditions where relative CO_2 concentration is low (Zelitch, 1973).

Despite its flaws, Rubisco was never replaced by a better CO_2-fixing enzyme, even though some exist in other pathways (reviewed in Rothschild, 2008). This is probably because it was too integrated in the photosynthetic metabolism, which happens to be the most successful autotrophic process. Rubisco enzymes with higher specificity were however gradually selected, which came at the expense of catalytic efficiency (Tcherkez *et al.*, 2006; Young *et al.*, 2012). In conditions where CO_2 depletion is strongest, this evolutionary fix reached its limits and plants had to find additional tricks to prosper. One of these is represented by the carbon-concentrating mechanisms (CCMs), which solve Rubisco's deficiencies by concentrating CO_2 around the enzyme, reducing the relative concentration of oxygen and therefore the amount of photorespiration (Sage, 1999; Christin and Osborne, 2013). In land plants, the most frequent CCMs are C_4 and crassulacean acid metabolism (CAM) photosynthesis, two adaptive novelties that represent exceptional evolutionary and ecological success stories. In this article, we will review the history of C_4 and CAM plants, from their evolutionary origins to their recent diversification across the globe.

C_4 and CAM Photosynthesis, Two Adaptations that Reduce Photorespiration

C_4 and CAM operate using the same biochemical mechanism, but diverge in their spatiotemporal organization. They use an enzyme other than Rubisco to fix atmospheric CO_2 into organic compounds, namely phosphoenolpyruvate carboxylase (PEPC). This enzyme has no affinity for O_2, but its product cannot be directly integrated into the Calvin–Benson cycle. Instead, the resultant four-carbon product is transformed and transported via different carbon shuttles until CO_2 is finally released by one of three possible decarboxylating enzymes to feed Rubisco and the Calvin–Benson cycle (Osmond, 1978; Hatch, 1987). Other enzymes are then involved to regenerate the intermediate compounds of the cycles (**Figure 1**). These additional enzymatic reactions increase the energetic cost of carbon fixation (Kanai and Edwards, 1999).

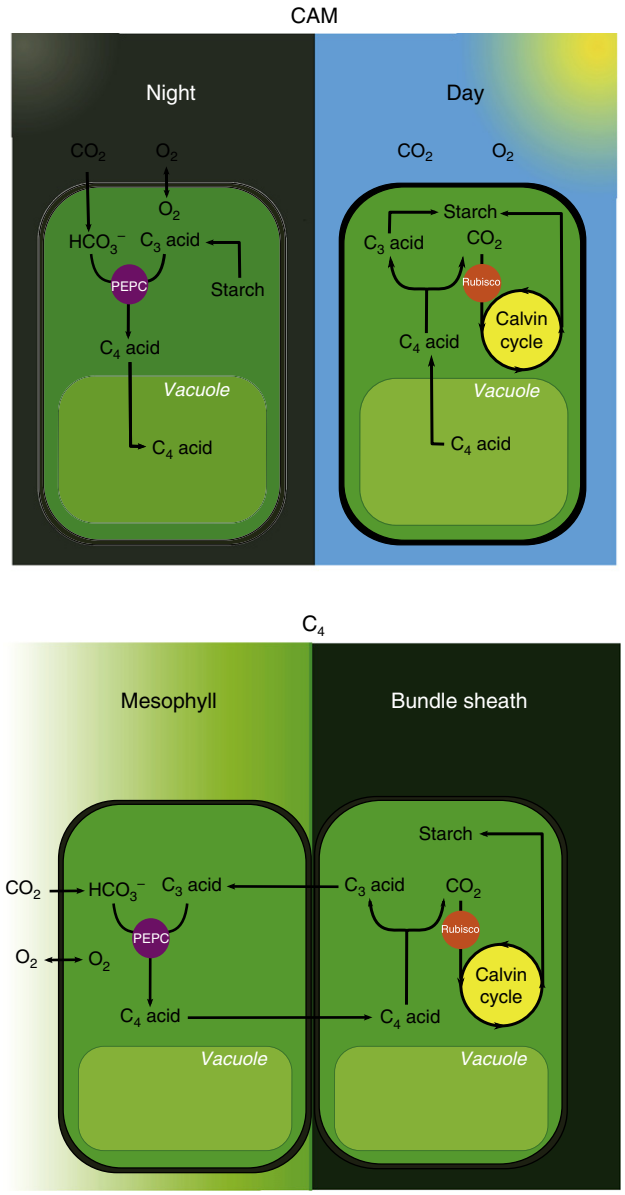

Figure 1 Schematic of C_4 and CAM cycles. In classical CAM, gas exchanges with the atmosphere take place at night. At this time, PEPC is expressed and catalyzes the fixation of atmospheric CO_2 (in the form of HCO_3^-) to a C_3 acid to create a C_4 acid, which is stored in the vacuole (usually in the form of malate). In the day, PEPC activity is downregulated and Rubisco activity is upregulated. The C_4 acid leaves the vacuole and is decarboxylated, releasing CO_2 which can be fixed by Rubisco and used to synthesize starch via the Calvin cycle. In C_4, gas exchanges with the atmosphere take place primarily in the mesophyll cells. There, PEPC is expressed and catalyzes the fixation of atmospheric CO_2 (in the form of HCO_3^-) to a C_3 acid to create a C_4 acid, which is actively transported into the bundle sheath cells. Here it is decarboxylated, releasing CO_2 which can be fixed by Rubisco and used to synthesize starch by the Calvin cycle. Note in both cases the separation of Rubisco activity and atmospheric oxygen.

In both CCMs, PEPC acts as an additional filter on the atmospheric gases that can reach Rubisco. The main consequence of this filter is that mostly CO_2 is available for Rubisco, and photorespiration is strongly decreased (Skillman, 2008). This effect requires a segregation of PEPC and Rubisco activities, and an isolation of Rubisco from atmospheric gases. This is achieved spatially in C_4 plants and temporally in CAM plants (Figure 1).

In C_4 plants, PEPC and Rubisco activities are synchronized and happen during the light period, when the photosystem is active and provides ATPs (Hatch and Osmond, 1976). PEPC activity is localized in compartments within the leaf that are in direct contact with atmospheric gases, which reach them via diffusion through the stomata (Lundgren *et al.*, 2014). Rubisco activity is segregated in compartments that are nested deeper within the leaf, where contact with the atmosphere is limited. In most C_4 plants, PEPC is localized in mesophyll cells while Rubisco is segregated in bundle sheath cells, which surround the veins and are encircled by mesophyll cells (Figure 1; Lundgren *et al.*, 2014). This segregation can however be

achieved within a single cell, in which case PEPC and Rubisco are segregated in different areas generated through a reorganization of subcellular components (Edwards *et al.*, 2004).

The main effect of the C_4 trait is to decrease photorespiration, but this benefit is partially offset by the extra energetic cost of the C_4 reactions, so that it is advantageous only in conditions where photorespiration rates are high (Ehleringer and Björkman, 1977). While low atmospheric CO_2 concentration is a necessary precondition for photorespiration, temperature plays an important role too. The solubility of CO_2 decreases faster with temperature than that of O_2 and the specificity of Rubisco decreases with temperature, so that relative O_2 concentration increases with leaf temperature (Ku and Edwards, 1978; Jordan and Ogren, 1981). C_4 is consequently mainly advantageous in warm climates, where most C_4 plants are distributed (Ehleringer *et al.*, 1997). Aquatic plants can similarly gain an advantage from the C_4 trait in high-light, high-temperature environments with limited dissolved CO_2 (Keeley and Rundel, 2003). Because C_4 plants can photosynthesize at low CO_2 concentrations, they can also maintain carbon assimilation despite limited exchange with the atmosphere. This allows for a closure of stomata, which limits water loss and provides an advantage in arid and saline conditions (Osborne and Sack, 2012). Finally, the C_4 trait increases the number of CO_2 molecules fixed per Rubisco protein, which improves nitrogen-use efficiency and can confer an advantage in nutrient-poor environments (Brown, 1978). In summary, the C_4 CCM is advantageous in all conditions where the benefit of reducing photorespiration offsets the additional energetic requirements (Sage *et al.*, 2012; Christin and Osborne, 2014).

In CAM plants, PEPC and Rubisco activities are not synchronized. Instead, the fixation of atmospheric CO_2 happens during the night, and the produced C_4 acids are stocked as malate in the vacuole. CAM is often associated with succulence, where large vacuoles allow the storage of high concentrations of malate (Nelson and Sage, 2008). The CO_2 is extracted from malate during the light period to feed Rubisco and the Calvin–Benson cycle, whose activity is synchronized with the photosystem (Osmond, 1978). The main consequence of CAM is to allow closure of stomata during the day, as atmospheric gases are sequestrated in the plant during the night (Osmond, 1978). Stomatal opening leads to water losses through transpiration, which is exacerbated during the warmth peaks of the light period. With water-use efficiencies up to sixfold higher than non-CAM plants (Borland *et al.*, 2009), CAM plants are consequently highly adapted to arid climates and saline environments, and several plants develop a CAM cycle only during periods of drought or high salt (Winter and Holtum, 2014). Some CAM plants can, in periods of extreme drought, keep their stomata closed throughout the diurnal cycle and recycle respiratory CO_2, which does not sustain growth but allows the plant to maintain functionality until more water is available (Lüttge, 2004). CAM species are also present in dry microenvironments in otherwise well-watered climates – in tropical forests, epiphytism is a life strategy that is linked to limited water availability and there are consequently many CAM epiphytic orchids, bromeliads, and ferns (Griffiths, 1989). CAM can even be advantageous when plants are fully immersed in water, which restricts CO_2 uptake during the day due to the low diffusivity of CO_2 in water (Keeley, 1998; Pedersen *et al.*, 2011). When CO_2 fixation continues during the day, the night fixation of CO_2 by PEPC extends the period of CO_2 uptake, potentially up to 24 h. This process has also been shown to enhance carbon uptake in bromeliads in cloud forests where dew can inhibit gas exchange (Pierce *et al.*, 2002). As in C_4, the additional reactions of CAM have an energetic cost and CAM plants are generally associated with low growth rates (Lüttge, 2004). Closing stomata comes at a cost, as it prevents oxygen produced during photosynthesis to efflux from leaves, potentially increasing oxygenic stress toward the end of the day (Lüttge, 2002). In summary, CAM is associated with a variety of lifestyles, and similar to C_4, can be associated to a number of ecological factors that all result in different ways from low CO_2 availability (Edwards and Ogburn, 2012).

Evolutionary Origins of C_4 and CAM Photosynthesis

The C_4 and CAM CCMs are traits of impressive complexity, which result from the coordinated action of multiple anatomical and biochemical components. Despite this complexity, each of them evolved multiple times independently. Over the last 15 years, phylogenetic efforts have elucidated the relationships between C_4 plants and those lacking this trait (e.g., Giussani *et al.*, 2001; Kadereit *et al.*, 2003, 2012; Grass Phylogeny Working Group II, 2012). These efforts have identified numerous monophyletic C_4 groups separated by other photosynthetic types in the phylogenetic trees. While some phylogenetic patterns might be interpreted in some cases as either multiple C_4 origins or fewer origins followed by losses of the C_4 trait (Duvall *et al.*, 2003; Ibrahim *et al.*, 2009), anatomical and biochemical differences among monophyletic C_4 groups as well as differences in the identity of genes co-opted to evolve the C_4 trait clearly point to a predominance of C_4 origins over losses (Christin *et al.*, 2010), and it is estimated that C_4 originated more than 62 times independently in angiosperms (Sage *et al.*, 2011). The number of CAM origins is not known with confidence, mainly because establishing whether specific plants are able to perform CAM can be challenging. For instance, some plants can switch to CAM depending on the environmental conditions or have a CAM cycle contributing to only part of their carbon assimilation (Winter and Holtum, 2014; Winter *et al.*, 2015). In such cases, determining the photosynthetic type requires detailed physiological analyses. Despite this uncertainty, CAM is present in distant phylogenetic groups, including lycophytes, gymnosperms, monocots, and eudicots, and multiple origins are established in some groups (e.g., Crayn *et al.*, 2004; Bone *et al.*, 2015). Overall, it is estimated that the tally of CAM origins might even exceed the number of C_4 origins (Edwards and Ogburn, 2012).

The apparent paradox between the complexity of CCMs and their recurrent origins is likely explained by the presence of CCM-like components in ancestors lacking these physiological adaptations. First, enzymes of the C_4 and CAM pathways exist in all plants, although they are ancestrally responsible for other functions (Aubry *et al.*, 2011). They can in some cases be already abundant in photosynthetic organs,

and it has been reported that C_4-like cellular localization of some enzymes existed before C_4 photosynthesis (Hibberd and Quick, 2002; Brown *et al.*, 2010). The C_4-specific expression of some enzymes, moreover, co-opted pre-existing regulatory mechanisms (Brown *et al.*, 2011). Low levels of CO_2 fixation in the dark, a possible precursor to CAM, have similarly been detected in some plants (Ikeda and Yamada, 1981; Winter and Holtum, 2015), and the similarity of the reactions controlling stomata opening to CAM has been suggested as a possible source of genetic material for CAM evolution (Cockburn, 1981). C_4-like anatomical features also existed before the C_4 physiology (Muhaidat *et al.*, 2011), and it has been shown that C_4 emerged from groups of plants that possessed C_4-like bundle sheaths (Christin *et al.*, 2011b; 2013). Succulence, which is associated with enhanced water storage as well as providing a large vacuole for malate accumulation, has been suggested as an enabler of CAM evolution (Sage, 2002) and indeed osmotically active malate accumulation in the vacuole can potentially facilitate water uptake (Lüttge, 2004).

The evolution of CCMs consisted of the co-option of all the required anatomical and biochemical components. It is established that this happened in a stepwise manner for C_4, with the existence of evolutionary stable intermediates (Sage, 2004; Christin *et al.*, 2011b; Sage *et al.*, 2012). These intermediates include plants with different degree of C_4 physiology, such as several yellowtops (*Flaveria*), some heliotropes (*Heliotropium*), and the perennial wall-rocket (*Diplotaxis tenuifolia*; Sage *et al.*, 2011). They are characterized by a weak CCM that relies on the segregation of photorespiratory reactions between the mesophyll and bundle sheath cells (Sage *et al.*, 2012). This trait, referred to as the C_2 pathway, uses anatomical features that are close to the C_4 requirements (Sage *et al.*, 2014) and might be advantageous in warm and dry conditions (Vogan and Sage, 2011). It therefore bridges the gap between the ancestral condition and C_4 plants, and models have suggested that the C_4 trait can be assembled through successively advantageous mutations from a C_2 ancestor (Heckmann *et al.*, 2013; Mallman *et al.*, 2014). Low levels of night-time CO_2 fixation, including recycling of respired CO_2, coupled with mostly Rubisco-based daytime photosynthesis, allows to reduce stomatal conductance during the day and thus improve water-use efficiency. This physiological strategy can lead to the evolution of better integrated CAM systems, which further limit water losses, therefore potentially acting as evolutionary intermediates (e.g., Sage, 2002; Edwards and Ogburn, 2012). The concentration of CCM-like components in some lineages of plants eases the transition toward C_4 or CAM photosynthesis, and likely explains both the repeated origins of CCMs and their clustering in some parts of the phylogenetic tree (Sage, 2001; Sage *et al.*, 2011; Edwards and Ogburn, 2012; Christin and Osborne, 2013).

Selective Pressures and Species Diversification

While many environmental factors can be linked to the selective advantages of CCMs, changes in atmospheric gas concentrations are thought to be a necessary precondition for C_4 and CAM photosynthesis. Indeed, C_4 is predicted to gain an advantage at high temperatures only in extremely low CO_2 concentrations (Ehleringer and Björkman, 1977; Ehleringer *et al.*, 1997) and the advantages of CAM in arid conditions are similarly tightly linked to CO_2 levels (Edwards and Ogburn, 2012). Molecular dating confirmed that all C_4 plants evolved in the low-CO_2 atmosphere that persisted for the last 30 million years (Christin *et al.*, 2008; Christin *et al.*, 2011a), a time that might also have seen the emergence of some CAM groups, although earlier origins are possible (Edwards and Ogburn, 2012, Keeley *et al.*, 2012). While low CO_2 seems a necessary precondition to CCM evolution, it is not sufficient, and other factors that exacerbate photorespiration probably promoted the evolution of C_4 or CAM in the different lineages. In grasses, C_4 photosynthesis evolved in open habitats of the warm regions (Osborne and Freckleton, 2009; Edwards and Smith, 2010), while C_4 origins in Caryophyllales happened in dry and saline environments (Kadereit *et al.*, 2012). In Bromeliaceae, CAM origins were more frequent in epiphytic taxa (Givnish *et al.*, 2014), and aridity is generally seen as the main driver of CAM evolution (Keeley *et al.*, 2012).

The evolutionary origins of CCMs are not linked in time to their ecological dominance. While C_4 origins are spread during the last 30 million years, the rise of C_4-dominated ecosystems is apparent in the fossil record in the last ten million years, and was driven mainly by C_4 grasses, which replaced either forested or open biomes depending on the geographical location (Edwards *et al.*, 2010). This ecological dominance is also linked to increased numbers of species. The C_4 trait has indeed be shown to increase diversification rates, but again, this occurred long after the initial emergence of C_4, suggesting that C_4 diversification was influenced by other phenotypic traits and ecological changes in addition to the photosynthetic type (Bouchenak-Khelladi *et al.*, 2014; Spriggs *et al.*, 2014). The Miocene, which saw the rise to dominance and increased diversification of C_4 grasses, also witnessed the convergent radiation of the major CAM lineages, including cacti and other groups typical of arid climates (Arakaki *et al.*, 2011; Horn *et al.*, 2014). The selective pressures for the origins of the C_4 and CAM CCMs are therefore likely decoupled from those that increased their ecological success. While Oligocene CO_2 decline and local ecological conditions promoted the origins of CCMs, the aridification and expansion of open habitats during the Miocene likely triggered the expansion and species diversification of both CCMs.

Effect of CCMs on the Ecological Niche

Both CCMs confer a number of physiological characteristics that are potentially influenced by other attributes of the plant and can confer advantages in various conditions depending on how the new photosynthetic types are integrated within the organism. It is therefore not surprising that the ecology of plants with CCMs reflects that of the ancestors lacking such CCMs (Edwards and Ogburn, 2012; Christin and Osborne, 2014). The ecology of plants with CCMs is however also influenced by the changes that happened after the origin of the CCM. In grasses, inferences of the ancestral ecological niches concluded that C_4 lineages shifted to slightly more arid conditions compared to their ancestors (Edwards and Smith, 2010), and C_4 has been shown to statistically increase the rate of transition to both arid and saline

habitats (Osborne and Freckleton, 2009; Bromham and Bennett, 2014). C_4 can therefore be considered as a niche opener. A recent study of C_4 ecological effects within a single species complex showed that C_4 initially broadened the niche without shifting it (Lundgren *et al.*, 2015). This would allow young C_4 groups to explore new areas of the ecological space, with a possible subsequent specialization to more extreme conditions (Christin and Osborne, 2014). The evolution of CAM photosynthesis similarly facilitated the colonization of new niches. It has been suggested that CAM-like physiology might promote succulence, strengthening the ecological association to arid environments in some groups (Edwards and Ogburn, 2012). Phylogenies have confirmed that CAM facilitated the transition from humid to dry habitats in some terrestrial orchids (Bone *et al.*, 2015) and *Kalanchoe* (Kluge *et al.*, 2001). The ability of many CAM plants to plastically get rid of CAM photosynthesis may also open niches in stressful, changing environments such as near the shore in lakes (Aulio, 1985), and is thought to contribute to the wide range of niches occupied by the *Clusia* genus of trees (Lüttge, 2008).

Concluding Remarks

C_4 and CAM photosynthesis are complex traits that were recurrently assembled by plants through the co-option of multiple anatomical and biochemical components. They represent evolutionary strategies to address the affinity of Rubisco for O_2, inherited from cyanobacteria, billions of years ago. Their main effects are to decrease photorespiration and increase water-use efficiency, which allow the colonization of a diversity of habitats. This includes warm, arid, saline, low-nutrient, and aquatic habitats, all of which lead to a depletion of internal CO_2 concentrations. These ecological attributes favored the spread and diversification of C_4 and CAM lineages during the Miocene, when open and arid environments expanded. In addition, the C_4 and CAM traits enable the exploration of new ecological niches when integrated with the other attributes of the organism. Overall, these properties contributed to the ecological success of C_4 and CAM plants, which nowadays cover most of the open habitats in the tropic and subtropical regions of the globe. C_4 photosynthesis alone is estimated to contribute to 25% of terrestrial primary production (Still *et al.*, 2003), and C_4 grasses have shaped multiple biomes, with an influence on major groups of herbivores, strong impacts on human evolution, and a key role in the feeding of human population (Sage and Stata, 2015).

Carbon Relations, the Role in Plant Diversification of

B Oberle, New College of Florida, Sarasota, FL, USA

Glossary

Biogeochemistry The integrated study of processes that involve chemical exchanges between living and nonliving systems at a global scale.

C4 photosynthesis A suite of anatomical and physiological adaptations in several lineages of plants, notably about half of all grass species, to concentrate CO_2 in and limit photosynthesis to bundle sheath cells that starts by fixing atmospheric CO_2 in a 4-carbon compound.

Calcifier An organism that precipitates calcium carbonate ($CaCO_3$) compounds from carbonate (CO_3^{2-}) ions dissolved in seawater.

Carbon pool A large reservoir of carbon compounds with relatively homogeneous dynamics, connected to other such pools via fluxes of organic and inorganic carbon compounds.

Residence time A model-based estimate for the average length of time a unit of carbon resides in a particular carbon pool.

Rock weathering The temperature-dependent chemical reaction of carbonate and silicate minerals with carbon acidic carbon compounds in rainwater or soils.

Slow carbon cycle The slow and largely geological exchange of carbon compounds from minerals in the crust, to dissolved carbon in the oceans, to carbonate minerals in the seafloor, to CO_2 emitted with volcanic eruptions.

Thermohaline circulation The movement of currents driven by variation in seawater density that arises from geographic gradients in marine temperature and salinity.

Tracheophyte An evolutionary lineage, also known as vascular plants, which includes clubmosses, flowering plants and their common ancestor, that is distinguished from other plants by lignified vascular tissues among other shared derived traits.

White rot A form of wood decay mediated by peroxidase enzymes that leaves whitish residues of crystalline cellulose.

Contemporary Carbon Cycle and Roles for Organisms

From an earth system perspective, the global carbon cycle consists of an interconnected set of carbon pools. A carbon pool represents a large reservoir of carbon compounds, generally measured in petagrams (10^{15} g, Pg), which exchanges carbon with other pools via fluxes of organic and inorganic carbon compounds. Modeling carbon pool dynamics, including the average residence time of carbon in any pool, requires simplifying assumptions that vary with the balance between precision and generality demanded by a particular research question. Consequently, the delineation of carbon pools varies from study to study. For a general understanding of the contemporary carbon cycle as it relates to biodiversity, the basic dynamics are captured by four carbon pools (Figure 1).

Atmosphere

The atmospheric carbon pool is relatively small (762 Pg) but cycles quickly, having a residence time of only three years (Sabine *et al.*, 2004). The short residence time reflects huge fluxes to other carbon pools. Each year, the atmosphere loses and regains over 190 Pg of carbon largely to photosynthesis on land (54%) or in the oceans (46%) (IPCC, 2013). Almost the same quantity of carbon returns to the atmosphere with respiration from plants and the heterotrophs they support. The biological drivers of atmospheric carbon dioxide concentrations are evident in its annual cycle (Figure 2). After the autumnal equinox, as day length and temperature fall in northern forests, the relative rate of photosynthesis falls. The atmospheric concentration of CO_2 concentrations rises to a peak 6 ppm higher in May, at which point increasing productivity during the northern spring drives a steep decline in atmospheric CO_2. The amplitude of this cycle reflects the massive effect of terrestrial ecosystems, and its sinusoidal shape reflects the near match of global photosynthesis and respiration across years. However, slight differences between input and output can drive changes in the size of the atmospheric carbon pool through time, over decades to millions of years.

Just as the short-term dynamics of the atmospheric carbon cycle are driven by the biological activity, biological dynamics are subject to feedback from atmospheric carbon through its effects on global climate. The two most abundant atmospheric carbon compounds, CO_2 and CH_4, are also among the two most important greenhouse gases (IPCC, 2013). Both transmit solar radiation but absorb and re-emit infrared radiation from the Earth's surface. Without the resulting greenhouse effect, Earth's surface would freeze, precluding the existence of life as we know it. Life also responds to variation in temperature associated with changes in greenhouse gas concentrations. The effects of climate change on biodiversity are complex and depend on both the direction and rate of change (Mayhew *et al.*, 2008; Oberle and Schaal, 2011). Today, habitats in warmer regions are more biodiverse, suggesting that a warmer world may accommodate more species (Allen *et al.*, 2002; Hawkins *et al.*, 2003). While this biogeographic pattern is clear, the mechanism driving it and the validity of the prediction are much more uncertain (Currie *et al.*, 2004). Compared to our incomplete understanding of how the direction of climate change impacts biodiversity, the effect of the rate of change is unambiguous: rapid climate change has accompanied every known mass extinction (Twitchett, 2006).

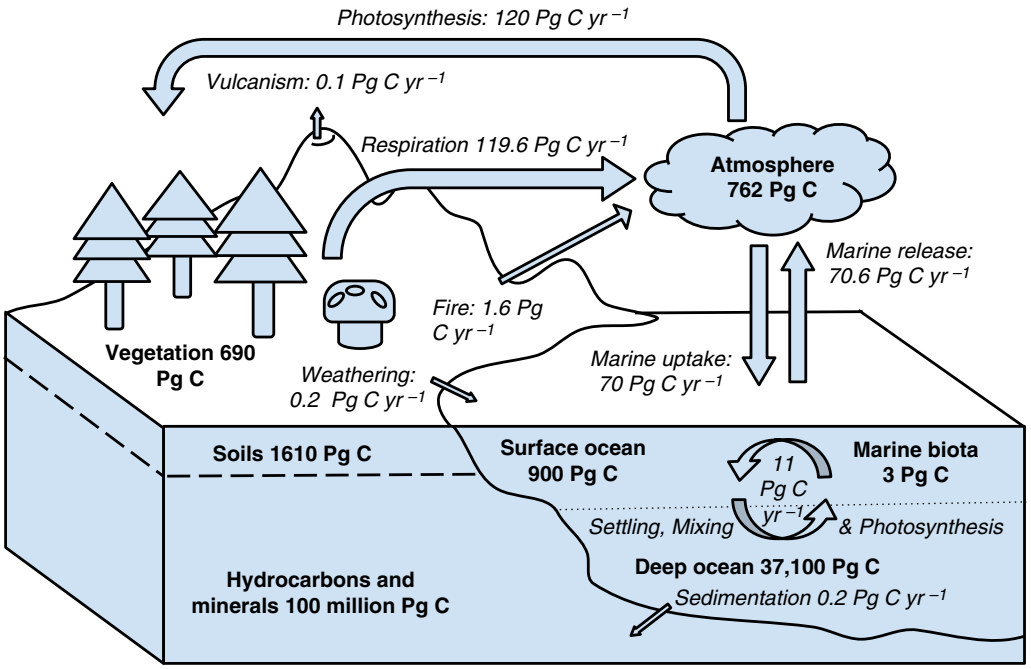

Figure 1 A representation of the natural carbon cycle in the 1990s based on estimates from IPCC (2013) with modifications from Sabine *et al.* (2004). Carbon pools are listed in bold while fluxes are in italic. Fluxes associated with human activity are not represented.

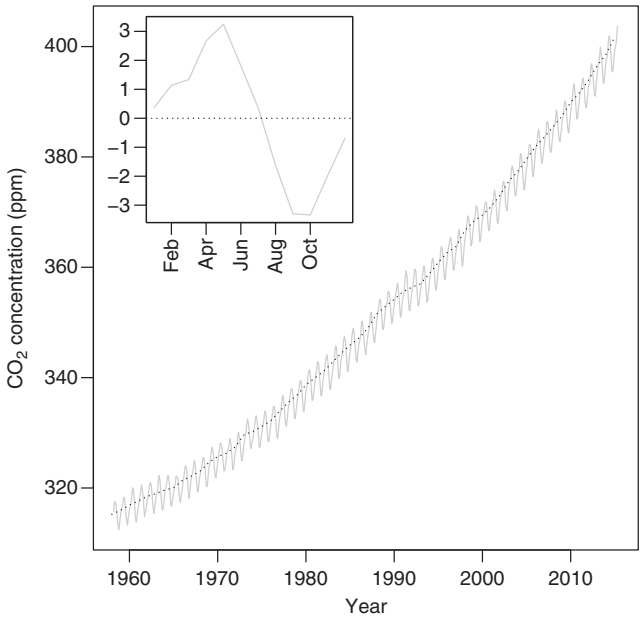

Figure 2 The instrumental record of atmospheric CO_2 concentrations as recorded at the Mauna Loa observatory curated by the Scripps Institute of Oceanography (https://scripps.ucsd.edu/). The inset shows monthly average deviations from the larger increasing trend.

Crust

While the atmosphere is the smallest and most quickly cycling major carbon pool, the largest and slowest cycling carbon pool resides in the Earth's crust. This carbon consists of two different kinds of compounds: hydrocarbons and carbonate minerals. Hydrocarbons represent approximately 4000 Pg of carbon bonded only to hydrogen that form when biological tissues sediment under anaerobic conditions. While hydrocarbons represent a huge carbon pool, 10 000 times more carbon is stored in other sedimentary rocks. The largest mineral reservoir of carbon is limestone, a sedimentary rock composed primarily of calcium carbonate ($CaCO_3$). Much of the calcium carbonate in limestone was produced by marine organisms with calcified shells, such as corals and foraminifera (Ridgwell and Zeebe, 2005). The abundance of their fossils in

many limestones, like roots of fossil trees above coal seams, attests to the biological origins of the geological carbon pool.

Exchange rates between the crust and other pools are small (0.1–0.5 Pg yr^{-1}) and residence times last millions of years. Nevertheless, this slow carbon cycle plays a critical role in regulating Earth's climate. Carbonate and silicate rocks react with atmospheric CO_2 at a rate which increases with temperature. Consequently, warm conditions tend to reduce the concentration of this key greenhouse gas, acting like a global thermostat over very long timescales. The buffering effect of the slow carbon cycle on climate is the most likely explanation for the relative stability of Earth's surface temperatures despite the gradual 40% increase in solar radiation since Earth's origins (Bonan, 2010).

Oceans

Besides the crust, Earth's oceans form the next largest carbon pool. The dynamics of oceanic carbon largely depend on depth (IPCC, 2013). The deep ocean, like earth's crust, forms a relatively large (37 100 Pg) and stable carbon pool, with a residence time near 1000 years. Over this timescale, the deep ocean gains carbon from settling detritus and loses it to the crust through sedimentation. The deep ocean also exchanges carbon via thermohaline circulation with the smaller (900 Pg) and more dynamic surface ocean. The surface ocean, which exhibits carbon residence times of months to years, directly exchanges CO_2 with the atmosphere (Cerling *et al.*, 2005). Once dissolved, CO_2 reacts with seawater to form bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) ions. These forms of dissolved inorganic carbon become available to calcifiers which drive sedimentation and primary producers which transfer dissolved and particulate organic carbon to the rest of the marine food web.

Compared to the geological carbon pool, carbon stored in Earth's oceans is more dynamic and entails important feedbacks with living organisms. One such feedback involves corals and their photosynthetic symbionts (Hoegh-Guldberg *et al.*, 2007). As atmospheric CO_2 increases, surface temperatures increase and pH decreases, reducing the rate of calcification by corals and driving the rejection of their photosynthetic symbionts. Both factors may limit oceanic CO_2 absorption and generate positive feedback that amplifies warming. Because corals form the backbone of reefs, one of the most biodiverse habitats on Earth, reduced coral productivity may portend major extinctions (Carpenter *et al.*, 2008). A contrasting pattern may prevail in some seagrass communities which are less extensive and diverse but more productive than corals. Under naturally elevated CO_2, some seagrasses grow faster and appear to shelter associated calcifying organisms (Garrard *et al.*, 2014). These contrasting dynamics of coral reefs and seagrasses illustrate how the physiology of species that characterize biomes may influence how carbon cycle and climate change interact with diversity.

Land

Life dominates carbon cycling on land. The terrestrial carbon pool is intermediate in size between the atmosphere and oceans, containing 1300 Pg C. Of this, more than two-thirds is stored in soils primarily as the living and dead tissues of organisms. Most of the rest is stored in living plant biomass. Turnover rates in the terrestrial carbon pool are also intermediate between atmosphere and ocean, and vary between soil and plant biomass (IPCC, 2013). Soil carbon turns over approximately every 25 years while living plant carbon turns over every 5 years. Considering that soils form from the interaction between plants, decomposing organisms, and mineral substrates, almost all of the terrestrial carbon pool represents living organisms or their remains.

The physiological and chemical characteristics of terrestrial organisms largely determine dynamics within the terrestrial carbon pool as well as exchanges to other pools. The annual flux from atmosphere to land, at 120 Pg C yr^{-1}, is the largest in the carbon cycle and almost completely determined by the rate of land plant photosynthesis (Sabine *et al.*, 2004). Photosynthetic rates, in turn, depend on plant functional traits (e.g., leaf shape, C:N ratio), which vary among species that characterize different biomes (Bonan, 2010). Of the carbon absorbed by land plant photosynthesis, about half is respired back into the atmosphere by plants themselves, and most of the rest is transferred to the soil through root exudation, tissue senescence, and mortality (Sabine *et al.*, 2004). Once in the soil, carbon dynamics largely depend on temperature, the chemical composition of the plant tissues, and the metabolic efficiency of decomposing organisms (Allison *et al.*, 2010). Among these organisms, bacteria and fungi play especially important roles. Bacteria are numerically dominant and drive soil nitrogen cycling, a major control on carbon uptake and breakdown. Fungi represent a huge portion of soil biomass with different taxonomic groups affecting soil carbon dynamics in different ways. Symbiotic fungi can increase plant productivity by providing limiting soil nutrients, while certain decomposers are largely responsible for breaking down the most recalcitrant plant compounds (Jastrow *et al.*, 2007).

Long-Term Drivers of Change in the Carbon Cycle

The foregoing description of the carbon cycle reflects the best contemporary estimates of recent dynamics (e.g., Sabine *et al.*, 2004; IPCC, 2013). In the distant past, the carbon cycle has had very different properties (Beerling and Royer, 2011; Berner, 1998; Beerling and Woodward, 2001). Ancient changes in carbon cycling have depended primarily on two long-term drivers: plate tectonics and physiological evolution.

Plate tectonics, or the gradual movement of Earth's crust relative to its mantle, produces two effects that are critical for carbon cycling. First, plate movement closes the slow carbon cycle by gradually recycling surface rocks, into CO_2 through volcanism. Second, changes in the geographic configuration and topography of continents influence the distribution and carbon dynamics of biomes. Rates of carbon accumulation in terrestrial ecosystems depend on local climates which shift as continents move and mountains rise (Bonan, 2010). The position and size of continents also alters global circulation. As wind and water move, they redistribute heat, generating important regional climatic patterns like monsoon rainfall (Cerling *et al.*, 2005). Changes in ocean currents are associated with the origin of novel biomes and major shifts in carbon cycling within them (Keeley and Rundel, 2005).

The second major driver of long-term change in carbon cycling is the evolution of physiological traits. Ever since

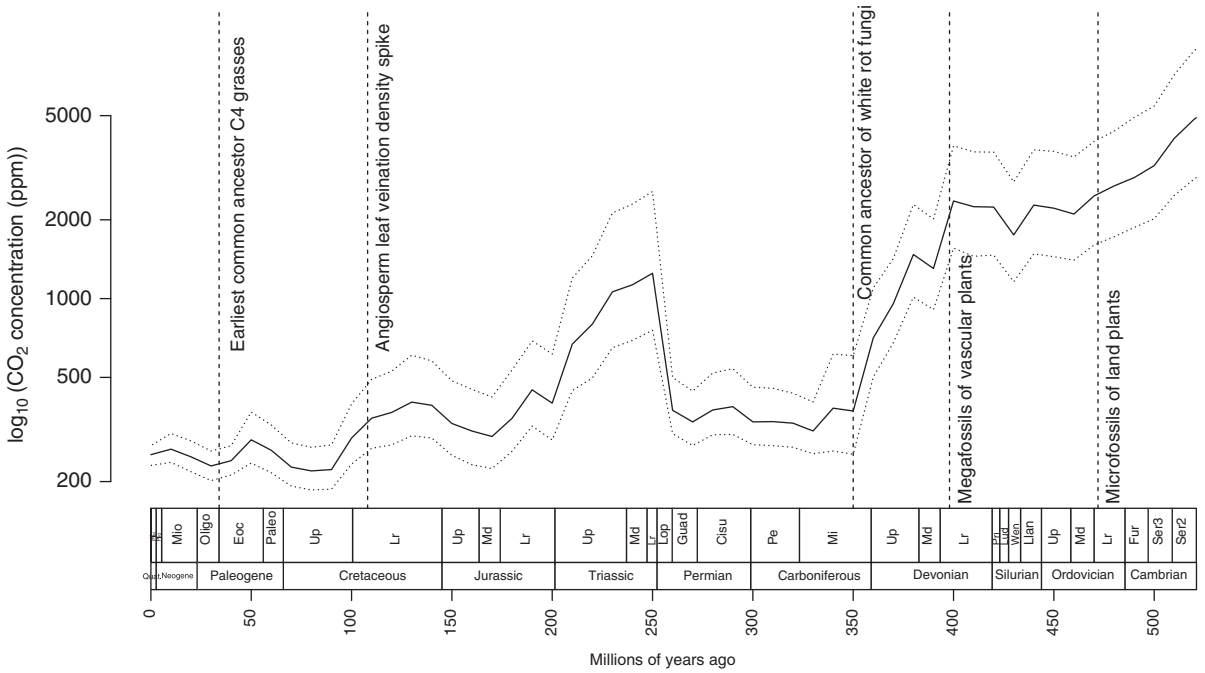

Figure 3 Timing of major events in physiological evolution with atmospheric CO_2 concentrations during the Phanerozoic based on the GEOCARBSULF model (Berner, R.A., 2006. Geochimica et Cosmochimica Acta 70, 5653–5664) as implemented using code available from D. Royer (Royer, *et al.*, 2014. American Journal of Science 314, 1259–1283). Dotted lines around the median trend line represent the 25- and 75-percentiles of simulations drawn from resampled input parameters. Vertical lines denote estimates of events described in the text. The timing of C4 origins is based on fossil calibrated phylogenies summarized in Edwards *et al.* (2010). The timing of the spike in angiosperm venation density is based on fossil evidence in Feild *et al.* (2011). The date for white rot origins is the posterior mean for the stem node of the Agaricomycetes in the fossil calibrated phylogeny in Floudas *et al.* (2012). The timing of tracheophyte origins is based on fossil evidence in Kenrick and Crane (1997). The date for the earliest fossil spore is presented in Rubinstein *et al.* (2010).

modern photosynthesis evolved in Precambrian oceans, competition for light, water, and nutrients in progressively more stressful habitats has driven physiological innovation among plants. Certain biochemical and anatomical adaptations that characterize major plant lineages influenced growth, mortality, and decay so dramatically that they shifted the distribution of carbon between land, atmosphere, and oceans with major repercussions for ancient ecosystems (Beerling and Berner, 2005; Beerling, 2005). Diverse sources of evidence, including biogeochemical markers, paleoclimate models, the fossil record, and comparative analyses bear testament to the lasting consequences of plant-driven revolutions in the global carbon cycle. Among these, three case studies illustrate the feedback between life and climate driven by physiological adaptation in plants and dependent heterotrophic organisms (**Figure 3**).

The Colonization of Land and Rock Weathering

Following the origins of chlorophyll-based photosynthesis, the next major evolutionary event that impacted both the carbon cycle and diversification was the colonization of land in the Ordovician. Prior to that time, terrestrial ecosystems were structurally and biogeochemically simple. They left few fossils, suggesting largely microbial communities of fungi, bacteria, and lichens that were physiologically incapable of forming deep soils (Quirk *et al.*, 2015). Consequently, rates of rock weathering were likely similar to those driven solely by abiotic processes, leaving considerable carbon dioxide in the atmosphere (Berner, 1998). In the interval between the origin of green plant ancestors and the spread of land plants, carbon cycling and terrestrial diversity changed dramatically, but conflicting paleontological, biogeochemical, and phylogenetic data obscure the sequence and therefore causality of major events (Kenrick *et al.*, 2012).

The earliest unambiguous fossil evidence for land plants comes in the form of microscopic spores (Rubinstein *et al.*, 2010). While only a few microns in diameter, the earliest spores are conspicuous for their preserved outer envelopes which likely contained sporopollenin, a tough polymer that resists desiccation and UV irradiation, allowing plants to spread inland (Hemsley *et al.*, 1992). For 60 million years, spores and enigmatic fragments represent some of the only fossil evidence for land plants, until 410 million years ago when abundant tissue fossils appear in the Rhynie chert (Kenrick and Crane, 1997). The variety and detail of these fossils document key adaptations that made land plants major players in the terrestrial carbon cycle. Among them are fossil stomates which mediate gas exchange and develop such that their density decreases with CO_2 concentrations, making fossil photosynthetic surfaces good proxies for CO_2 in the ancient atmosphere (Beerling and Royer, 2011). Belowground, fossilized primitive roots retain evidence of fungal ingrowths that characterize mycorrhizal symbiosis (Kenrick and Crane, 1997). Mycorrhizas today play a key role in plant nutrition, soil formation, and rock weathering.

The fossils of the Rhynie chert formed at a time when CO_2 concentrations and temperatures had been falling for millions of years, implying that land plant growth and associated increases in rock weathering had been driving changes in the carbon cycle (Berner, 1998). However, mixed evidence from more advanced models and physiological studies of basal embryophytes raises the question of whether land plants were the drivers or passengers of early Paleozoic carbon cycle changes (Quirk *et al.*, 2015). While the cause of cooling is ambiguous, it set stage for a host of subsequent changes in plant physiology, carbon cycling, and diversification.

Leaf Evolution, Plant Water-Relations and Biomes

As the organ specialized for photosynthesis in most plants today, leaves have played a key role in carbon cycling, climate, and diversification since their origin in the mid-Silurian. With plants having colonized land 60 million years earlier, the long delay before the simultaneous emergence of true leaves in unrelated lineages represents something of a paradox. Distantly related land plants with different leaf types share certain developmental pathways (Harrison *et al.*, 2005) and several fossil taxa produced leaf-like structures long before true leaves became widespread, suggesting that early land plants had the capacity to develop functional leaves (Beerling, 2005). However, prevailing high atmospheric carbon dioxide concentrations would have limited stomate density and ability of transpiration to cool large laminar surfaces. Once carbon dioxide levels began dropping in the mid-Silurian, higher stomate densities became selectively advantageous for carbon gain (Beerling *et al.*, 2001). As a side effect, increased evaporation from transpiring surfaces cooled them enough to unleash the development of leaves as key photosynthetic organs. The resulting spike in oxygen concentrations is associated with the diversification of giant insects in Paleozoic forests (Harrison *et al.*, 2010).

The evolutionary balance between carbon gain and water loss in leaves continued to influence biogeochemical cycles and diversification into the Devonian. Fossil leaves from those forests differed conspicuously from those of modern floras in their low average venation density (Feild *et al.*, 2011). Venation density, or the linear distance of vascular tissue within a fixed leaf area, strongly influences leaf function. Leaves with low venation density require water to diffuse further through parenchyma, limiting rates of photosynthesis and transpiration (Brodribb *et al.*, 2007). Higher venation densities, which occur in progressively more derived tracheophyte lineages, can gain carbon more quickly in moist habitats, where high soil moisture increases plant hydration, accelerating transpiration, canopy-level humidity, and the potential for recycling precipitation within forested habitats (Brodribb and Field, 2010). This hydrological feedback is characteristic of rainforests, which are the most diverse contemporary habitats. Falling CO_2 in the late Cretaceous is associated with a spike in angiosperm venation density that is coincident with the recruitment of this lineage into the rainforest canopy (Feild *et al.*, 2011). Several existing plant lineages took advantage of dry and low light microclimates in these emerging modern rainforests where they accumulated the majority of their current diversity (Schneider *et al.*, 2004). It is possible that hydrological feedback permits the accumulation of rainforest lineages during periods of dramatic external changes in climate forcing, reducing extinction and explaining why they are the ancestral habitat for most contemporary plant lineages (Wiens and Donoghue, 2004).

A more recent adaptation in leaf form and function that has impacted carbon cycling and diversification is the evolution of C4 photosynthesis among grasses. In most plants, atmospheric CO_2 is directly fixed into a 3-carbon compound (i.e., C3 photosynthesis) by the nonselective enzyme RUBISCO which increasingly accepts oxygen at high temperatures and low CO_2. To limit energy loss to the photorespiration the ancestors of certain grasses evolved a specialized leaf anatomy and physiology that restricts photosynthesis to cells surrounding veins where CO_2 is concentrated first into 4-carbon compounds (i.e., C4 photosynthesis, Edwards *et al.*, 2010). Because this pathway requires energy, C4 plants only have an advantage over their relatives under conditions of high temperature, periodic water stress, high light, and low atmospheric CO_2 (Osborne and Sack, 2012). These conditions arose in open habitats of the Oligocene when C3 grasses had already formed a distinctive disturbance-dependent biome characterized by high productivity, low above ground biomass, and deep soils (Strömberg, 2011). When tectonic and orbital processes exaggerated seasonality and monsoons, a shift in fire regimes prompted C4 grasses sweep to dominance (Keeley and Rundel, 2005). By the late Miocene, C4 grasses came to rival forests in terms of total net terrestrial productivity even though they account for only a small fraction of plant diversity. The greatest impact of these grasses on diversification may be mediated indirectly by humans, whose agricultural communities depend on C4 grasses and their grazers.

Stems and the Evolution of Lignin Synthesis and Degradation

The evolution of lignin metabolism played a dramatic role in Earth's carbon cycle beginning in the Devonian. At the time, short land plants were confined to wet habitats by the biophysical limitations of the structural polymer in their cell wall, cellulose (Kenrick and Crane, 1997). Cellulose can produce extremely rigid structures when dry but in water, the hydrogen bonds that hold parallel chains together are broken, leaving only the tensile strength along the β 1–4 glycosidic bonds. While these bonds resist turgor pressure in hydrated cells, supporting erect plant tissues in wet habitats, early land plants could not grow tall or away from consistent moisture.

The race for light changed radically when the common ancestor of tracheophytes evolved an accessory structural polymer, lignin. Formed from phenol groups with irregular bonding patterns, lignin surrounds cellulose microfibrils in plant cell walls, like concrete surrounding rebar, protecting the bonding arrangement of cellulose from breakdown (Weng and Chapple, 2010). With rigid cell walls, lignified plants could resist wilting and grow taller. Furthermore, lignified vascular cells are sufficiently rigid to maintain their shape under extreme negative pressures required for long-distance water transport under tension (Comstock and Sperry, 2000). With

the ability to grow taller, several tracheophyte lineages also evolved the ability to grow wider through the action of lateral meristems. These meristems deposit new vascular tissue around the stem to maintain vertical transport and structurally reinforce the canopy (Kenrick and Crane, 1997). Elevated plant canopies became more efficient, and habitats that were too dry for early land plants were quickly colonized. Across habitats, the increased demand for soil resources was met by increasingly elaborate roots and effective mycorrhizal symbioses which increased rock weathering (Stein *et al.*, 2012). Together, these factors drove a huge transfer of carbon from the atmosphere into living plant tissues and soils that continued into the Carboniferous (Mora *et al.*, 1996).

Not only did lignin revolutionize plant growth, it also transformed plant decay. The irregular bonding structure of lignin not only resists decay itself, but it shields embedded cellulose (Weng and Chapple, 2010). Consequently, much of the carbon flooding onto land stayed there, unavailable to heterotrophic organisms (Robinson, 1990). The resulting imbalance between photosynthesis and respiration, along with a continental configuration that supported extensive lowland rainforests, contributed to massive accumulation of terrestrial carbon sediments which characterize the Carboniferous. The simultaneous drawdown of CO_2 weakened the greenhouse effect. With falling temperatures and less resilient hydrological cycles, carboniferous rainforests collapsed causing over 80% local extinction of terrestrial plant species in some locations (DiMichele and Phillips, 1996).

The drop in atmospheric CO_2 and temperature that began with lignin synthesis among tracheophytes reversed with a complementary physiological innovation in the common ancestor of Agaricomycete fungi. These fungi today are generally associated with trees as mutualists, pathogens, or decomposers. A comparative analysis of 31 fungal genomes found that decomposers had many extra copies of peroxidase genes which produce enzymes and free radicals capable of degrading the complex bonding structure of lignin (Floudas *et al.*, 2012). In wood, prolonged peroxidase exposure strips lignin away to reveal a bleached mass of cellulose recognizable as 'white rot.' The common ancestor of the Agaricomycetes was likely a white rot fungus that introduced the physiological capacity for lignin degradation in the late Carboniferous, when coal deposition slowed, atmospheric CO_2 recovered, and temperatures gradually climbed (Floudas *et al.*, 2012). With this rebalancing of the Paleozoic carbon cycle came a recovery of biodiversity across a range of lineages that ended only as another physiological innovation among methanogenic Archea may have precipitated carbon cycle changes that accompanied the mass extinction at the end of the Permian (Rothman *et al.*, 2014).

General Patterns

The historical episodes of feedback between physiological evolution and carbon cycling suggest some general relationships with diversification. First, physiological innovations that persist among successful plant lineages may be more likely to arise as atmospheric carbon concentrations drop. The colonization of land, the evolution of tracheophytes, the increase in angiosperm venation density, and the origins of C4 photosynthesis all arose as carbon dioxide concentrations fell. This macroevolutionary pattern may relate to experimental results which have found that low CO_2 is a more effective agent of selection for traits related to fitness than is high CO_2 (Ward *et al.*, 2000; Collins and Bell, 2004). It is possible that the absolute decrease in atmospheric CO_2 since the Proterozoic has selected for clades with genetic architectures that moderate fitness loss with declining CO_2. On the other hand, diversification itself may have driven the long-term decline in carbon concentrations. If weathering increases with terrestrial biomass and biomass increases with species diversity, then diversification for whatever reasons may reduce atmospheric CO_2 (Rothman, 2001). In comparison to the scanty evidence linking increasing diversity with gradually declining atmospheric CO_2, the fossil record, biogeochemical models, and comparative analyses are unequivocal in showing that rapid changes in the carbon cycle are associated with major extinction events across taxonomic groups (Twitchett, 2006). With these precedents, the current spike in CO_2 may only exaggerate the ongoing mass extinction event.

Cellular Behaviors Underlying Pattern Formation and Evolution

CM Mizutani, Case Western Reserve University, Cleveland, OH, USA

Glossary

Morphogenetic gradients Gradients of chemicals that inform cells about their position in the body in a dosage-dependent fashion.

Pattern formation The spatial and temporal organization of cells of distinct fates during embryonic and organ development.

Pleiotropic Requirement of same genes in different developmental stages or tissue types.

Introduction

One of the greatest wonders in nature is the diversity of body shapes, sizes, textures, and color patterns seen across different species. To understand how this diversity is generated and evolves over time, it is necessary to uncover and compare the underlying cellular mechanisms in different species. This type of research is the subject of the multidisciplinary field of Evolution and Development, or Evo-Devo. This maturing field has been propelled by the establishment of emerging models that encompass different branches of the phylogenetic tree, and is providing us a new perspective about how genes pattern organisms and how they can be modified to generate the diversity seen in nature (Sommer, 2009; Müller, 2007).

This article discusses the importance of cell behaviors for the evolution of pattern formation. It first introduces the concept of morphogenetic gradients and cell fate specification during embryonic development. The focus given is on the fruit fly *Drosophila melanogaster*, a reference model that lent support to the theoretical idea that tissues are patterned by gradients of form-generating substances or morphogens, and allowed the discovery of main developmental mechanisms with broad implications to other invertebrate and vertebrate models alike (Veraksa *et al.*, 2000). There are two relevant aspects that challenge the classical notion on how morphogenetic gradients are formed and exert their function, which will be presented here. The first regards to the problem of scaling to size during evolution, and the second regards the cell proliferation and movements during morphogenetic pattern formation. Significant advances to address those problems are being achieved by a combination of comparative evolutionary studies, mathematical modeling, and by revisiting well-established morphogenetic systems in flies and vertebrates using novel tools for live-imaging and single cell analysis.

Morphogenetic Gradients and the French Flag Model

Embryonic Axis Formation Is Initiated by Maternal Information

The *D. melanogaster* embryo is an iconic textbook example for understanding how pattern formation arises from a field of undifferentiated cells. Its development begins as a syncytial blastoderm and is characterized by rapid cycles of nuclear divisions, followed by the migration of the nuclei to the embryo surface (Wolpert *et al.*, 2007). After the thirteenth cleavage cycle, about 6000 nuclei are arranged within a single layer, and cell membrane growth ensues without further nuclear divisions (Edgar *et al.*, 1986). By the end of the cellular blastoderm stage, the embryo is subdivided into several gene expression domains, prior to any major gastrulation movement. These domains specify cells into antero-posterior (AP) fates that contribute to the head, thorax, abdomen, and tail; and dorso-ventral (DV) fates that contribute to the major tissue types of the body, i.e., the mesoderm, neuroectoderm, and ectoderm (Ip *et al.*, 1992).

Several mutations that disrupt AP and DV patterning were isolated in genetic screenings in the fly (Nusslein-Volhard and Wieschaus, 1980; Nusslein-Volhard *et al.*, 1984). These screenings also identified mutations in two maternal genes, *bicoid* (*bcd*) and *dorsal* (*dl*), which encode transcription factors distributed in a graded fashion, with higher to lower levels of Bcd from anterior to posterior side, and higher to lower levels of Dl from ventral to dorsal side (**Figure 1(b)**) (Frohnhöfer and Nüsslein-Volhard, 1986; Driever and Nüsslein-Volhard, 1988a,b; Roth *et al.*, 1989). These gradients provide a system of coordinates that inform cells about their position along the axes. In an embryo mutant for Dl, for instance, ventral and lateral fates giving rise to the mesoderm and neuroectoderm are abolished. As a result, the embryo became dorsalized and assumes an ectodermal fate along the entire DV axis (Nusslein-Volhard *et al.*, 1980; Anderson *et al.*, 1985; Nusslein-Volhard *et al.*, 1984).

Studies on Bcd and Dl provided solid experimental evidence for the early theoretical ideas of pattern generation by morphogenetic gradients proposed by Alan Turing (Turing, 1952), and the French Flag model of positional information proposed by Wolpert (**Figure 1(a)**) (Wolpert, 1969). According to this model, cells can discern their relative positions by sensing different threshold levels of morphogens, and therefore acquire distinct fates. This patterning mechanism was found to be general, and shared by invertebrates and vertebrates. Additional morphogens were identified, including decapentaplegic/Bone Morphogenetic Protein (dpp/BMP-4), wingless/Wnt (wg/Wnt), and Hedgehog/Sonic Hedgehog (Hh/Shh), all of which play roles in embryonic, limb, and organ patterning (Affolter and Basler, 2007; Neumann and Cohen, 1997).

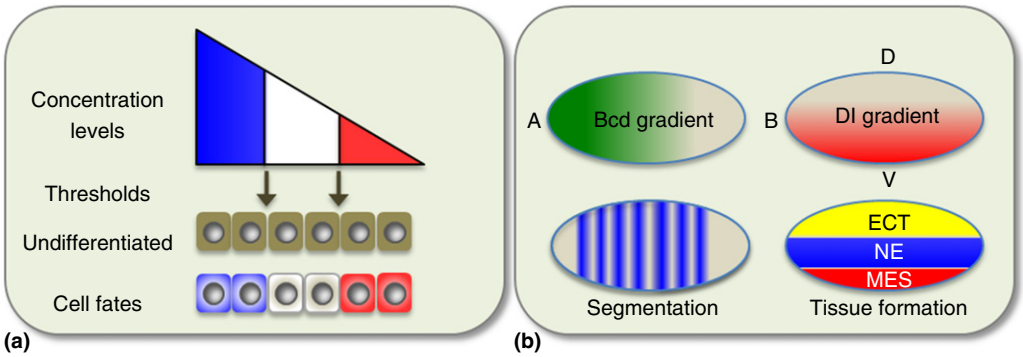

Figure 1 Morphogenetic gradients organize the embryonic axes. (a) A schematic representation of the classical French flag model. Graph shows the concentration levels of a morphogen, which establish different thresholds that are read by undifferentiated cells and cause their differentiation in three fates represented by the colors blue, white, and red. (b) Representation of the *Drosophila* maternal gradients Bicoid (Bcd) along the AP axis (left panel), and Dorsal (Dl) along the DV axis (right panel). The Bcd gradient establishes the expression patterns of segmentation genes (blue stripes), while the Dl gradient defines the main tissue types of the embryo (MES, mesoderm in red; NE, neuroectoderm in blue; ECT, ectoderm in yellow).

Over the several past years, our understanding of gradient formation and interpretation has greatly advanced. Seminal work found evidence that morphogens diffuse from localized sources (e.g., Bcd gradient (Berleth *et al.*, 1988), and the Shh and BMP gradients in vertebrate neural tube (Liem *et al.*, 2000); reviewed in (Cohen *et al.*, 2013). In *Drosophila*, gradients established by the same morphogen Dpp can be formed through distinct mechanisms in limbs and embryos. During wing formation, Dpp is secreted from an organizer region that is stabilized by a compartment boundary between the anterior and posterior regions of the developing wing (Basler and Struhl, 1994). In contrast, the Dpp gradient in the embryonic ectoderm is formed by a more unusual mechanism that involves the transportation of Dpp/BMP-4 to dorsal regions by extracellular antagonists (Eldar *et al.*, 2002; Mizutani *et al.*, 2005; Shimmi *et al.*, 2005). Furthermore, the identification of biochemical interactions involved in gradient formation and cell specification, along with improved methods in confocal microscopy and fluorescent protein tags, have allowed the acquisition of precise quantitative data, and spurred a series of mathematical models that expand our ability to test new predictions of pattern generation (Tomlin and Axelrod, 2007).

Evolutionary Modifications of Gradient Formation and Interpretation

The most general explanatory models of gradient formation and interpretation were first demonstrated in the *Drosophila* blastoderm, owing to its simple two-dimensional organization of a single cell layer and the genetic identification of Bcd and its target genes (Driever and Nüsslein-Volhard, 1988a,b). In the source–sink model (Crick, 1970), a morphogen is released from a localized source, and is asymmetrically distributed as a function of diffusion and degradation away from its source (sink). In the affinity-binding model, the interpretation of the gradient by cells is explained as a result of a differential sensitivity in Bcd DNA binding sites in the regulatory regions of its target genes (Driever *et al.*, 1989).

Although useful to define the basic mechanism of morphogen action, the models above are simplifications that do not fully account for the observed temporal and spatial scales in which gradients are formed. They also do not explain the formation of very precise and sharp borders of gene expression domains (Coppey *et al.*, 2007). Follow-up studies suggested alternative mechanisms to explain morphogen diffusion rather than simple passive diffusion (Müller *et al.*, 2013), including facilitated transport (Eldar *et al.*, 2002; Mizutani *et al.*, 2005; Shimmi *et al.*, 2005), or cell-based mechanisms such as dispersal through filopodial extensions called cytonemes (Fairchild and Barna, 2014). In addition, regulatory gene networks of target genes are necessary to refine and reinforce the expression borders initially established by gradients (Balaskas *et al.*, 2012; Stathopoulos and Levine, 2005).

The gradient mechanics also raise important issues of relevance to evolutionary biology. While direct experimentation *in D. melanogaster* has provided valuable insights into the mechanics of gradient formation and interpretation, this single species approach usually falls short of explaining how gradients define robust responses during evolution, or are reshaped to generate novel patterns. To address these issues and gain a more complete understanding of morphogenetic patterning, it is necessary to investigate other species. These species comparisons, coupled with experimentation in *D. melanogaster*, allow us to ask and test ideas that cannot be done in a single species. One example is how gradients can be established over variable distances to specify cell fates in relatively similar positions in embryos from related species that vary in egg size (**Figure 2**) (Gregor *et al.*, 2005; Chahda *et al.*, 2013).

Another fascinating issue regarding the mechanism by which morphogens instruct cells about their fate is the fact that they act on a field where the position of cells changes as a function of time. This observation challenges the positional information models, which assume that cells remain in a fixed position in relation to the gradient in order to acquire a given fate. Although this has been known for a long time, it is difficult to reconcile this observation with the current models of morphogenetic pattern (Affolter and Basler, 2007; Cayuso and Martí, 2005). It is possible that evolutionary changes in cell proliferation and movements could refine or even modify the

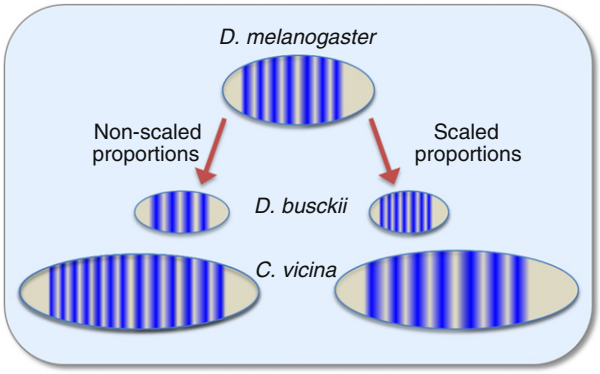

Figure 2 Hypothetical scenarios of scaled and non-scaled patterns of segmentation genes during the evolution of Diptera. An embryo from *Drosophila melanogaster* expressing a pair-rule gene is represented on top. The left panel represents the lack of segmentation scaling in small eggs (*Drosophila busckii*) and large eggs (*Calliphora vicina*). In this case, *D. busckii* would miss some stripes, while *C. vicina* would have additional stripes. The right panel represents the presence of scaling to size, as observed in actual experiments. The numbers and relative positions of the segmentation stripes would be preserved in all species.

overall pattern information provided by gradients, providing an alternative source for pattern changes across species. However, these possibilities remain largely untested.

On a broader view, the fact that tissue patterning arises in a dynamic field, and that different species can pattern tissues differently, has direct relevance to regenerative medicine as it may provide important insights into the scaling of organs during growth. Recent advances in applying quantitative methods to address the problem of scaling of gradients in a variety of system has been discussed elsewhere (Umulis and Othmer, 2013; Ben-Zvi *et al.*, 2011).

Scaling of Morphogenetic Gradients during Evolution

The AP System Employs Different Scaling Strategies within and across Diptera Species

Despite extensive work on maternal gradients in *D. melanogaster*, some questions regarding gradient dynamics can be best addressed using a combination of studies within and across species. One fascinating observation is the relatively proportional body pattern seen across different fly species. This scaling can be best illustrated by the embryonic position of stripes of various segmentation genes that respond to Bcd gradient, such as *hunchback*, *giant*, *paired*, and *even-skipped*. In embryos that significantly vary in size, not only the same number of stripes of these genes is conserved, but each individual stripe is located at relatively similar positions (**Figure 2**) (Gregor *et al.*, 2005a; Lott *et al.*, 2007; Hare *et al.*, 2008; Fowlkes *et al.*, 2011; Blechert *et al.*, 2011). This remarkable finding could be either explained by the ability of the Bcd gradient to scale to embryo length or by a differential sensitivity to Bcd levels caused by changes in the cis-regulatory sequences of target genes.

The quantitative measurement of the Bcd gradient in *Drosophila busckii*, a species with eggs twice as small as *D. melanogaster*, and in *Calliphora vicina*, a species with eggs three times larger than *D. melanogaster*, revealed that the Bcd gradient profile is similar in all species after normalization by embryo length (Gregor *et al.*, 2005). In this study, Gregor *et al.* show that the amplitude of the gradient scales with its constant length and reach farther distances, suggesting that the gradient threshold information is adjusted to size and that the generation of conserved expression domains may not necessarily involve the evolution in cis-regulation of Bcd target genes (Gregor *et al.*, 2005).

Considering one of the gradient formation models that involves the diffusion of Bcd from the anterior region, the scaling of the Bcd gradient in the different species could be explained by either changes in the Bcd effective diffusion constant or a modified time scale for the gradient formation, or alternatively, through an increased stability of the protein. The first two possibilities were ruled out given that all species tested display similar developmental rates, and the measured passive diffusion of an inert molecule injected in small and large embryos reveals no significant difference (Gregor *et al.*, 2005). The possibility that Bcd may have acquired distinct lifetimes during evolution remains open. In experiments in which the Bcd proteins from *C. vicina* and *Lucilia sericata* (two species with large embryos) were expressed in *D. melanogaster* revealed that the exogenous protein gradients assume the same shape of the host species gradient (Gregor *et al.*, 2008). Although these experiments indicate that the degradation of Bcd from *C. vicina* and *L. sericata* is the same as in *D. melanogaster*, an exhaustive test of Bcd degradation in species-specific environment has not been performed. In any case, it appears that the scaling of Bcd gradient is likely to depend on other species-specific factors that affect the gradient formation.

Another relevant question is whether scaling is achieved by similar or different mechanisms within same species. To answer this question, Cheung *et al.* used artificially selected strains of *D. melanogaster* with significantly different egg sizes (Cheung *et al.*, 2011; Miles *et al.*, 2011). They found that the Bcd gradients in strains with large eggs reach larger distances by having the production rate of Bcd scaled with embryo volume. The authors confirm that net amounts of maternally deposited Bcd RNA in the ovary increases in the strains with large eggs (Cheung *et al.*, 2011). Given that variation in embryo size is a fast evolving trait determined by multiple independent *loci* (Markow *et al.*, 2009; Warren, 1924), the increase of *bcd* RNA deposit provides a simple solution to buffer variations in embryo size and achieve gradient scaling within the same species, without requiring modifications in the Bcd protein sequence or its degradation pathways that would not have sufficient time to undergo selection.

The DV Axis Is Patterned by Two Opposing Gradients: One Regulated by a Fast Evolving Pathway, and Another That Is Highly Conserved across Evolution

The DV patterning system has also provided insights about how tissues scale during evolution. As mentioned before, the main tissue types are initially established along the DV axis in

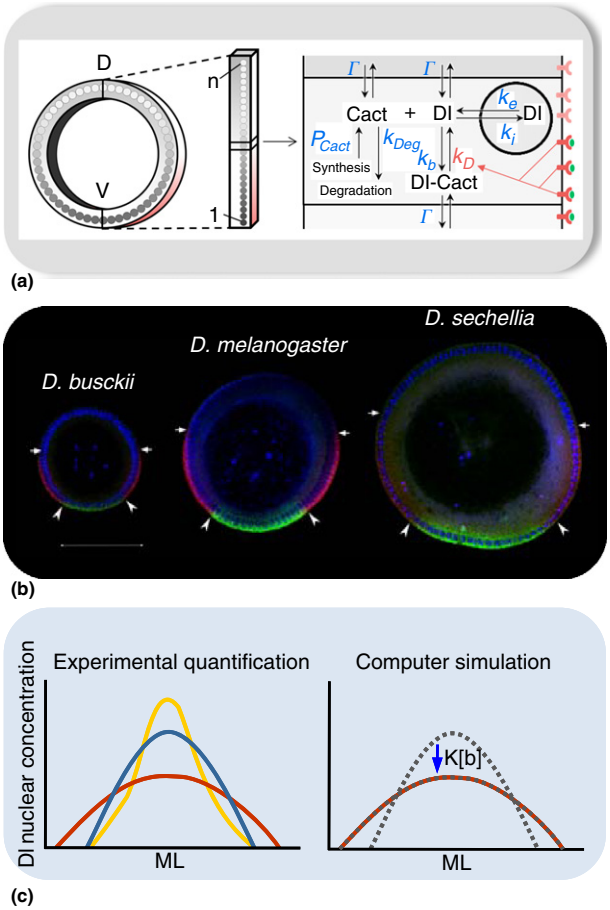

Figure 3 Scaling properties of the DV system. (a) Representation of a DV cross-section of a *Drosophila* embryo (left panel). The nuclei from ventral to dorsal side can be modeled as a single strip of cells. Right panel shows the Toll (Tl) signaling pathway. Partial differential equations representing the relationships between the cytoplasmic components of this pathway were used in a mathematical model to test the formation of the Dl gradients, and its scaling properties across species (see text for details). (b) Cross-section of related *Drosophila* embryos that vary in size, stained for a nuclear dye (blue), and markers for the mesoderm (*snail*, in green), and neuroectoderm (*short gastrulation*, red). Note variation in the mesodermal domains, indicated by arrowheads. (c) Computational modeling of the Dl gradient. Representation of Dl nuclear concentration levels quantified from different *Drosophila* species (left panel). Blue line, *D. melanogaster* and *D. sechellia* gradients; yellow line, *D. busckii* gradient; red line, *D. simulans* gradient. By adjusting parameters of the Tl pathway (e.g., K[b], binding rate between Dl and Cactus), it is possible to reproduce the flattened gradient of *D. simulans* species. Panel shown in (a) is reproduced from Ambrosi, P., Chahda, J.S., Koslen, H., Chiel, H.J., Mizutani, C.M., 2014. response to the maternal Dl gradient. Dl is an NFκ-B transcription factor that is transported into the nucleus following the activation of Toll signaling pathway (**Figure 3(a)**) (Anderson *et al.*, 1985). Unlike the Bcd gradient, which is thought to be established by the protein diffusion from tightly localized RNAs in the anterior region of the embryo (Gregor *et al.*, 2007) or arise as a result of a RNA gradient (Spirov *et al.*, 2009), both Dl and Toll (Tl) receptor are deposited ubiquitously in the embryo. The asymmetric distribution of nuclear Dl along the DV axis is achieved through a localized ventral source of the ligand Spätzle, which activates Tl in a graded fashion along the DV axis. The activation of Tl triggers the degradation Cactus, a cytoplasmic inhibitor of Dl. Once Dl is free from binding to Cactus, it is transported into the nucleus (Belvin *et al.*, 1995). High nuclear levels of Dl in the ventral side of the embryo activate mesodermal genes, whereas moderate nuclear levels activate neuroectodermal genes (Hong *et al.*, 2008). Finally, in the dorsal side of the embryo, the absence or low levels of nuclear Dl are insufficient to repress the expression of the secreted morphogen *dpp*/BMP-4, which in turn establishes an opposing dorsal-to-ventral gradient that induces the amnioserosa and ectodermal fates, and represses the expression of neural genes (Mizutani and Bier, 2008).

It is noteworthy that the Tl pathway, which ancestrally played a role in innate immune response against pathogens in both invertebrates and vertebrates (Hoffmann and Reichhart, 2002), became co-opted for DV patterning in derived dipterans like *Drosophila* (Lemaitre, 2004; Hoffmann and Reichhart, 2002; Belvin and Anderson, 1996). Components of the Tl pathway are fast evolving, likely due to the constant contact to new pathogens in the environment (Clark *et al.*, 2007; Jiggins and Kim, 2007; Sousa-Neves and Rosas, 2010; Obbard *et al.*, 2009; Schlenke and Begun, 2003). As discussed later, the fact that the DV patterning is regulated by some fast evolving genes shared by the Tl pathway appears to produce a high rate of variability capable to create diverse Dl gradient shapes, which might have been an important feature to adapt to the fast evolution of egg size.

In contrast to the newly acquired role of Dl in DV patterning, the *dpp*/BMP-4 is the most ancestral signaling pathway responsible for DV patterning among metazoans (Mizutani and Bier, 2008). This pathway plays a pivotal and conserved role in the formation of a centralized nervous system and in the establishment of neural domains of equivalent neural cell types within the neuroectoderm of organisms from the major branches of invertebrates (ecdyzoa and lophotrocozoa) and in the neural tube of vertebrates (Liem *et al.*, 2000; Mizutani *et al.*, 2006; Denes *et al.*, 2007). Thus, in *Drosophila*, cells along the DV axis receive information from a highly conserved DV signaling pathway (Dpp/BMP), and from a newly co-opted fast evolving pathway (Dl/NF-κB).

The Domains of Neural Identity Genes along the DV Axis Are Highly Constant during Evolution

One striking feature regarding the neuroectoderm described several years ago is the highly conserved numbers and types of neuroblasts (neural stem cell-like cells) across divergent

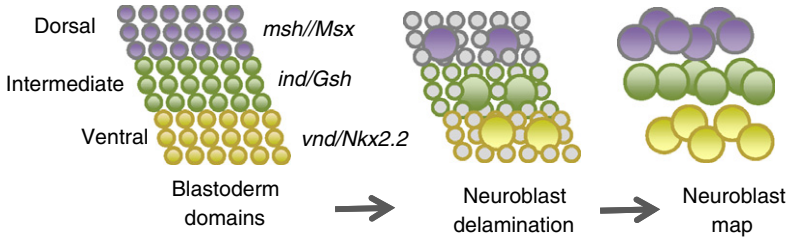

Figure 4 Developmental stages leading to the formation of a conserved neuroblast map. During blastoderm stage, three non-overlapping domains of neural identity genes subdivide the DV axis of the *Drosophila* neuroectoderm. Later in development, neuroblasts delaminate from the neuroectoderm. About 30 neuroblasts of unique identity are formed per hemisegment. This neuroblast map is highly conserved among insects.

insects. Early studies that defined the 'neuroblast map' in divergent insects, including grasshopper and *D. melanogaster*, found that each hemisegment generates about 30 neuroblasts of unique identity in these species (**Figure 4**) (Doe, 1992; Whitington, 1996; Bate, 1976). These neuroblasts give rise to homologous neuronal lineages that establish connectivity patterns of remarkable similarity in these species (Thomas *et al.*, 1984). The degree of conservation of neuroblast identity can even be observed to a certain extent in the crustacean branch (Ungerer and Scholtz, 2008).

After the description of neuroblast maps, studies in *D. melanogaster* identified three key homeobox transcription factors, *ventral nervous system defective* (*vnd*)/Nkx2.2, *intermediate neuroblast defective* (*ind*), and *muscle segment homeobox/Drop* (*msh*)/*Msx*, which are expressed in three non-overlapping domains in the ventral, intermediate, and dorsal regions of the neuroectoderm, respectively (McDonald *et al.*, 1998; Weiss *et al.*, 1998; Chu *et al.*, 1998; Isshiki *et al.*, 1997; Jimenez *et al.*, 1995). These genes were called neural identity genes because they define the types of neurons that are formed at distinct DV positions, such as motorneurons, serotonergic and secretory neurons (**Figure 4**).

The neural identity genes and mesodermal genes are part of a DV self-regulatory gene network, in which genes expressed ventrally repress genes expressed more dorsally in what is referred to as 'ventral dominance' (Cowden and Levine, 2003). In the ventral dominance model, the initial DV gene expression domains established by the Dl gradient are reinforced by the repression of neural genes by *snail* (*sna*), a mesodermal gene expressed in the ventral most region of the embryo, followed by the repression of *ind* and *msh* by *vnd*, and repression of *msh* by *ind*. This cross-regulation assures that the borders of neuroectodermal genes are reinforced.

In experiments that either induced expansions or retractions of the blastoderm domains of neural identity genes, there is a shift in ventral to dorsal neuroblast identity, or vice-versa, caused by an invasion of expression of the adjacent genes (McDonald *et al.*, 1998; Cornell and Ohlen, 2000; Weiss *et al.*, 1998; Isshiki *et al.*, 1997; Jimenez *et al.*, 1995). As a consequence, after neuroblast delamination from these altered domains, entire neural lineages are duplicated at the expense of other lineages that are eliminated altogether. These experiments, along with the observation of neuroblast map conservation, suggest that there is a strong selective pressure to precisely maintain the neuroectodermal domains in the early blastoderm. However, the underlying molecular mechanism that imposes this selective pressure has only recently begun to be understood.

The Germ Layers Formed along the DV Axis Are Unequally Scaled during Evolution

The remarkable constancy in the neuroectodermal expression domains occurs despite significant changes in embryo size in insect species that diverged over 300 MYA (i.e., grasshopper and *Drosophila*), and raises the outstanding question of how the remaining DV germ layers are specified. It turns out that while the neuroectoderm remains constant in size, the mesodermal and ectodermal domains can either retract or expand across *Drosophila* species (Belu and Mizutani, 2011). For instance, there is a significant reduction of the mesoderm in small eggs from *D. busckii*, and an expansion in large eggs from *Drosophila sechellia* (**Figure 3(b)**). The variation in mesoderm is not always correlated to egg size, since *Drosophila simulans*, a species more closely related to *D. sechellia*, but with similar egg size as *D. melanogaster*, also display an expansion in the mesoderm (Belu and Mizutani, 2011). The variation in the mesodermal size versus a more conserved neural patterning was also verified in the artificially selected *D. melanogaster* strains with variable egg sizes described above (Garcia *et al.*, 2013; Miles *et al.*, 2011).

The changes in the mesodermal domain across species appear to be directly caused by a lack of scaling in the Dl gradient since the quantification of the nuclear Dl distribution across species revealed striking modifications in the shape of the gradient varying from sharp to flat profiles (Chahda *et al.*, 2013). Furthermore, in experiments using hybrid embryos between sibling species *D. sechellia*, *D. simulans*, and *D. melanogaster*, it was possible to show that the mesodermal genes are activated by same Dl threshold levels, ruling out the possibility that the changes in their mesodermal domains are due to evolution in cis-regulation (Chahda *et al.*, 2013). This result is significant because it provides clear alternatives to affinity-binding models of pattern evolution and also reveals how the requirement of a signaling pathway that participates in both immune response and DV patterning can lead to extremely fast changes in the embryonic organization.

The experiments above also reveal the underlying mechanisms that restrict the neuroectoderm layer. Unlike what is seen with the Bcd gradient, the Dl gradient does not scale to size in the different species (Chahda *et al.*, 2013; Gregor *et al.*, 2008). Since mesodermal genes maintained their sensitivity to Dl activation, the ventral border between the mesoderm and neuroectoderm, and the dorsal border between the neuroectoderm and the ectoderm, are expected to be determined by a relatively constant slope of the Dorsal gradient across

species. Thus, the neuroectoderm can be shifted as a single block to a new DV position in response to novel Dl gradient shapes. The ability to shift the position of the neuroectoderm as a single block would ensure that correct numbers of neuroectodermal cells are formed in small and large embryos (Chahda *et al.*, 2013).

One might ask whether the expansions and retractions of the mesoderm could lead to a loss or gain of muscles in larvae. In experiments that addressed this question, it was shown that variations in mesodermal size are corrected during later developmental stages. The stereotyped pattern of the muscle body wall, for instance, is preserved due to a modified regulation in myoblast fusion during formation of individual muscle fibers (Belu and Mizutani, 2011).

Together, these results highlight the extreme versatility of the DV self-organizing system. This appears to be a very robust system capable of adjusting itself to a significant number of challenges imposed by embryo size and pleiotropic effects of the Tl pathway to produce fully viable individuals.

A Mathematical Modeling of Dl Gradient Indicates that Scaling Is Achieved by Changes in the Embryo Anatomy and Tl Signaling Pathway

Different factors could influence the modified shapes of the Dl gradient during evolution. One of them is the evolution of the Tl signaling pathway. Indeed, analyses of different species reveal that the ranges Tl signaling are modified and these changes are accompanied by variations in the size of mesodermal domains (**Figure 3(b)**). However, there are noticeable changes in embryo length and circumference, number and size of nuclei, and in nuclear density patterns across species that could in principle modify this gradient. This possibility was tested in experiments that manipulated the number and density of nuclei in *D. melanogaster*. Interestingly, these manipulations cause the sharpening or flattening of the Dl gradient as predicted, indicating that nuclear density and size contribute to the shape of the gradient (Chahda *et al.*, 2013).

To tease apart the relative contributions of anatomical changes and Tl signaling pathway evolution, a mathematical model originally developed for the Dl gradient formation in *D. melanogaster* (Kanodia *et al.*, 2009) was modified in order to identify which parameters are required to reproduce the different gradients observed from related *Drosophila* species (Ambrosi *et al.*, 2014). This model is based on partial differential equations that represent the interactions of the Tl pathway components (**Figure 3(a)**) (Belvin *et al.*, 1995; Kanodia *et al.*, 2009). The model also takes into consideration the anatomical features of the embryo, and was shown to correctly reproduce the dynamics of gradient formation in live-embryos expressing Dl tagged with green fluorescent protein (Kanodia *et al.*, 2009; DeLotto *et al.*, 2007). By testing different parameter sets, the model indicates that changes in anatomy alone are not sufficient to recreate the gradients from the species, and it is necessary to include modifications in the Tl pathway (**Figure 3(c)**) (Ambrosi *et al.*, 2014). This modeling experiment led to three important conclusions. First, pairs of very closely related species that diverged only ~0.5 MYA and produce similar changes in the mesoderm, but underwent separate speciation events (i.e., *D. sechellia* and *D. simulans*; and *Drosoplila santomea* and *Drosophila yakuba*), share similar modifications in the Tl pathway that correctly reproduce their gradients in model simulations. For instance, *D. simulans* has a flattened gradient in relation to the gradient of *D. sechellia*. Yet, the model can simulate these very different shapes after similar manipulations of Tl signaling parameters, such as increasing the rates of Cact degradation or decreasing the binding rate between Cactus and Dl (**Figure 3(c)**) (Ambrosi *et al.*, 2014). Furthermore, the modifications in the Tl pathway predicted by the model are supported by changes in amino acid sequences of Dl and Cactus protein domains related to these functions in these species. The second conclusion that can be drawn from this modeling is that the changes in anatomy and Tl pathway interact with one another. In order words, changes in Tl pathway are exacerbated by the changes in anatomy. Finally, the model also predicts that small additive changes in the Tl pathway are more likely to occur in nature, since more drastic changes of a single parameter affecting this pathway renders the model more unstable. This prediction is supported by the amino acid changes seen in many Tl pathway components from these species (Sousa-Neves and Rosas, 2010; Clark *et al.*, 2007; Jiggins and Kim, 2007; Obbard *et al.*, 2009).

Contribution of Cell Migration during Morphogenetic Gradient Patterning

The information for cell specification provided by gradients rarely occurs in a stable environment, and it is complicated by the constant proliferation and migration of cells that takes place during growth, such what is seen during the patterning of the vertebrate neural tube (Gouti *et al.*, 2015). As mentioned at the beginning of this article, the *Drosophila* blastoderm has been a highly successful model to understand pattern formation due to its simple arrangement of cells. Furthermore, the blastoderm cells seemed to be a close approximation to static fields of cells as they receive morphogen signals, since they are no longer dividing and appear mostly immobile (Edgar *et al.*, 1986). However, recent studies show that the nuclei actually move from one to three nuclear diameters in distance during blastoderm stage, and follow stereotyped trajectories that ultimately lead to species-specific nuclear densities that are polarized along the AP and DV axis (Keranen *et al.*, 2006; Meyer *et al.*, 2010; Fowlkes *et al.*, 2011). These stereotyped movements are abrogated in mutant embryos that eliminate either the Bcd or Dl gradients, and appear to contribute to a shift in the position of the stripes of the segmentation gene *fushi tarazu* in mutant versus wildtype embryos (**Figure 5(a)**) (Keranen *et al.*, 2006).

These novel observations are fascinating at several levels. First, they indicate that *Drosophila* might have remnants of the ancestral and more dramatic nuclear blastoderm movements that occur in the embryogenesis of short-germ band insects, as it has been shown in crickets (Nakamura *et al.*, 2010). Second, evidence mounts that species-specific cell movements in *Drosophilids* may produce some slight differences observed in the positioning of stripes of segmentation genes along the AP axis (Keranen *et al.*, 2006; Lott *et al.*, 2007; Gregor *et al.*, 2008; Fowlkes *et al.*, 2008; Meyer *et al.*, 2010; Blechert *et al.*, 2011). It

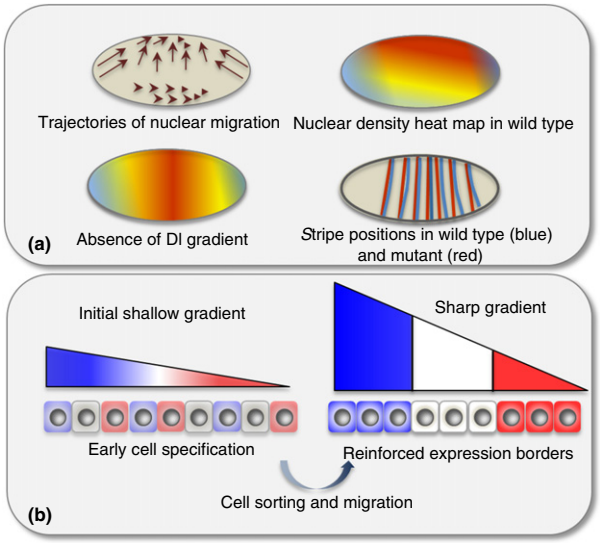

Figure 5 Contribution of cell sorting to pattern formation. (a) The *Drosophila* blastoderm embryo displays stereotyped nuclear movements. Top panel: Trajectories of nuclear migration are represented by arrows, which show a nuclear flow toward the dorsal midline. By the end of the blastoderm stage, the nuclear density becomes polarized, with high density levels in the dorsal side (red to yellow shades) and low density levels in the ventral side (green to blue shades). Bottom panel: Nuclear density patterns (left) and gene expression patterns (left) are disrupted in mutants that eliminate the Dl gradient. The new locations of the segmentation stripes (red) in relation to wild type stripes (blue) is predicted to be partly caused by disruptions in nuclear flow. (b) Revised version of the French flag model according to findings reported by Xiong *et al.*, 2013. The authors found that cells of the neural tube of zebrafish first acquire fate in a salt and pepper fashion while the Shh gradient is noisy. Over time, the gradient becomes sharp, and these cells maintain their fate and correctly sort to their final positions.

has also been reported that within the same species *D. melanogaster*, there is a dynamic shift in the positioning of stripes that occurs over time during the blastoderm stage, which was initially thought to be due to gene regulation (Jaeger *et al.*, 2004). However, in experiments that identify all individual nuclei in cohorts of fixed embryos of different stages, it was possible to develop a model for the observed nuclear flow and predict that the nuclear flow contributes to the shift in stripe positions (Keranen *et al.*, 2006). Together, these findings suggest cell sorting as a significant patterning mechanism that can sharpen the borders of AP segmentation, and that is most likely linked to morphogen regulation and distribution.

Another significant role for cell sorting was uncovered in a recent study that revisited the DV patterning formation of the neural tube in zebrafish. This well-established system is patterned similarly to the *Drosophila* neuroectoderm, and is subdivided by homologous DV neural patterning genes that cross-regulate each other (Cohen *et al.*, 2013). These neural genes are regulated by the *dpp*/BMP-4 gradient that emanates from the dorsal neural plate and by a ventral source of Shh gradient from the notochord, instead of the Dl gradient as seen in flies (reviewed in Mizutani and Bier (2008)). By tracking the formation of early ventral neural progenitor cells, Xiong *et al.* discovered that cell specification occurs in a salt and pepper pattern early in development, while the Shh gradient is still too shallow and noisy to provide reliable positional information (Xiong *et al.*, 2013). Unexpectedly, these specified cells apparently maintain their fate, and migrate to their final positions as the Shh gradient sharpens (**Figure 5(b)**). The directional movement of these cells is disrupted by the removal of the cell-adhesion molecule Cadherin-2, but it is not influenced by Shh (Xiong *et al.*, 2013). Although the exact molecular mechanisms for this cell sorting remain unclear, it is plausible that these progenitor cells respond to cues provided by different cell adhesion molecules that are asymmetrically distributed along the DV axis, which may in turn be regulated by other gradients. A candidate is the BMP-4 gradient, which has been shown to regulate the expression of Cadherin-2 and coordinate cell movements during dorsal convergence during early embryonic development of zebrafish (von der Hardt *et al.*, 2007). Models for cell sorting mechanisms that integrate morphogens to generate patterns from initially scattered cell fates have been proposed during the patterning of the slime mold Dictyostelium (Vasiev and Weijer, 1999; Kay and Thompson, 2009).

While there is no evidence that the *Drosophila* blastoderm development involves any massive salt and pepper patterns of specified cells that migrate to their final domains, there is evidence for a more subtle, but quantifiable, cell sorting mechanism that can contribute to the formation of gene expression borders (Keranen *et al.*, 2006). This mechanism could be relevant to achieving the final numbers of cells within the neuroectoderm across *Drosophila* species, since the nuclei within the lateral regions of the embryo that give rise to the neuroectoderm actively move toward the dorsal midline (**Figure 5(a)**) (Keranen *et al.*, 2006). Using *Drosophila* genetics, it may be possible to isolate candidate genes such as cell adhesion molecules that may be involved in cell sorting and test how this mechanism is integrated with morphogenetic gradients.

Glossary

Adaptive evolution Enhanced population fitness due to the increase in frequency of advantageous alleles through positive selection or elimination of disadvantageous alleles through negative selection.

Additive genetic variation A measure of heritable variation caused by the predictable effects of alleles at the current allele frequencies.

Artificial selection Human-mediated reproduction between individuals in a population to propagate desirable traits.

Aster models Maximum likelihood models for estimating fitness-based traits at different stages of the life cycle (e.g., survival and fecundity) and that have different underlying statistical distributions (e.g., binomial and Poisson).

Breeding values The expected phenotype of an individual's offspring (measured as the deviation of an individual's offspring from the population mean). It provides a measure of the heritable contribution of the genotype.

Dominance variance Phenotypic variation attributable to interactions between alleles at a locus.

Epistatic variance Phenotypic variation attributable to interactions between alleles at different loci.

Evolutionary response The difference in phenotype between generations that occurs when selection favors heritable traits in the parental generation.

Fitness The ability of an organism to survive and reproduce in a particular environment.

G-matrix The pattern of additive genetic variance and covariance for multiple traits or, in some cases, the same trait or character states in different environments.

Genetic architecture The distribution and nature of genetic variation at multiple scales including variation at the levels of species, region, population, family, and individual.

Genetic correlation A standardized estimate of the additive genetic effect shared between pair of traits.

Genetic linkage The tendency for alleles in close proximity on a chromosome to be inherited together.

Heritability The fraction of that variance in phenotype that can be attributed to genetic variation that is inherited directly from parents.

Natural selection Differences in fitness between individuals in a population in a single generation due to the traits that they possess.

Pleiotropic gene A gene that influences more than one phenotypic characteristic.

Polygenic trait A phenotypic trait that is influenced by more than one gene.

Relative fitness Individual fitness relative to the average fitness of other genotypes in the populations. Typically expressed as individual fitness divided by population mean fitness.

Resurrection ecology A technique that allows direct observation of evolutionary change rearing revived dormant propagules (e.g., eggs, seeds) that represent ancestors in a common environment with contemporary descendants.

Selection differential A composite measurement of direct and indirect selection on a trait.

Selection gradient A measurement of direct selection on a trait, measured as the linear relationship between a trait and relative fitness.

Introduction

Earth's biota is currently being challenged by an uncontrolled experiment imposed by climate change and other anthropogenic stressors. Natural populations will either survive these challenges through range shifts, adaptive plasticity and evolution, or face extinction (Davis and Shaw, 2001; Davis *et al.*, 2005). Extinction has occurred for some plant (Jackson and Weng, 1999) and animal species (Martin and Klein, 1989) during historical periods of climate change and continues to be a serious threat to biodiversity (Thomas *et al.*, 2004). However, there are also many taxa that have persisted in spite of climate change by range expansions and contractions (Mitton *et al.*, 2000), adaptation *in situ* (Mcgraw, Fetcher, 1992), and simultaneous evolution and range shifts (Cwynar Macdonald, 1987).

Biotic Response to Climate Change Is Already Happening

We have witnessed responses of native organisms to climate warming as increasing earliness of budburst (Nordli *et al.*, 2008), flowering (Miller-Rushing and Primack, 2008), and the spring phenology of insects and birds (Roy and Sparks, 2000; Gordo and Sanz, 2006). However, in only a few cases can phenotypic responses to longer growing seasons and warmer temperatures (i.e., plasticity) be distinguished from genetically based evolutionary change in response to changes in natural selection. Even in cases where there is evidence strongly implicating an evolutionary response, we lack understanding of the genetic basis of these changes. In spite of many studies documenting the strength of selection in natural populations (Kingsolver *et al.*, 2001), we have little information on one of the most basic aspects of ecological genetics: the rate of

evolution in the wild. Filling these gaps in our knowledge will advance understanding of the mechanisms of evolution, strengthen prediction of the limits to adaptation to anthropogenic changes in the environment, and provide baseline information to develop management approaches that reduce the extinction risk.

The goal of this encyclopedia article is to explain how we can use the tools of quantitative genetics to understand the extent to which populations have already adapted to climate change and the potential for ongoing evolution in response to anthropogenic and natural changes that are happening concurrent with climate change.

Evolution in Response to Climate Change Is Multidimensional

It is important to bear in mind that climate change is only a subset of anthropogenic factors that influences the evolutionary dynamics of native organisms. For example, fragmented populations embedded in a matrix of altered habitat may have reduced opportunities for range shifts and may be cut off from gene flow lowering the influx genetic variation (Swindell and Bouzat, 2006). For many species, contemporary population sizes are reduced, which may cause genetic diversity to be lost by drift and inbreeding and increase susceptibility to extinction by stochastic environmental events (Heschel and Paige, 1995). Increasingly, wild populations have been restored, which can alter population size and genetic composition (Fenster and Dudash, 1994). Habitat degradation may also allow invasion of exotic species including diseases, pests, and competitors that may compound the stress of climate change (Strauss *et al.*, 2006). Furthermore, positive interactions between organisms, such as between plants and pollinators, may become decoupled as species respond to climate change in different ways (Mccarty, 2001). Thus the persistence of organisms will depend upon a multiplicity of interacting factors. To the extent possible, other interacting biotic and abiotic factors should be taken into consideration in the design of quantitative genetic studies.

Why Use Quantitative Genetics?

Classical quantitative genetics is a powerful tool for investigating evolution in response to climate change. This discipline provides the tools to measure key components of the evolutionary process including the strength and direction of natural selection on traits, phenotypic plasticity and its potential for ongoing evolution, and genetic variability and correlation structure for traits that are targets of selection. These approaches can be used to quantify evolutionary change that has already occurred and predict ongoing evolution into the future. Quantitative genetics is largely a 'black box' approach where phenotypic variation is partitioned into genetic and environmental causal components but the underlying genetic details are not explicitly investigated.

Considering advances in our understanding of traits important for climate response at the molecular level (Stinchcombe *et al.*, 2004; Wilczek *et al.*, 2009), one may wonder why quantitative genetics is still a relevant approach? The answer is that despite the discovery of molecular mechanisms that underlie a few specific traits (e.g., Fangue *et al.*, 2006), our understanding is still woefully inadequate to describe more complex polygenic phenotypes as they interact with the environment in the wild. For example, timing of life history events, dispersal ability, thermal and drought tolerance, and competitive ability are traits with complex genetic underpinnings that will likely be the direct targets of selection with climate change. Although some of these traits are influenced by a few regions of chromosomes with major effects, called quantitative trait loci (QTLs), ongoing research has yet to resolve how many genes are represented within these regions and whether these genes are relevant under field conditions (e.g., Weinig *et al.*, 2002). Quantitative genetics offers alternative measurements of genetic variation for single traits (additive genetic variance and heritability) or multiple traits (G-matrix). Models have been developed that can accommodate genes of major effect into a quantitative genetic framework (Walsh, 2001).

Questions That Can Be Addressed Using Quantitative Genetic Approaches

Quantitative genetics has been used for decades to explore the underlying genetic architecture of natural populations, elucidate patterns of natural selection, and predict and measure evolutionary change. More recently, the scope of questions addressed in wild populations has expanded (reviewed in Kruuk *et al.*, 2008), and we expect this trend to continue into the future, given that many traits that contribute to fitness in nature have a genetic basis too complex to be fully understood at the molecular level (Buchanan *et al.*, 2006). Questions that are suitable for quantitative genetic approaches include:

1. How will patterns of selection on traits be altered with climate change?
2. What is the range of conditions that populations can tolerate through phenotypic plasticity?
3. To what extent are populations locally adapted to the environment they currently experience?
4. How fast can populations evolve in response to climate change?
5. What is the potential for evolution of a different climate optimum and/or a broader range of tolerance?
6. Has the population already evolved in to response to climate change?

In this article, the author will first explain basic quantitative genetic concepts with a focus on genetic architecture and natural selection. Second, the author will briefly review examples of how quantitative genetics has been used to predict evolutionary change, test the rate of evolution, and observe evolution in action.

Basic Quantitative Genetic Concepts

The potential for adaptive evolution depends upon both genetic and ecological factors including the genetic (co)variation

of traits and the strength and direction of natural selection. The relationship between these key components of the evolutionary process is expressed by the 'breeder's equation'

$$R = h^2 S$$

where the amount of phenotypic change expected in response to selection per generation (R) for a single trait is a function of narrow-sense heritability (h^2) and the strength of selection as measured by the selection differential (S). This simple expression shows that the magnitude and direction of an evolutionary response is dependent upon the extent to which traits have a heritable genetic basis and upon the strength and direction of natural selection. It is important to realize that this expression only predicts evolutionary response for the subsequent generation for several reasons. First, genetic variation is reduced by directional selection in each generation and this can reduce heritability, and thus evolutionary potential, over time. Second, heritability depends upon the environment in which the population was measured and this is likely to differ between generations. Finally, natural selection is rarely consistent between generations but fluctuates according to prevailing conditions, such as climate. In general, we expect a large response to selection to occur if natural selection is consistently and strongly targeting traits that are heritable and are not genetically correlated with other traits under selection. The following sections explain these fundamental quantitative genetic concepts in more detail.

Genetic Architecture

Genetic architecture is a general term that refers to genetic structuring at the level of species, regions, populations, families, and individuals. For the purposes of predicting evolutionary change, genetic architecture at the population level is of primary interest because this is the scale where evolution occurs. The genetic architecture of a population includes genetic variation that can be transmitted across generations (heritability), genetic correlations among traits, and variation in trait expression in different environments (plasticity).

Genetic variation

The most fundamental requirement for adaptive evolution is that populations harbor genetic diversity at loci that underlie traits that are the targets of selection. Narrow-sense heritability is an estimate of the fraction of that variance in phenotypic that can be attributed to additive genetic variation (V_A) that is directly inherited by offspring from parents. Phenotypic variation may also arise from dominance interactions between alleles at a single loci (V_D), and environmental variation (V_E), but variation due to genetic interactions are not typically inherited because offspring genotypes are created anew with each generation of reproduction. This discussion is restricted to the most basic quantitative parameters although experimental designs are available to estimate other sources of variance such as epistasis (V_I) and parental effects (V_M) (for a complete treatment see Lynch and Walsh, 1998).

Heritability

Heritability can be estimated by measuring individuals in families that are related to each other to some degree. Because relatives are expected to share a certain proportion of their genes, we can use this information to partition resemblance among relatives into genetic and environmental causal factors. The precision of heritability estimates is influenced by the type of relatives under consideration.

Formal crossing designs, such as combinations of full- and half-siblings or parents and their offspring, allows additive genetic variation to be partitioned from other effects (see Lynch and Walsh, 1998 for a discussion of design options). Natural family structure in wild populations that has been observed over several generations can also be used to build a pedigreed and estimate heritability (Kruuk, 2004; Shaw, 1987). The use of either experimental or natural pedigrees permits a more precise measurement which is referred to as 'narrow-sense heritability' (h^2):

$$h^2 = V_A/(V_A + V_D + V_I + V_E)$$

Although narrow-sense heritabilities are preferable, they are more difficult to obtain because some type of pedigree information for the offspring is required. The most common approaches to obtaining narrow-sense estimates include: (1) measuring traits in parents and offspring in the wild or in lab populations over several generations (e.g., Réale *et al.*, 2003), (2) measuring offspring that were produced by experimental matings between known parents according to a specific design (e.g., Etterson and Shaw, 2001), or (3) from response to artificial selection measured over several generations (e.g., Lenski, 2001).

If replicated genotypes (e.g., clones) or broods obtained from natural matings (e.g., nestlings or seed collected by maternal plant) are measured, a coarser heritability estimate, referred to as 'broad-sense heritability' (H^2), can be estimated. Because clones and siblings share parents, they are also expected to share some variance arising from dominance and epistatic interactions. These effects, however, are not transmitted to subsequent generations and therefore will not generally contribute to evolutionary change. Consequently, broad-sense heritability is a coarser upper-bound estimate of heritability that is confounded with dominance variance:

$$H^2 = (V_A + V_D + V_I)/(V_A + V_D + V_I + V_E)$$

Breeding values are the expected phenotypic value of an individual's offspring (measured as the deviation of an individual's offspring from the population mean). It provides a measure of the heritable contribution of the genotype. The variance in breeding values is the additive genetic variance, V_A. Breeding values are not confounded by other sources of variation (dominance, epistasis, parental effects), in contrast to a simple family mean. Thus, the difference between a breeding value and a family mean is analogous to the difference between narrow-sense and broad-sense heritability (**Figure 1**).

Genetic correlations

Genetic correlations arise between traits because single genes affect more than one trait (pleiotropy) or because alleles present at different genes (each of which may only affect a

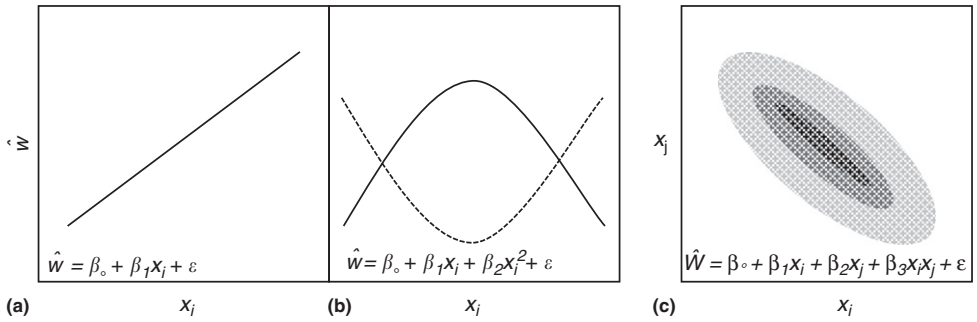

Figure 1 Illustration of some possible forms of selection obtained from regressing relative fitness onto values of trait x_i. (a) An example of linear selection where β_1 is the selection gradient. (b) The solid line provides an example of stabilizing selection where γ_2 is negative. The dotted line represents disruptive selection where the sign of γ_2 is positive. (c) An example of joint selection operating on a pair of traits x_i and x_j where the cross product term γ_3 is significant.

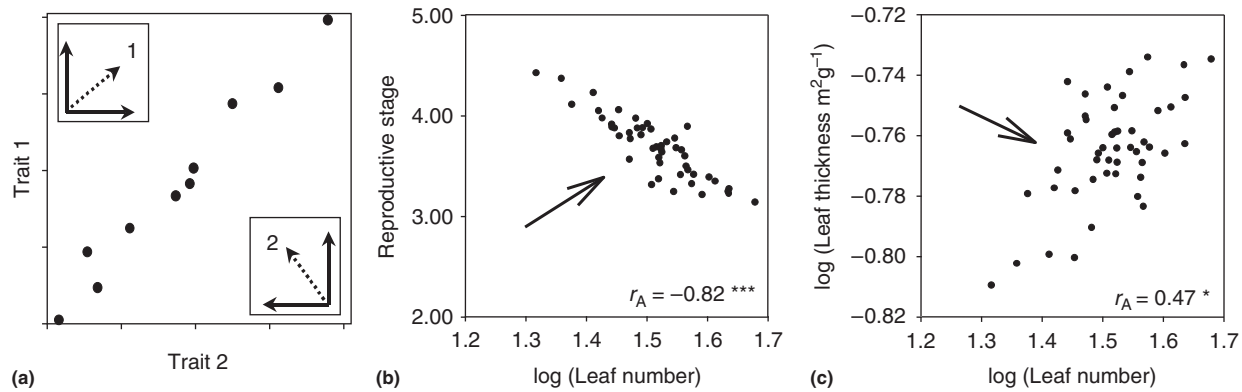

Figure 2 Examples of genetic correlations between traits. (a) Illustrates a hypothetical positive genetic correlation. The arrows in the inset box 2 shows a joint vector of selection on trait 1 and trait 2 that is in accord with the genetic correlation and will facilitate evolutionary response. Box 2 shows a joint vector of selection that is antagonistic to the direction of the correlation and will slow evolutionary response. (b) An example of a negative genetic correlation between plant phenology (reproductive stage) and leaf production that is antagonistic to the joint vector of selection show with the arrow. (c) An example of a positive genetic correlation between leaf thickness and leaf production is also antagonistic to joint vector of selection on these two traits, shown with the arrow.

single trait) tend to be inherited together as a unit (linkage disequilibrium). If traits are genetically correlated, it means that they are not inherited independently. This means that if natural selection exerts a change in one trait, a concomitant change will occur in the trait with which it is genetically correlated. A G-matrix describes the pattern of additive genetic variance and covariance for multiple traits (covariance is the unscaled version of the genetic correlation). The G-matrix is symmetrical with the additive genetic variances on the diagonal and additive genetic covariances on the off-diagonal as shown below for the three traits, *i*, *j*, and *k*.

$$G = \begin{pmatrix} V_{A_i} & \mathrm{cov}_{A_{ij}} & \mathrm{cov}_{A_{ik}} \\ \mathrm{cov}_{A_{ij}} & V_{A_j} & \mathrm{cov}_{A_{jk}} \\ \mathrm{cov}_{A_{ik}} & \mathrm{cov}_{A_{jk}} & V_{A_k} \end{pmatrix}$$

Two kinds of genetic correlations are relevant in the context of climate change: genetic correlations among traits and genetic correlations across environments.

Genetic correlations among traits

Additive genetic correlations among traits are important because they can enhance or retard selection response depending upon whether the direction of the correlation is in accord or antagonistic to the direction of selection (Etterson and Shaw, 2001). For example, if two traits are positively genetically correlated and selection is favoring high values for both traits, then the joint vector of selection on these two traits matches the direction of the correlation which 'reinforces' evolutionary response (**Figure 2(a)**, arrow 1). In contrast, if selection is favoring high values for one trait but low values for the other, then the joint vector of selection on these two traits is 'antagonistic' to the direction of the genetic correlation which may slow evolutionary response (**Figure 2(a)**, arrow 2). Adaptive evolution may be slowed and/or maladaptive evolution may occur if genetic correlations among traits are antagonistic to the direction of selection (**Figure 2(b,c)**). In addition, evolutionary change may occur for traits that are not directly under selection due to their genetic correlations with other traits that are targets of selection.

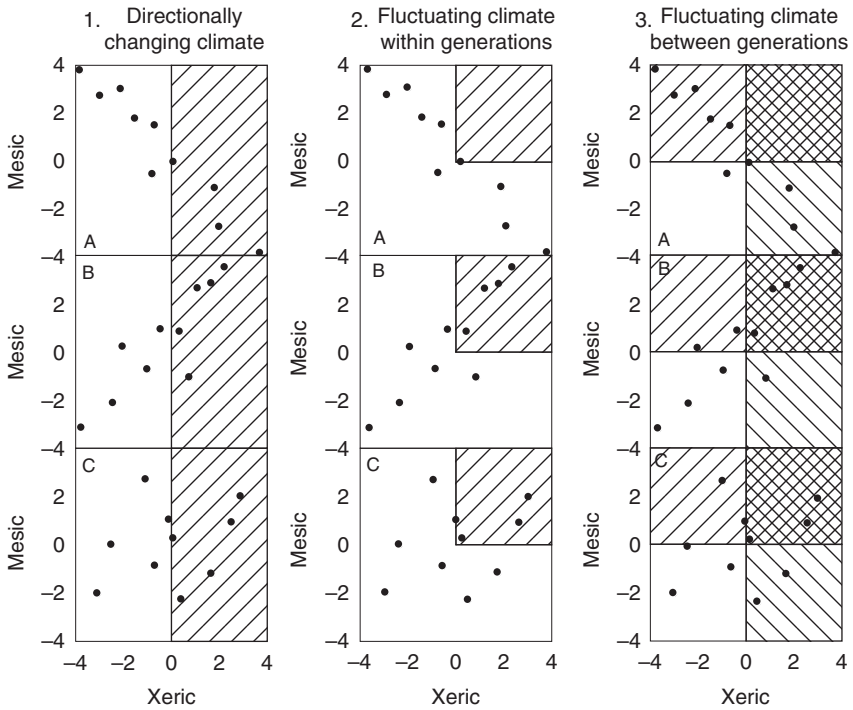

Figure 3 Illustration of the influence of the cross-environment genetic correlation, r_{Aij}, on evolutionary change given three different climate change scenarios: Column 1. A directionally changing climate becoming progressive drier. Colum 2. A climate that fluctuates between xeric and mesic conditions within the lifetime of the organism. Column 3. A climate that fluctuates between xeric and mesic conditions between generations. Hypothetical breeding values are plotted for a single population estimated in two different environments (*y* axis: mesic; *x* axis: xeric). Breeding values for each family reflect the deviation of that group from population mean fitness in one environment ($\bar{x}=0$). Panels A show a negative cross-environment genetic correlation and indicate a genetic tradeoff in performance. Panels B show a positive cross-environment genetic correlation and suggest preadaptation to a drier climate. Panels C show zero cross-environment genetic correlation and indicate potential for independent evolution toward high fitness in either or both environments. Column 1. If selection is consistently in the same direction, as depicted here, the genetic correlation across environments does not influence selection response. In each panel (A-C) there are genotypes with high fitness that can be selected under more xeric conditions (hatched rectangle). Column 2. When selection fluctuates within the lifetime of an organism, selection will favor genotypes that can obtain high fitness in both environments (hatched square). With this hypothetical data, selection response is least likely to occur when the genetic correlation is negative (A) than in other cases (B, C). Column 3. When selection fluctuates between generations, genotypes with high fitness in both environments are always favored (double hatched square). In addition to these genotypes, a distinct subset of genotypes is selected in alternate years (single-hatched square one year, alternative single-hatched square in the next year). Selection will be most efficient with a positive genetic correlation (B) than the other two cases (A, C) because fewer maladaptive genotypes are selected in the alternate years.

Genetic correlations across environments

The expression of genetic variation typically changes when genotypes are exposed to contrasting environments (e.g., mesic and dry conditions) and this can result in the production in different phenotypes, or character states (e.g., thin and thick leaves). This is commonly referred to phenotypic plasticity. Phenotypic plasticity itself may be genetically based and, therefore, can evolve in response to natural selection to contribute to adaptive evolution. When genotypes rank differently in contrasting environments, the relationship between their performance across environments can be described as a genetic correlation (Figure 3). This type of genetic correlation is important for climate change studies because it can influence evolutionary rates and is especially important if selection fluctuates over time (Etterson, 2004b). If climate change is consistent and directional (e.g., becoming monotonically warmer), then natural selection may favor adaptive evolution via fixed genetic changes such as greater thermal tolerance (Figure 3, column 1) and plasticity is not important. However, if natural selection fluctuates, such as is expected with increasing incidence of extreme weather events, then natural selection may favor adaptive solutions involving plasticity in traits that permit high fitness across a range of environments (Figure 3, columns 2, 3).

Application of Quantitative Genetics to Climate Change Questions

In the following sections, the author briefly reviews studies that have used quantitative genetic approaches to predict changes in natural selection and consequent evolutionary change, test evolutionary rates, and interpret evolutionary change over time.

Natural Selection

One of the most fundamental questions that must be answered to predict evolutionary change is how natural selection

changes with climate. The most direct way to estimate changes in climate and selection is to collect data on fitness and phenotype in natural populations over time. However, datasets that are complete enough to document such temporal changes in selection on wild populations are rare (but see Grant and Grant, 1995). An alternative approach is to compare natural selection in current environments to selection in experimental conditions that mimic those predicted for the future. However, most studies that have manipulated environmental conditions, such as temperature, precipitation, and CO_2, have focused on changes in species composition rather than on patterns of natural selection, though there are a few exceptions (Totland, 1999). Insight into temporal changes in selection may also be obtained by characterizing spatial changes in selection along gradients that encompass a range of environments similar to those predicted for the future (Etterson, 2004b) with the expectation that selection regimes will shift to higher elevations or latitudes with climate warming. However, an extensive study comparing trait variation along replicated latitudinal and elevational gradients did not reveal fully parallel patterns along these two types of environmental clines, which suggests that they are not interchangeable and may produce inconsistent results if they are used as a proxy for climate change (Jonas and Geber, 1999).

Substituting spatial variation for temporal change may provide an incomplete picture of future selection because community composition will also be altered by climate change and invasive species, pests, and diseases that expand their ranges add further changes to patterns of selection. Furthermore, natural selection may become increasingly erratic in the future if climates become more prone to extreme events such as drought, heavy precipitation, heat waves, and intense tropical cyclones. A meta-analysis of 5519 estimates of selection from 89 studies supports this assertion (Siepielski *et al.*, 2009) and reports that selection varies considerably between years, directional changes, and possibly the form of selection, are frequent, and that these shifts in selection are commonly associated with climate.

Local Adaptation

To determine whether or not evolutionary change is required for organisms to adapt to a changing climate, it is necessary to understand the extent to which populations are locally adapted to the environment that they currently experience. Species that occur across environmental gradients frequently express clinal patterns in phenotype that may suggest underlying local adaptation. However, these patterns do not necessarily reflect genetic differentiation, but may be a product of environmental responses or 'phenotypic plasticity,' which may or may not be adaptive. The extent to which clinal patterns in phenotype can be attributed to genetic differentiation, phenotypic plasticity, or some combination of these can be ascertained through 'common garden' experiments in which populations sampled from an environmental gradient and reared in common conditions. Because the populations experience the same environment, differences detected among them in morphology, physiology, and phenology must be genetically based. Furthermore, if this differentiation is related to the gradient from which they were sampled, they will retain clinal patterns in a common environment (e.g., Etterson, 2004a). Clinal patterns that disappear in a common garden can be attributed to phenotypic plasticity (e.g., Maherali *et al.*, 2002).

Local adaptation is most commonly tested with reciprocal transplant or 'provenance' experiments that compare the fitness of populations in their native environment to their fitness when they are reared in an alternative environment(s). Local adaptation is inferred if populations obtain higher fitness in their native site and this finding is common. A meta-analaysis showed that 71% of studies (published prior to 2005) yielded evidence of local adaptation and that the local population had a 45% fitness advantage of the nonlocal population (Hereford, 2009). Interestingly, the extent of local adaptation was positively associated with environmental divergence between sites but not with phenotypic divergence between populations. Reciprocal transplant experiments are particularly powerful if populations have been moved in a direction that is concordant with predictions of climate change. Such experiments provide insight into the extent and scale of local adaptation as well as decrements in fitness that may occur with climate change assuming no range shifts or adaptive evolution. This kind of experimental design was employed for large-scale provenance experiments of commercially important tree species that have been established for more than 50 years. Data from these experiments are now being reexamined in the context of climate change and show that populations have evolved different climate optima and breadth of tolerance and suggest that these populations have substantially reduced survival and growth in the future if climate changes as predicted (Rehfeldt *et al.*, 1999).

Phenotypic Plasticity

To understand the role of phenotypic plasticity in climate change response, common garden experiments can be enhanced by exposing populations sampled from contrasting environments to different environmental treatments, such as temperature, precipitation, CO_2, and/or competition. If a specific environmental factor, such as temperature, has been important in trait divergence, then populations should respond according to the conditions in their native habitats (i.e., populations from hotter environments perform better in the warmer treatment). The adaptive value of plastic responses can also be evaluated with this experimental design. For example, adaptive plasticity would be inferred if a plant maintained fitness across water-availability conditions by producing thicker leaves in more drought-prone environments to conserve water. Although instances of adaptive plasticity have been published, it often found that plasticity is passive and does not maintain fitness across environments (reviewed in Van Kleunen and Fischer, 2005). In at least one study in plants, the failure of plasticity to evolve was shown to related to the cross-environment genetic correlation structure that was antagonistic to the direction of selection (such as in **Figure 3**, panel 2A, see also Etterson, 2004b). In a 47-year study in birds, plasticity was shown to allow individuals to track climate but ongoing evolution of plasticity is not likely to occur because the genetic variation has already been exhausted (Charmantier *et al.*, 2008).

Response to Natural Selection

Do quantitative genetic studies predict that populations evolve rapidly enough to keep pace with climate change? A long-term study in Darwin's finches showed that theoretical predictions of evolutionary response based estimates of selection and heritability closed matched evolutionary outcomes in field populations (Grant and Grant, 1995). However, in a study of an annual prairie species the potential rate of evolutionary response was predicted to be slower than the rate of climate change and this was largely attributed to antagonistic genetic correlations (Etterson and Shaw, 2001). In contrast, in a study where phenological synchrony between and insect egg hatch and tree bud opening was disrupted, rapid evolutionary response of the insect species was predicted to restore the phenological match (Van Asch *et al.*, 2007). In general, too few studies of this kind have been conducted to draw strong generalizations probably because of the laborious and long-term nature of this kind of research.

Response to Artificial Selection

Rates and patterns of evolution can be directly characterized by comparing a population at one point in time with the same population at a later point in time. Artificial selection (Falconer and Mackay, 1996; Conner, 2003) and experimental evolution (Bennett *et al.*, 1992) are well-established examples of this approach that yielded tremendous insight into the evolutionary process in the lab and greenhouse. Evidence from artificial selection and experimental evolution studies suggest that it is at least plausible that adaptive evolution is contributing to observed changes in wild organisms. For example, a native herbaceous species flowered 13 days earlier after three generations of artificial selection (Burgess *et al.*, 2007) which is a larger than the 3–8-day change observed for plant species in nature. Likewise, artificial selection in the lab for over 2000 generations in the bacterium, *Escherichia coli*, showed that thermal tolerance can undergo adaptive evolution, even under conditions of fluctuating selection (Lenski *et al.*, 1991). Experimental evolution in fruit flies also showed that long-term natural selection for thermal tolerance led to evolution for some but not all traits and the evolutionary response was not consistent between life history stages (Gilchrist *et al.*, 1997). Other studies have shown that plasticity is the primary response to artificial selection under conditions that mimic future conditions (Potvin and Tousignant, 1996).

Observations of Evolutionary Change

Under rare circumstances, ancestor-descendant comparisons have been conducted in wild populations that have been the subject of long-term monitoring (reviewed in Bradshaw and Holzapfel, 2008). For example, over the last 30 years mosquitoes that breed in pitcher plants in the eastern US have evolved different genetically based photoperiodic cues for breaking dormancy that correspond to increases in the length

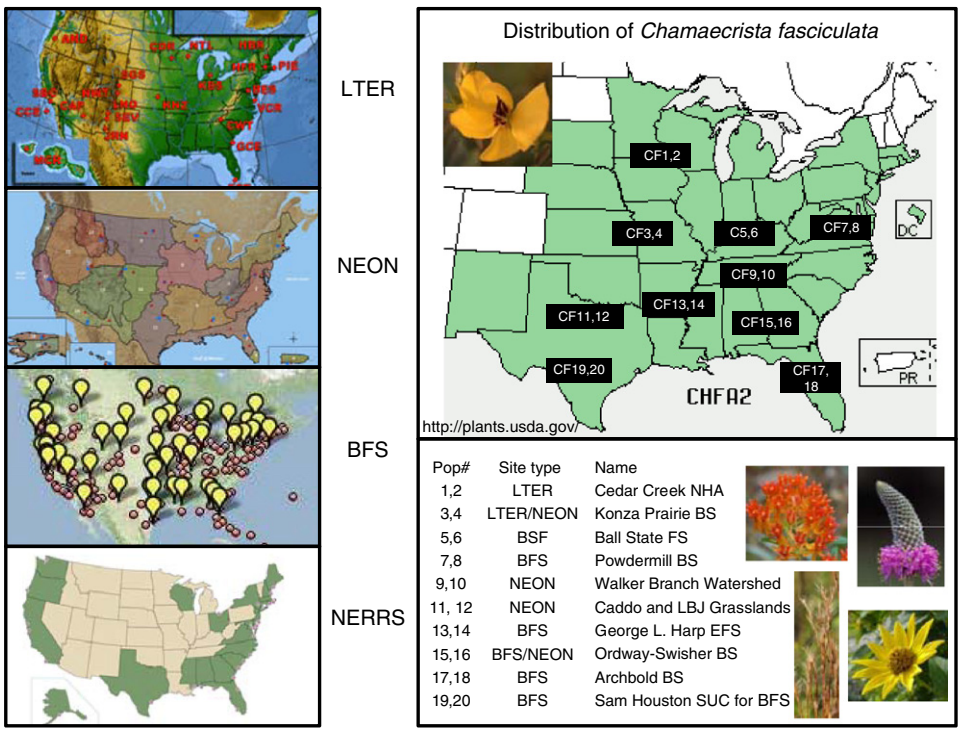

Figure 4 Illustration of how population are sampled for the Project Baseline collection according to two collection strategies. In sampling strategy 1, 20 populations (100–200 maternal liens) of each target species are identified for seed collection at sites that will be preserved into the future (e.g., LTER, NEON, BFS, NERRS, among others). In sampling strategy 2, species are selected that co-occur with the target species at as many sites as possible.

of the growing season in recent decades (Bradshaw and Holzapfel, 2001). These researchers were able to infer that these changes were attributable to evolution as opposed to plasticity because the cue to break dormancy is based on day length, a factor that has not changed over time with climate warming. In recent decades, changes in breeding phenology in red squirrels in Canada (Réale *et al.*, 2003) and migratory patterns in European blackcaps in Europe (Bearhop *et al.*, 2005) have also been observed based on long-term monitoring of wild populations. In the latter two examples, it was possible to estimate quantitative genetic parameters, such as heritability and plasticity, based on extensive records of the mating structure in the population over many years. By reconstructing a pedigree based on field observations of mating pairs on marked individuals, these researchers were able to distinguish genetic change from phenotypic plasticity on phenological traits and ultimately attributed the observed changes to both. The few studies of this kind that have been conducted suggest that the evolution of the timing of life history events may be a more important mechanism of adaptation to climate change in temperate regions than the evolution of thermal tolerance per se (Bradshaw and Holzapfel, 2001). However, this approach is rarely feasible and has only been accomplished in a few systems where individual animals in the population are marked. This approach is not tractable in plants because of wind or animal pollination and seed dispersal prior to germination.

Examining Evolution Using the Resurrection Approach

A powerful alternative approach to study evolution that is possible for organisms with dormant propagules, such as seeds, eggs, and bacteria, is often referred to as the 'resurrection approach' (reviewed in Davis *et al.*, 2005; Franks *et al.*, 2008; Angeler, 2007). In a few cases, direct demonstration of the nature of contemporary change in wild organisms has been possible because propagules were recoverable (Vavrek *et al.*, 1991; Bennington *et al.*, 1991; Hairston *et al.*, 1999; Mcgraw *et al.*, 1991; Kerfoot and Weider, 2004), fortuitously available in storage (Franks *et al.*, 2007; Bustos-Segura *et al.*, 2014; Nevo *et al.*, 2012) such that ancestors could be revived and compared side-by-side with their contemporary descendants in a common environment. This approach has also been applied in long-term experimental evolution studies in bacteria and has yielded the most detailed picture of evolution in action to date (Lenski *et al.*, 1991; Lenski and Travisano, 1994). A fundamental problem with resurrection studies based on wild-collected materials is that surviving propagules are not likely to represent an unbiased sample of the ancestral gene pool. This problem can be minimized if propagules are systematically collected and stored using best practices rather than fortuitously recovered from nature.

The use of resurrection ecology in plants will be much more feasible in future decades due to a new research seed bank, called Project Baseline. The goal of this living seed bank

Table 1 Predictions that can be tested with genetic material collected by *Project Baseline*

Trait evolution
- Longer growing season → Later flowering, altered seed dormancy
- Earlier spring but earlier summer drought → Earlier flowering and potentially compressed life cycle
- Increased temperature → Change in temperature optima for photosynthesis
- Frequent drought/elevated CO_2 → Changes in water use efficiency and specific leaf mass
- Altered pollinator communities → Changes in floral morphology, breeding system
- Altered herbivore communities → Changes in defensive traits
- Altered soil microbial community → Change in nutrient requirements/uptake ability
- Shifting climate envelope → Increased dispersal ability at leading range edge
- Reduced pollinator services due to phenological mismatches → Floral traits that promote selfing

Evolution of genetic architecture
- Selection response due to frequency shifts at a few loci of large effect, vs. many of small effect
- Strong selection responses → Reduced genetic variance
- Reduced pollinator availability due to phenological mismatches → Increased selfing and inbreeding depression
- Increased climate variance → Increased phenotypic plasticity
- Selection responses constrained by genetic correlations
- Phenotypic evolution through fixation of alleles with positive epistatic interaction
- Differential evolutionary responses among species within a ploidy series

Genomic evolution
- Selection response from novel mutations vs. standing variation
- Strong selection on locus → Reduced variation at linked neutral loci (selective sweeps)
- Selection response due to functional divergence of duplicate genes

Phylogeography/population genetic structure/extinction
- Low genetic variability → Higher extinction probability
- Extinction rates correlated to rate of climate change
- Dwindling population size at leading and trailing edge of range → Increased drift
- Neutral markers indicate net direction of dispersal

is to systematically collect, preserve, and archive seeds to be made available to future biologists for studies of evolutionary responses to anthropogenic and natural changes in the environment in the coming decades (Etterson *et al.*, 2016; Franks *et al.*, 2008). Seeds are being collected from multiple populations of ~125 species with diverse life history attributes in different habitats and climates across the species' geographic range and from numerous individuals per population (**Figure 4**). When seeds are collected, they are separated by maternal line (full or half-sib families) which will permit future quantitative genetic studies on these ancestral populations. Overall, the sampling scheme is designed to capture both variation differentiating populations and genetic variation within populations. Seeds are stored at the USDA National Center for Genetic Resources Preservation, a world-renowned germplasm repository. This project will provide seed collections that can be accessed and germinated by future evolutionary biologists for studies that address a wealth of questions and test a range of predictions in evolutionary biology (**Table 1**). Undoubtedly, advances in evolutionary theory and genetic techniques over the next few decades will expand the realm of questions that can be addressed using this collection to probe the genetic architecture of evolutionary change.

Coalescent and Models of Identity by Descent

J Wakeley and PR Wilton, Harvard University, Cambridge, MA, USA

Glossary

Coalescence The occurrence, looking backward in time, of common ancestors of two or more alleles.
Effective population size A standardized measure of population size based on the rate of change of genetic variation as a result of reproduction but not selection.
Gamete Haploid germ cell, for example, sperm or egg.
Gene conversion A recombinational process during meiosis in which a tract of sequence is replaced by corresponding sequence from a different chromatid.
Haplotype Any haploid set of multi-locus genetic variations; more specifically, here, any particular segment of DNA sequence in a genome.
Markov process A statistical model of successive changes in the state of a system in which transition rates or probabilities depend only on the current state.
Monecious Having a single mating type; hermaphroditic.
Path coefficients Weights of factors in linear statistical models, used to assess causation.
Phenotype The physical characteristics of an individual organism.
Poisson process A random process that counts numbers of events, usually as they occur in time, in which the times between events are exponentially distributed.

Identity by descent (IBD) is a property of genetic material in related individuals. Specifically, two alleles – i.e., two pieces of DNA from the same genetic locus, and therefore segregating at meiosis in a diploid organism – are identical by descent if one of them is descended from the other or if both are descended from a third allele which existed at some time in the past. Descent, here, means DNA replication and the transmission of genetic material from parents to offspring. The voluminous literature on IBD diverges as to whether mutations are allowed in descent between IBD alleles, though it is probably more commonly allowed than not. In addition, although it usually denotes pairwise identity, IBD can be extended to more than two alleles. For example, the common ancestral, third allele mentioned above is identical by descent with both of its descendant alleles.

IBD describes an important type of sameness which arises in biological systems. Cotterman (1940) took pains to define IBD clearly along with two other kinds of genetic identity: allelic identity, meaning from the same locus, as above, and functional identity, meaning alleles that are interchangeable without consequence for function or phenotype. Crow (1954) coined the term identical by descent (Cotterman had used 'derivative') and contrasted it with a specific kind of functional identity, namely identity in state, which means having the same DNA sequence. When mutation is understood to preclude IBD, then IBD may be viewed as a special case of identity in state. Similarly, it should be noted that 'alleles' and 'allelic' are used confusingly in the literature, to refer either to sequences from the same locus only, as here, or to functionally different sequences at a locus.

The concept of IBD is general, but it is specifically used to indicate close genetic relationship, in excess of background levels in a population. Because any two individuals, even from different species, may be said to be related if a sufficiently long time frame is considered, detailed definitions of IBD depend on what is chosen to measure close relationship. Notions of IBD have been developed for (1) individuals related by a known family structure or pedigree; (2) alleles descended from a common ancestral allele within a specified time and/or without any mutations between them; and (3) genomic tracts of strong genetic similarity demarcated by recombination events. Here, these are referred to, respectively, as pedigree definitions of IBD, coalescent definitions of IBD, and ancestral-segment definitions of IBD.

The ultimate utility of any population-genetic concept, including IBD, is in the interpretation of genetic variation. Theoretical treatments of IBD have guided analyses of genetic and genomic data, and provided avenues for inference by making connections between patterns of variation and key population-genetic parameters or sources of shared common ancestry.

Pedigree Identity by Descent

Studies of what later became known as IBD began early in population genetics, with efforts to allow some non-independence of alleles in the context of the Hardy–Weinberg Law (Hardy, 1908; Weinberg, 1908). The Hardy–Weinberg Law by itself leaves little room for relatedness. In it each individual receives two alleles independently at random from an essentially infinite population. Alleles are either identical (in state) or they are different. Only if a particular relationship or set of relationships is specified and embedded within the population does it become possible to consider IBD. We may think, for example, of a single parent and its offspring, which share exactly one pair of alleles that are identical by descent, while the other two alleles possessed by these two individuals would represent independent random samples from the population.

Early notions of IBD trace back to Wright's work on inbreeding coefficients, which may be interpreted in terms of IBD. Wright applied his general method of path coefficients for decomposing correlations to compute inbreeding coefficients

given a pedigree (Wright, 1921a,b, 1922). Specifically, for a pair of individuals (a possible mating pair) who are connected to common ancestors through K different paths, or 'loops' (Cotterman, 1940) in the pedigree, the inbreeding coefficient of an offspring of the pair is

$$f_o = \sum_{i=1}^{K} \left(\frac{1}{2}\right)^{n_i + n'_i + 1} \quad [1]$$

in which n_i and n'_i are the numbers of generations on path i from each individual back to a common ancestor. Equation [1] neglects the possibility that common ancestors might themselves be inbred, but this is easily remedied if f_a is known for each ancestor (Wright, 1922).

As an illustration, it is well known that Charles Darwin married his first cousin, Emma Wedgewood. Together they had eight children, plus an additional two who did not survive infancy. The relevant family tree, genealogy, or pedigree, is depicted in **Figure 1**. Two paths must be considered in computing f_o: one in which the two alleles both came from Josiah Wedgewood and one in which they came from Sarah Wedgewood. For each path connecting Charles and Emma Darwin to their grandparents, $n_i = n'_i = 2$. Applying [1] gives

$$f_o = 2\left(\frac{1}{2}\right)^{2+2+1} = \frac{1}{16} = 0.0625 \quad [2]$$

as the inbreeding coefficient of any child of Charles and Emma Darwin.

Although Wright (1921a,b) derived [1] by considering the decomposition of the correlation of uniting gametes, it can also be interpreted in terms of IBD. Specifically, 1/2 is the probability that a randomly selected allele in an individual came from a particular one of its parents. The $n_i + n'_i$ factors of 1/2 in [1] give the chance that the two alleles which unite to form a gamete came from a given common ancestor. Another factor of 1/2 gives the chance that the two alleles traced back to that common ancestor are derived from the same allele. Finally the sum is taken over all paths.

For Charles and Emma Darwin's children, there are two paths with $n_i = n'_i = 2$. Thus, [2] gives the probability that the two alleles at a locus in one of Charles and Emma Darwin's children are identical by descent. This sort of thinking underlies the general likelihood calculations on pedigrees that have been of crucial importance in human genetics (Cannings *et al.*, 1978).

Wright (1921b) also used the method of path coefficients, later switching from f to F (Wright, 1931), to establish recursive equations of the type discussed in Section 'Coalescent Identity by Descent,' which relate inbreeding coefficients in the current generation to those in previous generations, and to quantify deviations from Hardy–Weinberg genotype proportions. For two alleles A_1 and A_2 with relative frequencies p and $q = 1 - p$ in the population, Wright described deviations from Hardy–Weinberg proportions using

$$\begin{aligned} A_1A_1 &: \quad p^2(1-F) + pF \\ A_1A_2 &: \quad 2pq(1-F) \\ A_2A_2 &: \quad q^2(1-F) + qF \end{aligned} \quad [3]$$

Then F is the correlation in allelic state of gametes that unite to form a diploid zygote, and ranges from -1 to $+1$. If inbreeding is the source of the correlation, F ranges between 0 and 1 and may be interpreted as the probability of IBD. Equation [3] says that an individual is formed either by sampling two alleles at random (with probability $1 - F$) or by sampling one allele and duplicating it to make a diploid individual (with probability F). Implicit in this interpretation, there is a 'separation of time scales' between a slow population-level process and a fast individual-level or sub-population-level process (Rousset, 2004, p. 57).

The pedigree concept of IBD has proven useful in a number of settings. Malécot (1948) and Kempthorne (1955) employed it to re-derive and extend the calculations of correlations in trait values between relatives which form the basis of quantitative genetics (Fisher, 1918; Falconer and and MacKay, 1996). Another important class of applications uses 'gene dropping' simulations (MacCluer *et al.*, 1986) to account for IBD within a pedigree in generating null distributions of genotypes under selection; for a recent example, see Gao *et al.* (2015).

Coalescent Identity by Descent

Wright (1931, p. 107) referred to F as the 'correlation between uniting egg and sperm' and the 'total proportional change of heterozygosis.' He also used path coefficients to study the rate of increase of F over time under various mating schemes,

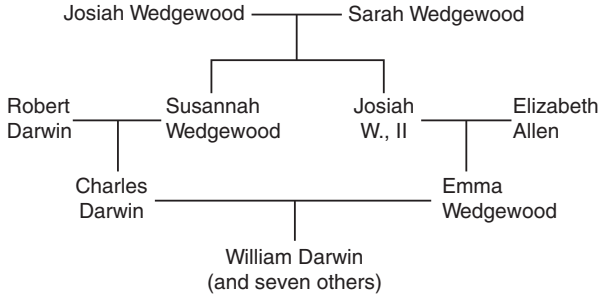

Figure 1 Part of the genealogy of Charles Darwin and Emma Darwin (*née* Wedgewood), who were first cousins. Their common grandparents, Josiah Wedgewood and Sarah Wedgewood, were also third cousins. Using a more complete pedigree, Berra *et al.* (2010) estimate that Charles and Emma Darwin's children had an inbreeding coefficient of 0.0630, which is only a little larger than the 0.0625 computed here, based only on the relationships above.

including what is now well known as the Wright–Fisher model of random mating in a finite population (Fisher, 1930; Wright, 1931). In the simple case of a diploid, monecious organism, over one generation

$$F_g = \frac{1}{2N} + \left(1 - \frac{1}{2N}\right) F_{g-1} \qquad [4]$$

in which g refers to the current generation and $g-1$ to the previous generation. Equation [4] can be rearranged and applied iteratively to obtain

$$1 - F_g = (1 - F_0)\left(1 - \frac{1}{2N}\right)^g \qquad [5]$$

which, with reference to the second line of [3], shows that heterozygosity is lost at rate $1/2N$ in a population of constant size N diploid individuals. More complicated populations behave similarly if they are large, and are described in relation to this monecious case using the concept of effective population size (Wright, 1931).

Malécot (1941, 1946, 1948) called F the 'average coefficient of consanguinity' and clearly understood it as the probability of IBD for two alleles in an individual. He derived recursive equations like [4] and [5] by explicitly considering the occurrence of common ancestors. In the simple example given by [4], which includes the possibility that the individual is produced by self-fertilization, $1/2N$ is the product of the probability that two alleles came from the same parent ($1/N$) and the probability they are descended from the same allele in that parent ($1/2$). When the parents are distinct, the two alleles in an individual descend from two alleles in different individuals in the previous generation, and here Malécot used 'average coefficient of kinship' to refer to the probability of IBD. Because he introduced the notion of tracing allelic lineages back to common ancestors, Malécot is credited with fundamental idea behind the gene-genealogical or coalescent approach to population genetics (Kingman, 1982; Hudson, 1983; Tajima, 1983).

Coalescent theory is reviewed in Hein *et al.* (2005) and Wakeley (2008). In the context of (pairwise) IBD, it is enough to consider the number of generations, G, back to the common ancestor between two alleles. Under the Wright–Fisher model above, G is geometrically distributed:

$$P(G = g) = \frac{1}{2N}\left(1 - \frac{1}{2N}\right)^{g-1}, \quad g = 1, 2, \ldots \qquad [6]$$

If, as typical in coalescent theory, time is rescaled so that it is measured in units of $2N$ generations and N is taken to be very large, technically taking the limit $N \to \infty$ and using $T = G/2N$, then the pairwise coalescence time, T, is exponentially distributed:

$$f_T(t) = e^{-t}, \quad t > 0 \qquad [7]$$

Thus the expected value of the time back to the most recent common ancestor of a pair of alleles is equal to one on the coalescent time scale, or $2N$ when measured in generations.

Two notions of close relationship have been used in gene genealogical or coalescent approaches to population genetics. The first defines IBD relative to an arbitrarily chosen past population, as for example: "The probability of identity by descent is defined as the chance that two genes are descended from the same gene in some ancestral population" (Whitlock and Barton, 1997). Fixing a given generation g in the past and using [6], the probability of IBD would be

$$P(G \le g) = \sum_{i=1}^{g} P(G = g) = 1 - \left(1 - \frac{1}{2N}\right)^g \qquad [8]$$

and for the corresponding coalescence time $t = g/2N$, the probability of IBD would be

$$P(T < t) = \int_0^t f_T(x)dx = 1 - e^{-t} \qquad [9]$$

When g and t are small, these probabilities are both small because it is unlikely for two alleles to be descended from a very recent common ancestor, while both probabilities approach 1 as g and t approach infinity. The occurrence of IBD under this definition is illustrated in **Figure 2(a)**.

Under this time-based notion of IBD, as under the pedigree definition of IBD in Section 'Pedigree Identity by Descent,' IBD has been defined alternately to require or not require identity in state. For example, Crow (1954, p. 544) considered that two alleles are identical by descent if both are 'derived from a single gene in some common ancestor' but added that they 'may be unlike in state if there has been a mutation since their common origin.' Similarly, Cotterman (1940, p. 171) considered that all eight combinations of his three kinds of sameness/difference are possible. In contrast, studying

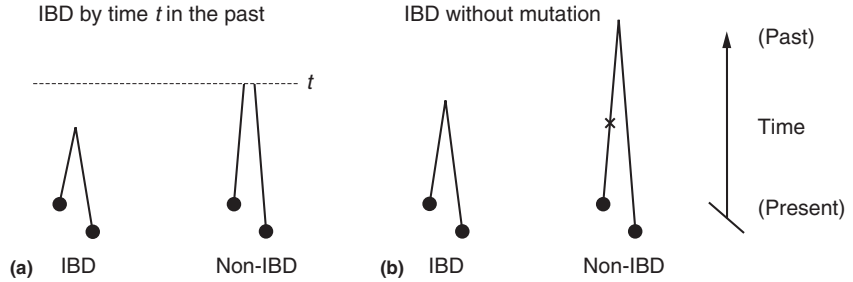

Figure 2 Two different definitions of IBD in gene-genealogical or coalescent models: (a) two alleles are identical by descent if they are descended from a common ancestral allele by time t (or $g = 2Nt$ generations) in the past, and (b) two alleles are identical by descent if they are descended from a common ancestral allele without mutation (x).

F in the face of mutation with probability u per allele per generation (so that $(1-u)^2$ gives the probability that neither allele underwent mutation in the previous generation) and writing

$$F_g = \frac{(1-u)^2}{2N} + (1-u)^2\left(1-\frac{1}{2N}\right)F_{g-1} \qquad [10]$$

Malécot (1946) implicitly assumed that IBD precludes mutation. Nagylaki (1989), interpreting Malécot, states: "Two homologous genes are identical by descent if and only if they are derived from the same gene or one is derived from the other (in both cases without mutation)."

The second coalescent definition of IBD follows Malécot's logic, and can be restated under the backward-time view of coalescent theory (Ewens, 1990) as follows. The probability of IBD is equal to the probability that coalescence, rather than mutation, is the first event encountered when the ancestry of two alleles is traced back into the past. Equations [6] and [7] offer two ways of computing the probability that no mutation occurs on either allele's lineage back to their common ancestor:

$$\sum_{g=1}^{\infty} P(G=g)(1-u)^{2g} = \frac{(1-u)^2}{(2N-1)(2-u)u+1} \qquad [11]$$

$$\int_0^{\infty} f_T(t)e^{-\theta t}dt = \frac{1}{\theta+1} \qquad [12]$$

in which $\theta=4Nu$ is the usual population mutation rate parameter in coalescent theory. A graphical illustration of this definition of IBD is given in **Figure 2(b)**. Equation [11] is also the solution to [10] for $F_{g-1}=F_g=F$. Malécot (1946) obtained [12] as an approximation to this solution, and noted its accuracy for most biologically reasonable values of N and u, which is to say when N is large and u is small.

The coalescent definitions of IBD described in this section apply to allelic variation at a single locus without recombination. Important extensions include considerations of subdivided populations (Wright, 1951; Slatkin, 1991; Rousset, 2004) and patterns of identity and difference in samples of more than two alleles (Ewens, 1972; Thompson, 2013).

Ancestral-Segment Identity by Descent

With the advent of DNA sequencing, and now whole-genome sequencing and genotyping, single-locus concepts of IBD have given way to a genomic perspective which has yielded new insights, particularly in the field of human population genetics (Thompson, 2013). In this context, it is the joint action of coalescence and recombination that determines close relationship, and IBD refers to segments of genomes which descend from recent common ancestors.

To illustrate, consider a focal site which is identical by descent under the pedigree definition of IBD. If there were no recombination, every site would have the same ancestry as the focal site and the entire chromosome would be identical by descent. Recombination decouples the ancestries of different sites and allows IBD to vary along the chromosome because each recombination event chops the chromosome into maternal and paternal pieces which then may have different ancestries. The result is that IBD will occur in segments, as depicted in **Figure 3**, such that some number of sites on either side of the focal site will share the same ancestry and be identical by descent.

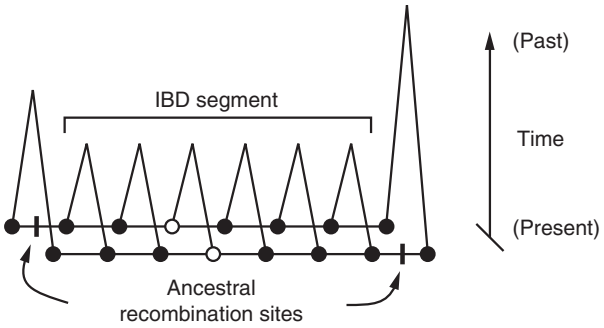

Figure 3 An IBD segment defined by two sites of recombination in the ancestry of two chromosomes. Every site in the IBD segment has the same most recent common ancestor and hence the same time until most recent common ancestry. The focal site is denoted by the open circles.

Under this ancestral-segment view of IBD, two homologous segments in an alignment of two chromosomes are identical by descent if they share a most recent common ancestor, and hence the same coalescence time, at every site. Here these are referred to as IBD segments, but they could also be called IBD tracts or IBD blocks. Note that this definition of IBD implies that every pair of chromosomes is IBD everywhere, because at every site there is a most recent common ancestor which is the same for some number of adjacent sites. As IBD is meant to indicate close relationship, interest is focused on recently co-inherited IBD segments. Younger IBD segments tend to be longer due to the limited opportunity for recombination in their ancestries. Thus, ancestral-segment IBD is typically defined in terms of a minimum length cutoff for segments.

Detection of IBD segments involves finding long haplotypes that are identical in state, although some mismatches are allowed due to the presence of genotyping or sequencing error, mutations that have occurred since the most recent common ancestor defining the IBD segment, and even short gene conversion events that effectively incorporate mutations from other haplotypes. Some IBD detection methods use dense genotype data (Purcell *et al.*, 2007; Gusev *et al.*, 2009; Browning and Browning, 2011), allowing reliable detection of IBD segments as short as two centiMorgans (cM). Recently, other methods have been developed to take advantage of sequence data, enabling reliable detection of IBD segments as short as 0.2 cM (Browning and Browning, 2013; Tataru *et al.*, 2014). Tataru *et al.* (2014) present comparisons of current IBD detection methods.

Fisher (1949, Chapter 3) made the first theoretical examination describing the lengths and counts of IBD segments (bordered by what he termed 'junctions') in regular mating systems, for example, full-sib or parent-offspring mating. Stam (1980) considered the same quantities in the context of random-mating populations, and Chapman and Thompson (2003) studied IBD tracts in subdivided

populations. These studies attempt to simultaneously model many IBD segments across the genome, which is a very difficult problem.

More recently, coalescent theory has been employed to model IBD-segment distributions. The foundation for this work is the coalescent with recombination, which describes the genetic ancestry of recombining chromosomes as an 'ancestral recombination graph' (Griffiths and Marjoram, 1997), allowing different ancestries at different loci. Wiuf and Hein (1999) provided a formulation of this model that proceeded along the chromosomes rather than backward in time, laying the groundwork for practical applications of coalescent theory to IBD segments. McVean and Cardin (2005) proposed a simplified Markov process to approximate this model, immensely improving its computational efficiency, with a subsequent improvement by Marjoram and Wall (2006). These latter models are referred to as sequentially Markov coalescent (SMC) models.

Palamara *et al.* (2012) derived the IBD-segment length distribution as follows. Consider a single focal site in two aligned chromosomes, and assume that the two copies at that site last shared a common ancestor g generations ago. If every ancestral recombination event defines a new IBD segment, which is equivalent to assuming the SMC model of McVean and Cardin (2005), the length of an IBD segment can be modeled by considering the nearest ancestral recombination events on either side of the focal site. This SMC assumption, that a recombination event invariably terminates an IBD segment, is reconsidered below.

There are $2g$ meioses separating the two chromosomes since the most recent shared ancestor at the focal site. If recombination occurs without interference and the distance between recombination sites is measured in Morgans, then in each meiosis recombination can be modeled as a Poisson process along the chromosome with mean equal to 1. Recombination across all $2g$ meioses is then a Poisson process with mean $2g$, and the length L of the IBD segment surrounding the focal site can be described as the sum of two independent exponential random variables with rate $2g$, each representing the distance along the chromosome in one direction away from the focal site.

Given g, the length L is gamma distributed (Palamara *et al.*, 2012):

$$f_{L|G}(l|g) = 4g^2 e^{-2gl} \qquad [13]$$

However, in most contexts the age g is not an observable quantity, so it is integrated out to give the overall IBD-segment length distribution. Using an exponential distribution with rate $1/2N$ to approximate the geometric distribution in [6],

$$\begin{aligned} f_L(l) &= \int_0^\infty f_G(g) f_{L|G}(l|g)\, dg \\ &= \int_0^\infty \frac{1}{2N} e^{-g/2N} (2g)^2 l e^{-2gl}\, dg = \frac{32N^2 l}{(1+4Nl)^3} \end{aligned} \qquad [14]$$

which is a power-law distribution, with infinite mean and variance.

Equation [14] gives the distribution of L when IBD segments are sampled by selecting a position (the focal site) uniformly at random over a long chromosome. Each IBD segment is effectively weighted by its length. It is perhaps more intuitive and more useful to consider the distribution of IBD segments that arises from sampling entire segments uniformly at random rather than weighting them by their lengths. The difference between the two distributions is often referred to as the inspection paradox. If the length of a uniformly sampled IBD segment is denoted S, the density function of S can be derived by weighting [14] by $1/l$ and normalizing, which gives

$$f_S(s) = \frac{\frac{1}{s}\frac{32N^2 s}{(1+4Ns)^3}}{\int_0^\infty \frac{1}{l}\frac{32N^2 l}{(1+4Nl)^3} dl} = \frac{8N}{(1+4Ns)^3} \qquad [15]$$

This is also a power-law distribution, with mean $1/4N$ and infinite variance. Note that deriving [15] without first deriving [14] would require knowing the distribution of coalescence times at IBD-segment edges. The derivation proceeds as above because the distribution of coalescent times at a fixed site arises more naturally from coalescent theory.

The density [15] suggests that in a diploid population of size $N = 10\,000$, the fraction of all IBD segments that are longer than 0.2 cM is $\sim 1.5 \times 10^{-4}$, while the fraction longer than 2 cM is $\sim 1.5 \times 10^{-6}$. Viewed from the other perspective, the density [14] indicates that the mean fraction of the genome contained in IBD segments larger than 0.2 cM is ~ 0.025, while the mean fraction contained in IBD segments larger than 2 cM is 0.0025.

The shapes of these distributions change under variable population sizes or when migration occurs between subpopulations, allowing data on IBD to be used for demographic inference about the recent past. Palamara *et al.* (2012) used this to infer recent population size changes in the Ashekenzi Jewish and Maasai populations, later generalizing to include migration between two subpopulations (Palamara and Pe'er, 2013). Independently, Ralph and Coop (2013) used IBD sharing to characterize the recent geographic and demographic structuring of Europe.

Common to all of these studies is the assumption that recombination events always terminate IBD segments. In fact one-third of all recombination events do not create a new IBD segment (see Theorem 2.4 in Griffiths and Marjoram, 1997) because they are 'healed' by coalescent events in which the two ancestral lineages separated by recombination coalesce back together. These events were ignored in the original formulation of the SMC, but were included in the subsequent SMC' model (Marjoram and Wall, 2006). IBD-segment length distributions can be derived under the SMC' in the manner above, and predictions for overall IBD length distributions under the SMC' match simulations under the full ancestral recombination graph very well, which is not true of the SMC (Carmi *et al.*, 2014). The resulting equations are cumbersome and involve special mathematical functions. Furthermore, for recent IBD segments there is little opportunity for back coalescence, and the differences between the SMC and SMC' predictions are negligible. However, for older, or shorter, IBD segments (smaller than ~ 0.5–1 cM) and for populations that have a small recent effective population size, it is important to base calculations on the SMC'.

With this minor caveat, it is clear that IBD segment-based techniques offer novel and practical ways of using genetic data to learn about the very recent past. IBD approaches to inference depend heavily on accurate detection of IBD segments, emphasizing the importance of recent improvements in IBD detection (Browning and Browning, 2013; Tataru *et al.*, 2014). Considering these developments, along with the recent theoretical advances outlined above, there is promise that IBD-segment methods will continue to reveal new insights into recent demographic processes in ways that complement other traditional approaches of population genetics.

Codon Usage and Translational Selection

R Hershberg, Technion-Israel Institute of Technology, Haifa, Israel

The Codon Bias Phenomenon

Messenger RNAs (mRNAs) are translated into proteins according to the genetic code, which determines which triplets of nucleotides, termed codons, correspond to what amino acid. The genetic code is redundant. This means that most amino acids are encoded by more than one codon. Because of this redundant structure of the genetic code, approximately a quarter of mutations within protein-coding sequences do not result in an amino acid change. Such mutations are often, sometimes incorrectly, assumed to have no effect on function and/or fitness. Due to this assumption they are referred to as 'synonymous' or 'silent' mutations, and the sites at which such mutations may occur are referred to as synonymous sites.

Although different synonymous codons encode the exact same amino acid, they are not used equally within a genome. Instead, a phenomenon of 'codon-bias' by which various synonymous codons are systematically more or less frequently used within the protein-coding sequences of an organism is ubiquitous among all living creatures. Codon bias is driven by both biases in the background substitution patterns of the genome and by natural selection favoring certain codons over others (Hershberg and Petrov, 2008; Plotkin and Kudla, 2011).

Background Substitution Biases and Their Effect on Codon Usage

The GC-content of organisms is a highly variable trait. For example, in bacteria GC-content can range from lower than 25% to higher than 75% (Lynch, 2007; Bentley and Parkhill, 2004; Sueoka, 1962). Variation in nucleotide content is observed in a correlated manner across all types of sites, including nonprotein-coding regions, synonymous sites and nonsynonymous sites (Hershberg and Petrov, 2009, 2010, 2012; **Figure 1**). For many years it was thought that the nucleotide composition of a genome is determined by mutational biases (e.g., Andersson and Sharp, 1996; Chen *et al.*, 2004; Hershberg and Petrov, 2008; Shields, 1990; Muto and Osawa, 1987; Sueoka, 1962). In other words, it was thought that GC-rich genomes arose form GC-biased mutation patterns, while AT-rich genomes arose from AT-biased mutation patterns. However, recently it has been shown that mutational biases in themselves cannot explain nucleotide content variation, as for both AT-rich and GC-rich genomes, mutations are universally more likely to occur from G/C to A/T (Hildebrand *et al.*, 2010; Hershberg and Petrov, 2010). The causes of variation in GC-content have therefore not been satisfactorily resolved. In the end, the GC-content of an organism is likely determined by a complex combination of neutral and selective processes that can cause the substitution patterns of the genome to be biased either toward GC or toward AT (Duret and Galtier, 2009; Foerstner *et al.*, 2005; Hershberg and Petrov, 2010; Hildebrand *et al.*, 2010; Reichenberger *et al.*, 2015).

It is clear that even in the absence of any selection on codon usage, a certain level of codon bias can be generated by these biases in substitution patterns. For example, nucleotide substitution biases toward GC will increase a genome's GC-content and also increase usage of G and C ending codons.

Codon Usage Can Affect Translation Accuracy and Efficiency

It is thought that the identity of the codons used to encode amino acids within a protein-coding sequence can affect the efficiency and accuracy with which that coding sequence will be translated. The major reason for this effect is thought to be that codons recognized by transfer RNAs (tRNAs) that are more abundant within the cell will be translated more accurately and more efficiently.

It is largely thought that codons encoded by more abundant tRNAs will be translated more efficiently because more abundant tRNAs will become available more frequently. There has recently been much debate as to whether this model is indeed correct. Older studies, using a variety of low-throughput techniques have demonstrated a link between tRNA

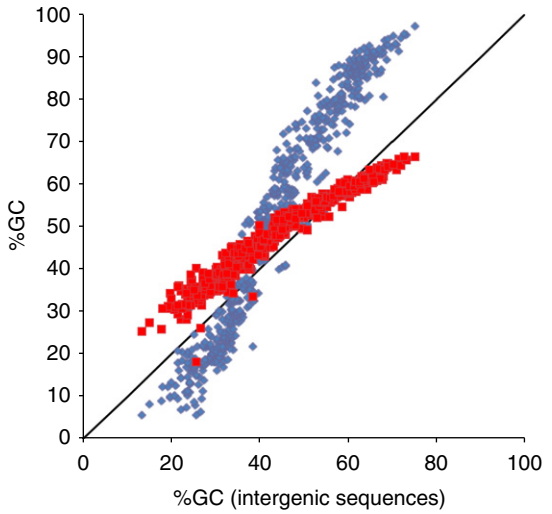

Figure 1 The GC-content of bacteria varies in a consistent manner across types of sites (reproduced from Hershberg, R., Petrov, D.A., 2010. Evidence that mutation is universally biased towards AT in bacteria. PLOS Genetics 6, e1001115). GC-content of nonsynonymous (red) and synonymous (blue) sites are plotted against the GC-contents of intergenic regions from the same bacteria. Each point represents a different fully sequenced bacterial genome. The plot demonstrates a very clear correlation between the GC-contents of all three categories of sites. For synonymous sites, GC-content follows that of intergenic regions, but values tend to be more extreme. In GC-rich genomes, there is higher GC-content of synonymous sites compared to intergenic sites. At the same time, in AT-rich genomes, synonymous sites are even more AT-rich than intergenic sites.

abundance and the speed with which codons are translated (Curran and Yarus, 1989; Sorensen *et al.*, 1989). However, these results were put into question by a number of more recent studies that utilized high-throughput ribosome profiling data and have failed to demonstrate such a relationship (Ingolia *et al.*, 2011; Li *et al.*, 2012; Qian *et al.*, 2012). The last word in this debate so far comes from recently published studies that used the same type of ribosome profiling data, but different analyses methodologies (Dana and Tuller, 2014; Gardin *et al.*, 2014). These studies contradicted previous ribosome profiling studies, observing highly significant correlations between tRNA concentrations and decoding times of the codons they recognize, both in prokaryotes and in eukaryotes (Dana and Tuller, 2014; Gardin *et al.*, 2014).

Codons that are recognized by more abundant tRNAs are expected to be translated more accurately because by arriving more frequently their tRNAs will provide less time for other tRNAs to arrive and incorporate an incorrect amino acid (Akashi, 1994; Precup and Parker, 1987; Stoletzki and Eyre-Walker, 2007).

Translational Selection Increases Codon Bias

Given that codon bias can affect both the efficiency and the accuracy of translation, it is possible that natural selection acting on the fidelity and efficiency of translation will increase usage of certain codons over others. Those codons that are favored by selection because they are translated more accurately and/or efficiently are referred to as favored or preferred codons. Selection to consistently increase usage of certain codons can of course increase codon bias. Whether or not selection at the level of translation will affect codon bias depends on whether the effects of codon usage on translation are strong and important enough to be noticed by selection. For this reason, across organisms, codon usage is more biased in highly compared to lowly expressed genes (Castillo-Davis and Hartl, 2002; Duret, 2002; Duret and Mouchiroud, 1999; Ghaemmaghami *et al.*, 2003; Goetz and Fuglsang, 2005; Gouy and Gautier, 1982). It is more important that a highly expressed gene be translated in an efficient manner. Otherwise, ribosomes will spend a disproportionate amount of time translating such a gene, which may hinder the cells' ability to properly express all the proteins needed for it to function. It is also more important for a highly expressed gene to be translated accurately. This is because mistranslated proteins may undergo misfolding. A highly expressed gene that is often mistranslated and misfolded could lead to misfolded protein aggregation and cell death (Drummond and Wilke, 2008). In contrast, mistranslation of a less abundant protein would not lead to such high levels of misfolded proteins and would therefore not lead to the same levels of aggregation.

It is likely that selection to use favored codons within highly expressed genes often acts at the level of the entire genome, rather than just at the level of individual genes. In other words, if a highly expressed gene is encoded by disfavored codons, the entire organism will be globally affected, rather than just the translation of that specific gene (Andersson and Kurland, 1990). While selection acting at the individual gene level may only rarely be strong enough to drive changes in codon bias, selection at the entire genome level might more often do so. This view is supported by a recent study in which the 'green florescent protein' (GFP) gene, under the regulation of a strong promoter, was introduced into *Escherichia coli* cells (Raghavan *et al.*, 2012). In *E. coli*, favored codons tend to be GC-rich (Hershberg and Petrov, 2009). The authors of this study introduced different copies of the gene with varying nucleotide contents (and thus varying codon usages). When they introduced the GFP gene encoded by disfavored AT-rich codons they found that cellular growth (a proxy for fitness) decreased (Raghavan *et al.*, 2012). Since the GFP gene in itself is not important for *E. coli* growth, this most likely demonstrates that the effect codon usage within this highly expressed gene has on growth is unrelated to the function of that specific gene. Rather, it is likely that the high expression of a gene with strongly disfavored codon usage led to a slowdown in protein translation and/or aggregation of misfolded proteins that affected the entire cell.

At the same time, selection at the level of individual genes has also been demonstrated. For example, it has been shown that even relatively moderate alterations to the codon usage of the *Drosophila* ADH gene can lead to substantial alteration in its expression, leading to reduced ability of the flies carrying the altered genes to tolerate ethanol (Carlini, 2004; Carlini and Stephan, 2003). Such changes in codon usage would likely be under selection due to their effect on the activity of the specific genes in which they reside. It is important to note, however, that it is not clear whether the changes made to the ADH gene affected its expression by affecting its translation accuracy or efficiency. Synonymous changes could, after all, also affect other stages of gene expression as well (see below).

Selection on Codon Usage Is Ubiquitous but May Vary between Organisms

Over the years there has been some debate as to whether selection on codon usage is ubiquitous to all creatures, or whether it is limited to only some. This debate seems to now be settled, as studies have shown that natural selection affects codon usage across all bacteria, and can also affect codon usage in eukaryotes, including mammals (Drummond and Wilke, 2008; Akashi, 1994; Stoletzki and Eyre-Walker, 2007; Hershberg and Petrov, 2009; Marais and Duret, 2001; Supek *et al.*, 2010). Whether or not selection acts for the same reason in all organisms is less clear. For example, it has been demonstrated that selection to increase translation accuracy acts in both prokaryotes and eukaryotes (including in humans) (Drummond and Wilke, 2008; Akashi, 1994; Stoletzki and Eyre-Walker, 2007). This has been demonstrated via the Akashi test (Akashi, 1994).

The Akashi test compares levels of codon bias between codons encoding highly conserved protein residues and codons encoding less conserved protein residues. The idea behind this approach is that amino acid residues that are more important for protein folding are expected to be more conserved than less important amino acid residues. Conservation is therefore used as a proxy for the importance of an amino acid residue to the folding of its protein. By showing higher levels of codon bias in codons encoding more conserved

amino acid residues the Akashi test shows that selection favors usage of specific 'accurate' codons precisely at residues for which accuracy would be more important. This in turn indicates that selection is acting on codon usage to increase translation accuracy.

Whether or not selection on codon usage to increase translation efficiency is also ubiquitous across organisms is, at this point, less clear (Plotkin and Kudla, 2011; Hershberg and Petrov, 2008).

Selection on Codon Usage – Weak and Constant, or Variable and Sometimes Strong?

As mentioned above, synonymous mutations are often assumed to have no or very low effects on function and fitness compared to nonsynonymous mutations. Therefore it is largely assumed that even if there is selection acting on codon usage, such selection will tend to be weak.

While codon bias greatly varies between organisms it is generally intermediate. This means that there are no cases in which only a single codon is used to encode a given amino acid within a genome. The generally accepted model of codon bias maintains that these, generally intermediate, levels of codon bias are maintained by a balance between background substitutions biases (often mis-referred to as mutation), natural selection and genetic drift. Selection increases codon bias in the face of nucleotide substitution biases that counter this increase. In most models, selection on codon usage is implied to be constant (Akashi and Schaeffer, 1997; Akashi, 1995; Mcvean and Vieira, 2001; Nielsen *et al.*, 2007). It is easy to demonstrate that if selection on codon usage is indeed constant, selection would have to be weak (fitness coefficient (s) $\sim 1/N_e$, where N_e is the organism's effective population size), across all organisms, in order to explain intermediate levels of codon bias (Figure 2). Given that different organisms can have very different effective population sizes, it is unclear why the fitness coefficient of synonymous substitutions would be so fine-tuned to each organisms N_e.

A possible solution to this conundrum could be that selection on synonymous sites is not in fact constant. Selection may act in a nonconstant manner on codon bias in two different non-mutually exclusive manners:

(1) It is possible that selection on codon usage varies as a function of levels of codon bias (Figure 3; Hershberg and Petrov, 2008). Suppose there is an optimal level of codon bias for a certain gene. This optimal level may be determined by such parameters as the level of expression of that specific gene. Let us imagine, for example, a highly expressed gene that is at its optimal codon usage. This would mean this gene is encoded by a sufficient proportion of favored codons as to allow for efficient and accurate enough translation as to not cause aggregation of misfolded proteins and/or reduction in the global efficiency of translation. Any increase in the proportion of favored codons used within this gene may either not change fitness at all, or under certain scenarios may even decrease fitness. It is possible that a single mutation at a single favored codon leading to a small downward shift from the optimum proportion of favored codons will be subject to only weak selection. After all, such a single change may not greatly affect the accuracy and efficiency with which a whole gene is translated. However, if more synonymous mutations were to occur reducing the proportion of favored codons further and further, such additional mutations may be subject to stronger selection. Indeed, they may even prove lethal (Figure 3). Similarly, if a new gene is introduced into a genome via horizontal gene transfer (HGT), and if that gene has very different codon usage than the optimum, there may initially be very strong positive selection for mutations that move codon usage of this gene toward the optimum. Once codon usage of this newly introduced gene becomes more similar to the optimum such selection may become weaker and weaker.

(2) It is possible that selection on synonymous sites varies greatly between sites. As I mentioned above, codon bias tends to be intermediate across all organisms studied. In other words, there are no cases in which only the most preferred codon is used to encode a certain amino acid

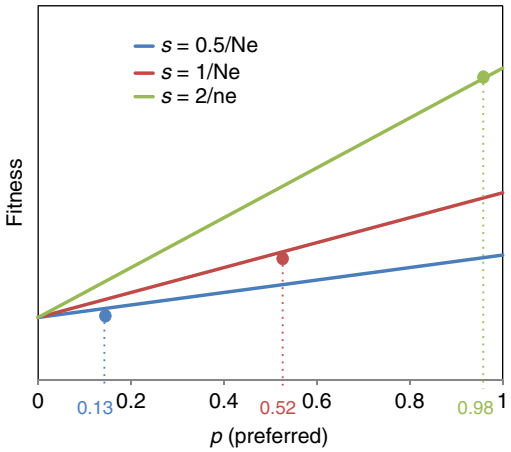

Figure 2 (Reproduced and adapted from Hershberg, R., Petrov, D.A., 2008. Selection on codon bias. Annual Review of Genetics 42, 287–299). Under a model of constant selection on codon usage, fitness is a linear function of the level of codon bias. Under such a model fitness $= s \times p$ (preferred) + constant, where s is the selection coefficient and p (preferred) is the proportion of codons that are fixed for the preferred state. The relationship between fitness and p(preferred) is drawn for three different selection coefficients ($s=0.5/N_e$, $s=1/N_e$, and $s=2/N_e$). For this figure $N_e=10^6$, constant = 0.2. The equilibrium proportion of codons that are fixed for the preferred state (small circles) was calculated for each value of s using the formula: $\hat{p}\,(\text{preferred}) = \frac{1}{\left(1+\frac{\text{bsub}_p}{\text{bsub}_u}\times e^{-4Nes}\right)}$ where bsub_p and bsub_u are the background substitution rates from preferred to unpreferred and from unpreferred to preferred, respectively. For this calculation the ratio between the two was arbitrarily set to 50. For the equilibrium proportion of codons that are fixed for the preferred state to be intermediate (as is true for most genes), the selection coefficient, s, must be in the range of $1/N_e$, as larger values of s lead to genes that are almost entirely encoded by preferred codons (exemplified here by the case of $s=2/N_e$), whereas lower values of s lead to genes with levels of codon bias determined solely by the background substitution patterns of the genome in question (exemplified here by the case of $s=0.5/N_e$).

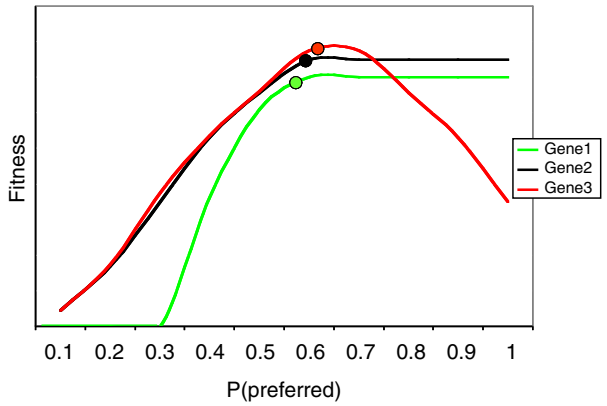

Figure 3 Schematic of the model under which the strength of selection on synonymous mutations changes as a function of codon bias (reproduced and adapted from Hershberg, R., Petrov, D.A., 2008. Selection on codon bias. Annual Review of Genetics 42, 287–299). When the proportion of preferred codons nears an optimum, a selection-background substitution-drift equilibrium is reached. Under this equilibrium, selection is weak. However, shifts from equilibrium can result in strong selection on additional synonymous mutations. The equilibrium proportion of codons that are fixed for the preferred state are marked by small circles. Three possible relationships between fitness and codon bias are depicted: For all three genes at low levels of codon bias, selection for preferred mutations is strong and the strength of selection decreases as codon bias nears equilibrium. For gene 1 very low levels of codon bias are lethal. For both gene 1 and gene 2 fitness reaches a plateau after which additional preferred mutations neither increase nor decrease fitness. For gene 3 there is an optimal level of codon bias that is close to the equilibrium level of codon bias for that gene, and once the gene reaches this level, additional preferred mutations are selected against.

(unless that amino acid is encoded by only one codon). A second way to explain this, without selection on synonymous mutations being constantly weak, is to invoke variation in the fitness effects of synonymous mutations as a function of the genes in which they reside and their positions within these genes. Under such a model, selection could be weak or even absent on synonymous mutations occurring in many genes and at many sites, but much stronger on such mutations occurring at other sites.

As we have already discussed above, selection on codon usage is expected to be stronger on highly expressed genes, and within these genes more selection may be applied on codons encoding amino acid residues important for protein folding. In addition to these well-established levels of variation, other sources of variation may also apply. For example, it is possible that certain synonymous sites may be important for creating mRNA secondary structures. Such secondary structures were suggested to play an important role in stalling translation at codons encoding amino acids important for protein folding and function. This in turn is thought to slow down translation at these important residues, allowing for higher accuracy of translation (Yang *et al.*, 2014). mRNA secondary structures may also play an important role in other levels of regulation, for instance, by affecting mRNA stability in the face of degradation. Additionally, synonymous mutations could also affect such regulatory functions as splicing and the binding of transcription factors and other regulatory proteins.

The best line of evidence currently available showing that selection on synonymous sites can be strong comes from a study carried out by Lawrie *et al.* (2013). In this study the frequency spectra of polymorphisms segregating within *Drosophila melanogaster* was utilized to examine the intensity of selection. Mutations under purifying selection will segregate at lower frequencies within populations. This is why the frequency spectra of polymorphisms can be used to estimate the efficiency with which natural selection acts on a group of mutations. Indeed, examination of the frequency spectra of synonymous polymorphisms in *Drosophila* was among the first ways in which selection on synonymous sites was demonstrated (Akashi and Schaeffer, 1997). A limitation of this approach is that, unless a very large number of individuals are sequenced from a population, only weak selection will allow mutations to persist at frequencies high enough to be observed. Any mutation subject to stronger purifying selection will simply be too rare to be observed. Because the polymorphism data Lawrie *et al.* (2013) utilized was extensive, they were able to also consider the class of 'missing polymorphisms.' This allowed Lawrie *et al.* to estimate what proportion of synonymous sites within *D. melanogaster* was subject to strong selection.

The results were very surprising. Lawrie *et al.* (2013) found that an estimated 22% of fourfold synonymous sites in *D. melanogaster* are subject to very strong purifying selection. Much fewer sites were found to be subject to weak selection. It did not seem that mutations from favored to unfavored codons were more likely to be strongly selected against than other synonymous mutations. Thus, it appears that the main reason for this strong selection is not directly linked to selection in favor of codons that optimize translation. At the same time a significant correlation was observed between levels of gene expression of a gene and the fraction of synonymous sites within that gene that were subject to strong constraint. Highly expressed genes are often more functionally important, and indeed genes with higher numbers of strongly constrained synonymous sites tended to be functionally important, and were found to often be involved in key developmental pathways (Lawrie *et al.*, 2013). Synonymous mutations, located in such important genes and subject to such strong constraint may sometimes be involved in genetic diseases on the one hand, and in adaptation on the other. Indeed, several recent studies have begun reveling examples of synonymous alleles that are involved in disease and adaptive phenotypes (Bailey *et al.*, 2014; Fung *et al.*, 2014; Supek *et al.*, 2014; Gartner *et al.*, 2013; Sauna and Kimchi-Sarfaty, 2011).

Favored Codon Identity and Shifts in Codon Usage

Different organisms have distinct codon usages. Such variation in codon usage between organisms is likely to be contributed by differences in background substitution biases. At the same time, they are also likely to be the result of differences in the identities of the codons that are favored by selection within different organisms.

Variation in the identity of favored codons between organisms begs two questions: First, one must ask which

codons are favored in each organism, and whether there are general rules determining the identities of favored codons. Second, the question arises of how changes are achieved in the identity of favored codons. After all, in order to obtain a change in codon usage one would have to change a very high number of sites within a genome. It is hard to imagine how such a change would be feasible in the face of selection to maintain codon usage. For a long time it was assumed that the identity of favored codons within each organism is a frozen accident. Meaning, the choice of tRNAs that are most abundant was more or less random and this drove a certain codon usage. Once this codon usage was established it was more or less frozen, since changing it would be very difficult in the face of selection. Changes in codon usage under this model would be made possible during long periods of relaxed selection (Bulmer, 1987).

Contrary to the idea that the choice of favored codon is random, we have demonstrated that in bacteria the identity of favored codons tracks the background substitution patterns of the genome (Hershberg and Petrov, 2009). In other words, in GC-rich bacteria favored codons will tend to be GC-rich, while they will be AT-rich in AT-rich bacteria. This leads to a trend, we have dubbed 'going with the flow.' According to this trend codon bias will always go in the direction of the background substitution biases of a bacterial genome, but to a more extreme extent. If the background substitution biases of a genome determine that this genome will be GC-rich, this will mean the synonymous sites of this genome will be even more GC-rich (Hershberg and Petrov, 2009; 2012). This can be seen by comparing the GC-content of synonymous sites to that of intergenic regions of the same genome (**Figure 1**).

It is important to note that there is no trivial a priori reason to expect that tRNA abundance and the background substitution biases of a genome would be linked in such a manner. However, it suggests another mechanism for changes in codon usage that does not require long periods of relaxed selection. Suppose an organism starts experiencing a shift in nucleotide substitution biases. (Note that our model does not claim to explain why such shifts would happen. However, clearly such shifts do occur, or all organisms would have similar nucleotide contents). At first, highly expressed genes will not change their nucleotide content alongside the rest of the genome, since they will be under selection to continue using the most favored codons, recognized by the most abundant tRNAs. Yet, the remainder of the genes which are not highly expressed will shift their nucleotide content and alongside it their codon usage. Once a sufficient amount of non-highly expressed genes are using codons that totally do not match the tRNA pool, it may become advantageous for the tRNAs matching the codons used most by this large group of genes to increase in abundance. After all, even though these genes are not highly expressed, there are many of them and if all of them are translated inefficiently it could reduce the global efficiency of translation and also lead to aggregation of misfolded proteins. Once these tRNAs increase in abundance it will allow the highly expressed genes to follow suit and also alter their codon usage. This may eventually result in a total shift in codon usage toward the direction determined by the genome's new background substitution biases (Hershberg and Petrov, 2009).

Concluding Remarks

Over the past few years we have made much progress in understanding the effects of selection at the level of translation on codon usage. For one, we have moved from thinking that synonymous mutations had very limited functional and fitness consequence, to an increasing realization that synonymous variation needs to be taken into account as a major source of functional variation. At the same time much remains to be understood. Open questions include: (1) What is the relative contribution of translation optimization considerations in the shaping of codon usage? (2) What are the selective pressures beyond translation optimization that affect codon usage? (3) How ubiquitous is selection on codon usage at the level of translation efficiency, and what determines whether a genome will be subject to such selection? (4) What are the determinants of strong selection being applied on a large proportion of synonymous sites? (5) How do shifts in codon usage occur? The next few years should bring forward many new answers to these and other open questions regarding this most intriguing 'codon-bias' phenomenon.

Coevolutionary Fitness Landscapes

BJ Ridenhour, University of Idaho, Moscow, ID, USA

Glossary

Coevolution Evolutionary change that is reciprocated between two interacting groups (usually species). For example, evolutionary change in group A leads to evolutionary change in group B which in turn causes evolutionary change in group A and so forth.

Covariance A statistical measure that indicates to what degree two variables change in concert. The covariance is formally defined as the difference between the mean of the product and product of the means (i.e., $\mathrm{Cov}(x,y) = \overline{x \cdot y} - \bar{x} \cdot \bar{y}$ where the bar indicates the mean). A negative covariance indicates that as one variable increases, the other decreases; a positive covariance indicates that as one variable increases, the other increases as well.

Gene flow The movement of genes from one population to another. Note that gene flow is considered different from migration of individuals because of the added requirement that the genes of transitory individuals get passed on in the populations into which they travel. Thus, for example, gene flow could happen without migration if an individual traveled to another population, successfully mated, and then returned to their home population.

Genetic drift Sampling error on gene frequencies that occurs in populations. For example, assume a population has two individuals, one with genotype A and one with genotype B. Thus the frequency of both A and B is 50%. If one of the two individuals, say individual B, is randomly lost from the population, then the frequency of genotype A becomes 100%. The effect of genetic drift on evolution scales with population size, where small population sizes have the largest sampling error (such as the previous example).

Phenotypic interface The suite of traits in two species that determine the outcome of an interaction. An example of this would be antigens of pathogens and antibodies in hosts. The ability of antibodies to detect antigens determines whether a disease infects a host and thus these two traits form a phenotypic interface.

Phenotype matching A system where the traits of each species have distinct fitness optima or minima based on the phenotypic value of the individual they interact with. For example, in Darwin's orchids and moths, the orchids (*Angraecum sesquipedale*) have a very long nectar-bearing spur and the moths (*Xanthopan morganii*) have a matching proboscis length to guarantee that pollination occurs.

Population and metapopulation The traditional definition of a population is a group of individuals who are breeding with each other at random. A metapopulation is a group of populations that are connected via migration. Within a metapopulation other processes besides migration, such as extinction and recolonization, may occur.

Population and quantitative genetics Population genetics studies the frequencies of different, explicit genotypes or alleles within populations of organisms (e.g., tracking the frequency of the *AA*, *Aa*, and *aa* genotypes for a diploid organism at a gene locus having alleles *A* and *a*). Quantitative genetics focuses on phenotypic values – such as body weight – and their means and variances, and assumes that these traits are controlled by many genes that each have small effects on the expressed trait.

Shifting balance theory Proposed by Sewall Wright in 1932, this theory examines how local adaptation occurs in subdivided populations. Essentially, populations in a metapopulation may transiently become maladapted by genetic drift but then attain a new higher fitness peak by natural selection after crossing through a maladaptive phenotypic space. Once a new fitness peak is achieved, gene flow can then export more fit genotypes to other populations.

Introduction

The process of species coevolving with each other has been central to the formation of the broad diversity of life that currently exists on Earth. Of the three domains of life – Archaea, Bacteria, and Eukarya – eukaryotes are thought to have arisen due to a coevolutionary, mutualistic relationship between Archaea and Bacteria. Strong evidence indicates that mitochondria were once free-living Alphaproteobacteria that formed an endosymbiotic relationship with Archaea (Margulis, 1993). Further evidence suggests that this capture of a free-living bacterium has been repeated again in eukaryotes capable of photosynthesis; phylogenetic and other analyses indicate that chloroplasts are descendent from Cyanobacteria (Cavalier-Smith, 2000). The mutualistic relationships between mitochondria, chloroplasts, and their hosts led to the formation of complex organisms with sophisticated nutrient uptake mechanisms, which now make up all macroscopic biota. While this example is a notable event, coevolution is continually shaping biological diversity at both the macroscopic and microscopic levels.

This article focuses on how interacting with another species affects the fitness of a focal species. These fitness 'outcomes' then feedback into and define how species coevolve. Evolutionary (or coevolutionary) biologists are particularly interested in fitness because the strength of natural selection depends on how fitness varies among individuals. Thus, fitness drives the process of adaptation to local conditions and ultimately determines whether a species persists or goes extinct. It has long been realized that coevolution has shaped the

adaptation of most (if not all) species on Earth (Mode, 1958). In fact, within the coevolutionary literature it is not uncommon to see the "Tangled Bank Hypothesis" referenced. This hypothesis comes near the end of *On the Origin of Species* by Darwin (1859), where he states: "It is interesting to contemplate an *entangled bank*, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp earth, and to reflect that these elaborately constructed forms, so different from each other, and *dependent on each other in so complex a manner*, have all been produced by laws acting around us" [emphasis added]. Clearly, even at this early time in the study of evolution, the importance of interactions between species in shaping biological diversity was already being noted.

Natural Selection

To understand how fitness plays a role in natural selection and adaptation, one needs to understand how selection is defined. In general, evolutionary biologists work with 'soft selection'; soft selection means that a population is neither increasing nor decreasing in size. The opposite of this is 'hard selection' where population size fluctuates (Wallace, 1975; Débarre and Gandon, 2011). The fitness measure used for soft selection is called 'relative fitness' and it is typically denoted with the symbol w; a fitness measure is considered relative when its average value (symbolized as $\overline{w}$, where the bar denotes the average value of w) is 1. Selection (s) is formally defined as the change in the average of some trait z (e.g., body weight) between two time points (call them $\overline{z}^*$ and $\overline{z}$ with the bar notation again indicating an average and the asterisk noting the mean after selection), but prior to inheritance (i.e., the organism has not reproduced); this gives the simple equation $s = \overline{z}^* - \overline{z}$ (Lande, 1979). By definition, mean relative fitness is 1, so we can rewrite this as $s = \overline{z}^* - \overline{z} \cdot \overline{w}$. To find the mean at the later time point ($\overline{z}^*$), we need to know that relative fitness tells us what the change in frequency of the trait will be after a selective event. More intuitively, if $w > 1$ then a particular trait value will be over-represented after selection; conversely, if $w < 1$ then a particular trait value will be under-represented after selection. Therefore, the mean of the product of z and w gives the mean post-selection (see Lande and Arnold, 1983 for more detailed explanation of this), and our equation becomes $s = \overline{w \cdot z} - \overline{z} \cdot \overline{w}$. The right-hand side of this last equation is the statistical definition of a covariance between two variables, thus producing $s = \mathrm{Cov}(w, z)$ (Lande and Arnold, 1983). This simple derivation leads to often-used phrase, "selection is the covariance of (relative) fitness and phenotype." While the derivation shown comes from the field of quantitative genetics, the same – or at least nearly so – result has been found starting from first principles in population genetics (Price, 1970). This equation highlights how fitness ties directly into natural selection and adaptation.

Building upon this simple definition, it is then helpful to investigate two questions in order to understand how selection driven by coevolution affects biodiversity. First, we wish to know how interactions between species affect fitness. At a more basic level we simply need to understand what causes something to be more or less fit and why it varies. Second, we need to understand the coevolutionary process and the factors outside of natural selection (e.g., genetic drift) that are also important to that process. The following sections address these two questions separately.

A Multi-Scale View of Fitness

What is fitness? This seems like a very basic question for evolutionary biology, yet the answers that are given are often varied and complex. Furthermore, fitness is often difficult to measure experimentally and proxies are often used. For example, for many plant studies, seed set is used as measure of fitness, but it is usually unknown whether the seeds in question are viable and contribute to the subsequent generation. For microorganisms like bacteria, doubling-time estimates are used as measure of fitness, but this is more of a population-level estimate of fitness rather an estimate of fitness for an individual bacterium. A safe definition of fitness is simply the number of progeny that survive to reproductive age. The issue here is that 'progeny' can be defined in multiple ways.

Traits of individuals are shaped by genetic and environmental factors. If we assume for simplicity that one gene controls one trait (e.g., flower color in Mendel's pea plant experiments), then we can think of fitness at the gene level. Fitness would then be the number of copies of a gene that are found in the next-generation. This definition of fitness is overly simplistic because genes do not exist in a vacuum; rather, many genes make up an individual and selection (potentially) acts on the individual. Despite this, many evolutionary (or coevolutionary) models – including some of those discussed later in this article – use a gene-centric definition of fitness. However, this difference between thinking at the gene level and at the individual level gives rise to ideas such as 'coadapted gene complexes' (Dobzhansky, 1948, 1950; Wallace, 1968); in other words, the genes within an individual must interact in such a way as to produce a fit individual to ensure their survival. But conflict does arise between the gene and individual level; a gene should favor any mechanism that favors its continuation in the next-generation, whether or not the organism survives (Williams, 1966). This thinking has led to the concept of inclusive fitness (Hamilton, 1964a, 1964b), wherein a gene aids the success of copies of itself passed on globally via related individuals; this argument has been popularized in Dawkin's (1976) *The Selfish Gene*. Inclusive fitness has been used to explain the evolution of altruism and caste systems in eusocial insects (such as honey bees where most individuals forego reproduction).

Regardless, fitness at the individual level is clearly the result of the expression of many genes that underlie many traits. This leads to a 'multivariate' view of natural selection and evolution (Lande, 1979). The theory underlying multivariate evolution makes it possible to study selection on specific traits while taking into account genetic correlations that may exist between the genes responsible for each trait. From the coevolutionary perspective, being able to study traits separately using multivariate approaches is very important. Within a coevolutionary system, a trait (or perhaps a suite of traits) is often thought to form a 'phenotypic interface' between coevolving species; how

these traits interact at the phenotypic interface determines the fitness derived from interactions with members of other species (Brodie and Ridenhour, 2003).

Combining the knowledge that fitness may be derived from various sources and that multivariate analysis is needed to study specific traits, the selection coefficient (s) can be broken down in the following manner: If we consider fitness from two different sources, one coevolutionary (w_c) and one not (w_0), we can simply rewrite our selection coefficient as $s = \mathrm{Cov}(w_c + w_0, z)$. Using some statistical properties of covariances, this equation can be simplified to $s = \mathrm{Cov}(w_c, z) + \mathrm{Cov}(w_0, z) = s_c + s_0$, where s_c and s_0 respectively represent the selection pressure on a trait due to coevolutionary and noncoevolutionary sources (Ridenhour, 2005). For the sake of simplicity, this example of breaking down selection into different sources does not describe the full multivariate approach but the results are easily extended to such approaches.

So far, selection at the gene and individual level has been described, but both population-level and metapopulation-level perspectives of selection are needed to understand how coevolution affects adaptation. Natural selection causes the mean fitness of the population to increase; therefore at the population level it is useful to look at the 'adaptive surface' (Wright, 1967; Cresswell and Galen, 1991; Fear and Price, 1998). An adaptive surface is obtained when individual fitnesses are averaged across a distribution of traits whose mean is allowed to vary (Figure 1). Conceptually one can think of evaluating the individual fitness function at the population mean phenotype, however the variance in trait values affects the adaptive surface. Metapopulation processes (e.g., migration) and population processes (e.g., genetic drift) will also affect the means and variances of traits in populations, and thus also play a role in adaptation. Sewall Wright's 'shifting balance theory' (1932) was perhaps the first significant scientific argument regarding how processes that occur with metapopulations drive the adaptive process. These ideas still play a critical role in modern coevolutionary thinking.

Coevolution and Fitness

Janzen (1980) defined coevolution as reciprocal evolutionary change that occurs between interacting groups (typically species). This is the most commonly used definition of coevolution, however, other broader definitions of coevolution are sometimes used (e.g., diffuse coevolution; Iwao and Rausher, 1997; Fox, 1988). Regardless of the definition, interactions between species are the building blocks of the coevolutionary process and can be broken down into several categories: competitions, mutualisms, antagonisms, commensalisms, and

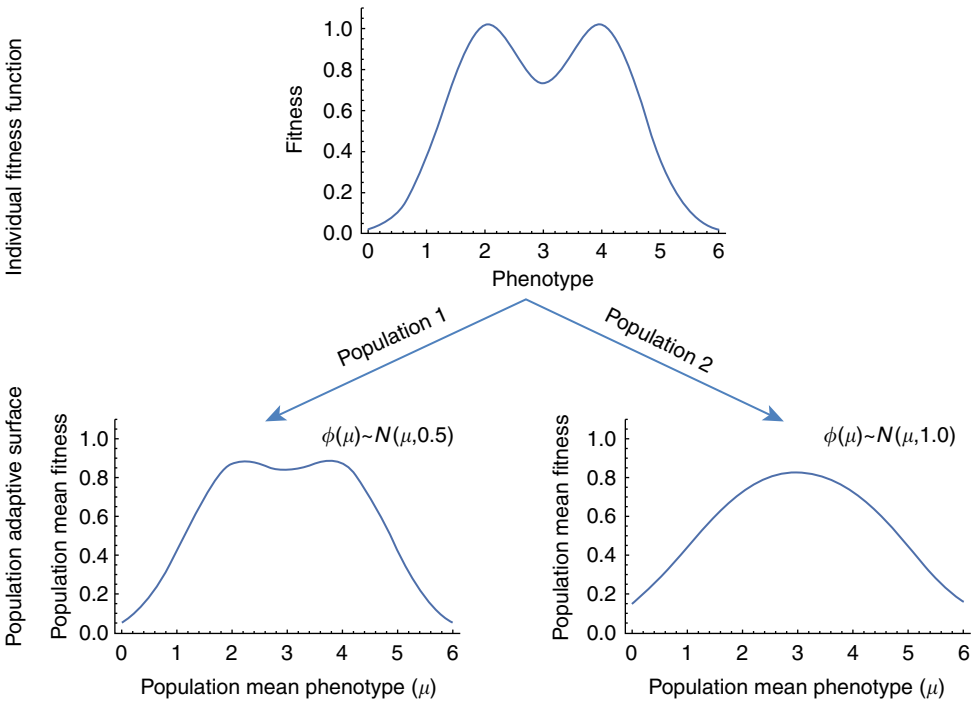

Figure 1 Individual fitness versus the population adaptive surface. The top plot shows an individual fitness function where the optimal phenotype is either $z=2$ or $z=4$. The lower row of plots shows the adaptive surface for two populations. Population 1 has phenotypic distribution that is normal with a standard error of 0.5 ($\varphi(\mu) \sim \mathrm{N}(\mu, 0.5)$); in contrast, population 2 has a distribution with a larger standard error of 1.0 ($\varphi(\mu) \sim \mathrm{N}(\mu, 1.0)$). Note that population 1 and population 2 have different optima favored by natural selection. In population 1, two potential evolutionary optima exist (i.e., two peaks) while only one exists for the population with greater variance in phenotypes. Furthermore, the maximum population mean fitness in population 1 is greater than the maximum for population 2. Also, the population mean fitness is less than the maximum individual fitness. The only way the population could have the maximum individual fitness would be for the phenotype to become fixed at a value of either 2 or 4. In situations like this, there should be stabilizing selection that reduces the phenotypic variance in the population so that the population mean fitness can increase. Coevolution occurs within metapopulations which makes the fitness landscapes even more complicated because then metapopulation processes (e.g., migration) affect the adaptive surface.

amensalisms. These categories come from the fitness consequences of two species interacting together. If we let (+) indicate a fitness benefit, (−) indicate a fitness loss, and (0) indicate neutral fitness consequences, then a (−,−) species pair is a competition, a (+,+) species pair is a mutualism, a (+,−) species pair is an antagonism, a (+,0) species pair is a commensalism, and a (0,−) species pair is an amensalism. For completeness, (0,0) is sometimes referred to as a neutralism, but is typically considered a lack of interaction. Understanding these types of interactions and their fitness consequences is central to understanding coevolutionary outcomes (Thompson, 1982).

Because host–pathogen (e.g., Burdon and Thrall, 2009) and host–parasite systems (Morran *et al.*, 2011) have strong public health, agricultural, and conservation implications, antagonisms are probably the most commonly studied form of coevolutionary interactions. However, many classic examples of antagonisms exist that are not host–pathogen/parasite interactions. For example, Brodie *et al.* (2002) demonstrates how garter snakes have evolved high levels of resistance to deadly tetrodotoxin that is found in elevated levels in their prey, the rough-skinned newt. Toju and Sota (2006) explores similar 'arms race' dynamics in the coevolution of Japanese camellias and camellia weevils. Other classic studies of antagonisms display 'phenotype matching' dynamics, such as seen in parsnip and parsnip webworms (Zangerl and Berenbaum, 2003) or nest-parasitic cuckoos (Krüger, 2007). Cyclical dynamics are also possible in antagonisms as observed in snails and their parasites (Morran *et al.*, 2011).

While mutualisms have possibly been less studied than antagonisms, mutualism has been of enormous interest to evolutionary biologists throughout history. Early research on mutualisms includes Darwin's (1862) treatise on orchids and their pollinators. Mutualisms between plants and their subterranean mycorrhizal fungi may be one of the most important interactions between all biotic organisms, and display a range of forms and evolutionary strategies (Powell *et al.*, 2009); in fact, mutualisms with mycorrhizal fungi may exist for 80% of flowering plants (Bronstein *et al.*, 2006). Some other classic examples of mutualisms are: the relationship between fig and their pollinating fig wasps (Kerdelhue *et al.*, 2000); ants that practice 'agriculture' by farming fungi that provide antibiotics (Mueller *et al.*, 2005); and the obligate mutualism has evolved between yuccas and yucca moths (Althoff *et al.*, 2006).

Regardless of the form of the coevolutionary interaction that is taking place, the 'geographic mosaic theory' (Thompson, 1994, 2005) has been one of the central frameworks for coevolutionary thinking since its introduction. This theory is made up of a set of three 'ecological predictions' and three 'evolutionary hypotheses.' The general ecological predictions of the geographic mosaic theory are as follows:

- trait 'matching' between species will happen only within communities,
- there will be variation in the mean phenotypes among populations, and
- there will be few species-level coevolved traits.

These general ecological predictions are typically supported by empirical studies but are not necessarily outcomes unique to the geographic mosaic theory (Gomulkiewicz *et al.*, 2007). However, with regard to coevolutionary fitness landscapes, the 'evolutionary hypotheses' are more interesting and are:

- different populations will become hotspots and coldspots of coevolution,
- selection mosaics will lead to variable evolutionary trajectories across populations, and
- trait remixing will alter the spatial distribution of coevolving traits.

Theoretical work has shown that selection mosaics and trait remixing have important – and sometimes nonintuitive – effects with regard to local adaptation (Gandon and Michalakis, 2002; Ridenhour and Nuismer, 2007). Empirical studies have also borne out some of the novel predictions related to the geographic mosaic theory. For example, Jokela *et al.* (2009) demonstrate that sexual reproduction of organisms can be favored by host–parasite coevolution, despite being costly. Thompson (2009) highlights some of the most important advances that have resulted from the geographic mosaic theory.

The three evolutionary hypotheses are central to understanding coevolutionary fitness landscapes. First, hotspots and coldspots represent sources and sinks of coevolution. Hotspots (sources) are populations in which reciprocal evolution (per Janzen, 1980) occurs; coldspots (sinks) are populations where either coevolutionary selection pressures are absent or no genetic variation exists for the traits involved in the interaction. Vogwill *et al.* (2009) and Thompson *et al.* (2002) both demonstrate the important role of hotspots and coldspots in the rate of evolution and local adaptation within coevolving species. There are various causes of hotspots and coldspots. For example, crossbills (*Loxia curvirostra*) are seed predators of lodgepole pine (*Pinus contora*). Lodgepole pine have evolved different pinecone morphologies to protect their seeds from crossbills, and, in response, crossbills have evolved different bill morphologies to continue their consumption of lodgepole pine seeds. However, populations that have both crossbills and lodgepile pine present are not always coevolutionary hotspots. Benkman *et al.* (2001) find that crossbills are not significant sources of selection on lodgepole pine when a third species, squirrels, is present to act as the dominant pinecone predator (thus creating a coldspot in the crossbill–lodgepole coevolutionary landscape). Differences in productivity among populations can also lead to the formation of hotspots and coldspots (Hochberg and van Baalen, 1998). While hotspots and coldspots are observed in the crossbill–lodgepole system at a broad geographic scale, evidence that hotspots and coldspots can occur at very localized scales has been found in plants and their pathogens (Laine, 2006).

Selection mosaics are the most novel – and perhaps difficult to understand – concept within the framework of the geographic mosaic theory. A selection mosaic occurs when fitness outcomes of a specific interaction vary due to some third factor (the first two factors being the genotypes/phenotypes of the two interacting species). Thus, selection mosaics have been described as being a genotype × genotype × environment (G × G × E) interaction that affects fitness (Thompson, 2005). To be more specific, the difference in fitness outcomes between two populations is a result of the

environment (E) if a selection mosaic is present. The environment that may cause this difference is often the biotic environment (i.e., the community of species in which an interaction takes place). Thus the presence or absence of tertiary species can lead to the formation of selection mosaics, such as described in crossbill–lodgepole–squirrel example given previously (Benkman, 1999). Actually, measuring G × G × E interactions that alter the resulting fitness of an interaction between species is not a simple task. (Some methods, such as those developed in Kirkpatrick and Heckman (1989) or Kingsolver *et al.* (2001) have potential for doing so.) Most studies that hint at selection mosaics have involved some form of experimental evolution. One example of this is a study by Rudgers and Strauss (2004) that demonstrates geographically variable selection by manipulating ant interactions with cotton across population. Fewer studies have attempted to look at selection mosaics *in situ* due to logistical difficulties. However, one example of this is a study of garter snakes (*Thamnophis sirtalis*) and newts (*Taricha granulosa*) by Hanifin *et al.* (2008) that suggests the nature of coevolutionary selection changes in populations in which predator or prey phenotypes are extremely exaggerated.

The third evolutionary process of the geographic mosaic theory, trait remixing, is probably the most easily demonstrable and least controversial aspect of the geographic mosaic theory. Trait remixing is broadly defined as any nonselective force that causes evolution in a metapopulation. Microevolutionary forces such as gene flow, mutation, and genetic drift can therefore all be sources of trait remixing. Many studies of gene flow – such as Dybdahl and Lively (1996) regarding snails and their castrating trematode parasite, or Ridenhour *et al.* (2007) concerning coevolving garter snakes and newts – have demonstrated that patterns of gene flow are important to the coevolutionary process. Gene flow's influence on coevolution has been extensively studied from a theoretical standpoint as well (e.g., Nuismer *et al.*, 1999). Particularly interesting are results demonstrating that gene flow, traditionally considered to be a maladaptive force, can improve the opportunity for local adaptation by introducing novel genetic variants (Gandon and Michalakis, 2002). Empirical demonstrations of these effects exist in plant–pathogen systems (Thrall *et al.*, 2002). Schulte *et al.* (2010) show that coevolution may speed up the process of reciprocal adaptation via increases in mutation rates. While these forces are, by definition, not part of coevolutionary selection they do influence the fitness landscape. Trait remixing is important to coevolutionary fitness landscapes for three reasons: First, gene flow imports/exports individuals (genotypes) from other populations thus either increasing or decreasing the population mean fitness and variance that changes the adaptive surface for a population (**Figure 1**). Second, any mutations that lead to the creation of novel phenotypes increase the variance of a trait in a population and furthermore may create a phenotype with higher fitness than any other extant phenotype. Third, genetic drift reduces the phenotypic variance within small populations. Reductions in phenotypic variance can potentially lead to achieving higher population mean fitness (**Figure 1**), but have the drawback of limiting strength of selection (the covariance of fitness and phenotype decreases) and the ability of the population to respond to that selective force (there is less genetic variation available). In summary, all of these sources of trait remixing affect the fitness landscape and more importantly adaptation via mechanisms described by the shifting balance theory (Wright, 1932).

Conclusions

Coevolutionary fitness landscapes are complex and require an understanding of the source of fitness components, the multivariate nature of selection at the organismal level, how populations adapt to their local environment, and finally how interactions between species change across both time and space. The process of adaptation on fitness landscapes – without regard to coevolution – has been thoroughly studied; much of this research stems from ideas put forth in the shifting balance theory (Wright, 1932). The geographic mosaic theory (Thompson, 1982, 1994, 2005) is, to some degree, an extension of the shifting balance theory that incorporates concepts specific to how interactions between (coevolving) species shape fitness landscapes. In particular, two of the evolutionary processes of the geographic mosaic theory, the formation of hotspots and coldspots and of selection mosaics, offer novel insights into how adaptation occurs for coevolving species. These contributions have illuminated how coevolutionary interactions may have nonintuitive outcomes. Further research is needed to understand and document the G × G × E interactions that form selection mosaics. The need to understand how coevolution shapes diversity is continually growing; the evolutionary and ecological principles of adaptive coevolution are being brought to bear on more modern data regarding bacterial biofilm formation, microbiomes (human, environmental, or otherwise), and the complex interactions (such as protein–protein interactions) that occur at the molecular level. These data potentially offer a wealth of knowledge regarding the coevolutionary process, and reciprocally, coevolution offers explanations for the diversity observed in these complex modern data.

Coevolution, Bacterial-Phage

B Koskella, University of California – Berkeley, Berkeley, CA, USA

Glossary

Adsorption Generally describes the process of phage recognition of and attachment to receptors on the host cell surface, often directed by the phage tail fibers.

Apparent competition Indirect interactions among competitors through a shared natural enemy, such as a predator or parasites.

Burst size The average number of phage particles produced per bacterial cell that is infected.

CRISPR/Cas system Array of clustered, regularly interspaced short palindromic repeats (CRISPRs) within the bacterial genome in which small segments of phage DNA can be integrated as 'spacers.' These spacers are used to generate RNA that is carried by the Cas complex to cleave the phage DNA at the matching 'protospacer.'

Host range A given phage type is only capable of infecting a subset of bacteria in the environment, and this subset is termed the phage's 'host range.' A phage's host range is a function of its ability to recognize and bind to receptors on the surface of each bacterial cell (adsorption) and on its ability to escape detection and silencing or degradation once inside the cell.

Lateral gene transfer (also called horizontal gene transfer) Movement of genes between genomes of unrelated individuals or species.

Lytic phage Phages in the lytic cycle reproduce and assemble within host cells and must lyse the cell in order to transmit to the next host.

Metagenomics The genomic analysis/characterization of microorganisms through direct sequencing of DNA from samples thought to contain a community of microorganisms.

Phage display Method for testing interactions among proteins, or proteins and peptides, using phage expression of genes encoding a protein of interest.

Phage therapy Describes the therapeutic use of bacteriophages to treat populations of pathogenic bacteria during infection.

Phase variation The variable expression of proteins, often in an on–off fashion, among genetically identical bacterial cells in a population.

Proteomic tree A new approach for assigning phage taxonomy in which whole phage genomes are compared to those of all other sequenced phages in order to predict many aspects of the phage's biology and phylogeny.

Temperate phage Phages that undergo lysogenic infection, whereby the phage genome is integrated into that of its host and phage reproduction happens concurrently with bacterial reproduction. Once within the genome, these phages are referred to as 'prophages,' which can retain their ability to excise from the host genome and enter the lytic cycle.

Time-shift experiment Approach used to explore the dynamics of coevolution between bacteria and phages in which bacteria (or phage) are challenged against phages (or bacteria) from either earlier points in time, contemporary time points, or future time points. This approach is possible because of cryogenic storage and subsequent resurrection of both phages and bacteria from either experimental or natural settings.

Introduction

Bacteriophages (or phages) are viruses that infect bacterial cells. Phage particles are made up of proteins encapsulating either a DNA or RNA genome that is either single or double stranded, and either circular or linear depending on the family of phage. Despite the codiscovery of phages by Twort in 1915 and d'Herelle in 1917 (Duckworth, 1976) and the ubiquity of phages across all examined ecosystems on earth (Clokie *et al.*, 2011), our understanding of the role that phages might play in shaping the genomes, populations, and communities of their bacterial hosts is still expanding rapidly. Early research into phages focused on their possible use as therapeutic agents against pathogenic bacteria, but this interest was mainly eclipsed by the discovery of antibiotics. In part, phages were considered as inferior treatment options to antibiotics because of their relative specificity to particular host species and even strains. However, even as interest in phage therapy waned, the relative specificity of phages was a key feature of the successful influence of phage biology in shaping contemporary biotechnology (Petty *et al.*, 2007) and building the central dogma of molecular biology (Cairns *et al.*, 1966). Two of the major advances offered by phage research have been the use of 'phage display' technology to express exogenous proteins or peptides on the surface of phages (Azzazy and Highsmith, 2002) and the use of phage vectors in DNA cloning (Amemiya *et al.*, 1994). This applied interest has led to an in-depth and impressive understanding of a few bacteria–phage model systems, but has only rarely led to exploration of novel phages in the environment or the impact of phages in natural systems.

Recent resurgence of interest in phage ecology and evolution has been driven by both the imminent need for alternatives to antibiotics (Lu and Koeris, 2011) and the technology-driven discovery of high phage abundance even in the most extreme habitats (Engelhardt *et al.*, 2014). Many of the most common phages have been hiding in plain sight, and it is only through the use of next generation sequencing and sophisticated microscopy that we have uncovered their true ubiquity. For example, genome sequencing of a bacteriophage infecting one of the most abundant marine bacteria, SAR11,

allowed for the assignment of up to 25% of previously unknown sequencing reads from viral metagenomes of the Pacific and Indian Oceans (Kang *et al.*, 2013). Similarly, the discovery of the so-called 'crAssphage,' which most likely infects the common human gut-associated *Bacteroides* genus of bacteria, allowed assignment of up to 90% of previously unknown sequence reads from the human fecal metagenome (Dutilh *et al.*, 2014). As our understanding of phage prevalence and host range in nature expands, so too does the possibility that phages play a central role in many key ecological and biogeochemical processes shaping life on earth.

Phage Life History and Adaptation

As would be expected given their long evolutionary history, contemporary phages display great diversity in terms of genome content and structure (Breitbart and Rohwer, 2005; Hendrix *et al.*, 1999), host range (Hyman and Abedon, 2010; Koskella and Meaden, 2013), and life cycle (**Figure 1**; Abedon, 2008; Clokie *et al.*, 2011). Indeed, due to the lack of conserved sequences across phage genomes, there are currently no individual molecular markers developed with which phage communities can be easily examined (i.e., no equivalent of the 16S rRNA gene most commonly used for characterizing bacterial communities (Adriaenssens and Cowan, 2014)). As such, taxonomic assignment of phages often requires a more complex approach such as whole genome sequencing, microscopy, or the use of 'proteomic trees' (Rohwer and Edwards, 2002). To date, there is relatively little known about the diversity or biogeography of phages in nature, and most of this understanding comes from either viral metagenomic studies or microscopy. For example, phylogenetic profiling of phage metagenomes from either free-living or host-associated environments suggests these two communities are remarkably distinct from one another; a result that mirrors the findings for the bacterial communities with which they interact (Caporaso *et al.*, 2011). Such genomic data can also be used to predict the phage life cycle with surprisingly high accuracy (McNair *et al.*, 2012).

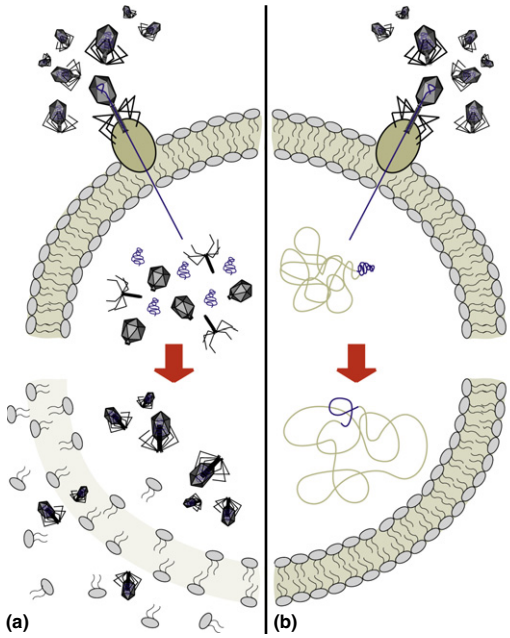

Figure 1 Illustration of the two most common phage life history strategies: lytic (a) and lysogenic (b) infection. In both cases, phages must first recognize and attach to bacterial host cells. This rate of 'adsorption' will be a function of both the likelihood that a given phage encounters a bacterium which is directly related to the ratio of bacteria to phage in the environment, and the probability that the phage successfully attaches to the cell. Once attached, the phage genetic material is injected into the cytoplasm and is either translated and replicated by the host cell machinery, thereby creating new phage virions which are released into the environment after lysis of the cell (a), or else integrated into the host genome and replicated along with the host genome during cell division (b).

Phages are unable to reproduce outside of host cells, but are able to survive for long periods outside of the cell. This means that phage presence is not necessarily indicative of host presence, especially if phages are able to better disperse to, or survive for longer in particular habitats than their hosts (Díaz-Muñoz and Koskella, 2014; Muniesa *et al.*, 1999). For free phage particles to successfully reproduce, they must first encounter and recognize a suitable bacterial cell, at which point phage 'adsorption' can occur (**Figure 1**). Phages recognize bacterial receptors, such as lipopolysaccharides or proteins in the outer membrane, where they attach to cells and attempt to inject their own genome (Labrie *et al.*, 2010) via ejection of genetic material mediated by the phage tail fiber (Molineux and Panja, 2013) or via endocytosis-like mechanisms (Romantschuk *et al.*, 1988). Upon successful infection, the phage DNA/RNA is either translated using the host cell's replication machinery, or integrated into the host genome (**Figure 1**).

Lytic Phages

For phages in the lytic cycle replication requires translation of viral proteins by the host cell machinery, where self-assembly of new virions occurs and the phage genomes are repacked into capsids (Aksyuk and Rossmann, 2011). Phage adaptations that increase replication efficiency include altered codon bias to better match that of its host (Chithambaram *et al.*, 2014; Lucks *et al.*, 2008) and selection on phage genome size (Bull *et al.*, 2004). During the process of assembly and repackaging, bacterial DNA as well as DNA from other coinfecting phages, can be incorporated into the capsid. This process is responsible for the highly dynamic nature of many phage genomes (Rokyta *et al.*, 2006) and allows for the possibility of phage-mediated lateral gene transfer from one bacterial genome to another (Canchaya *et al.*, 2003a). At the completion of phage replication, bacterial cell lysis is induced and phage progeny are released into the environment (Young, 2013). Infection of new hosts once again requires a chance encounter with susceptible cells, as phages are capable of only passive dispersal in the environment.

Lytic phages can vary in host range, adsorption efficiency, time to lysis, burst size, and survival in the environment. Phage host range is determined by many factors including the coevolutionary history, tail fiber length, and expression of particular receptors on host cells (Hyman and Abedon, 2010).

Furthermore, while some phages are only capable of infecting a small subset of bacterial hosts in the environment, others are capable of infecting bacteria from different genera (Holmfeldt *et al.*, 2007; Koskella and Meaden, 2013). Experimental coevolution of bacteria and phages can result in increased host range over time as a result of stepwise mutations (Hall *et al.*, 2013), but shifts from one bacterial host type/species to another is typically more constrained. As with many phage life history traits (Keen, 2014), host range is likely shaped by a trade-off whereby increased breadth of infectivity comes at a cost to other measures of phage fitness, such as adsorption rate or burst size (Duffy *et al.*, 2006), but such costs are not universal (Bono *et al.*, 2013; Poullain *et al.*, 2008). Adsorption rate, time to lysis, and burst size are characteristics shaped by both the phage and host genotype, and can also be influenced by interactions between phages within the cell (Leggett *et al.*, 2013). The optimal time to lysis will also depend on the environment, in particular the density of host cells, as shorter time to lysis typically comes at the benefit of shorter generation times but the cost of fewer phage progeny being produced per generation (Bull *et al.*, 2004; Wang, 2006). Finally, variation in phage survival in the environment is a trait that is much less well-studied, but there exists some evidence that survival might be negatively correlated with phage multiplication within the host cell (De Paepe and Taddei, 2006).

Temperate Phages

Unlike lytic phages, temperate phages can integrate into the host genome as 'prophages' and are replicated along with the host cell during division. These phages can retain the ability to enter the lytic cycle in order to transmit horizontally to new hosts, and this process is often triggered by stressful conditions (Oppenheim *et al.*, 2005). However, over evolutionary time, prophages can lose the ability to excise from host cells, at which point they can be considered 'cryptic prophages.' Bacteria hosting prophages are referred to as 'lysogens' and can attain many important and often beneficial traits from their phages. Indeed, there is now good evidence that prophage acquisition plays a key role in bacterial evolution (Bobay *et al.*, 2014). Among the bacterial traits known to be phage-encoded are the production of toxins (Waldor and Mekalanos, 1996), resistance to antibiotics (Modi *et al.*, 2013), pathogen virulence to eukaryotic hosts (Fortier and Sekulovic, 2013), and increased resilience under stressful conditions (Wang *et al.*, 2010).

Phage integration into the host genome is also a process that can be shaped by selection. The enzymes involved in mediating recombination between the phage and bacterial genomes, the phage integrases, are known to preferentially target particular sites such as intergenic regions or conserved genes (Bobay *et al.*, 2013). Once associated with the host genome, prophages will be under the same selection pressures as those faced by their bacterial hosts. For instance, there is good evidence that selection for bacterial genome reduction often results in the loss of prophages from the genome (Canchaya *et al.*, 2003b). Prophages can also undergo rapid decay and inactivation after integration, including point mutations, genome restructuring, and integration of further foreign DNA. However, recent evidence suggests that many so-called 'domesticated' prophages (i.e., those that have been stably integrated into the host genome for long periods of time) have undergone purifying selection on genes involved in host fitness as well as those encoding key phage traits such as lysis and structure (Bobay *et al.*, 2014). This is particularly relevant to bacteria–phage coevolutionary dynamics, as temperate phages can acquire DNA from defective prophages via recombination, thus increasing the potential for rapid host-specific adaptation (De Paepe *et al.*, 2014a).

Alternative Phage Life Cycles

Although lytic and temperate strategies represent the majority of phage life histories, there are cases in which phages neither integrate into the genome nor enter the lytic cycle, and this state has generally been referred to as 'pseudolysogeny' (Abedon, 2009). For example, 'filamentous' phages are able to replicate within host cells in a similar way to lytic phages but without requiring cell lysis to transmit to a new host (Rakonjac *et al.*, 2011). As with prophages, filamentous phages can influence the phenotype of their hosts. In the case of the human pathogen *Vibrio cholera*, for example, toxin production and increased pathogenicity have been associated with infection by a filamentous phage (Waldor and Mekalanos, 1996). More generally, the pseudolysogeny strategy has been shown to have some unique benefits both in terms of dispersing phages into the environment, and therefore potentially lysing unrelated host cells (Gama *et al.*, 2013), and increasing tolerance to certain environmental conditions (Siringan *et al.*, 2014). Although very little is known about how phages in this state may be adapting to their hosts, there is some evidence that filamentous phages can increase the damage they cause to host cells under conditions in which transmission horizontally from cell to cell is more common that transmission vertically from mother to daughter cell (Messenger *et al.*, 1999).

Phage Adaptation to Host Populations

In addition to general adaptations to the host environment, there is growing evidence that phages evolve quite specific adaptations to particular bacterial host genotypes and species. Natural phage populations can be particularly well adapted to local populations of their hosts, but the scale of such adaptation differs among systems. For example, phages isolated from soil in a flood plain were more likely to infect bacterial hosts from the same sample than from samples collected only centimetres away (Vos *et al.*, 2009). In contrast, phages collected from leaves of horse chestnut trees were just as likely to infect bacterial hosts from other leaves of the same tree, but were much less likely to infect bacteria from neighboring trees (Koskella *et al.*, 2011). Similarly, reanalysis of the infection network of 215 phage types and 286 host types from multiple sites in the Atlantic ocean found that phages were 10 times more likely to infect bacteria from the same sample than those isolated from a different sample (Flores *et al.*, 2013). Evidence for rapid and specific phage adaptation has also come from numerous experimental microcosm studies (Gómez and Buckling, 2011), although in many of these studies phage adaptation is eclipsed by bacterial resistance, and phages are found to be less infective to local relative to foreign bacteria

(Buckling and Rainey, 2002a; Morgan *et al.*, 2005; Vogwill *et al.*, 2010). Importantly, both the direction and magnitude of local adaptation for *in vitro* bacteria–phage systems can be influenced by the rate of migration (Forde *et al.*, 2004; Morgan *et al.*, 2005) and the heterogeneity of resources among populations (Lopez-Pascua *et al.*, 2012).

Phage-Mediated Selection

Given the evidence that phages can readily adapt to infect local host populations and the incredible abundance of phage particles in both aquatic (Fuhrman and Schwalbach, 2003; Waterbury and Valois, 1993) and terrestrial environments (Ashelford *et al.*, 2003; Fancello *et al.*, 2012; Iriarte *et al.*, 2007), it is no surprise that phages have been shown capable of influencing everything from bacterial evolution and diversity (Benmayor *et al.*, 2008; Buckling and Rainey, 2002b; Middelboe *et al.*, 2009) to global biogeochemical cycles (Fuhrman, 1999). Among the direct impacts phages may have on their host populations are mortality-driven changes in density (Fuhrman and Noble, 1995), altered bacterial phenotype and fitness (Bohannan and Lenski, 2000a; Koskella *et al.*, 2012), including changes in bacterial virulence to eukaryotic hosts (Boyd and Brüssow, 2002; De Paepe *et al.*, 2014b), and horizontal transfer of genes among host cells (Canchaya *et al.*, 2003a; Kidambi *et al.*, 1994). Phage-induced mortality can have important consequences for nutrient cycles, and phages have been shown to alter the availability of carbon, nitrogen, and phosphorus in marine food webs (Lennon and Martiny, 2008). Furthermore, phage-mediated selection can influence the composition and stability of whole microbial communities both directly, for example, through apparent competition when phages are shared among species, and indirectly. A study across bioreactor populations found that phage abundance was both dynamic and correlated with the abundance of corresponding bacterial host species (Shapiro *et al.*, 2010), and phage genotypes were observed to fluctuate in accordance with the abundance of matching bacterial strains in an aquaculture environment (Rodriguez-Brito *et al.*, 2010).

The 'Kill the Winner' hypothesis puts forward the idea that population growth of otherwise dominant bacterial species should be hampered by increased prevalence of phages capable of infecting them (Thingstad, 2000; Winter *et al.*, 2010). Indeed, the introduction of phages in experimental microbial communities can alter the biomass of each species depending on the host range of the phage introduced (Middelboe *et al.*, 2003). Similarly, in a community of 15 human gut symbionts transplanted into germ-free mice, phages were found to affect both the density and diversity of bacteria (Reyes *et al.*, 2013). Given the abundance of phages found in human fecal samples (Dutilh *et al.*, 2014), there is therefore good reason to think phages may play a significant role in shaping human-associated microbiota (Abeles and Pride, 2014), as well as those of other eukaryotes (De Paepe *et al.*, 2014b; Koskella, 2013).

Mechanisms of Bacterial Resistance

The pervasive nature of phage-mediated selection, combined with the ubiquity of phages in the environment, has resulted in a wide array of bacterial resistance mechanisms and phage counter-adaptations. Indeed, despite an estimated marine cyanophage abundance of 10^3–10^4 ml^{-1} of water, coexisting cyanobacteria populations were found to be mostly resistant to local phages (Waterbury and Valois, 1993). Bacterial cells can resist phage infection by blocking phage attachment, reducing phage reproduction within cells, and/or interfering with phage transmission (**Figure 2**; Hyman and Abedon, 2010; Labrie *et al.*, 2010). As a first line of defense, bacteria can evade or block phage attachment, for example, by altering expression of the recognized receptor or by producing an extracellular matrix to prevent phages from coming into contact with receptors. If phages are able to successfully adsorb, hosts are still able to respond by either blocking phage replication or degrading phage DNA prior to translation. The currently best-studied mechanism for such recognition is the CRISPR-Cas system, which has been discovered in over half of bacterial species examined (Barrangou *et al.*, 2007; Jore *et al.*, 2012). This system allows for the integration of small segments of phage DNA into the host genome which, when expressed, leads to cleavage of invading phage DNA at matching sites (reviewed in Westra *et al.*, 2012). Even in cases where phages are able to replicate within host cells, bacteria are still able to prevent phage transmission to new hosts through abortive infection systems, which trigger cell lysis prior to phage assembly (Fineran *et al.*, 2009).

These diverse resistance systems differ from one another not only in mechanism, but also with regard to how readily phages can counter-adapt to each (Samson *et al.*, 2013), how costly each is to express (Bohannan and Lenski, 2000b), and how general/specific conferred resistance might be against different phages (Hyman and Abedon, 2010). Moreover, the mechanism of bacterial resistance and phage counter-adaptation will shape the coevolutionary dynamics observed (Betts *et al.*, 2014; Hall *et al.*, 2011; Jessup and Bohannan, 2008). This is in part due to the differences in costs associated with each, which have been found to range from an increased cost of carrying deleterious mutations (Buckling *et al.*, 2006), to altered metabolism of carbon (Middelboe *et al.*, 2009), to increased susceptibility to other phage types (Avrani *et al.*, 2011; Marston *et al.*, 2012).

Bacterial Adaptation to Local Phage Populations

Insight to the scale of bacterial adaptation to phage populations can be obtained from studies that match the CRISPR spacers found in the bacterial genome to phage types circulating in the environment. For example, CRISPR sequences of bacteria from bioreactors were found to diverge in response to local phage-mediated selection despite little divergence in bacterial strain diversity overall (Kunin *et al.*, 2008). Similarly, CRISPR sequences from the human microbiome project were found to differ substantially according to body sites and individual sampled (Rho *et al.*, 2012).

Phage Counter-Adaptation

In response to the diversity of bacterial resistance mechanisms that have evolved, phages have counter-adapted with an

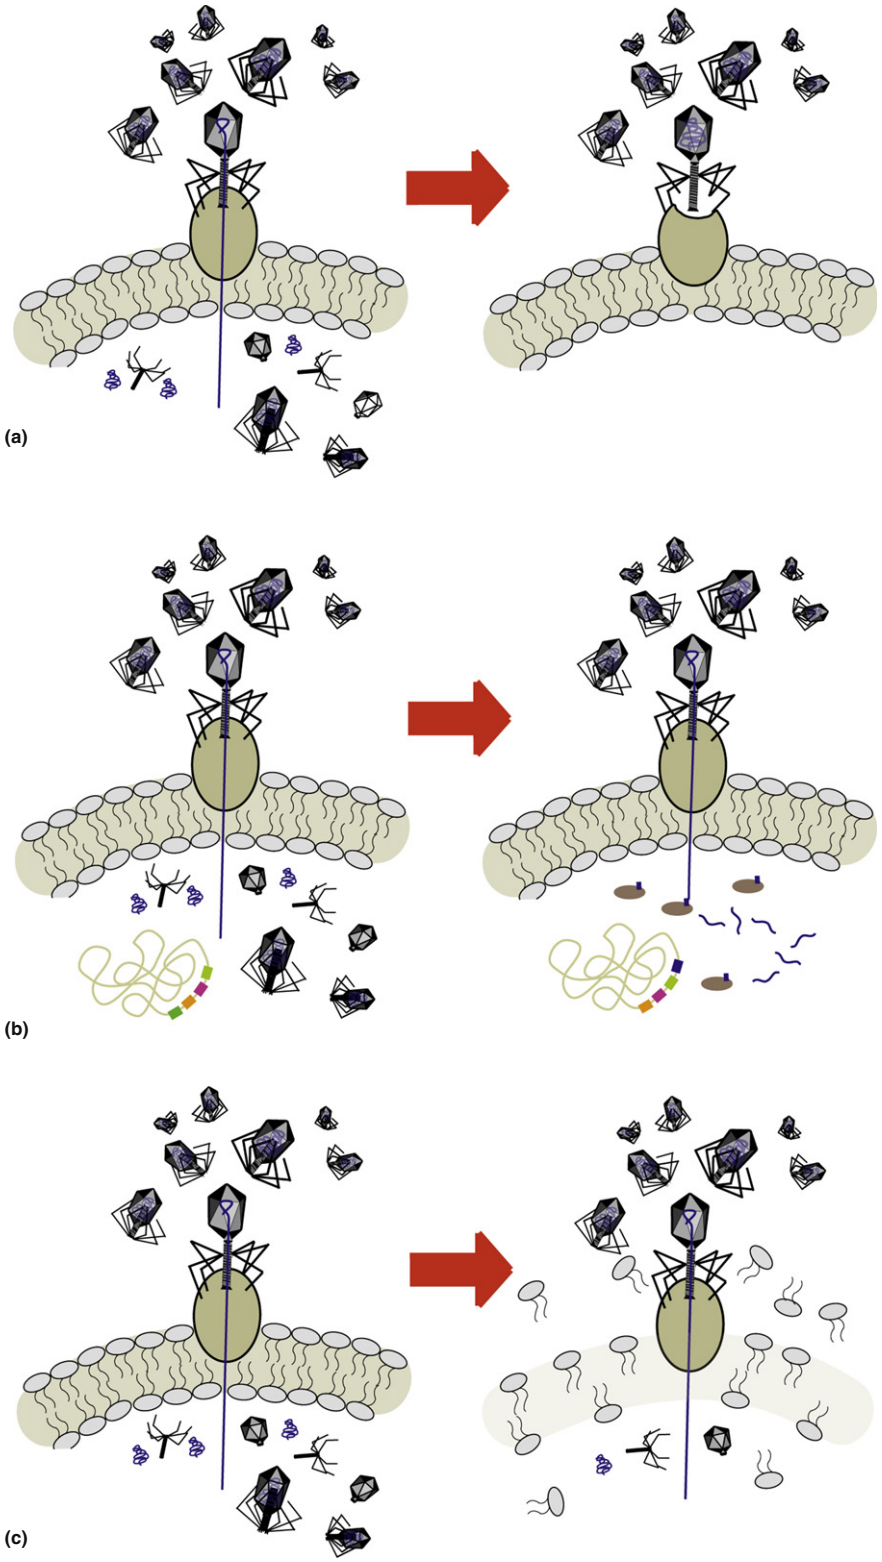

Figure 2 Illustration of common bacterial resistance mechanisms to phages. First, bacteria can alter or lose the receptor recognized by the phage, thus blocking phage adsorption (a). Next, bacteria can either degrade phage DNA or block the translation and replication of the phage genome, for example, using the CRISPR-Cas system (b). Finally, upon successful phage replication within the cell, bacteria can still interfere with phage transmission to neighboring cells by triggering cell lysis before the phage particles are fully assembled (c).

equally diverse array of mechanisms to overcome such resistance (reviewed in Samson *et al.*, 2013). In response to adsorption-blocking mechanisms, for example, mutations in phage tail fiber genes can lead to recognition of altered or entirely new receptors on the bacterial cell (Hyman and Abedon, 2010; Meyer *et al.*, 2012; Scanlan *et al.*, 2011). In addition, some phages are capable of degrading the extracellular matrix produced by bacterial cells, thereby gaining access to otherwise inaccessible receptors (Chibeu *et al.*, 2012; Yan *et al.*, 2014). In response to bacterial-mediated degradation of phage DNA, phage evolution can lead to loss of, or mutations at, sites recognized by bacterial endonucleases or even the acquisition of methylase genes within the phage genome (Samson *et al.*, 2013). Furthermore, counter-adaptations to the CRISPR-Cas system include mutations in the protospacer regions of the phage genome (Sun *et al.*, 2013), phage-encoded 'anti-CRISPR' genes (Bondy-Denomy *et al.*, 2012), and the recently discovered phage-encoded CRISPR-Cas system targeting bacterial chromosomes (Seed *et al.*, 2013).

Evidence for Bacterial-Phage Coevolution

As evidenced by the numerous adaptations and counter-adaptation observed in natural bacteria and phage populations, coevolution is likely to be a common process shaping microbial populations and communities. Direct evidence for bacteria–phage coevolution has come primarily from controlled laboratory studies, where bacteria and phage populations can be frozen and later resurrected to examine (co)evolutionary change over time (**Figure 3**; Koskella and Brockhurst, 2014). Early studies focused on the tailed-phages of *Escherichia coli* B or cyanophages often resulted in only a few coevolutionary cycles before the emergence of a resistant bacterial type that phages were seemingly unable to overcome (Barnet *et al.*, 1981; Chao *et al.*, 1977; Cowlishaw and Mrsa, 1975; Lenski and Levin, 1985). However, evidence for sustained and persistent coevolution has subsequently been uncovered in a number of systems, including *Pseudomonas fluorescens* (Buckling and Rainey, 2002a; Hall *et al.*, 2011), *Cellulophaga baltica* (Middelboe *et al.*, 2009), and *E. coli* O157:H7 (Mizoguchi *et al.*, 2003). Experimental coevolution studies have also highlighted the potential role of coevolution in shaping diversity (Benmayor *et al.*, 2008; Buckling and Rainey, 2002b; Poullain *et al.*, 2008), molecular evolution (Pal *et al.*, 2007; Paterson *et al.*, 2010; Scanlan *et al.*, 2011), and apparent competition among bacteria (Bohannan and Lenski, 2000b; Joo *et al.*, 2006; Koskella *et al.*, 2012). The rate of dispersal is a critical determinant of the speed and scale of coevolution, with low to intermediate rates acting to accelerate the coevolutionary process (Brockhurst *et al.*, 2007a; Vogwill *et al.*, 2008) while high rates act to synchronize dynamics across populations (Vogwill *et al.*, 2009, 2011).

Insight to the mode of bacteria–phage coevolution has been gained through the use of so-called 'time-shift' experiments, whereby bacteria/phage from one point in time are crossed against phages/bacterial hosts from either earlier,

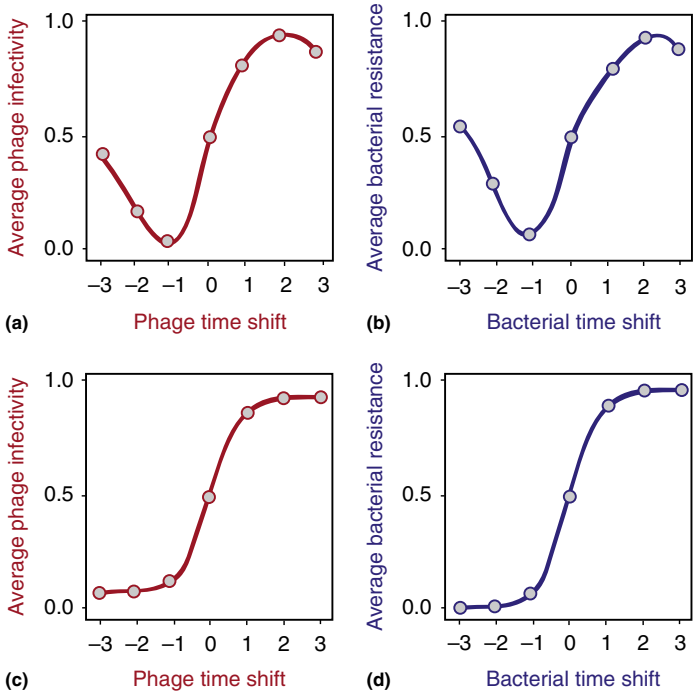

Figure 3 Simplified illustration of the predicted results of a time-shift experiment where either time-shifted phages are tested against fixed hosts (panels (a) and (c)) or the time-shifted hosts are tested against fixed phages (panels (b) and (d)). In the case of fluctuating coevolutionary dynamics (a and b), bacteria/phages from the future are predicted to be most resistant/infective. However, moving further forward in time, we expect resistance/infectivity to drop off as a result of loss of specific adaptations to those earlier populations. In contrast, under arms race coevolution (c and d), we expect phage infectivity and bacterial resistance to increase over time.

contemporary, or later time points (**Figure 3**; Gaba and Ebert, 2009). In this way, researchers can examine whether phage infectivity/bacterial resistance increases in a linear fashion through time, such that phages/bacteria from the future always perform best, or whether they fluctuate through time, as might be expected if infection genetics are highly specific or there are costs associated with increased range of infectivity/resistance (Koskella and Brockhurst, 2014). Experimental coevolution results suggest that the speed and/or mode of coevolution can be influenced by resource availability (Lopez-Pascua and Buckling, 2008) and the presence of other bacterial species (Gómez and Buckling, 2011). Furthermore, the mode of coevolution has been shown to change over time (Hall *et al.*, 2011) and can differ across phage types, even when interacting with the same bacterial host (Betts *et al.*, 2014).

Coevolution in Nature

Evidence of bacteria–phage coevolution in natural populations, although scarce, has confirmed many of the results observed *in vitro*. First, seminatural mesocosm experiments, in which ecological complexity is introduced into otherwise controlled experimental settings, have been used to explore how coevolution in nature might differ from that in the laboratory. Bacteria–phage coevolution in soil mesocosms with the natural microbial community present has demonstrated that coevolution in this environment is more in line with fluctuating selection than arms race dynamics (Gómez and Buckling, 2011), and that coevolution does not necessarily lead to increased mutation rates (Gómez and Buckling, 2013). These results are both in contrast to those observed in the same system when coevolved *in vitro* (Brockhurst *et al.*, 2007b; Pal *et al.*, 2007). Fully natural systems are also amenable to time-shift experiments, as bacteria and phages can be sampled and stored through time. In this way, microbial communities from horse chestnut leaves were collected over the course of a growing season to test for signatures of bacteria–phage coevolution within trees over time (Koskella, 2013). Bacterial isolates were found to be more resistant to phages from 1 month earlier and less resistant to phages from 1 month in the future, suggesting a rapid response to phage-mediated selection. A follow on study examining infectivity of individual phage clones demonstrated that phages were, on average, most infective to bacterial hosts from the recent past, but lost infectivity on bacterial hosts from earlier in the season (Koskella, 2014). This is again in line with fluctuating, rather than arms race dynamics, suggesting that this mode of coevolution might be less common in natural populations than it is in laboratory experiments. Overall, it is increasingly clear that phage-mediated selection can and does play an important role in shaping the ecology and evolution of host populations and that bacteria–phage coevolution can have impressive and often unexpected impacts on the health of individual eukaryotes (Abeles and Pride, 2014; De Paepe *et al.*, 2014b) and ecosystems (Peduzzi *et al.*, 2014).

Coevolution, Introduction to

JB Yoder, University of Minnesota, Saint Paul, MN, USA

Glossary

Antagonism An interaction in which one species gains a benefit at the expense of another.

Arms race A coevolutionary dynamic in which two interacting species gain advantage if they have greater values of the traits that mediate the interaction – such that over time these traits evolve to greater and greater values.

Competition An interaction in which two species make use of the same resource, in which the use of the resource by one species precludes the other from using it, and vice versa.

Mutualism An interaction in which one species provides a benefit to another, and receives a reciprocal benefit.

Parasitism An antagonistic interaction, usually symbiotic, in which individuals of one species live inside another and derives sustenance from this host. This is usually damaging to the host. Typically, hosts are much longer-lived than their parasites, and many parasite individuals infest a single host.

Predation An antagonistic interaction in which individuals of one species capture and consume individuals of another species. Typically, predators and prey have similar lifespans, and predators consume many prey individuals over the course of their lives.

Symbiosis Any interaction, antagonistic, mutualistic, or even non-coevolutionary, in which one species lives most of its life on or within individuals of another species.

Virulence The damage done to a host individual by parasites.

Introduction

No organism is an island. Every living thing contends with predators, parasites, and competitors, and most also receive benefits from mutualists (Table 1). These interactions with other species exert natural selection – and predators, parasites, competitors, and mutualists may also experience selection in return. The mutual evolutionary change that results from this reciprocal selection is 'coevolution' (Janzen, 1980; Thompson, 2005).

The idea that other living things are a significant source of natural selection is found as early as Charles Darwin's (1859, pp. 94–95) description of reciprocal evolutionary changes occurring in populations of clover and honeybees:

> The tubes of the corollas of the common red and incarnate clovers (*Trifolium pratense* and *incarnatum*) do not on a hasty glance appear to differ in length; yet the hive-bee can easily suck the nectar out of the incarnate clover, but not out of the common red clover… Thus it might be a great advantage to the hive-bee to have a slightly longer or differently constructed proboscis. On the other hand, I have found by experiment that the fertility of clover greatly depends on bees visiting and moving parts of the corolla, so as to push the pollen on to the stigmatic surface… Thus I can understand how a flower and a bee might slowly become, either simultaneously or one after the other, modified and adapted in the most perfect manner to each other, by the continued preservation of individuals presenting mutual and slightly favourable deviations of structure.

Darwin applied this principle to predict that the Malagasy orchid, *Angraecum sesquipedale*, which produces nectar at the bottom of a dangling spur up to 30 cm (12 in) long, must be pollinated by a moth with a proboscis long enough to reach the nectar, picking up or depositing the orchid's pollen in the process (Darwin, 1877, pp. 162–163) – and, decades later, such a moth was found (Rothschild and Jordan, 1903).

As with any question about evolutionary processes, it is important to differentiate patterns consistent with coevolution from direct evidence of reciprocal selection. Complementary traits in interacting species may arise for reasons unrelated to coevolutionary selection (Nuismer *et al.*, 2010; Gomulkiewicz *et al.*, 2007). Moreover, an interaction that has a strong selective effect on one species may be much less important in the evolutionary history of the other. For example, congruent traits may occur because the two interacting species encounter each other in a common environment that selects directly for the traits observed in both species, or because one species interacts

Table 1 Major categories of coevolutionary species interactions defined by their selective effects on interacting species

Interaction type	*Selective effect for*		*Examples*
	Species 1	*Species 2*	
Mutualism	+	+	Plants and their pollinators; legumes and nitrogen-fixing rhizobia; plants and mycorrhizal fungi; corals and photosynthetic algae
Antagonism	+	–	Hosts and parasites; predators and prey; herbivores and plants
Competition	–	–	Competitive interactions are well documented between different species of *Anolis* lizards, between subspecies of three-spined sticklebacks, and between carnivorous mammals – among many other cases

 doi:10.1016/B978-0-12-800049-6.00185-2

with many other species that all have similar requirements. Identifying which interactions have long-term evolutionary importance, and how they shape the evolution of the species involved, has proven to be a complex, yet fascinating, question.

Coevolutionary Dynamics

Coevolution emerged as a specialized field of research in the second half of the twentieth century. One of the earliest examples is H.H. Flor's discovery that genetically different strains of flax rust fungus were able to infect some lines of flax, but unable to infect others (Flor, 1955, 1942). Flor concluded that the parasite and its host had 'complementary genic systems' (Flor, 1956). Based on Flor's data, Charles J. Mode (1958) constructed a mathematical model of flax rust 'coevolution' – perhaps the first use of this term – which predicted that selection by infectious rust should lead to an increased frequency of host genotypes that can resist infection, and that these more resistant hosts would in turn select for more virulent strains of rust. Coevolutionary dynamics differ from simple responses to natural selection in that a species' response to coevolutionary selection leads to a change in the original source of selection: the other interacting species. This means that coevolution is an ongoing process even when every other element of the interacting species' environment is stable. Coevolutionary dynamics take several different forms.

Arms Races

Consider a mollusk with a shell that protects it against predators. Selection should favor predators with jaws strong enough to break the shell. If strong-jawed predators become common enough, they may select for mollusks with stronger shells. Exactly such 'arms races' have been identified in the fossil record of mollusks and their predators (Vermeij, 1994). Patterns of escalating defense suggestive of arms races have also been documented in many contemporary species interactions. Milkweeds (genus *Asclepias*) evolved greater production of toxic phenolic compounds over a long history of coevolution with insect herbivores (Agrawal *et al.*, 2009). Over just a few decades, North American populations of wild parsnip (*Pastinaca sativa*), a weed introduced from Europe, evolved greater production of toxic furanocoumarins after parsnip-eating webworms (*Depressaria pastinacella*) were brought over from Europe (Zangerl *et al.*, 2008).

There are limits to coevolutionary arms races. The rough-skinned newt, *Taricha granulosa*, secretes tetrodotoxin, which can incapacitate the garter snakes that prey on the newts. In many cases, populations of newts that produce more tetrodotoxin live alongside coevolved snakes that can tolerate greater doses of the poison; but in some populations the snakes are able to tolerate far more poison than the local newts produce, suggesting that the snakes have 'escaped' (or maybe simply won) the arms race (Hanifin *et al.*, 2008).

Cycles

When a coevolutionary arms race is constrained by the costs of producing a defense or a counter-defense, coevolutionary cycles are possible (**Figure 1**). As one species reaches the upper limits of defense production, individuals with reduced defenses may gain a selective advantage if the cost of increased predation or herbivory is offset by the savings of not producing a massive shell or lots of toxin. Greater frequency of undefended prey creates an advantage for predators or herbivores with reduced counter-defenses, and so this species evolves to a lower-cost state as well. When both defense and counter-defense have evolved to a lowered state, the arms race can begin anew (Berenbaum *et al.*, 1986; Agrawal and Lively, 2002).

Cycles may also occur when different genetic lines of an antagonist species specialize on specific genetic variants in its victim, as in Flor's (1942, 1955) wheat rust. Selection first favors the antagonist genotype that specializes on the most common victim genotype, but the increased frequency of this antagonist genotype selects against the victim genotype it targets – and eventually a different victim genotype will be the most common in the population, which in turn favors a different antagonist genotype. This negative frequency-dependent selection is found in populations of the New Zealand mud snail, *Potamopyrgus antipodarum*, which are attacked by a trematode worm in the genus *Microphallus*. Within individual lakes, the most common genetic line in the local mud snail

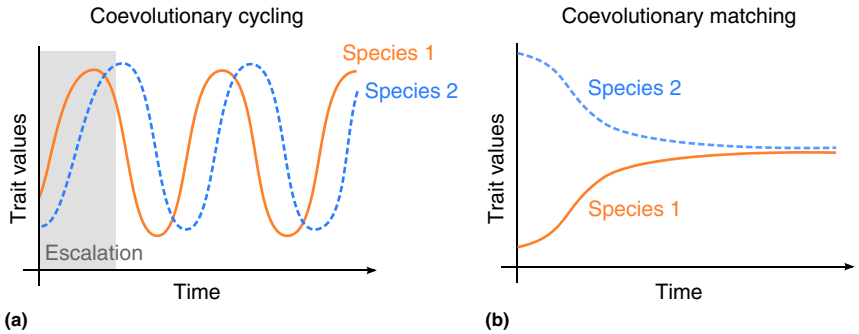

Figure 1 Coevolutionary dynamics. (a) Coevolutionary escalation (shaded area) occurs when prey or hosts evade their antagonists by evolving defenses superior to their predators' or parasites' counter-defenses; and if greater defenses and counter-defenses are costly, then coevolutionary cycles may occur. Cycles can also occur if antagonists are more successful when they match the most common host genotypes, creating negative frequency-dependent selection. (b) In many mutualisms, interacting species benefit from closer matching to each other, which creates selection for better-matched traits.

population changes in a cyclical fashion, and trematodes are more infective against snails from the previous year's population (Dybdahl and Lively, 1998). This dynamic is thought to maintain diversity in the genes that mediate immune responses in mammals, birds, and even plants – and in the genes of parasites and disease organisms that mediate resistance to immunity (Tiffin and Moeller, 2006; Westerdahl, 2007; Tellier and Brown, 2007).

Matching

Mutualism is often expected to favor individuals whose traits are better matched to their mutualistic partner, leading to a stable equilibrium when each species is optimally matched to the other (Kiester *et al.*, 1984). This may be the case for yucca plants and their pollinators, specialized moths in the genus *Tegeticula* that lay eggs in yucca flowers before depositing pollen. The moth larvae feed on developing yucca seeds, so the moths drill into the floral ovary with a needle-like ovipositor, laying their eggs adjacent to the ovules that will develop into seeds. However, if the moth does too much damage in the course of oviposition, it risks triggering the plant to abort the damaged flower. Consequently, the length of the pollinator's ovipositor is closely matched to the thickness of the yucca's ovary wall. In the case of one yucca species, Joshua tree (*Yucca brevifolia*), this selection for matching seems to have led to differentiation in floral shape among populations serviced by different pollinator species with different ovipositor lengths (Yoder *et al.*, 2013; Pellmyr and Huth, 1994).

However, it is not clear how well this simple model describes many other mutualistic interactions. Darwin's original prediction of coevolutionary dynamics between the orchid *A. sesquipedale* and its pollinator is more like an arms race, in which the orchids with longer spurs gain more effective pollination by forcing pollinators to reach deeper for a nectar reward, and pollinators with longer proboscises gain easier access to nectar (Darwin, 1877). Similarly, evidence for simple matching is lacking in the mutualistic interaction between plants in the legume family and rhizobial bacteria, which colonize their hosts' roots and fix atmospheric nitrogen in exchange for sugar resources. Patterns of compatibility between different strains of rhizobia and different host plant family lines suggest that there is no single 'best' combination of host and rhizobia, as would be expected from matching (Heath, 2009; Heath *et al.*, 2012).

The above-described dynamics explain coevolution over just a relatively small number of generations. Many lines of evidence suggest that coevolutionary interactions have also shaped species over millions of years, but how specific coevolutionary dynamics connect to these larger patterns of diversity remains an area of ongoing research.

Coevolution and Speciation

As Flor and Mode initiated the modern study of coevolutionary dynamics, their contemporary, Verne Grant began to document the importance of coevolutionary interactions in speciation. In a 1949 study, Grant compiled taxonomic descriptions of plant species and grouped them by the manner in which they exchange pollen. This data showed that in comparison to plants pollinated by wind and water, plant species pollinated by birds or by specialized insects were more easily distinguished based on features of their flowers (Grant, 1949; **Figure 2**). That is, interactions with animal pollinators meant that traits involved in pollination were more likely to define differences between animal-pollinated plant species.

Paul Ehrlich and Peter Raven (1964) further popularized the notion that species interactions contribute to macroevolutionary processes, in a study of butterfly species and the plants upon which those butterflies feed as larvae, and specifically called this process 'coevolution.' Ehrlich and Raven

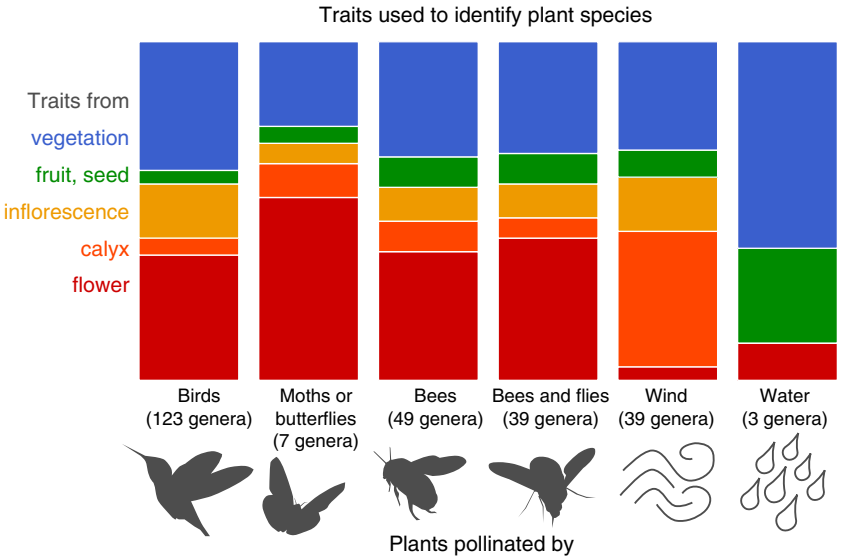

Figure 2 Plant–pollinator interactions affect traits important in plant species delimitation. Floral traits are more likely to be important in the taxonomic descriptions of plant species when those species are pollinated by animals, rather than wind or water. Data taken from Grant, V., 1949. Pollination systems as isolating mechanisms in angiosperms. Evolution 3, 82–97 (Table 1).

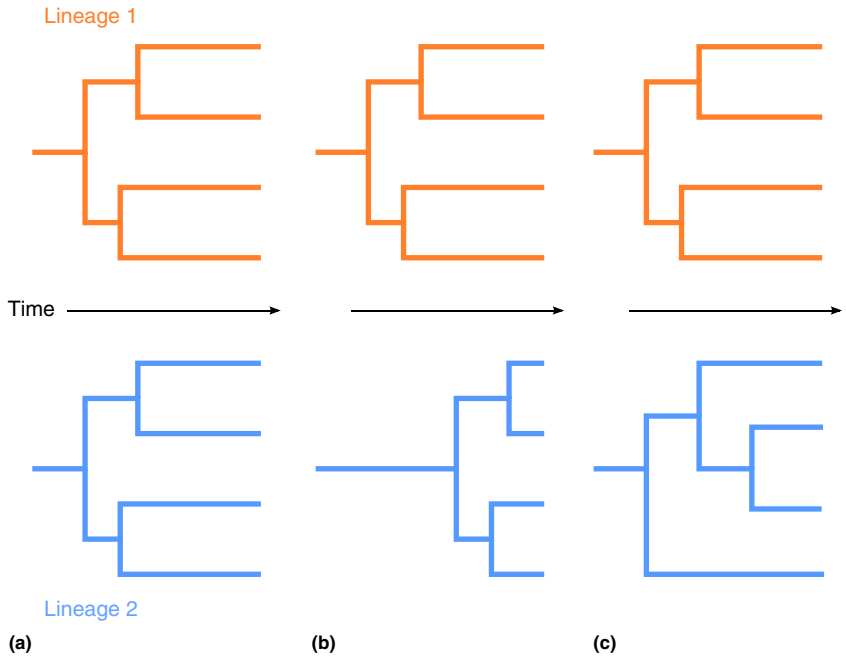

Figure 3 Stepwise and simultaneous diversification. Coevolution between two interacting lineages over evolutionary time may lead them to have congruent phylogenies (a), but this pattern may also occur if one lineage depends strongly on the other without exerting reciprocal selection. Coevolution over ecological timescales may also lead to phylogenies that are congruent in shape but without simultaneous speciation events (b) or largely incongruent (c) if pairwise associations between species shift frequently.

noted that butterfly species descended from a common ancestor frequently feed on plants from a single, closely related group of plants; and that such groups of plant species tend to have similar defenses against insect herbivores.

Ehrlich and Raven proposed that this pattern developed in a series of stepwise evolutionary transitions, starting when a plant species evolved a new anti-herbivore defense. If this defense was sufficiently effective to reduce or eliminate herbivore attacks, it would allow the plant species to expand its population, colonize new habitats, and, over time, diversify into an array of new species, all carrying the novel defense. As the group of plant species became more common in a landscape, it would become advantageous for any insect species that evolved a means to counter the new defense – and the lucky insect that did so would spawn its own array of new species as its descendants shifted and diversified into the already-diverse group of previously resistant plants. This stepwise diversification came to be known as 'escape-and-radiate' coevolution (Thompson, 2005).

In recent decades, our ability to reconstruct evolutionary relationships among species using DNA sequence data has allowed extensive verification of the general idea that coevolutionary interactions are associated with greater diversity. For example, lineages of beetles that feed on flowering plants contain orders of magnitude more species than their sister lineages that feed on gymnosperms – since the former plant group is itself much more diverse, this implies that insect specialization on individual host plant species contributed to this dramatic contrast (Farrell, 1998). A time-calibrated evolutionary tree for one of the largest groups of beetles, the weevils, shows that they did not begin to diversify until well after flowering plants had come to dominate terrestrial communities, which fits Ehrlich and Raven's model (McKenna *et al.*, 2009).

Similarly, lineages of plants with bilaterally symmetric flowers, which are often adapted to fit specific pollinators – like the orchid Darwin examined – are consistently more diverse than sister lineages whose flowers are radially symmetric, and which usually have less-specialized interactions with their pollinators (Sargent, 2004). Studies of the relative timing of diversification in such interactions suggest that in many cases clades of specialized plants may diversify by adapting to attract a preexisting diversity of pollinators, rather than speciating simultaneously and in parallel with their partner lineages (**Figure 3**; Ramírez *et al.*, 2011; Schiestl and Dötterl, 2012).

These complexities highlight the difficulty of connecting specific phylogenetic patterns to coevolutionary dynamics. When two interacting lineages have highly congruent evolutionary histories (**Figure 3(a)**), it is tempting to infer that their interaction is coevolutionary – but this pattern can also arise if one lineage depends strongly on the other without exerting reciprocal selection. Alternatively, the phylogenies of two lineages may be congruent in shape, but not in timing of their respective speciation events (**Figure 3(b)**); this is consistent with Ehrlich and Raven's model, but the same pattern may result when one lineage adapts to track the other, absent any reciprocal selection. Finally, two lineages that are currently coevolving may have entirely different evolutionary histories (**Figure 3(c)**) if species associations frequently change. Indeed, switching between pollinators may often contribute to the formation of new flowering plant species (Van der Niet and Johnson, 2012). In such cases, coevolutionary interactions spur speciation via a process that explicitly breaks down patterns of phylogenetic congruency.

It seems indisputable that the types of species interactions that often generate coevolutionary selection are associated with adaptive diversification. However, coevolutionary species interactions may often play a role in the formation of new species without causing both interacting species to diverge simultaneously – indeed, documented cases in which coevolutionary selection has led to speciation are quite rare (Althoff *et al.*, 2014; Hembry *et al.*, 2014). Increasingly, research on coevolutionary interactions and their long-term outcomes looks beyond simple, pairwise interactions to understand how groups of species influence each others' evolution, and how that influence changes in the context of different environments.

Coevolution in Mosaics and Networks

One reason coevolution may rarely result in tidy patterns of co-diversification is that few, if any, organisms interact with only one other species. Even a yucca moth living on and around the host plants on which she will mate and lay her eggs must also contend with disease, predators, and competition with many non-pollinating herbivores for plant resources. Sometimes the interaction of multiple species means that the effects of coevolution propagate from one level of the food chain to another. For example, when domesticated apples were introduced into North America, populations of the native fruit fly *Rhagoletis pomonella* evolved to specialize on apples – and parasitoid wasps that attack *R. pomonella* larvae have differentiated in parallel to specialize on the apple-feeding flies (Forbes *et al.*, 2009).

Variation in the environment and in the broader biological community can dramatically alter the outcome of a single, pairwise interaction. In western North America, the seeds of lodgepole pine trees, *Pinus contorta* subspecies *latifolia*, are eaten by pine squirrels, *Tamiasciurus hudsonicus*, and red crossbills (*Loxia curvirostra*). These two seed predators have rather different approaches. A squirrel bites cones off the tree's branches, and targets larger cones containing more seeds; but a crossbill uses the crossed tips of its parrot-like bill to pry open the scales at the tip of a pine cone and then extracts the seed under each scale using its tongue.

In most of lodgepole pine's range, more seeds are lost to squirrels than to crossbills, so the squirrels are the primary selective force acting on lodgepole pine cones. However, some isolated populations of lodgepole pine grow in habitats where no squirrels are present. In these sites, crossbills are the dominant seed predator; and the cones of lodgepole pines are larger and narrower than cones from populations attacked by squirrels, with thicker scales at their tips where crossbills prefer to attack (Benkman *et al.*, 2003; Edelaar and Benkman, 2006).

This complex interaction of pines, squirrels, and crossbills is considered one of the classic examples of a 'geographic mosaic' – in some populations, lodgepole pine cones are shaped by selection from squirrels; but in others, crossbills are the dominant selective force. In his geographic mosaic theory of coevolution, John Thompson (2005, 2013) predicted that interactions between species will rarely be straightforward, pairwise interactions – but rather that the form and consequences of coevolutionary selection will differ whenever species interact in different environmental contexts and ecological communities. Furthermore, if the interacting species move freely between contexts, it may often be the case that local populations are maladapted – badly suited to each other or the context in which they interact – because of immigration from populations experiencing different selective conditions (**Figure 4**; Gomulkiewicz *et al.*, 2000).

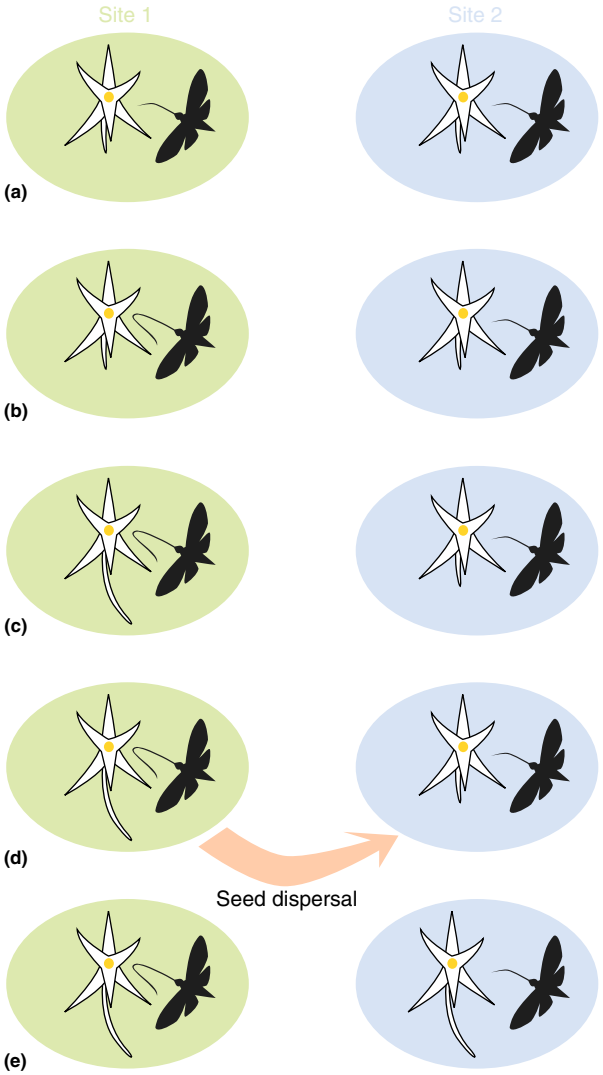

Figure 4 Migration across a geographic mosaic of coevolution can lead to local maladaptation. Consider a fictional pollination interaction similar to that between the orchid *Angraecum sesquipedale* and the hawk moths that pollinate them. In two separate sites, orchids attract moths with nectar secreted at the bottom of a dangling nectar spur. (a) Initially, the orchid's nectar tubes are just long enough that when a moth reaches its proboscis to the bottom of the spur, it comes into contact with the orchid's stigma and anthers, and picks up or deposits pollen. (b) Moths with longer proboscises can more efficiently reach the nectar, and at Site 1, this benefit causes the moth population to evolve longer proboscises. However, at Site 2, cooler temperatures make longer proboscises more physiologically expensive, enough to offset the benefit of better nectar removal. (c) The longer proboscises of moths at Site 1 select for orchids with longer nectar spurs. (d) Orchid seeds disperse from Site 1 to Site 2, introducing longer-spurred orchids into Site 2 – (e) where the local moths are poorly matched to them.

Because almost all species live in a variety of environments and encounter different communities of organisms across their native ranges, geographic mosaics of coevolution are probably common. They may also suggest a way in which coevolutionary interactions contribute to the formation of new species. If the nature and strength of coevolutionary interactions vary from population to population, different populations may follow very different evolutionary trajectories – over time, enough to become different species. For instance, the differences in lodgepole pine cone shape selected by the presence or absence of pine squirrels are sufficiently large that crossbills in squirrel-free pine populations have evolved deeper bills to open the thicker pine cone scales. This may have contributed to a change in the birds' mating calls that partially reproductively isolates them from other crossbill populations (Benkman *et al.*, 2003; Smith and Benkman, 2007).

The fact that species' evolution may be influenced by indirect interactions suggests that studying coevolution may often require an understanding that looks beyond simple, pairwise, and reciprocal adaptation. One line of research that offers such a view considers the structure of interaction networks, such as all the plant–pollinator relationships, within a given geographic area or biological community. In many such networks, the most specialized species that interact with only one or a few other species tend to interact with partner species that are more generalized and that interact with many other partners. This asymmetric specificity results in 'nested' networks (**Figure 5**).

Nestedness emerges in a wide variety of interaction types. These include networks of interaction between plants and pollinators, seed-dispersing animals, protective ants, and herbivores (Bascompte *et al.*, 2003; Guimarães, 2006; Cagnolo *et al.*, 2011) – and also networks of insect herbivores and parasitoid wasps, and cleaner shrimp species and the fish they service (Guimarães *et al.*, 2007; Cagnolo *et al.*, 2011). This phenomenon may be a simple consequence of species-abundance patterns; if more specialized species tend to be rarer, nestedness can arise because less-specialized species will be more likely to encounter each other, while the most specialized species will be most likely to encounter the most generalized species (Krishna *et al.*, 2008). However, mathematical modeling suggests that coevolution in large communities of interacting species can shape the structure of the interaction networks – and it can cause many species in similar ecological roles to converge on similar traits (Nuismer *et al.*, 2012; Guimarães *et al.*, 2011).

One example of such convergence may be the pollination syndromes of flowering plants, in which plant species pollinated by the same broad groups of animals tend to have flowers of similar shape and color (Rosas-Guerrero *et al.*, 2014). For example, species pollinated by hummingbirds often have red, tubular flowers that are open during daylight; whereas species pollinated by moths generally have white flowers that open in the evening, and produce strong fragrances. Pollination syndromes unite distantly related plant species via selection from a shared group of pollinators, and they suggest that even when individual pollinator species do not exert strong selection on individual plant species, the collective effects of selection to attract many similar species add up to a major evolutionary force. Such 'diffuse coevolution' would not create patterns of simultaneous speciation, or even reciprocal adaptation over the course of a few years, and yet it seems to be capable of shaping whole biological communities.

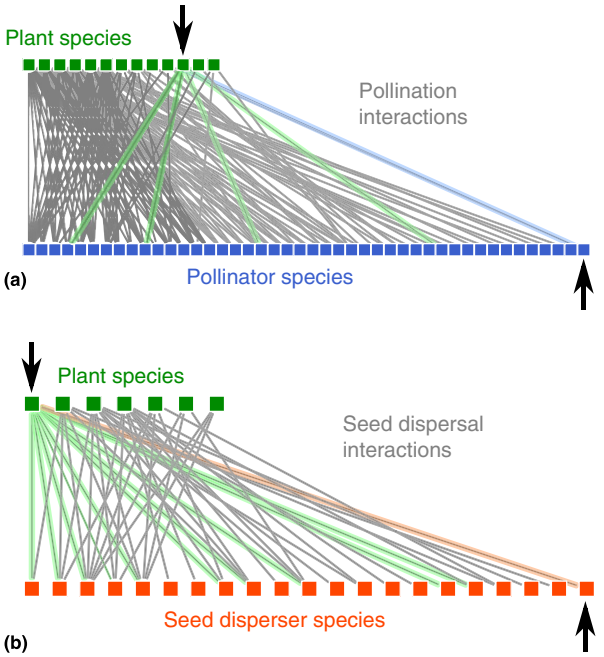

Figure 5 Nestedness in interaction networks. Nestedness, in which specialists interact mainly with generalists, and generalists interact mainly with each other, is common in species interaction networks. (a) In a network of flowering plants (green squares) and their animal pollinators (blue squares) in the forest of North Carolina, USA (Motten, 1986), a pollinator indicated with an arrow interacts with only one plant species (blue-shaded line), but that plant species is also visited by several other pollinators (green-shaded lines). (b) In a network of plants (green squares) and seed-dispersing birds (orange squares) in New Jersey, USA (Baird, 1980), a selected bird (arrow) disperses seeds from a single plant species (orange-shaded line), but that plant species also interacts with many other dispersers (green-shaded lines). Conclusions

Research on coevolution is only beginning to explore how pairwise species interactions are woven into the 'entangled bank' of a biological community, or a whole ecosystem. The big questions for future studies of coevolution are, in many ways, questions for all of evolutionary ecology – understanding how specific processes of reciprocal selection create patterns of speciation and extinction that manifest over millions of years:

How Often Does Coevolutionary Selection Directly Contribute to the Formation of New Species?

In Joshua trees, selection by pollinating yucca moths seems to be responsible for differentiation; but in many other

pollination interactions, pollinator switching seems to be important for species formation. In the case of crossbills, the presence or absence of squirrels changes the form of selection on exerted crossbills by lodgepole pine cones. If it truly does promote speciation, coevolutionary selection may often do so by reinforcing differences created by other evolutionary processes – but we lack data to differentiate between these possibilities, and to say which is more common.

How Do Different Kinds of Ecological Interactions Affect Diversification?

Mutualism, antagonism, and competition all produce different kinds of coevolutionary dynamics, so it makes sense to expect that they will have very different effects on long-term patterns of speciation. Establishment of a mutualistic relationship may have an effect similar to exploitation of a new resource – allowing lineages to diversify into new habitats that would otherwise be inaccessible. On the other hand, antagonistic interactions often directly create negative frequency-dependent selection that can promote divergence, particularly if played out across a geographic mosaic. Finally, competition has a widely documented role in creating and maintaining differentiation among species. However, the geographic mosaic theory of coevolution tells us that how we classify a particular species interaction may change dramatically with the context in which it occurs. Understanding the different effects of each interaction type, and how they relate to each other, will be a major topic for ongoing research.

How Do Coevolutionary Dynamics Extend to Highly Asymmetrical Interactions?

The body of research on species interaction networks suggests that tight pairwise interactions are relatively rare – often when a species is highly reliant on a single other species, that mutualist, prey, or host interacts with many other species. Similarly, new DNA sequencing methods have allowed us to track changes in the microbial diversity inside the bodies of multicellular organisms, including humans (Cho and Blaser, 2012). We can infer that hosts exert strong selection on their microbial communities, and we are beginning to understand how microbial community can affect their hosts' health. However, it is harder to say that individual species of bacteria are coevolving, in the classic sense, with the animals whose guts they inhabit. Can our existing theory of coevolution explain patterns arising in such asymmetric interactions?

The study of coevolution is literally the study of how all living things on Earth have evolved, together. In that sense, it promises to help us understand the origins and future of every biological community – and how we humans fit within them.

Commensalism, Amensalism, and Synnecrosis

JP Veiga, Museo Nacional de Ciencias Naturales, CSIC, Madrid, Spain

Glossary

Allolimy A biological interaction between two or more organisms in which one starves the other(s) without benefit or damage to the active party.

Allotrophy A biological interaction between two or more organisms in which one provides nutrition to the other(s) without benefit or damage to the donor.

Antibiosis A biological interaction between two or more organisms that is detrimental to at least one partner or an antagonistic association between an organism and the metabolic substances produced by another.

Endobiontic A reference to organisms that live within the substratum.

Ichnogenus Any genus known only from trace fossils, such as footprints, coprolites, or nests.

Metabiont A multi-celled organism.

Symbiotic relationships have been attractive study systems for evolutionary biologists because they frequently promote and/or result from coevolution between the interacting organisms. Long-term interactions between two or more organisms through evolutionary time can be powerful drivers of selection and adaptation. One result is that some symbioses – mutualisms, competition, and predator/prey interactions – are common among living organisms. However, three other kinds of symbioses – commensalism, amensalism, and synnecrosis – have received less attention from researchers. These include symbioses where the fitness of a species is unaffected by the interaction, or where all interacting species are strongly negatively affected. Some of these fitness relationships are not predicted to be favored by natural selection and are therefore not expected to commonly occur in nature. In this article we define these three types of symbioses, illustrate known examples of each, discuss some of the controversies regarding the definitions, and acknowledge the difficulties involved when classifying symbioses into established categories.

Commensalism

Commensalism is an ecological relationship between two organisms in which one species benefits from the association without impacting the fitness of the other. Originally this term described the use of waste food by scavengers (e.g., Wilson, 1975), but has been expanded to include any fitness benefit gained by the commensal.

Examples

Commensalism occurs in both the plant and animal kingdoms, and is also prevalent among bacterial species. We recognize three distinct types of commensal relationships, although more complex variants of these basic types can be established:

1. 'Phoresy' refers to a form of commensalism where one species (the phoretic) is mechanically transported by another species (the host) without exacting nutritional or developmental penalties on the host. Phoresy is a way of locating discrete or temporary microhabitats with a high degree of predictability, and provides a potential for emigration when a temporary habitat degrades or disappears (Houck and O'Connor, 1991).

The most commonly described phoretic associations are those occurring between different groups of arthropods. According to Houck and O'Connor (1991), the most spectacular radiation and diversification of adaptations for phoresy is found among the Acari (mites). Approximately 30% of hippoboscid flies exhibit phoretic associations with skin mites of the families Epidermoptidae and Cheyletidae as well as with chewing lice of the family Philopteridae. Skin mites attach themselves preferentially to the ventral surface of their host, between the metathorax and the first abdominal tergite and the ventral surface of wings. Chewing lice have been observed attached to the mesotibia of one hippoboscid fly (Amaral *et al.*, 2013). Another phoretic mite, *Trichouropoda shcherbakae* (Acari: Mesostigmata), is found on beetles of the genus *Tetropium* (Coleoptera: Cerambycidae) living in natural forest areas of Central Europe. Most mites were attached to the beetles' legs (Bloszyk *et al.*, 2013; **Figure 1**).

An overview of the phoretic mites of the Astigmata has led Houck and O'Connor (1991) to operationally define phoresy as a phenomenon in which one organism (the phoretic) receives an ecological or evolutionary advantage by migrating from the natal habitat while superficially attached to a selected interspecific host for some portion of the individual phoretic's lifetime. The phoretic species benefits from the host species' capacity to move more effectively among habitats than could the unaided phoretic. Phoresy compensates for the disadvantages of small size in long-distance migration, the lack of morphological adaptation (e.g., wings) for independent migration, and the vulnerability to predation during migration (Houck and O'Connor, 1991). Okabe (2013) has reviewed insect–mite symbiotic associations to develop hypotheses concerning the factors that favor different fitness relationships. He hypothesizes that many cases of species-specific symbiosis, including mutualisms and parasitic relationships, begin with phoresy.

 doi:10.1016/B978-0-12-800049-6.00189-X

Figure 1 Phoresy is a common form of commensalism in which one species is transported by another species to locate discrete microhabitats or migrate. Phoresy is common among the mites (Acari) which frequently attach themselves to an arthropod host.

Phoresy among other arthropods (especially pseudoscorpions) is also common. Pseudoscorpions have the ability to attach themselves to a wide variety of arthropods more mobile than themselves, including at least 44 families of insects and three families of arachnids (Poinar *et al.*, 1998). For example, the pseudoscorpion *Cordylochernes scorpioides* is frequently found under the elytra of the giant harlequin beetle, *Acrocinus longimanus*. Evidence supports attachment being valuable in dispersal, and also indicates that male *C. scorpioides* defend beetles' abdomens as strategic sites for intercepting and inseminating dispersing females (Zeh and Zeh, 1992). Similarly, the pseudoscorpion *Semeiochernes armiger* (Pseudoscorpiones: Chernetidae) interacts phoretically with the giant tropical fly *Pantophthalmus tabaninus* in Amazonian rain forest habitats. As many as two hundred individual *P. tabaninus* mites have been found on the thorax of a single host fly (Santos *et al.*, 2005). Pseudoscorpions also frequently maintain phoretic associations with mammals and even birds (Villegas-Guzmán and Pérez, 2005; O'Connor, 2000).

2. 'Inquilinism' describes the use of a second species as a platform or cavity for the living circumstance of the beneficiary species. More broadly, an inquiline can also be any animal that lives commensally in the nest, burrow, or dwelling place of an animal of another species. This definition overlaps with the term metabiosis or tanatocresia, wherein one species modifies a habitat or creates a new habitat that can then be exploited by a second species. Oft-cited examples of the inquiline relationship include the gall wasps in the Cynipidae family. Most species in this family are gall formers on various plants (parasites), but the family also includes inquilines. The inquilines differ little in structure from the gall-inducing species but they do not induce galls themselves; instead, they deposit their eggs inside the galls induced by other cynipids. These cynipid 'cheaters' are not a clear-cut example of inquilinism: although it has been suggested that some inquilines do little harm to the original gall inducer, all inquilines studied in detail so far have been shown to affect the host gall-inducer negatively (Wiebes-Rijks and Shorthouse, 1992).

   A more straightforward example of inquilinism is found among barnacles that live on shells of mussels. Individuals found on living mussels were shown to grow significantly faster than those on empty mussel shells, and the presence of barnacles had no effects on growth of mussels. This relationship has been formally described as a commensalism (Lahionen and Furman, 1986).

   As an example of metabiosis, the holes excavated on trees by woodpeckers are used by a great variety of secondary hole nesters, either due to a scarcity of natural holes or because they provide better shelter than natural cavities (e.g., Santharam, 2004; Leonard, 2009; Cockle *et al.*, 2011; Wesolowski, 2012). It has also been proposed that a large proportion of soil organisms may be considered metabionts, as they modify soil habitats in a manner that allows other organisms to colonize (Waid, 1999).

3. 'Chemical commensalism' is most often, but not always, associated with two bacterial species, such that one bacterium metabolizes a chemical not useful to the second, producing a waste metabolite that is a useful energy source for the beneficiary second bacterium (Hogan, 2012). For example, a chemically defined medium can be established which support the growth of *Saccharomyces cerevisiae* but not *Proteus vulgaris*, when each is in pure culture. However, in a mixed culture alongside the yeast, *P. vulgaris* can grow. The bacterial population is dependent on the growth of the yeast because the latter produces a niacinlike factor required by the former. Since the numbers of *S. cerevisiae* are identical in pure or mixed culture, the interaction has been suggested as an example of a true commensalism (Shindala *et al.*, 1965).

   Another two-membered bacterial culture has been used to perform complete degradation of dodecyldimethylamine. *Burkholderia cepacia* can degrade the alkyl chain, whereas *Stenotrophomonas maltophilia* degrades dimethylamine, the product of the former. Batch culture experiments revealed that the two-membered culture consisting of *B. cepacia* and *S. maltophilia* is a commensalistic relationship under carbon-limited conditions but a mutualistic relationship under nitrogen-limited conditions (Kroon and Van Ginkel, 2001).

Ambiguity of the term 'Commensalism'

The term symbiosis has probably suffered much more misuse, changes in definition and controversy than any other definition concerning biological interactions (reviewed by Martin and Schwab, 2012, 2013). And among symbioses, confusion has surrounded commensalism more than other type of interactions, likely because mutualism, commensalism, parasitism, and predation are not categories with discrete boundaries; they occupy positions in a continuum of species interactions (Martin and Schwab, 2013; Douglas and Smith, 1989; Leung and Poulin, 2008). In a narrow sense, commensalism should be defined as an interaction between two organisms with strictly neutral fitness consequences for one

and positive consequences for the other. However, this narrow version of commensalism is difficult or even impossible to demonstrate due to its overly formal premises (see Zapalski, 2011 for details). In a broad understanding, commensalism can be viewed as an interaction that has positive effects for one interacting species, and a weak (either positive or negative) effect on the other. However, handling the term this way is very subjective, to the point where it is impossible to distinguish commensalism from other interactions (Zapalski, 2011).

Not only are objective measurements of commensalism difficult to apply, the costs and benefits that determine net effects of interactions can vary greatly in both space and time (e.g., Bronstein, 1994). For example, Lee *et al.* (2009) describe an annelid–crayfish association in which the interaction fluctuates between commensalism and mutualism depending on environmental conditions. Similarly, scaleworms of the genus *Arctonoe* have been found in symbiotic association with certain mollusk, echinoderm, and polychaete hosts. This relationship has generally been regarded as commensal. However, Wagner *et al.* (1979) suggest that the attraction of the sea star *Dermasterias imbricata* to its symbiotic scaleworm *Arctonoe vittata* implies that both host and symbiont derive benefit from the relationship, such that the association should better considered as mutualism. Another consideration is that organisms that usually commensal can become serious pathogens in certain contexts, as has been described for *Fusobacterium variu*, *Escherichia coli*, and other microorganisms (Leavis *et al.*, 2007; Drake, 2008; Ohkusa *et al.*, 2009). Similarly, some microorganisms that are benign for one individual can be pathogenic for another (Casadevall and Pirofski, 2000; Sachs and Wilcox, 2006).

It is also possible to describe many cases of species interactions as 'facultative commensalisms.' For example, white-fronted terns (*Sterna striata*) sometimes associate with Hector's dolphins (*Cephalorhynchus hectori*) while feeding near shore. Dolphins drive small fishes toward the surface where terns can more easily catch them, an activity that incurs no cost or benefit for the dolphins. This relationship may be particularly advantageous to terns during breeding seasons when energetic demands are high (Brager, 1998). Similarly, in shrimp-eating fish (Cichlidae) that forage in groups, an individual fish in a mixed-species group gets more food than when it forages singly. This varied searching and capturing behavior favors group foraging and utilization of prey that other fish may have overlooked (Yuma *et al.*, 1998). Various shrimps and crabs associate with the anemone *Bolocera tuediae* and the cerianthid *Pachycerianthus multiplicatus* by aggregating beneath their tentacles. The main benefit for these crustaceans to be associated with the anthozoans is protection against predators, but they also probably scavenge food (Jonsson *et al.*, 2001). Such associations are presumably facultative commensalism, as crustaceans live as non-symbionts on the sea floor as well, and the anthozoans do not seem to gain any benefits from the associations.

Coevolution and Selection in Commensal Organisms

In a strict commensal relationship we expect selection to operate on the commensal but not on the host, and as such commensalism is not a coevolutionary relationship. For example, remoras that hitch rides on the skin of sharks have deviated from a typical swimming fish design and possess derived sucker structures, but no parallel adaptations are seen in their shark hosts.

Long-lasting commensal associations that lead to highly specific adaptations may result in obligate commensalism. For example, phoresy in pseudoscorpions, which is obligatory in many cases, has a long history in the fossil record (Poinar *et al.*, 1998). Similarly, phoresy in mites is likewise the product of co-association through long evolutionary time. Commensal interactions lacking such a long history of interaction also occur in nature (Houck and O'Connor, 1991). A familiar example is the house sparrow (*Passer domesticus*), which became a sedentary human commensal 10 000 years ago, with wild populations having practically disappeared in present days (Saetre *et al.*, 2012).

Amensalism

Amensalism has received much less attention from researchers than commensalism. Amensalism is an interaction between organisms of two different species in which the individuals of one species adversely affect the fitness of a second species but receive no apparent fitness benefit themselves.

Examples

Amensalism is often used to describe strongly asymmetrical competitive interactions, such as those observed between ibex (*Capra pyrenaica*) and weevils of the genus *Timarcha* which feed upon the same type of shrub (Gómez and González-Mejías, 2002; **Figure 2**). In experimental manipulations, ibex exclusion increased abundance of weevils, whereas weevils had no effect on ibex. Ibex affected weevils both by exploitative competition and by incidental predation, with the total number of weevils emerging per shrub being more than fourfold higher in shrubs with ibex excluded than in shrubs open to ibex. In other words, while the presence of the weevil has almost no influence on food availability, the presence of ibex has an enormous detrimental effect on weevil numbers, as they consume significant quantities of plant matter and often incidentally ingest the weevils upon it. This study is a demonstration that small phytophagous insects may often be involved in amensal relationships with other herbivores highly dissimilar in size, ecology, and taxonomy, such as ungulates. Such asymmetric interactions are better classified as amensalism than competition.

Many cases described as competition for nesting space are also probably better ascribed to amensalism. For example, hole-nesting birds exhibit a size hierarchy in their access to tree holes, such that smaller species only can utilize holes that are inaccessible to bigger species. Some researchers have reported that several small birds recognize European starlings (*Sturnus vulgaris*) as aggressors and react aggressively toward them (Olsen *et al.*, 2008). Starlings in this study usurped and depredated nests of five other bird species. The difference between neutralism (a term that describes the relationship between two species that interact but do not affect each other) and amensalism may be a matter of resource availability. Starlings and nuthatches (*Sitta europea*) used the same tree

(a) (b)

Figure 2 Spanish ibex (*Capra pyrenaica*) (a) exhibits amensal relationship with weevils of the genus *Timarcha*. Ibex feed on the same plants as weevils so that ibex affect weevils both by exploitative competition and by incidental predation, as they consume significant quantities of plant matter and often incidentally ingest the weevils upon it. However, as weevils may cause significant damage to some plants they feed upon (b), no evidence was found that weevils affected the food available to ibex. This relationship may be better classified as amensalism than competition. © Marlin E. Rice.

holes for nesting in a study conducted in middle Europe (Mazgajski, 2000). The experimental increase of nest site availability providing nest boxes reduced considerably the negative effect of starlings on breeding success of nuthatches. When sufficient sites are available for all species, the relation between them can be considered neutralism. However, spotless starlings (*Sturnus unicolor*) studied in Spain occupied all 100 nest boxes erected by researchers. Only in a few occasions did smaller birds such as nuthatches and great tits (*Parus major*) attempted to use the boxes; spotless starlings invariably evicted the other species. There is no evidence that evicting other species from nest boxes causes any cost to starlings, so that this relationship seems amensal (Veiga and Polo, unpublished data).

Similarly, amensalism in the context of nesting space may describe the relationships observed between honeybees and wasps in tropical ecosystems of East Africa (Veiga *et al.*, 2013b). Nest boxes placed by researchers studying reproduction of birds were frequently occupied by either honeybees (*Apis mellifera*), wasps of the Vespidae family (paper wasps), or wasps of the Crabrionidae and Sphecidae families (mud daubers) (**Figure 3**). Wasps never used nest boxes occupied by bees during the previous breeding season while honeybees were observed to take over nest boxes irrespective of whether they were previously occupied or not by wasps. Although interactions between both groups of hymenopterans have not been described in detail, wasps were apparently reluctant to use any cavity where honeybees had bred even several months before. This is an apparent example of amensalism as there was not even a single case in which wasps were able to occupy a nest box previously used by bees. This implies that even eventual recolonizations of previously used cavities by bees are not hampered by the presence of wasps.

Ambiguity of the Term 'Amensalism'

Amensalism suffers, at least qualitatively, from similar problems of definition and classification as those discussed above for commensalism. Even some apparently clear examples of amensalism in which only one of two interacting species is obviously harmed by the relationship do not completely exclude the possibility that the other species is negatively affected in some way. For instance, the example of ibis and weevils has been alternatively described as an example of extremely asymmetric competition because the weevils may affect to some degree the quality of the ibex's food plants. Thus, although the negative effect of the weevil may be subtle and probably only perceptible under particular, infrequent ecological conditions, the relationships may not constitute a 'pure' case of amensalism. Similarly, the convergence of hole-nesting bees and wasps on tree cavities may entail costs for the dominant species under certain conditions. For example, dominant species may have to remove nesting material brought by other species to cavities before they have enough space to use the cavity, and this could entail energetic costs (Mazgajski, 2007). Also, cavities with multiple nesting species may become infested with nest parasites (e.g., Olsson and Allander, 1995), such that dominant species face non-negligible fitness costs in previously occupied cavities. Alternatively, some honeybee species are known to kill wasps (Ono *et al.*, 1995; Sugahara and Sakamoto, 2009), so it is conceivable that these bees also kill or actively displace nesting wasps. If attacks on wasps by bees elicit a cost for bees, this system may be an example of competition, not amensalism.

Coevolution and Selection in Amensals

As with commensalism, pure amensalism is not a coevolutionary relationship. Theoretical simulations using Lotka–Volterra equations have shown that although amensalism may be a stable solution, extinction of the negatively affected species may also occur (Ribeiro *et al.*, 2010; Cabella *et al.*, 2011). Amensalism is predicted to be a long-lasting relationship only if negative effects are not so high as to lead to total extinction of the handicapped species. In the example of honeybees and

Figure 3 Honeybees (*Apis mellifera*) frequently use nest boxes to build their combs (a), but also paper wasps of the Vespidae family (b) and mud daubers of the Cabrionidae and Sphecidae families (c) like these artificial cavities for nesting. Honeybees take over nest boxes irrespective of whether they were previously occupied or not by another hymenopteran, but wasps never used nest boxes occupied by bees during the previous breeding season. This is an example of amensalism in which the presence of bees hampers the use of cavities by wasps while bees use cavities irrespective of the previous occupation by wasps.

wasps presented above, the handicap suffered by wasps is probably small in most instances provided that there are other suitable cavities, as would seem to be the case in forest ecosystems (Veiga *et al.*, 2013a). However, in savanna habitats, where birds compete with wasps for the scarce cavities available (Veiga *et al.*, 2013b), additional restrictions imposed by honeybees to accede to cavities may seriously impact wasps populations.

Just as competition may promote selection for character displacement (Brown and Wilson, 1956), a similar mechanism may drive character displacement in amensal relationships. If the negatively impacted species cannot escape pressure from the harmful species (e.g., by migrating to new habitats), selection for characters that reduce the detrimental effect of amensalism may lead to changes in morphology or behavior.

Synnecrosis

Synnecrosis is probably the symbiotic interaction that has received the least amount of attention from researchers. The term is poorly defined in the literature. For the purpose of this entry, synnecrosis is a mutually detrimental interaction between two organisms that results in their mutual death. Although most authors agree with such definition (Christian *et al.*, 1974; Kasinger *et al.*, 2008; Martin and Schwab, 2013), synnecrosis has also been (incorrectly) applied to describe a coextinction event, wherein two obligately coevolved taxa die out in concert with one another (Kaiser and Boucot, 1996).

Synnecrosis is rarely studied. This is likely due to the idea that synnecrosis is a necessarily short-lived relationship, and is expected to be strongly selected against (Kasinger *et al.*, 2008). Theoretical modeling using Lotka–Volterra equations has confirmed on mathematical grounds that while amensalism or competition may lead to coexistence or to the extinction of one of the two interacting species, synnecrosis is not a stable phase in the model (Ribeiro *et al.*, 2010; Cabella *et al.*, 2011). For this reason, the term synnecrosis, as well as other similar terms including allotrophy, antibiosis, and allolimy have been avoided by most authors (Burkholder, 1952; Martin and Schwab, 2013). Note however that, unlike commensalism or amensalism, synnecrosis does describe a coevolutionary relationship.

Compensatory Evolution

N Osada, National Institute of Genetics, Mishima, Shizuoka, Japan; and Hokkaido University, Sapporo, Hokkaido, Japan

Glossary

Compensatory mutations Mutations that ameliorate the deleterious fitness effects of other mutations.

Effective population size The number of individuals in an idealized population, which has the same genetic diversity as the population of interest. N_e is often used to represent effective population size.

Evolutionary capacitance The idea that cryptic genetic variation, which is hidden by the robustness in genetic systems, is released by environmental perturbation and help organisms to move to a new adaptive peak.

Fitness landscape A metaphor to represent the relationship between organismal fitness and other characters, such as phenotypes, allele frequencies, and genotypes. Height represents fitness.

$N_e s$ Product of effective population size and strength of natural selection, which indicate efficacy of natural selection in population.

Nearly neutral theory of molecular evolution The molecular evolution theory, which emphasizes the importance of mutations affected by both genetic drift and natural selection in molecular evolution.

Concept and Definition

History and Definitions of Compensatory Mutations

Compensatory evolution refers to the evolution through the fixation of compensatory mutations that ameliorate the deleterious fitness effects of other mutations. Although phenotypic masking effect of different mutations has been observed in classical genetic experiments, molecular mechanisms of compensatory mutations had been unknown until early molecular genetic experiments using bacteria started. In microbiological genetics, compensatory mutations are called suppressor mutations, which could mask the phenotype of preexisted (mostly deleterious) mutations. For example, insertions and deletions in open reading frames may cause frameshift and create a premature stop codon at the downstream of the mutation; the deleterious effect of such a frameshift could be restored if another insertion or deletion arises at the upstream of the stop codon. The study of suppressor mutations has greatly contributed to the understanding of translation mechanisms in early molecular biology research and the analysis of such revertants has also helped to estimate the rate of spontaneous mutations in a gene (Riddle and Roth, 1970) and the mutagenic effect of chemicals to DNA (Ames, 1979).

A wide range of molecular mechanisms contributes to compensatory evolution. In a broad sense, all back (reversal) mutations can be regarded as compensatory mutations. For example, if nucleotide A is mutated to G, the mutation from G to A at the same site is a compensatory mutation for the first mutation. In narrower sense, compensatory mutations occur between different site of molecules (intramolecular compensation), between different molecules (intermolecular compensation), or even between different genomes (inter-genomic compensation).

Population Genetics Model

In this subsection, compensatory evolution is defined in the context of population genetics. The theoretical population genetics model of compensatory evolution was studied by Haldane for deterministic case (Haldane, 1930) and by Kimura for stochastic case (Kimura, 1985). The model assumes simple biallelic two-locus model. Suppose there are two loci, A and B. Genotypes *AB* and *ab* represent wild type and mutant type, respectively. Under the compensatory neutral model of Kimura, individuals of genotypes *AB* and *ab* have the same fitness value but individuals of genotypes *aB* and *Ab* have smaller fitness value than wild type individuals. Kimura showed that under tight linkage between the locus A and B, the rate of evolution from genotype *AB* to *ab* is possible in a realistic order of timescale.

In the compensatory neutral model, there is little chance for intermediate deleterious states (*aB* and *Ab*) to fix in the population. However, the model could be extended to the compensatory weak selection model, where the fitness decline of *aB* and *Ab* is very small (i.e., slightly deleterious); such slightly deleterious alleles could fix in the population by genetic drift and the deleterious effect is later restored by slightly advantageous mutations (Ohta, 1992; Hartl and Taubes, 1996; Innan and Stephan, 2001; Carter and Wagner, 2002; Osada and Akashi, 2012). Although these two models have the same evolutionary outcome (fixation of *ab*), the trajectories of allele frequency are quite different. In the compensatory neutral model, fixation of mutations *a* and *b* simultaneously occurs and the genotype *ab* jumps over the deep fitness valley, whereas in the compensatory weak selection model, the genotype goes down through the shallow fitness valley. In **Figure 1**, the evolutionary paths of the compensatory evolution are shown. Distinguishing compensatory neutral and weak selection model is important for understanding how organisms evolve by crossing a fitness valley (see next subsection). The effect of population size on compensatory evolution may be complicated. In populations with small N_e, the compensatory weak selection would have higher contribution than the compensatory neutral because deleterious alleles are more easily fixed by stronger genetic drift. On the other hand, the elevated rate of occurrence of double mutants (*ab*) in large populations increases the

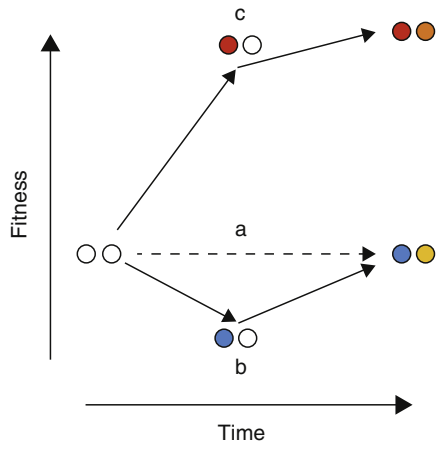

Figure 1 Schematic illustration of compensatory evolution in haploid system with two loci. Each circle represents a genotype at one locus. The blue and yellow circles denote compensatory mutations, which are deleterious without the other mutation. Three different paths are shown. (a) Compensatory neutral model, where two compensatory mutations (blue and yellow) reside in the same haplotype and become fixed together. (b) Compensatory weak selection model, where a slightly deleterious mutation (in this example, mutation in blue) fixes in the population and the fixation of slightly advantageous mutation (mutation in yellow) recovers the fitness decline. (c) Compensatory modifier model, where a strongly beneficial mutation (mutation in red) is initially fixed and the pleiotropic deleterious effect is restored by additional mutations (in this example by mutation in orange).

contribution of compensatory neutral evolution. Carter and Wagner (2002) showed that the rate of compensatory evolution can peak at intermediate population sizes for particular scenarios, when deleterious alleles (*a* and *b*) are recessive and the genotype *ab* has higher fitness than the genotype *AB*.

The term compensatory evolution is sometimes used in a very different context from the above model. If mutations are strongly advantageous in environments, those mutations become quickly fixed in the population. The initially beneficial mutations may have pleotropic deleterious effect. For example, some drug-resistant mutations in bacterial species reduce viability and the fitness cost is compensated by additional mutations (reviewed in Andersson and Hughes, 2010). In addition, fixation of strongly advantageous mutations could make other weakly deleterious mutations fixed together, which is referred to as genetic hitchhiking (Maynard Smith and Haigh, 1974). After the hitchhiking, the effect of deleterious mutations could be ameliorated by additional mutations or back mutations. Such processes are often called compensatory evolution but the evolutionary trajectory is quite different from the two models and the process can be termed 'compensatory modifier evolution,' to make a distinction (Akashi *et al.*, 2012).

Potential Evolutionary Role of Compensatory Mutations

The idea of compensatory evolution helps to understand how organisms could move to different adaptive peaks of fitness landscape, which is conceptualized by Wright (1932). **Figure 1** can be interpreted as fitness landscape in terms of genotypes. Compensatory neutral mutations would be one of the molecular mechanisms that create rugged fitness landscape. In contrast, Ohta incorporated the idea of slightly advantageous mutations in the nearly neutral theory of molecular evolution (Ohta, 1973). The fixation of slightly deleterious mutations in population must open up a space for slightly advantageous mutation that restore the fitness decline (Ohta, 1992), which is referred to as compensatory weak selection model here and shown in **Figure 1**.

Compensatory evolution is not restricted to the pair of loci. One example is the masking effect of deleterious mutations by molecular chaperons. One of the molecular chaperons, heat-shock protein Hsp90, is highly expressed under environmental stress and assist proper protein folding (Rutherford and Lindquist, 1998). It also helps folding of proteins with deleterious mutations (mostly destabilizing mutations) and could mask deleterious phenotypes. There is an idea of evolutionary capacitance, in which organisms could accumulate cryptic phenotypes and become the source of evolvability, which was developed by Waddington (Waddington, 1942). The compensatory process would promote the accumulation of many cryptic phenotypes and bring organisms to a totally different adaptive fitness peak when cryptic genetic variations are released by some reasons, such as environmental changes (reviewed in Paaby and Rockman, 2014). However, it remains unclear whether such genetic robustness through compensatory mutations plays a key role in organismal adaptation or simply as a by-product of robustness against environmental fluctuation (Lehner, 2010).

Molecular Mechanisms of Compensatory Evolution

Intramolecular Compensatory Evolution

Frameshift mutations are one of the examples of intramolecular compensation. However, there are many other mechanisms that promote intramolecular compensatory evolution. One of the clearest evidence of intramolecular compensatory evolution has been described in stem-loop structures in RNA molecules (Wheeler and Honeycutt, 1988). As shown in **Figure 2**, transcribed RNA molecules often form Watson–Crick pairs between A and U bases, and between C and G bases, in stem-loop structure. Mutations in one strand would dismiss the pairing and secondary structure of the RNA molecules may become unstable or may shift to a different state. However, if the base coding the opposite strand have another mutation that could form correct pairing, the two ribonucleotides could form proper pairing again. Many RNA structures such as tRNA and ribosomal RNA structure have the potential to promote compensatory evolution, and studies have shown that compensatory evolution is a prevalent mode of RNA sequence evolution (Wheeler and Honeycutt, 1988; Stephan and Kirby, 1993; Meer *et al.*, 2010).

Proteins are folded into complex three-dimensional structures and many amino acid residues interact with one another in the folding process, which provide huge opportunity for compensatory evolution between different amino acid sites (DePristo *et al.*, 2005). For example, positively charged amino

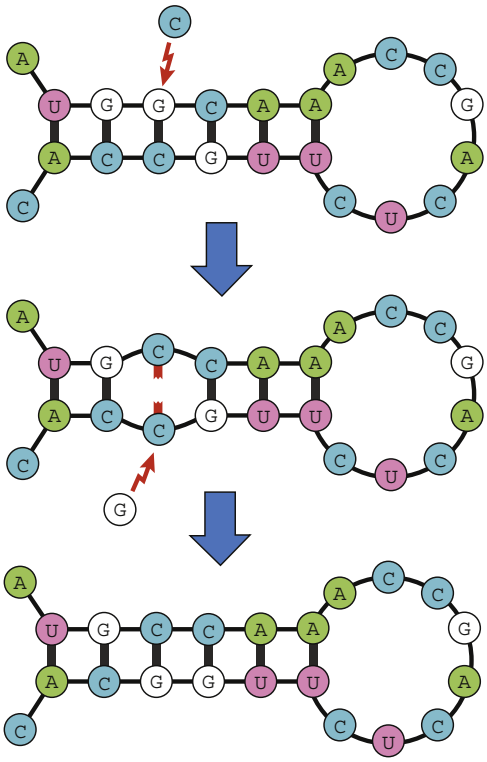

Figure 2 Example of compensatory evolution in RNA stem-loop structure. Watson and Crick pairs bound with each other with hydrogen bonds. Change of RNA sequence from G to C in the stem region (which is C to G mutation in the coding strand of genome) would break up the coupling, but the bond could be restored by additional mutation in the opposite strand.

acid site and negatively charged amino acid sites that are physically close to each other are bound with electrostatic interaction. Change of the one amino acid to lose proper charge may disrupt the interaction and may be detrimental for protein folding and stability, but the stability may be recovered by paired change at interacting sites. Complex protein structure offers large potential for other kinds of interaction between amino acid sites, such as hydrophobic interactions and covalent bonds between amino acid residues (reviewed in Ivankov *et al.*, 2014). In laboratory experiments, many compensatory mutations that could affect the stabilization of proteins have been identified (Lunzer *et al.*, 2010). Note that compensatory evolution here is not restricted to two-locus interaction as presented in the simple population genetics model. Indeed, experimental evidence showed that the effect of deleterious mutations are often compensated by many different mutations around deleterious mutations (e.g., Poon and Chao, 2005). In addition, many molecular evolution studies have identified coupled amino acid substitutions along lineages especially when the coevolving sites are close in three-dimensional structure (e.g., Shim *et al.*, 2005; Wang and Pollock, 2007; Yeang and Haussler, 2007). Large part of these correlated amino acid substitutions could be due to compensatory evolution.

Another example of intermolecular compensatory evolution is the evolution of codon bias (Akashi, 1995). In many genomes, both in eukaryotes and prokaryotes, the preference of codon usage in degenerative codons has been observed and preferred codons often correspond to the most abundant tRNA in the genomes (Ikemura, 1981). The frequency of preferred codons would be different among genes and correlate with gene expression level (Duret and Mouchiroud, 1999). Because the selective effect of each codon is presumably weak and one gene harbors many degenerative codons, gain and loss of preferred codons within genes are considered to be evolving under compensatory weak selection evolution. Population genetics studies on codon usage bias in *Drosophila* showed that the strength of natural selection was indeed very weak and in the range of weak selection ($|Nes| \sim 1$) (Akashi, 1995). Similar argument could be applied to the evolution of nucleosome binding sites, where nucleotide A and T are preferred for nucleosome binding and GC content at genome-wide level is under compensatory weak selection (Kenigsberg *et al.*, 2010).

Intermolecular Compensatory Evolution

Intermolecular compensatory evolution is caused by a wide range of molecular systems. For example, transcription of genes is regulated by many transcription factors, which bind to promoter or enhancer regions of DNA adjacent to the target gene. Since both DNA-binding motif of proteins and target DNA sequence could be changed by mutations and the strength of binding is determined by their level of matching, the deleterious effect of changes could be compensated by other mutations in the partners. In addition, if gene expression is regulated by multiple regulatory sites, gain or loss of some binding sites may not largely affect the expression pattern of genes. For example, some genes with a function in important developmental process possess shadow (secondary) enhancers, which have redundant function with the other enhancers (Perry *et al.*, 2010). Such redundancy would produce the robustness of regulatory systems under environmental and stochastic perturbation during development. Gain and loss of regulatory sites would promote compensatory evolution, which leads the turnover of regulatory sites. The turnover of regulatory sites under compensatory evolution explains why gene expression pattern has been evolutionarily conserved while regulatory regions have been evolutionarily unconserved (Ludwig *et al.*, 2000; Doniger and Fay, 2007).

Because many proteins are often forming protein complex, compensatory evolution between different protein subunit is also possible. In addition, any interaction between proteins and between protein and DNA may be the target of compensatory evolution. However, the information on protein complex structure is much more scarce than that of protein three-dimensional structure. Compensatory evolution in such a complex system is mostly shown by indirect evidence using molecular phylogenetic methods, which is discussed later.

Inter-Genomic Compensation

Compensatory evolution could occur even between different genomes in an organism: between host and endosymbiont genomes. Because of their particular reproductive strategy, endosymbiont populations have experienced huge reduction of

effective population size, which could promote the accumulation of slightly deleterious mutations in their genomes. However, the effects could be compensated by mutations in host genomes. Compensatory evolution between host and endosymbiont genomes may explain the higher mutation rate and massive loss of essential genes in endosymbiont genomes after endosymbiosis event (Moran, 1996). In addition, experimental evidence supports that global loss of protein stability by the fixation of destabilizing mutations in endosymbiont genomes is compensated by the higher level of molecular chaperon expression in endosymbiont genomes (Fares *et al.*, 2002, 2004).

Organelles in eukaryotes such as mitochondria and chloroplasts are also originated from ancient endosymbionts, and compensatory evolution between host and organelle genomes are also possible (Rand *et al.*, 2004; Osada and Akashi, 2012). During the course of evolution, many protein-coding genes encoded in organelle genomes have been moved to host genomes. Those proteins are translated in nuclear, transported into organelle, and form protein complex or interact with each other. Like other endosymbiont genomes, organelle genomes often have many different evolutionary features such as mutation rate, recombination rate, and effective population size, which potentially accelerates compensatory evolution between nuclear and organelle genomes. Compensatory evolution between host and organelle genomes could initiate hybrid incompatibility, which is called cytonuclear incompatibility, and seems widespread across many taxa (Barr and Fishman, 2010). The genetic incompatibility between closely related species might be related to speciation processes.

Molecular Evolution Methods for Detecting Compensatory Evolution

Several molecular evolution analysis methods have been proposed to find the signature of compensatory evolution. One approach is to infer conditionally deleterious mutations in a particular species. Deleterious mutations in one species sometimes do not show any phenotypic defect in other species with different genetic background; these mutations are likely to be compensated by other mutations. The studies of mammalian and *Drosophila* genomes showed that ~10% of pathogenic mutations are not deleterious in the other species, suggesting that compensatory mutations would be widespread in genomes (Kondrashov *et al.*, 2002; Kulathinal *et al.*, 2004).

Another approach is to detect correlated changes of amino acid or nucleotide sites along lineages; however, the pattern of coevolution does not always show the evidence of compensatory evolution (but see Pollock *et al.* (1999) for particular implementation). For example, positive epistatic effect of mutations, which increase fitness more than the summation of the effect of independent mutations, would also result in such correlated substitution pattern. In addition, strong mutation bias or other substitution biases may have created similar pattern. The phylogenetic analysis of correlated changes in protein sequences started in 1970 by Fitch (Fitch and Markowitz, 1970), and later a number of computational methods have been intensively developed to identify coevolving sites within proteins or between proteins (reviewed in de Juan *et al.*, 2013). Those methods have identified many amino acid and nucleotide substitutions that are phylogentically correlated with one another, especially when correlated sites are in close proximity to each other in three-dimensional structure (Fukami-Kobayashi *et al.*, 2002; Dutheil and Galtier, 2007; Yeang and Haussler, 2007). Assuming the physical vicinity of coevolving sites, such coevolutionary information can be used to predict protein three-dimensional structures (Marks *et al.*, 2012).

Distinguishing compensatory neutral and compensatory weak evolution is often quite challenging. One of the expected differences between the two models is whether we could observe intermediate states, where fitness of the genotype is supposed to decline. For example, Meer *et al.* (2010) analyzed stem-loop regions of tRNA encoded in mtDNA and observed the excess of joint substitutions along lineages, but deficiency of intermediate states among lineages and within populations, which supports the compensatory neutral model. Analyzing temporal orders of substitutions with dense phylogenetic sampling may help to find the intermediate states and subsequent fixation of slightly advantageous mutations (Osada and Akashi, 2012). In addition to these viewpoints, growing data of protein structure and mutation experiments in laboratories would make it possible to understand the prevalence and mode of compensatory evolution in nature.

Complexity, the Role of Oxygen in Evolution of

T Burmester, University of Hamburg, Hamburg, Germany

Glossary

Aerobic Aerobic organisms require oxygen for adenosine triphosphate (ATP) production.

Anaerobic Anaerobic organisms do not require oxygen for ATP production.

Cambrian explosion The Cambrian explosion describes the rapid radiation of major animal phyla during the Cambrian period 541–485 million years ago.

Eukaryote A eukaryote is an organism with a nucleus that contains the genetic material and organelles enclosed within membranes. The Eukaryotes are one of the three domains of life.

Great Oxidation Event (GOE) The GOE describes the appearance of free oxygen, released by photosynthetic cyanobacteria, in the atmosphere about 2.4 billion years ago.

Molecular clock The molecular clock allows the estimation of dates of divergence between taxonomic groups. A molecular clock assumes a fairly constant rate of nucleotide or amino acid substitutions over time and must be calibrated by known (mostly fossil) dates.

Mya Million years ago.

Prokaryote A prokaryote is an organism without a nucleus or any membrane-bound organelle. Prokaryotes are divided into two domains, Archaea and Bacteria. The third domain of life covers the Eukaryotes.

Romer's gap Romer's gap is an apparent gap in the fossil record of tetrapods in the early Carboniferous period from about 360 to 345 million years ago.

The Importance of Oxygen for Life

Oxygen (or dioxygen, chemical symbol: O_2) is a colorless gas. The air that surrounds us consists of 20.95% O_2, 78.09% nitrogen (N_2), 0.04% carbon dioxide (CO_2), 0.93% argon, and traces of other noble gases. O_2 also dissolves in the water body at variable amounts. Almost any O_2 is produced by photoautotrophic organisms, including cyanobacteria, algae, and plants (Figure 1).

O_2 drives the energy metabolism of 'aerobic' organisms (which include most animals, plants, fungi, unicellular organisms, and many bacteria). Humans and higher animals usually die within a few minutes without sufficient O_2 supply. In eukaryotes, O_2 serves as an electron acceptor in the electron transport chain of the mitochondria, which leads to the production of metabolic energy in the form of adenosine triphosphate (ATP) (Figure 2). Therefore, mitochondria are also called the 'power plants' of a cell. The electrons that fuel the electron transport chain derive from the oxidation of nutrients and are delivered as reduction equivalents ($NADH + H^+$ and $FADH_2$). The transfer of electrons to O_2 leads to the formation of (metabolic) H_2O. In prokaryotes, which lack mitochondria and other membrane-bound organelles, the electron transport chain is located at the plasma membrane. Some organisms dwell in O_2-free environments and are called 'anaerobic.' They either rely on fermentation or use other terminal electron acceptors than O_2. These alternative electron acceptors have smaller reduction potentials than O_2 and, therefore, in anaerobic metabolism much less metabolic energy (ATP) is extracted from the nutrients than in aerobic respiration. However, an efficient, O_2-driven energy supply is required to support higher life-forms. Therefore, most animals only thrive in a well-oxygenated atmosphere and changes in the ambient O_2 levels during the Earth's history were an important factor in evolution (Berner *et al.*, 2007; Hsia *et al.*, 2013; Ward, 2006). In this article, the development of the free O_2 level over the past 4.5 billion years and its relationship to the evolution of life is described.

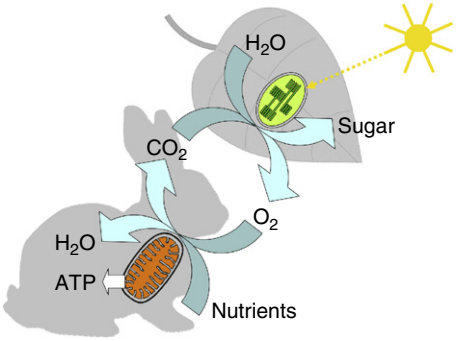

Figure 1 The oxygen cycle. Photoautotrophic organisms (cyanobacteria, algae, and plants) use sunlight to fixate CO_2; O_2 is released in photosynthesis as a by-product. O_2 is used by aerobic organisms (most animals, plants, fungi, unicellular organisms, and many bacteria) as an electron acceptor to produce metabolic energy (ATP). O_2 is reduced to H_2O; CO_2 is produced by oxidation of metabolites in the catabolic pathways.

The Rise of Oxygen in the Early Earth

Geochemical data suggest that the atmosphere of the early Earth was devoid of O_2 and mostly contained CO_2, N_2, methane, and water vapor. Thus, life on earth evolved in an O_2-free, highly reduced atmosphere (Figure 3).

The energy metabolism of the first, bacterium-like cells relied on the reduction of inorganic compounds (sulfur, iron, etc.) or free organic matter. Only with the emergence of oxygenic photosynthesis in the ancestors of the blue algae

 doi:10.1016/B978-0-12-800049-6.00269-9

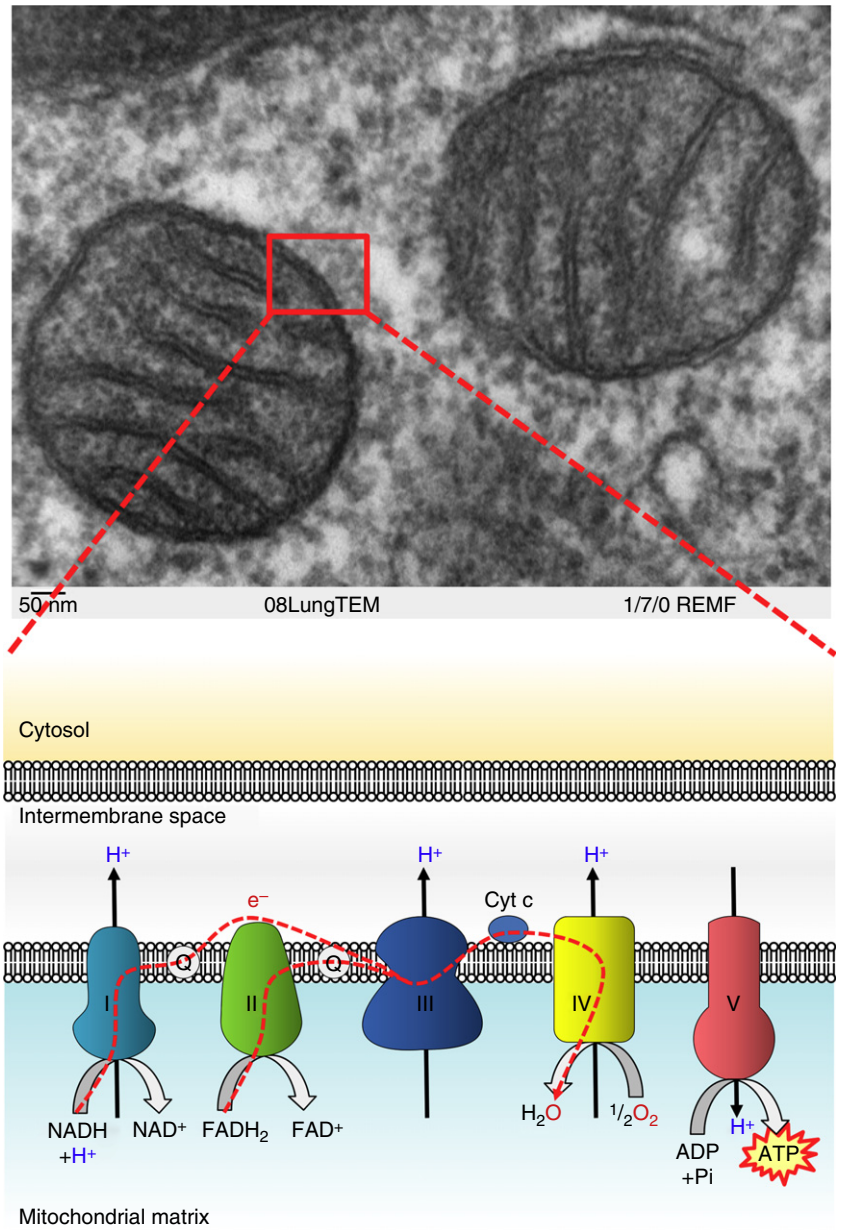

Figure 2 Mitochondria and the electron transport chain (also called respiratory chain). The mitochondria (upper panel; Louisa Howard – http://remf.dartmouth.edu/imagesindex.html http://remf.dartmouth.edu/images/mammalianLungTEM/source/8.html) are the site of aerobic energy metabolism, which is fueled by electrons that derive via NADH + H^+ and $FADH_2$ from the oxidation of food. The electrons are transported by a series of four complexes (I–IV) via redox reactions that pump protons (H^+) from the mitochondrial matrix to the intermembrane space between the inner and outer mitochondrial membrane. Ubiquinone (Q) acts as an electron carrier. O_2 is the final electron acceptor of the electron transport chain in complex IV. The proton gradient provides energy that drives the ATP synthase (complex V), which produces metabolic energy in the form of ATP.

(cyanobacteria) free O_2 appeared (Figure 4). The timing of this event is controversial, but there is evidence that photosynthetic organisms evolved more than 2.7 billion years ago (Brocks *et al.*, 1999; Lyons *et al.*, 2014). In photosynthesis, light energy is used to transfer electrons from chlorophyll to nicotinamide adenine dinucleotide phosphate (NADPH) in photosystem I and produces ATP (Figure 5). This metabolic energy is used to fixate CO_2 in the light-independent reactions of photosynthesis (Calvin cycle). Photosystem II replenishes the electrons in the chlorophyll by oxidation of various electron donors. In oxygenic photosynthesis, as it occurs today in plants, algae, and most cyanobacteria, H_2O is oxidized, and O_2 is released as a by-product (Figures 1 and 2). Early photosynthetic organisms, however, did not produce O_2 because they used free iron (Fe^{2+}), hydrogen sulfide (H_2S), or other reductants as electron donors, and even today some cyanobacteria retained the ability to switch to anoxic photosynthesis if no O_2 is available.

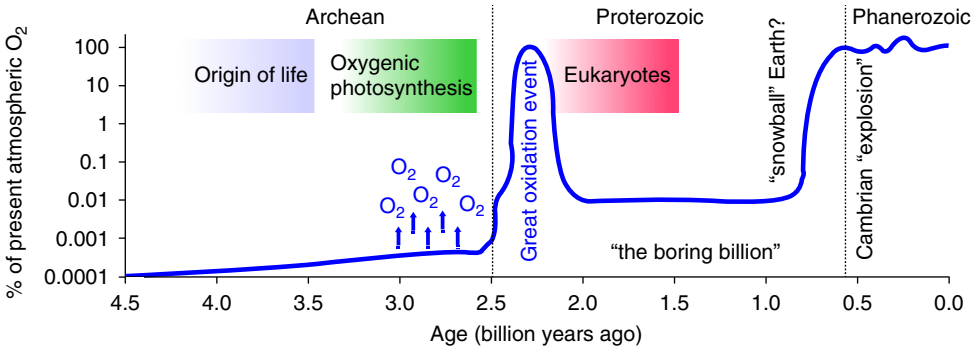

Figure 3 Evolution of atmospheric oxygen. The blue curve shows the estimated O_2 concentration over time in percent of the present atmospheric O_2 level (Berner, 2009; Kump, 2008; Lyons *et al.*, 2014). The early atmosphere was devoid of O_2, which accumulated only after the evolution of oxygenic photosynthesis. After the Great Oxidation Event 2.4 billion years ago, O_2 levels were low for a long period and only increased a few 100 million years before the Cambrian 'explosion.'

After the invention of oxygenic photosynthesis, O_2 did not significantly accumulate in the atmosphere for the next hundreds of million years because O_2 was taken up by sinks such as Fe^{2+}, H_2S, or organic matters. The oxidation of soluble Fe^{2+} to insoluble Fe^{3+} led to the massive deposition of banded-iron formations, which are today commercially important iron ore resources. The O_2 sinks in the ocean and atmosphere became gradually saturated, and first traces of free O_2 appeared. At that time, the concentration of O_2 in the atmosphere was still very low (probably less than 0.001% of today's levels: Lyons *et al.*, 2014) and only about 2.4 billion years ago the O_2 content of the atmosphere had notably increased, which is known as the 'Great Oxidation Event' (GOE: Holland, 2006; Lyons *et al.*, 2014). Two billion years ago, the sun was weaker, and the relatively warm climate on Earth mostly relied on methane, which is a powerful greenhouse gas. It has been speculated that during the GOE O_2 reacted with free methane, thereby reduced its concentration in the atmosphere and brought about the Huronian glaciation of the Earth, which lasted from about 2.4 to 2.1 billion years ago.

The First Oxygen-Breathers

O_2 is a double-edged sword: On the one hand, O_2 is a potent electron acceptor (thus having a highly negative reduction potential) that enables the efficient extraction of energy from the nutrients; on the other hand, O_2 is a dangerous toxin that causes oxidative stress and damages macromolecules, which may lead to cell death. The early prokaryotes 2.4 billion years ago were probably not adapted to high O_2 levels, and thus the GOE was likely the cause for one of the biggest extinction events in the Earth's history (Margulis and Sagan, 1986). Only species that evolved antioxidant mechanisms and that were able to eliminate O_2 survived. Other prokaryotes retreated into an O_2-free milieu, and some of their descendants still live today in anoxic environments.

The accumulation of O_2 also spurred the evolution of an electron transport chain that employs O_2 as the terminal electron acceptor. The electrons derived from the oxidation of food and the electron flux in the respiratory chain is used to pump protons (H^+) out of the cells; the resulting electrochemical gradient (pH and charge) drives a reverse proton pump that produces ATP (ATPase). It is not known whether the electron transport chain first evolved to eliminate toxic O_2, or whether the high affinity of O_2 to electrons and the resulting higher energy extraction provided a crucial evolutionary advantage.

The Emergence of Eukaryotes by Endosymbiosis

The electron transport chain first evolved in proto-bacteria, in which it is located in the cell membrane. Eukaryotes are characterized by the possession of a nucleus and various other organelles, which have specific functions and which are usually enclosed within membranes. Mitochondria and chloroplasts are unique among these organelles because they possess their own genomes and the associated machinery for gene expression. According to the endosymbiotic theory, mitochondria are descendants of ancient α-proteobacteria and were incorporated into a proto-eukaryote host (Esser and Martin, 2007; Pisani *et al.*, 2007; **Figure 6**). The origin of the putative eukaryote host is less clear. It has been suggested, for example, that it derived from ancient methanogen or sulfur-metabolizing Archaea (Pisani *et al.*, 2007). In a second endosymbiosis event, a eukaryote lineage took up a cyanobacterium, which gave rise to the chloroplasts (**Figure 5**; Elias and Archibald, 2009). These eukaryotes were the ancestors of algae and plants (**Figure 6**). Secondary endosymbiotic events, in which a chloroplast-possessing eukaryote was engulfed by another eukaryotic host, have occurred several times independently and gave rise to, for example, brown algae.

The timing of the origin of eukaryotes is notoriously difficult, with proposed dates ranging from 3.8 to 0.8 billion years ago (Roger and Hug, 2006). The first microfossils that have been attributed to the eukaryotes were found in rocks that are 1.8 billion years old (Knoll *et al.*, 2006), but biomarkers of putatively eukaryotic origin may be as old as 2.7 billion years (Brocks *et al.*, 1999). Recent molecular clock estimates (i.e., assuming an approximately constant rate of amino acid substitutions over time) calculated the age of the last common ancestor of extant eukaryotes about 1–1.9 billion years ago (Parfrey *et al.*, 2011). In any case, eukaryotes emerged in an environment with comparably low O_2 levels.

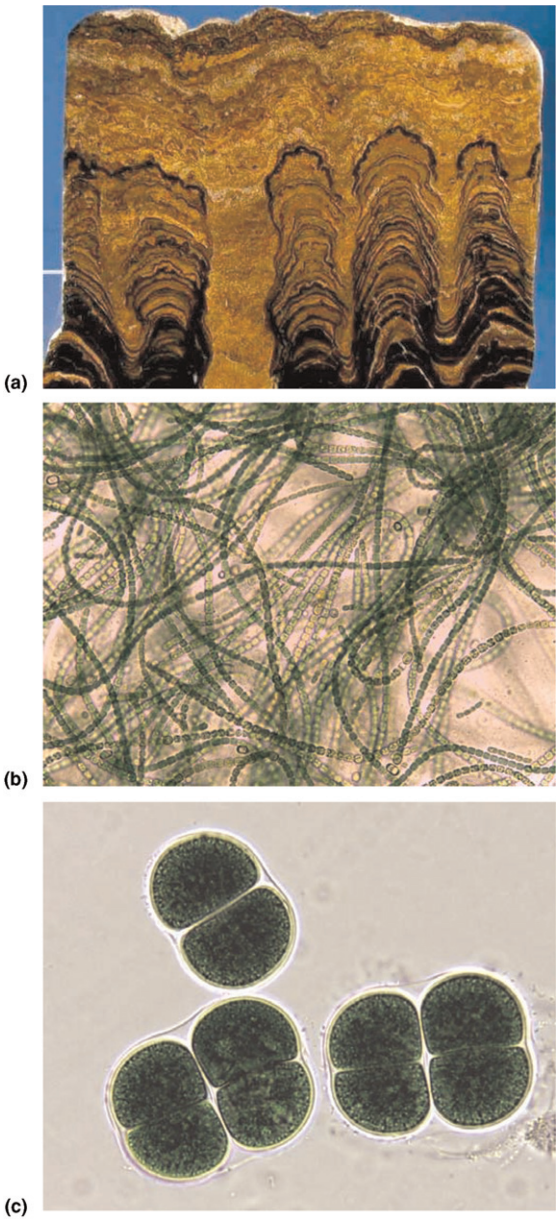

Figure 4 Fossil and extant cyanobacteria (blue algae). Stromatolites are fossil signs of cyanobacteria. These laminated rocks have been formed by biogenic processes due to the growth of cyanobacteria. The upper picture (a) shows stromatolites from the Proterozoic period from Eastern Andies South of Cochabamba, District of Cochabamba, Bolivia, South America (http://upload.wikimedia.org/wikipedia/commons/5/57/Proterozoic_Stromatolites.jpg, licensed under CC-BY 3.0). The lower pictures show extant cyanobacteria of the genera *Anabaena* (b) and *Chroococcus* (c). (b) and (c): Reproduced with the kind permission of Dieter Hanelt, University of Hamburg, Germany.

From the Rise of Oxygen to the Cambrian Explosion

Even after the GOE about 2.4 billion years ago, the concentration of O_2 remained low for a long time (**Figure 3**) and there was little progress in the complexity of life for a period that has been dubbed the 'boring billion' (Lyons *et al.*, 2014). Only the atmosphere and the surface waters were oxygenated while the deep oceans remained anoxic. However, there must have been sufficient O_2 to support relatively large, colonial life-forms 2.1 billion years ago (El Albani *et al.*, 2010). A second peak of O_2 causing persistent oxygenation of the water masses occurred much later, probably at the end of the Proterozoic period some 800–600 million years ago (mya) (Johnston *et al.*, 2009; Lyons *et al.*, 2014). Around that time, the first large, complex animals appeared, which diversified in the Cambrian period 541–485 mya. The relatively sudden appearance of most modern animal phyla within a – at the geological scale – short period of time has been named 'Cambrian explosion' (Conway Morris, 1993; Gould, 1989) and linked the rising oxygen levels (Canfield and Teske, 1996; Saltzman *et al.*, 2011; Shen *et al.*, 2008). Other factors, such as the enhanced availability of dissolved calcium, an increase in temperature after a global glaciation ('snowball earth' during the Cryogenian about 850–635 mya) or an arms race between predators and prey, may have also played a role in Cambrian explosion, but certainly O_2 was an essential prerequisite for the emergence of complex life-forms.

The size of the large animals that appeared in the Cambrian period exceeded anything that was before and required the evolution of morphological and physiological adaptations that ensured a sufficient supply with O_2. These adaptations include specialized respiratory surfaces (mostly gills in the aquatic environment) and a circulatory system with a heart that pumps oxygenated blood from the surface to the inner tissues (Schmidt-Nielsen, 1997). Respiratory proteins (hemoglobin, hemocyanin, or hemerythrin) enhance O_2 supply either by transporting it in the blood or by storing it in tissues (Burmester and Hankeln, 2014; Kurtz, 1999).

The Impact of Oxygen Fluctuations on Animal and Plant Evolution

In the Phanerozoic, which is the geologic eon in which complex animal and plant life has existed and which covers the past 541 million years, the atmospheric O_2 levels fluctuated between about 10% and 35% (**Figure 7**; Berner *et al.*, 2000, 2007). In the Early Cambrian period around 540 mya O_2 levels were probably about the same as they are today ($\sim$20%). The first plants originated from green algae and conquered land 500–470 mya (Steemans *et al.*, 2009; Wodniok *et al.*, 2011). They probably resembled modern liverwort. First vascular plants evolved around 30 million years later in the early Silurian period.

Oxygen is more abundant in the atmosphere than in the water body. However, various morphological adaptations were required that allowed animals to make use of the comparably high O_2 concentrations. These adaptations included, first of all, the respiratory organs, which are a tracheal system in arthropods or the lungs in vertebrates. Animals invaded land during two independent phases: First the ancestors of spiders, myriapods, and hexapods independently became terrestrial in the early Devonian period 420–410 mya. Between 380 and 365 mya vertebrates that resembled intermediates between fish and amphibians went on land. While in the arthropods trachea only evolved after terrestrialization, the ancestor of the terrestrial vertebrates (tetrapods) had lungs, similarly to the

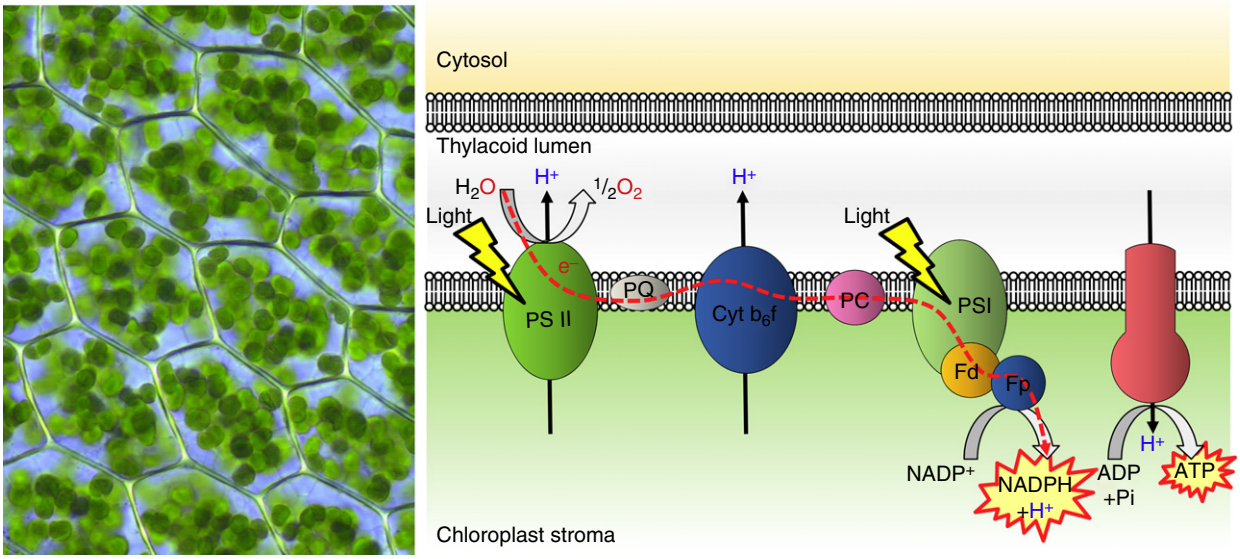

Figure 5 Chloroplasts and oxygenic photosynthesis. The picture on the left side shows chloroplasts inside leaf cells of the thyme-moss *Plagiomnium affine* (http://upload.wikimedia.org/wikipedia/commons/4/49/Plagiomnium_affine_laminazellen.jpeg; licensed under CC-BY 3.0). The picture on the right shows the light reaction of photosynthesis, in which light (photons) is converted into metabolic energy (NADPH and ATP). In plants, this reaction takes place in the thylakoid membranes of the chloroplasts, which contains four major complexes: photosystem II (PS II), cytochrome b6f (Cyt b6f), photosystem I (PS I), and ATP synthase. PS I and PS II absorb photons via pigments (mainly chlorophyll). The absorption of photons in PS II causes the oxidation of H_2O and the release of O_2. The electrons are transferred via plastoquinone (PQ), Cyt b6f and plastocyanin (PC) to PS I, in which (via ferredoxin [Fd] and ferredoxin-NADP reductase [Fp]), NADPH is produced after absorption of an additional photon. In addition, the electron transport chain generates a proton gradient, which is used by the ATP synthase to produce ATP.

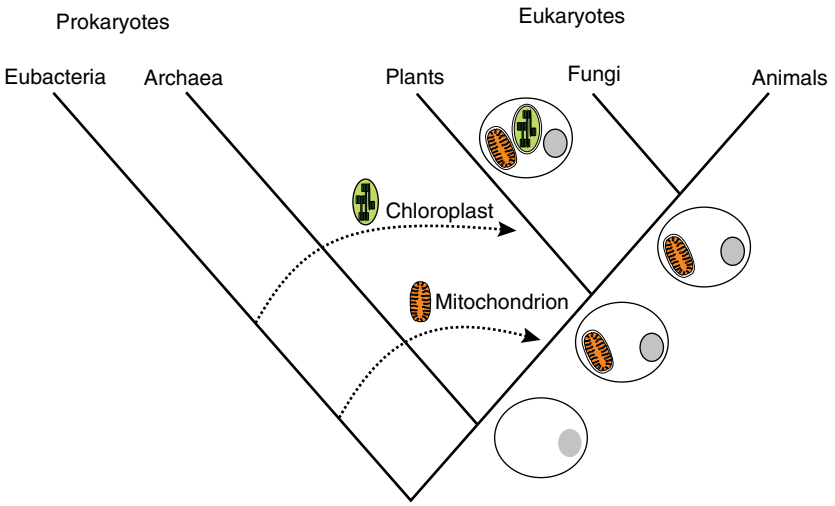

Figure 6 Origin of eukaryotes by endosymbiosis. According to the endosymbiotic theory, mitochondria of eukaryotes derive from eubacteria (probably α-proteobacteria). The host may be more closely related to the Archaea. A following endosymbiosis gave rise to the chloroplasts of algae and plants.

extant lungfish. It has been suggested that the rising O_2 levels during these phases were a main driver because terrestrial animals had to evolve respiratory systems that are adapted to the air, and first, primitive trachea and lungs were probably less efficient (Ward *et al.*, 2006). Between 360 and 345 mya there is a notable lack in the fossil record, which is known in paleontology as 'Romer's gap' (Figure 7). Romer's gap is preceded by a period of low atmospheric O_2 levels, which may have caused a reduction of terrestrial biodiversity (Ward *et al.*, 2006).

A great rise in O_2 level was observed in the Carboniferous period, commencing around 300 mya, and was likely caused by enhanced photosynthesis that accompanied the evolution of large vascular plants (Berner *et al.*, 2007). The appearance of trees on Earth was associated with an increased burial of organic matter, which can be found today as coal deposits. It has

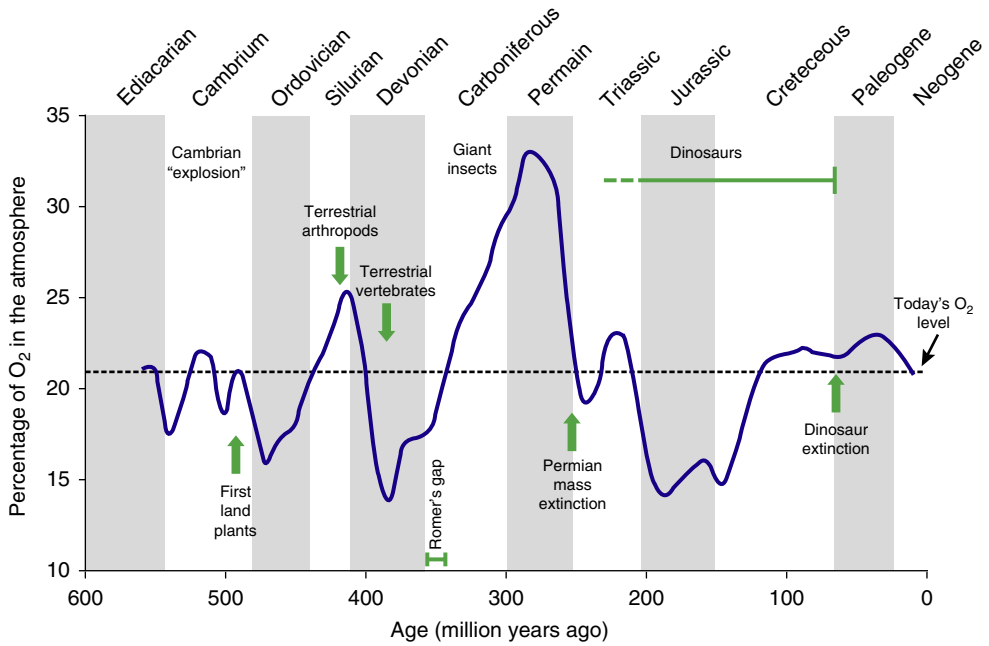

Figure 7 Changes in O_2 levels during the Phanerozoic period. The blue curve shows the estimated atmospheric O_2 concentration over time in volume-% (Berner, 1999, 2009; Ward *et al.*, 2006). Major events in plant and animal evolution are indicated (see also Hsia *et al.*, 2013); see text for details.

been speculated that the high O_2 levels during the Carboniferous period spurred insect gigantism (Graham *et al.*, 1995; Hsia *et al.*, 2013): For example, the late Carboniferous dragonfly *Meganeura* had a wingspan of up to 70 cm. However, there may be alternative explanations for the large insects during the Carboniferous period, such as the lack of other aerial predators (Clapham and Karr, 2012).

By the end of the Permian period about 250 mya the atmospheric O_2 levels had dropped dramatically. The boundary between the Permian and Triassic periods, which also marks the boundary between the Paleozoic and Mesozoic eras, is characterized by the largest known mass extinction event in the Phanerozoic that drastically reduced biodiversity. The causes of the late Permian extinction are still elusive and have been linked to enhanced volcanic activities, asteroid impact events, massive methane release into the atmosphere causing a greenhouse effect, etc. In any case, there is convincing evidence that large parts of the oceans became anoxic during that period, triggering the extinction of 80% to 96% of all marine species (Benton, 2005). Terrestrial animals suffered somewhat fewer losses, and about 70% of land vertebrate species disappeared.

Most of the Mesozoic period until about 110 mya is characterized by comparably low O_2 levels in the atmosphere. Therefore, dinosaurs, which are a synonym for animal gigantism, evolved and lived at low O_2 levels, at least until the middle Cretaceous period (Tappert *et al.*, 2013). Thus the large body size of many dinosaur species cannot be attributed to higher O_2 availability, but may be caused by other factors such as the high temperature in the Mesozoic period or enhanced plant growth augmented by high CO_2 levels. Additionally, physiological and anatomical adaptations, including air sacs and a bird-like respiratory system, may have supported an efficient extraction of O_2 from the thin air (Ward, 2006). In the past about 100 million years, which observed the extinction of dinosaurs at the end of the Cretaceous period 66 mya and the rise and radiation of mammals until today, the atmospheric O_2 levels remained comparably constant and in the range of today's levels.

Adaptations to Low and Changing Oxygen Environments

Today, an adequate supply with O_2 is essential for most animals. However, many species live in environments with low or changing O_2 levels, for example, in high altitudes or in poorly oxygenated waters. These organisms have evolved various adaptations that allow them to cope with unfavorable conditions. Such mechanisms include enlarged respiratory surfaces, better blood flow, higher hemoglobin concentrations, high-affinity hemoglobin, and a reduced metabolism. At the molecular level, a conserved pathway that involves a prolyl hydroxylase (PHD) and the hypoxia-inducible transcription factor (HIF) is essential for sensing the O_2 levels within an animal cell (Greer *et al.*, 2012). The PHD, which actually binds O_2, evolved already in early eukaryotes during the Proterozoic period (Place and Domann, 2013). The more sophisticated HIF pathway that transfers the signal and regulates gene expression came later with the evolution of multicellular animals and helps today to maintain cellular O_2 homeostasis, even under changing ambient environments.

Consensus Methods, Phylogenetic

JH Degnan, University of New Mexico, Albuquerque, NM, USA

Introduction

When evolutionary trees are estimated from different sources, biologists need to be able to describe the similarities between the trees. When two or more evolutionary trees are constructed for the same set of species, or taxa, a consensus tree can be used to visualize similarities between these different trees. In addition to answering questions about what a set of trees has in common, this approach summarizes a potentially large amount of information (in the form of many trees) with a single tree.

There are many applications for consensus trees. Consensus trees have often been used descriptively and as a visualization tool for understanding data in the form of trees. However, consensus trees can also be used inferentially as estimates of evolutionary trees.

An early application of consensus trees was when an evolutionary tree was inferred from two sources. For example, one tree is estimated from morphological data, while the other tree on the same species is from DNA data. Similarly, you could have one tree estimated from mitochondrial DNA and the other from nuclear DNA. Often the two trees would have many similarities, but also some disagreement. In this case, a consensus tree could indicate which evolutionary relationships were in agreement in the two trees. Disagreement between two or more trees can be represented in the consensus tree as an unresolved relationship.

The idea for the consensus tree approach is illustrated in Figure 1. In the figure, the three trees at the top can be considered as input, and the consensus method returns a single tree that summarizes relationships that the input trees have in common.

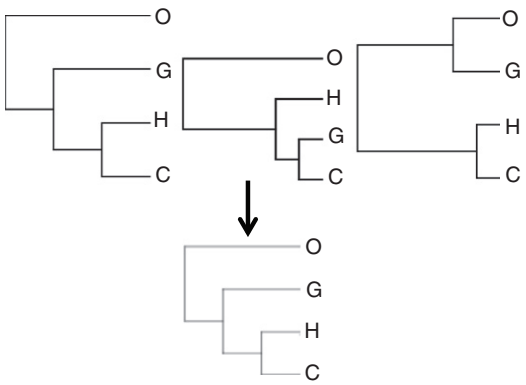

Figure 1 An example of a consensus tree. Here there are three input trees on the species chimpanzee (C), human (H), gorilla (G), and orangutan (O). A consensus method combines the three trees into an overall tree. In this case, the consensus tree happens to be the same as the left-most input tree. Some consensus methods will lead to this result, while others will lead to different consensus trees. See the text for details.

Consensus Tree Methods

Researchers in biology, computer science, mathematics, and statistics have devised dozens of consensus tree methods. The best method can depend on the data being used and the purpose for which the consensus tree is being constructed. In this section, some of the more common and historically earlier methods for consensus are described.

Consensus trees are often based on information that can be extracted from the input trees. Before illustrating consensus methods, we will first consider some of the ways of summarizing trees that are used for different types of consensus methods. Some of this summary information can also be distinguished by whether it applies to rooted versus unrooted trees. Examples of summary information used to construct consensus trees include clades, splits, rooted triples, and unrooted quartets, which are usually called just quartets.

For a rooted tree, a *clade* is a subset of taxa for which the most recent common ancestor does not have any descendant taxa in the study not included in the set. An example is shown in Figure 2. A *split* partitions the taxa of an unrooted tree into two non-overlapping sets, and there is a split associated with each branch of an unrooted tree (Figure 1(b)). A rooted triple is the tree on a subset of three taxa implied by a larger rooted tree. Similarly, a quartet is the four-taxon unrooted tree implied by a larger unrooted tree.

An important concept for both clades and rooted triples (and splits and quartets) is compatibility. Two clades are *compatible* if they can both occur on the same tree. The idea of compatibility also applies to splits, rooted triples, and quartets. For example, for a tree with taxa X, let X_1 and X_2 be mutually exclusive subsets of X with $X_1 \cup X_2 = X$. That is, every taxon belongs to one, and only one, of the subsets X_1 and X_2. Let Y_1 and Y_2 be another partition of X into two subsets of taxa. Then X_1 and Y_1 are compatible clades if (1) they have no taxa in common, or (2) either X_1 is a subset of Y_1 or Y_1 is a

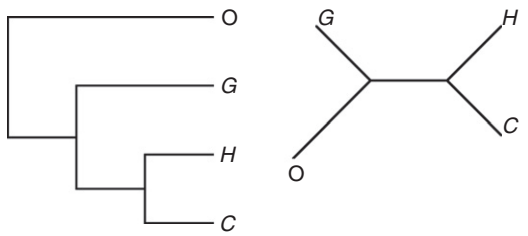

Figure 2 Rooted vs. unrooted trees. The tree on the left is rooted, where the most recent common ancestor of species *C*, *H*, *G*, and *O* is on the left, and time proceeds to the right. The tree on the right is the unrooted version of the tree on the left. The tree on the left includes {*C*,*H*} and {*C*,*G*,*H*} as clades, subsets of taxa which have a common ancestor that include no other taxa in the tree. For an unrooted tree, an analogous concept is a split, where removing one edge splits the taxa into two sets. For example, *CH*|*GO* is a split for the unrooted tree.

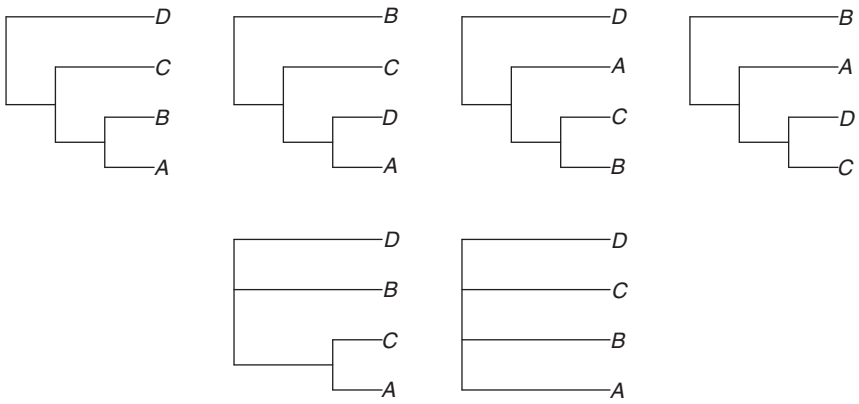

Figure 3 Example with four input trees. If the four trees on the top row are the input trees, then the first tree in the bottom row is the R^* consensus tree, and star tree on the bottom right is the Majority-Rule tree, and the Greedy consensus tree is any of the four input gene trees with equal probability. The example illustrates that the R^* consensus tree can include a clade that did not occur in any input tree.

subset of X_1. Similarly, splits $X_1|X_2$ and $Y_1|Y_2$ are compatible if either $Y_1 \subset X_1$, $Y_1 \subset X_2$, $X_1 \subset Y_1$ or $X_2 \subset Y_1$.

Compatibility of rooted triples is similar. The idea is that rooted triples are compatible if they can be displayed on the same tree. As an example, for trees on four species – *A*, *B*, *C*, and *D* – a triple can be represented by expressions such as *BC*|*D*, meaning that *B* and *C* share a common ancestor that is not ancestral to *D*. An example of a set of triples which is not compatible is *AB*|*C*, *BC*|*D*, and *AD*|*C* (Ranwez *et al.*, 2007). The only 4-taxon tree which has both rooted triples *AB*|*C* and *BC*|*D* is (((*A*,*B*),*C*),*D*), and this tree does not have the rooted triple *AD*|*C*.

Strict Consensus

A strict rooted consensus tree (Rohlf, 1982) consists of all clades that occur on all input trees. For unrooted trees, a strict consensus tree consists of all splits that occur on all input trees. Clades (or splits) that occur on some but not on all input trees lead to lack of resolution in the consensus tree (**Figure 3**, bottom row). The strict consensus tree can easily result in highly unresolved trees. It is particularly sensitive also to the problem of *rogue taxa*, in which several trees agree on relationships for most taxa, but one taxon with unpredictable placement in the trees makes strict agreement between the trees rare.

Semi-Strict or Combinable Component Consensus

The *semi-strict* consensus method (also called combinable component) generalizes the strict consensus method for the cases when input trees are not fully resolved (Bremer, 1990; Swofford, 1991). This is particularly useful in that trees estimated from DNA sequences are often not fully resolved and have polytomies (multifurcations) in which an ancestral node has three or more daughter nodes. In this case, a clade is on the rooted consensus tree if at least one input tree includes the clade, and no input tree contradicts that clade. Similarly, an unrooted semi-strict consensus tree has a split if at least one input tree has that split and no input tree contradicts that split.

Adams Consensus

Adams consensus (Adams, 1972) is somewhat similar to strict consensus in constructing a tree based on what all input trees have in common, but instead of using clades, the Adams consensus tree is based on the rooted triples that are not contradicted by any input tree. An appealing feature of the Adams consensus tree is that it is more robust to rogue taxa than strict consensus. It is therefore possible that a set of input trees would be completely unresolved using strict consensus but partially resolved using Adams consensus.

A surprising result due to Steel *et al.* (2000) is that an unrooted analogue to Adams consensus does not preserve all of the properties of the rooted Adams consensus if we wish to construct a tree from all quartets that occur in all input trees, then there are cases in which this procedure will not work. In their example, consider the input trees ((1,2),(3,4),(5,6)) and ((2,3),(4,5),(1,6)). A consensus tree must preserve the quartets ((1,2),(4,5)), ((1,6),(3,4)), and ((3,4),(5,6)). However, this means that the consensus tree must be one of the two input trees, and the choice is arbitrary. In particular, any particular choice could be reversed by relabeling the taxa. This problem does not arise for the rooted Adams consensus tree. This example illustrates that while many rooted consensus methods have unrooted analogues, at least some rooted consensus methods do not have satisfactory unrooted versions.

Majority-Rule consensus

Majority-Rule consensus includes all clades that occur in more than 50% of the input trees. The method can be generalized to only allow clades that occur in more than p% of the input trees, where p is any number strictly greater than 50%. The inequality is strict because it is possible for two clades to each occur on 50% of the input trees but that cannot coexist on the same tree.

Extended Majority-Rule or Greedy consensus

In Extended Majority-Rule, the clades on the consensus tree are determined one at a time, using the most frequently occurring clade first, then accepting the most frequently occurring clade compatible with clades already accepted. Any clade on the

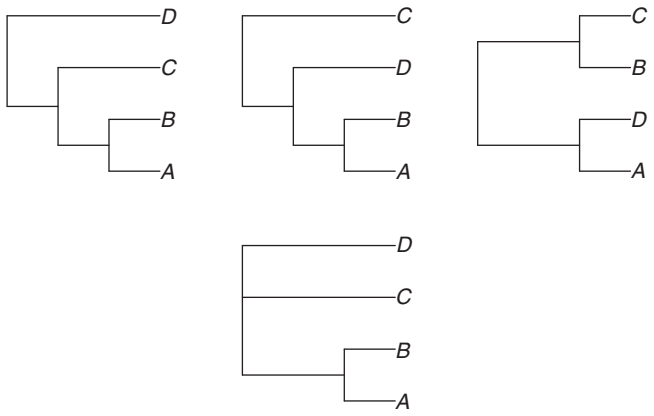

Figure 4 Example with three input trees. If the three trees on the top row are the input trees, then the tree in the bottom row is both the R^* consensus tree and the Majority-Rule tree. The Greedy consensus tree for this example is either of the first two trees in the top row with probability 50%.

Majority-Rule tree will also be on the Extended Majority-Rule tree, but this algorithm also allows the acceptance of clades that occur on less than 50% of the input trees. Because incompatible clades are eliminated, it is also possible for the Extended Majority-Rule tree to have clades that occur less frequently than other, incompatible clades. In the case of ties in frequency, the next clade accepted is either chosen arbitrarily (as is often implemented in software) or one of tied clades is chosen randomly. In practice, software packages might pick one clade arbitrarily (depending on alphabetical order or the input order of taxa in a file) rather than randomly.

Plurality consensus tree

The Plurarity consensus tree modifies the Extended Majority-Rule tree by stopping the algorithm if there are no clades more frequent than a clade that has been eliminated from consideration (Steel and Velasco, 2014). This leads to a tree that can be more resolved than the Majority-Rule consensus tree (and possibly have some clades that occur less than 50% of the time), but can also be less resolved than the Greedy consensus tree.

R^* consensus

The R^* consensus tree is obtained by determining, for each subset of three taxa, which is the most frequent rooted triple (Bryant, 2003). For example, if the taxa are the set X, then for taxa $x,y,z \in X$, if $((x,y),z)$ more often than $((x,z),y)$ and $((y,z),x)$, then we say that the triple $x,y|z$ is the favored rooted triple for that set of taxa. The R^* consensus tree consists of a tree that only displays these favored rooted triples. Some complications of the method are that (1) there might not be a favored triple for some subsets of three taxa due to ties for the most frequent triple, and (2) the set of favored triples might not be compatible. Examples of these cases are shown in Figures 3 and 4, respectively. In the case of ties, the resulting consensus tree should be unresolved with respect to the given triple. Favored triples that are incompatible will also lead to less resolution in the R^* consensus tree. Although the R^* consensus tree is based on the idea of rooted triples, an algorithm for constructing the R^* consensus tree can be based on determining the clades in the final tree on taxa X:

Rule for R^* consensus: The set of taxa $C \subset X$ forms a clade if for all $x,y \in C$ and all $z \in X \backslash C$, $xy|z$ is a favored triple.

The R^* consensus tree is necessarily a resolution of the Majority-Rule tree, meaning that any clade that is on the Majority-Rule tree is also on the R^* tree, even if the R^* tree is not completely resolved.

Q^* consensus

The Q^* consensus tree replaced by quartets is analogous to the R^* consensus with the role of rooted triples being (Bryant, 2003). That is, letting X_1 and X_2 be mutually exclusive subsets of the complete taxon set X with $X_1 \cup X_2 = X$, we can express the rule for Q^* consensus as:

Rule for Q^* consensus: The bipartition $X_1|X_2$ forms a split if for all $x,y \in X_1$ and all $w,z \in X_2$, $x,y|w,z$ is a favored quartet.

Consensus Trees for Maximum Likelihood and Bayesian Phylogenetics

Consensus of Bootstrapped Trees

When evolutionary trees are estimated using maximum likelihood or parsimony, a statistical technique called the bootstrap is often used to quantify uncertainty in the tree estimate (Felsenstein, 1985). The bootstrap resamples columns from the DNA alignment to make new DNA alignments, and evolutionary trees are estimated from these altered datasets. The technique produces one tree for every bootstrap replicate. Typically, between 100 and 1000 bootstrap replicates are used, and the resulting set of trees can be described using a consensus tree. Typically, Extended Majority-Rule, also called Greedy consensus, is used, and the counts of how many times each clade occurred in the final tree are used as a measure of bootstrap support.

Although a consensus tree is often reported from the bootstrap replicates, the resulting consensus tree might have a different topology from the tree inferred to be optimal and is not considered a more reliable estimate than the maximum likelihood or parsimony tree itself. The purpose of reporting the bootstrap estimates is to estimate the uncertainty

associated with particular clades in the inferred tree (Wheeler, 1991; Holder *et al.*, 2008).

Consensus of Estimated Posterior Distribution of Trees

Bayesian estimation of phylogenies usually uses Markov chain Monte Carlo (MCMC), in which trees are sampled in a Markov chain. The set of trees is used as an estimate of the posterior distribution of the tree being estimated. Typically a sample is taken from the trees visited in the MCMC run – for instance sampling every thousandth tree to avoid correlation between trees – and a consensus tree is made from the resulting sample. This consensus tree is then treated as the Bayesian estimate of the species tree, with posterior probabilities being placed on branches of the tree indicating the proportion of times each clade occurred in the sample. In this application, there might be hundreds to thousands of trees used as input for a consensus method. Like the bootstrap consensus tree, the Bayesian consensus tree requires a method that can deal with a lot of variation in the input gene trees. Holder *et al.* (2008) argue that although a Majority-Rule bootstrap consensus tree does not necessarily optimize the likelihood (and so is not preferable to the maximum likelihood tree), the Majority-Rule tree taken from the posterior distribution does minimize the Bayesian posterior expected loss, and therefore is an optimal tree to report for a Bayesian estimate of a phylogeny.

Summarizing bootstrap and posterior distributions of trees to quantify uncertainty in maximum likelihood and Bayesian trees has become one of the most common uses of consensus trees, although this was not an original application of consensus trees.

Median Trees

Median trees are trees that optimize some criterion with respect to set of input trees (Phillips and Warnow, 1996). For example, one might find the tree that minimizes the number of incompatible clades between the optimal tree and the input trees. The number of clades on one tree and not on the other is called the *Robinson–Foulds (RF) distance* (Robinson and Foulds, 1981) or *symmetric difference* between two trees. Thus, finding the tree that minimizes the sum of RF distances between the output tree and input trees is an example of a median tree. Other examples include finding the tree that minimizes the sum of rooted triple distances between the output tree and input trees, where the rooted triple distance is the number of triples on which two trees disagree (Critchlow *et al.*, 1996). The median tree approach extends naturally to unrooted trees using split or quartet distances.

The median tree approach introduces an optimality criterion for the output tree instead of directly computing the consensus tree from a set of input trees. This generally requires some sort of search over the space of possible trees, a problem which is often NP-hard and therefore computationally intensive, although heuristic approaches to get near-optimal solutions are often available that can run in polynomial time (Phillips and Warnow, 1996).

Consensus of Gene Trees to Estimate Species Trees

A natural reason to have multiple trees that need to be combined is when trees are estimated at independent orthologous loci for the same set of taxa. As an example, in a study of 23 species of yeast using 1070 loci, every estimated gene tree had a unique topology (Salichos and Rokas, 2013). There are several reasons that trees estimated at different loci often have different topologies. One reason is that due to short DNA sequences, trees are estimated with some uncertainty and often some degree of error. Interpreting the length of the DNA as analogous to sample size, this creates sampling error that leads to differences in estimated trees at different loci.

However, even if there were no sampling error (i.e., sequences were infinitely long or gene trees were known), there would still be variation in gene tree topologies due to biological causes. Commonly cited causes for such gene tree incongruence include hybridization between closely related species, recombination within loci, gene flow after speciation between non-sister taxa, horizontal gene transfer between non-sister taxa, gene duplication and loss, ancestral population structure, and incomplete lineage sorting.

Methods to combine gene trees into an overall tree for the purpose of estimating a species tree were developed early for the setting of gene duplication and loss (Page and Charleston, 1997). In this problem, a gene makes an additional copy of itself in a genome, and the two copies subsequently diverge in sequence and possibly also in function. The two gene copies are called *paralogs*. An example is the α-hemoglobin and β-hemoglobin genes, which are thought to have diverged several hundred million years ago in verterbrates (Jeffreys *et al.*, 1980; Hardison *et al.*, 2009). Comparing an α-hemoglobin gene from one species and two β-hemoglobin genes from two other species could lead to erroneously grouping taxa.

An early method for combining gene trees to produce an overall estimate of the species tree is called *gene tree parsimony* (Wehe *et al.*, 2008; Chaudhary *et al.*, 2010), where the idea is to find the species tree which minimizes the number of gene duplication events that could explain the discrepancies between the species tree and the gene trees. For this approach, for a given candidate species tree, a score is assigned to each gene tree based on the number of duplication and loss events required to explain the differences in the topologies. The overall score for a species tree is obtained by summing over the score for each gene tree. The species tree with the lowest total score is the preferred score. There is no guarantee that there is a unique minimum parsimony score, and in practice, because the search space is large, the tree that minimizes the parsimony score might have to be estimated with heuristics.

Many methods for estimating species trees from gene tree topologies in the context of incomplete lineage sorting have also been developed. These methods are only sometimes described as consensus methods, yet because they all take gene tree topologies as input and output a single tree, or a set of trees tied for some optimality criterion, they can all be considered consensus methods. An early approach was called *minimizing deep coalescence* (Maddison and Lacey Knowles, 2006; Than and Nakhleh, 2009), which scores the minimum number of times incomplete lineage sorting events must have occurred to explain discrepancies between the candidate species tree and the gene

trees, and an overall parsimony score is summed over gene tree topologies, similarly to the gene tree parsimony approach.

Several other consensus approaches for the incomplete lineage sorting setting have been tried. Properties of traditional consensus methods, where the consensus tree is interpreted as an estimate of the species tree (Degnan *et al.*, 2009), have been investigated. Converting input gene trees to sets of rooted triples and quartets have also been used. Here variations on R^* consensus – Rooted Triple consensus (Ewing *et al.*, 2008) and Q^* consensus – BUCKy (Larget *et al.*, 2010) can be used to combine rooted triples or quartets. Even if only using triples or quartets of the gene trees, branch lengths of the species tree can still be inferred, such as in the methods MP-EST (Liu *et al.*, 2009) and BUCKy (Larget *et al.*, 2010). This is because the frequencies of the most likely triple and quartet depend on the branch lengths in the species tree. Another set of approaches is to convert each gene tree into a distance matrix based on a pairwise distance for each pair of taxa based on how far apart the taxa are on the tree. These approaches are implemented in STAR for rooted trees (Liu *et al.*, 2009) and NJst for unrooted trees (Liu and Yu, 2011). One of the most recent approaches has been a median tree of quartets taken from the input gene trees (Mirarab *et al.*, 2014; Mirarab and Warnow, 2015).

Controversy around Consensus Trees

There has been debate around the use of consensus trees for inferring evolutionary trees. When there are several sources of data, for example both morphological data and DNA data, or DNA data from multiple genes, two strategies emerged: (1) make separate estimates of evolutionary trees on different datasets, then use a consensus tree as an overall estimate, and (2) combine all of the data and make an estimate of the best evolutionary tree to explain all of the data. There have been advocates for both approaches, with the combined data method sometimes being called a *total-evidence* approach (Barrett *et al.*, 1991; De Queiroz, 1993; Eernisse and Kluge, 1993).

The original debate had many papers in the 1990s, at which time gene trees and species trees were often not distinguished. However, the debate has resurfaced in the context of estimated species trees (Song *et al.*, 2012; Gatesy and Springer, 2013; Wu *et al.*, 2013) with some researchers advocating concatenating DNA alignments to form 'supergenes,' which are analyzed as if coming from a single tree topology, although often with partitions to allow different evolutionary processes for different genes (de Queiroz and Gatesy, 2007; Rokas *et al.*, 2003). Other researchers have preferred estimating gene trees separately, and combining these into an estimated species tree (Miyamoto and Fitch, 1995; Liu *et al.*, 2009). Some methods combine elements of both. For example, using multi-locus alignments to infer relationships on subsets of taxa and then using rooted triple or quartet methods (essentially supertree methods) to build the tree (DeGiorgio and Degnan, 2010; Chifman and Kubatko, 2014).

Generalizations: Multilabeled Trees, Supertrees, and Consensus Networks

The concept of a consensus tree has been generalized in many ways. For most applications of phylogenetics, each tip of the tree has a unique label, such as a taxon name. However, in some applications, it is useful to let tip labels not be unique, so that some labels are repeated. Such trees are called MUL-trees. Consensus methods for such trees have also been developed (Lott *et al.*, 2009). A special type of consensus reduces a single MUL tree into a tree with unique labels (Deepak *et al.*, 2013).

Another generalization of consensus methods is to allow different input trees to have different subsets of some larger taxon set. In this case, missing data, due for example, to some genes not being available for some taxa, lead to trees with overlapping but not identical taxon labels. Many methods for combining such trees have been developed, and the combined tree is called a *supertree* (Bininda-Emonds, 2004). Consensus trees are special case of supertrees in which each input tree happens to have the same taxon set. Therefore, a method motivated by the supertree context can be evaluated for its performance in the consensus setting, and this leads to many new potential consensus methods. One of the most popular is called Matrix Representation with Parsimony (Baum, 1992; Ragan, 1992). In this method, gene trees are converted into sequence data by recording, for each clade of the gene tree, which taxa are present or not present. Traditional parsimony, designed to infer trees from sequence data, can then be applied. Supertree methods have also been evaluated for their use in estimating species trees from gene trees (Kupczok *et al.*, 2010; Wang and Degnan, 2011).

A last generalization we mention is that instead of trees, one might have networks as input. Networks are generalizations of trees in which two edges might combine, corresponding to two species merging, in addition to edges splitting to represent speciation. Taking as input a set of networks defined on the same set of taxa, the goal for this problem is to find a network that summarizes the input networks (Holland *et al.*, 2004). A variation on this problem is to take as input a set of trees, and to find the network that best represents the disagreements between the trees (Chen and Wang, 2010; Yu *et al.*, 2011).

Glossary

Heterozygosity A measure of the genetic variation within individuals in a population; mean observed heterozygosity refers to the proportion of individuals sampled carrying two different alleles at a given loci.

Demographic rates Per capita (per individual) birth and death rates, these determine the rate at which a population grows or declines over time.

Density-dependent population growth When the rate of increase of a population is not a constant, but varies as a function of population size.

Overdominance Also referred to as 'heterozygote advantage'; individuals with two different alleles at a loci have the highest fitness.

Quantitative trait A trait that is the result of the cumulative effects of many genes and the environment; quantitative traits (such as body size, and limb length) vary among individuals such that the range of phenotypes is continuous, rather than falling into discrete categories.

Stochastic Describes a process for which the outcome is determined at least by one random factor.

Introduction

Conservation biology as a discipline is deeply rooted in evolutionary biology. The overarching goal of conservation biology is to protect and maintain biodiversity, and biodiversity spans multiple levels of biological organization, including the diversity of genes, species, communities, and ecosystems. Evolutionary processes determine or influence diversity at all levels in this hierarchy. For example, loss of genetic diversity within a population can decrease population growth rate and persistence (Frankham *et al.*, 2002); genetic diversity within a population can also have important ramifications for community and ecosystem-level processes, such as the strength and stability of species interactions, community structure, primary productivity, and nutrient cycling (e.g., Lankau and Strauss, 2007; see review by Hughes *et al.*, 2008).

Within conservation biology, the subdiscipline of conservation genetics focuses on the application of genetic tools and methods pulled from a range of evolutionary fields (including systematics, phylogeography, population genetics, and increasingly genomics) to conservation problems. Conservation genetics is an active and growing field of study: a peer-reviewed journal of that name has been in print since 2000, in addition to the many papers exploring genetic topics in conservation published in journals with broader conservation or ecological themes. Conservation genetics has also received thoughtful attention in several textbooks (e.g., Groom *et al.*, 2005; Carroll and Fox, 2008); we recommend these sources and others listed at the end of this article for further reading.

Here we briefly discuss some of the areas where evolutionary biology and molecular genetics intersect with conservation biology. We divide our review into two broad topics: first, we consider some of the many ways in which molecular genetic patterns have been used to inform current conservation practice. Then we review the evolutionary processes most important for the persistence of small, demographically threatened populations, and how evolutionary principles might be incorporated into active management plans.

Pattern: What Can Genetic Patterns Tell Us about Biodiversity and Taxa of Conservation Concern?

The use of genetic techniques to answer ecological questions has exploded in frequency over the last decade as molecular techniques have become increasingly powerful, efficient, and inexpensive. Molecular markers such as microsatellites and DNA sequences have provided conservation biologists valuable insight into the basic biology (e.g., mating system, dispersal) and demographic history of species of concern. For example, molecular analyses have been used to illuminate the effect of kinship on social behavior of African elephants (Archie and Chiyo, 2012), and estimate the pre-whaling abundance of gray whales (Alter *et al.*, 2008). Molecular markers have also been utilized for forensic applications, such as identifying the geographic origins of captive chimpanzees (Goldberg, 1997), and determining what species of whale meat is being sold in Japanese markets (Baker and Palumbi, 1996).

Identification of Units of Biodiversity

'DNA barcoding,' the standardized use of short ($\sim$600 bp), highly conserved regions of the genome to distinguish species-level taxonomy (see review by Kress *et al.*, 2015), can be used to identify cryptic species and resolve taxonomic disputes. For example, analysis of the mitochondrial gene encoding cytochrome *c* oxidase subunit 1 (CO1; the most common 'barcode' marker used for animal taxa) revealed that the neotropical skipper butterfly *Astraptes fulgerator* represents a complex of at least 10 well-resolved species (Hebert *et al.*, 2004). Molecular genetic analysis has also been applied extensively to document variation within species, and to identify populations that are sufficiently differentiated that they require separate management. This is the idea behind evolutionarily significant units, or ESUs (Ryder, 1986). ESUs are recognized by the Endangered Species Act and have been broadly embraced by management agencies since first proposed in the mid-1980s, in spite of the fact that there is ongoing debate about the practical

application of the label, and what, exactly, counts as evolutionary significance (see review by Crandall *et al.*, 2000). Of key concern is the relative importance of adaptive divergence versus longstanding reproductive isolation. Neutral or nearly neutral molecular markers (i.e., noncoding DNA) are most often used to evaluate population divergence, and these may not reflect the same patterns as quantitative traits or adaptive differences among populations (McKay and Latta, 2002).

Conservation Planning

Most terrestrial conservation efforts are based upon a framework of protecting habitat; thus an active field of conservation biology (systematic conservation planning) involves developing methods for prioritizing different areas for conservation. These assessments typically use information on species distributions or their proxies (e.g., vegetation type, environmental parameters) and maximize representation of diversity based on different criteria, such as within-site species richness and complementarity of species assemblages, patterns of endemism or restricted-range species, and representation of threatened species. An ongoing challenge is to better incorporate genetic and trait diversity below the species level into conservation assessment. There are theoretical reasons why genetic diversity and species diversity might be broadly correlated across space, since they are influenced by processes that act in parallel at both scales (e.g., connectivity, habitat heterogeneity; see review by Vellend and Geber, 2005). However, empirical evidence thus far is mixed; thus conservation planning based on species-level patterns may not adequately protect within-species patterns of divergence (e.g., Thomassen *et al.*, 2011; Rissler *et al.*, 2006; Moritz, 2002).

Another way that evolutionary biology has been used to inform spatial conservation planning is by incorporating species' evolutionary history into the 'ranking' process. Some species are more important than others for maintenance of diversity from an ecological perspective (e.g., keystone species, ecosystem engineers); other species are more important from an evolutionary perspective, arguably because they represent greater evolutionary depth (e.g., basal taxa), or because they are more evolutionarily labile and thus (may) have higher potential for future diversification (e.g., species-rich clades). A variety of metrics have been proposed to integrate taxonomic diversity into conservation planning (e.g., Steel *et al.*, 2007; Graham and Fine, 2008; Rosauer *et al.*, 2009). The most commonly used metric currently is phylogenetic diversity, or PD (Faith, 1992), which incorporates both the topology of the phylogenetic tree as well as branch lengths for the species in question. A recent example of this approach is the Zoological Society of London's Evolutionarily Distinct and Globally Endangered (EDGE) program, which pairs PD with information on extinction risk, as assessed by the International Union for Conservation of Nature (IUCN) Red List criteria (Isaac *et al.*, 2007).

The primary challenge facing conservation planning is to preserve not just the existing patterns of genetic and species diversity, but also the evolutionary processes that create and maintain these patterns (Moritz, 2002; Hendry *et al.*, 2011; Brooks *et al.*, 2015). Cowling and Pressey (2001) tackle this problem for a major biodiversity hotspot, the Cape Floristic Region in southwestern Africa. They identified key landscape components thought to contribute to the evolutionary process, especially gradients (fine scale, edaphic gradients as well as macrogeographic climatic gradients), and corridors of movement allowing exchange between inland and coastal areas. This example is exceptional in that the Cape Floristic Region is better studied than many other regions of conservation concern; however, the basic message – preserve gradients, species interactions, and dispersal – is broadly applicable.

Process: The Problem of Small Populations

Much of conservation genetics has focused on the challenges facing small, fragmented populations, for obvious reasons. Of central concern is the loss of genetic diversity as populations decline in size, and the resulting interplay between genetic diversity and population demography. Preservation of genetic diversity is considered critical for two reasons. First, genetic diversity within individuals (e.g., heterozygosity) can directly influence individual fitness, and thus have immediate impacts on demographic rates in small, inbred populations. Second, loss of genetic diversity at the scale of the population broadly equates to a loss of evolutionary potential. This idea can be traced back to Fisher's Fundamental Theorem: under selection, the rate of change of mean fitness is equal to the additive genetic variance in fitness (Fisher, 1958). As the environment shifts, small populations may lack the heritable variation in functional traits necessary to respond adaptively.

Adaptive genetic change that allows a declining population to avoid extinction is called 'evolutionary rescue' (reviewed by Gonzalez *et al.*, 2013; Carlson *et al.*, 2014). Both theory (e.g., Holt and Gomulkiewicz, 1997) and increasing experimental evidence (Bell and Gonzalez, 2009) show that the likelihood of evolutionary rescue depends on the direct and interactive effects of three factors: the degree of mismatch between mean phenotype and environment, the supply of genetic variation, and population size. In general, population size is positively correlated with genetic diversity, at least as measured by neutral or nearly neutral molecular markers (Frankham, 1996). Spielman *et al.* (2004) conducted a meta-analysis of 170 taxonomically paired comparisons of threatened and nonthreatened species; they found that in 77% of cases, heterozygosity (measured at microsatellite or allozyme loci) was lower in the threatened species (**Figure 1**). However, Mendelian molecular markers are often a poor predictor of quantitative diversity (Reed and Frankham, 2001), and adaptive variation may be maintained by selection while neutral variation is lost (McKay and Latta, 2002). Empirical data collected thus far suggest that only the smallest populations show reduced evolutionary potential (see review by Willi *et al.*, 2006). Nevertheless, the trajectory of evolutionary rescue is a race with extinction – even if small populations do contain individuals with appropriate traits (or if these appear by mutation or gene flow), small populations will have a more difficult time achieving rescue than larger ones, both because the rate at which adaptation must occur is faster and because stochastic processes (like genetic drift, discussed below) dominate in small populations.

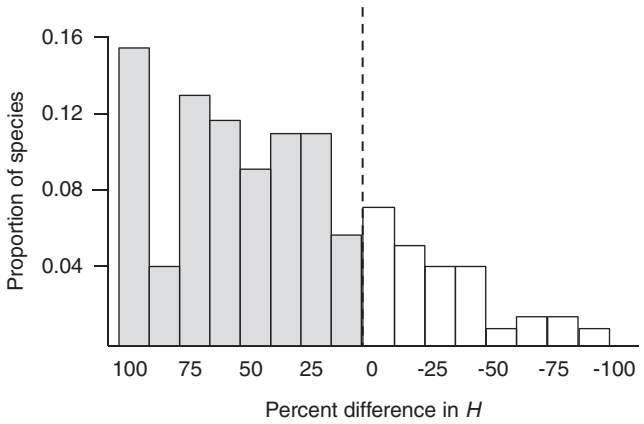

Figure 1 Distribution of percent differences in heterozygosity (*H*) between threatened and taxonomically related non-threatened taxa. Shaded bars (77% of all comparisons) show cases where *H* is lower in the threatened taxa. Data from Spielman, D., Brook, B.W., Frankham, R., 2004. Most species are not driven to extinction before genetic factors impact them. Proceedings of the National Academy of Sciences of the United States of America 101, 15261–15264.

Genetic Drift

Genetic drift is the change in allele frequencies in a population over time due to random sampling events (e.g., differences among individuals in survival or fecundity that are unrelated to their phenotype/genotype). Although the specific genetic consequences of genetic drift during a given demographic bottleneck are unpredictable, the overall effect of drift is to erode genetic diversity.

Effective population size, or N_e, is a measure of how sensitive a population is to genetic drift. N_e is defined as the size of a hypothetical, theoretically ideal population that would experience the same level of inbreeding, loss of heterozygosity, and genetic drift per generation as the real population in question (Kimura and Crow, 1963). Other factors besides the census size of a population will influence the change in allele frequencies over time (e.g., an uneven sex ratio, past fluctuations in population size, nonrandom variation in family size); by excluding these factors, N_e makes it possible to evaluate and compare measurements of drift across species with very different life histories. There are different ways to empirically estimate N_e over both short- and long-term time scales (see review by Hare *et al.*, 2011), but N_e is virtually always smaller, and often much smaller, than the census size of a population. Frankham (1995) reviewed published estimates of N_e/N for wildlife species, and found that N_e averaged only 10–11% of total census size.

In large (unthreatened) populations, it takes a long time to see a major effect of genetic drift on allele frequencies; genetic diversity represents a balance between mutation and natural selection. However, when $N_e s \ll 1$, where s is the selection coefficient describing the difference in fitness between two alleles, drift can counter selection, and the alleles will behave as if they are neutral (Wright, 1931). Thus through this mechanism, small populations may show greater maladaptation (i.e., mismatch between environment and mean phenotype) than larger ones. By similar logic, mildly deleterious mutations will tend to accumulate in small populations, because selection is ineffective at removing them. This can lead to 'mutational meltdown': as deleterious mutations become fixed, they drive down population growth rate (and size), making the population progressively more susceptible to fixation of future mutations (Lynch *et al.*, 1995).

Inbreeding and Inbreeding Depression

Small populations are often subject to inbreeding, or the mating of closely related individuals. Inbreeding per se does not affect allele frequencies; however, because closely related individuals are likely to share alleles that are identical by descent, this increases the likelihood that progeny will inherit the same allele from both parents. Thus inbreeding causes a decline in mean heterozygosity. This in turn can lead to inbreeding depression, typically defined as the relative reduction in fitness of inbred progeny compared to outbred progeny. This fitness differential varies with environment: the expression of inbreeding depression is often greatest in physiologically stressful environments (reviewed by Reed *et al.*, 2012). For example, inbreed white-footed mice (*Peromyscus leucopus*) displayed equivalent survival to outbreed mice in the lab but significantly reduced survival when released into the wild (Jimenez *et al.*, 1994). Similarly, Keller *et al.* (1994) showed that a severe winter selected against relatively inbred individuals in a wild population of song sparrows (*Melospiza melodia*).

Inbreeding depression can be caused by several different genetic mechanisms: the expression of deleterious recessive alleles (i.e., alleles that were 'masked' in the heterozygous state, but expressed in homozygotes), or the loss of overdominance at loci where heterozygotes have the highest fitness. Reduction in fitness caused by the first mechanism can be alleviated over time by selection, assuming that inbreeding occurs gradually and selection against homozygous recessive individuals is not overwhelmed by genetic drift. This process is referred to as purging the genetic load. Support for the role of purging in declining populations is mixed; some reviews suggest that purging only occurs in some cases and does not completely remove fitness costs associated with inbreeding (Ballou, 1997; Byers and Waller, 1999), which underscores the

need to better understand the genetic mechanism of inbreeding depression across taxa (Crnokrak and Barrett, 2002).

Interplay between Genetic versus Nongenetic Processes Affecting Demography

In addition to genetic drift and inbreeding, there are also critical nongenetic processes that influence the viability and persistence of small populations. For example, small populations may be subject to positive density-dependent population growth (called an Allee effect, or depensation in fisheries science). Any mechanism that causes a particular component of individual fitness (e.g., individual survival, growth rate or fecundity) to increase with increasing population size or density is considered a 'component Allee effect'; if the net result of all component Allee effect (plus possible compensatory changes in other components of fitness) is an increase in population growth rate, this is a 'demographic Allee effect' (Stephens *et al.*, 1999). The three most commonly reported mechanisms leading to an Allee effect are mate limitation, cooperative defense behavior, and predator satiation (see review by Kramer *et al.*, 2009). For example, groups of bighorn sheep (*Ovis canadensis*) smaller than five individuals show reduced group vigilance in spite of the fact that individuals in these small groups increase their vigilance behavior; further, the per capita risk of predation is greater in small groups if a predator attack does occur (Mooring *et al.*, 2004).

Small populations are also vulnerable to environmental and demographic stochasticity. Year-to-year variation in population growth rate, as well as larger environmental perturbations ('catastrophes'; e.g., storms, fires, etc.), will have a greater impact on small populations than larger ones, simply because larger populations have a greater numerical buffer between the number of individuals at any given time and extinction. Demographic stochasticity is the variation in realized population growth rate that occurs even when the underlying vital rates (e.g., birth and death rates) that determine population growth are constant – the result of applying a rate to real (whole) numbers. Like genetic drift, the relative magnitude of this effect increases as population size declines.

The relative importance of genetic versus nongenetic factors for population persistence has been debated since the inception of conservation genetics (see review by Brook, 2008). Demographic processes are often thought to impact small populations before genetic effects become important; this idea dates back to an influential paper by Lande (1988). However, there is no doubt that inbreeding depression can be an important cause of decline for wild populations (Keller and Waller, 2002). A direct link between inbreeding and extinction risk has been shown in experimental populations of *Drosophila* (Wright *et al.*, 2008), the whitefly *Bemisia tabaci* (Hufbauer *et al.*, 2013), the plant *Clarkia pulchella* (Newman and Pilson, 1997), and in both experimental and wild populations of the Glanville fritillary butterfly *Melitaea cinixi* (Saccheri *et al.*, 1998; Nieminen *et al.*, 2001). Further, the processes described above do not act in isolation: any negative consequences of inbreeding for population growth rate will have implications for all other processes mediated by population size. Gilpin and Soule (1986) first coined the term 'extinction vortex' to describe the sequence of events and synergy between direct and indirect (genetic) demographic consequences of small population size (**Figure 2**). If an ecological impact (e.g., harvest, pollution, or an invasive species) reduces population size, this exposes the population to demographic stochasticity and possible Allee effects; these in turn reduce population growth rate and size, increasing the likelihood of inbreeding and the magnitude of genetic drift, further reducing population growth rate and size.

Dispersal and Gene Flow

One of the fundamental processes that affects population dynamics and persistence is the movement of individuals (dispersal) and their genes (gene flow) from one population to another. This movement may either help or hinder the recovery of threatened populations, depending on the particular circumstances. First consider dispersal alone: on the

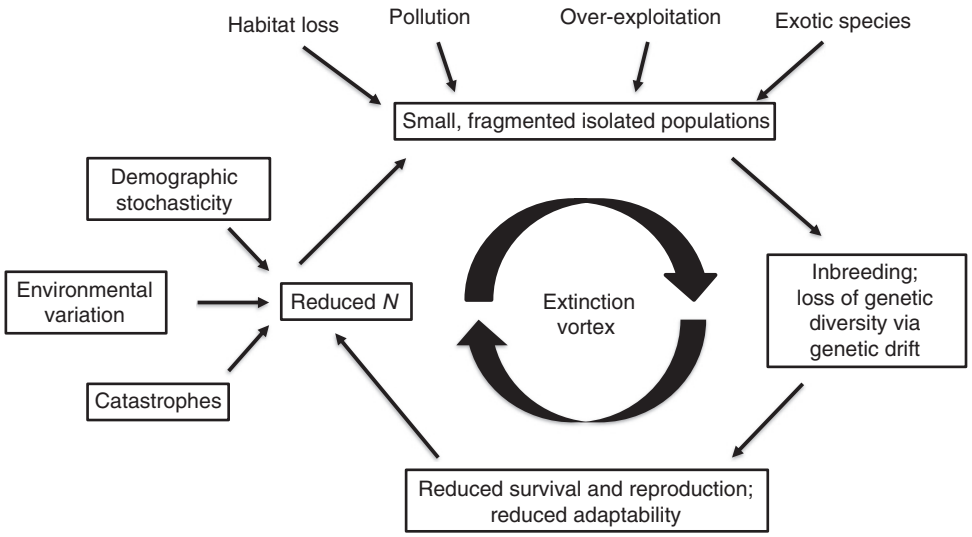

Figure 2 The interplay between genetic and demographic consequences of small population size can lead to an 'extinction vortex.' Reproduced from Frankham, R., Ballou, J.D., Briscoe, D.A., 2002. Introduction to Conservation Genetics. Cambridge: Cambrige University Press.

one hand, the movement of individuals into a declining population serves to pump up population size, and thus can reduce the impact of Allee affects, demographic stochasticity, and genetic drift. Thus, dispersal can have a positive impact on adaptive evolution and population persistence, even in the absence of corresponding gene flow, by potentially maintaining a population in decline (i.e., a demographic sink) long enough for adaptation to occur (Holt *et al.*, 2003). However, in theory, dispersal could also increase population size past its local carrying capacity, thus reducing the fitness of all genotypes; this would make it harder for a new beneficial allele to increase in frequency (Gomulkiewicz *et al.*, 1999).

The effect of gene flow on population dynamics and adaptation is equally complicated (see review by Garant *et al.*, 2007). Gene flow typically acts to increase the genetic diversity within populations; if gene flow increases additive genetic variation for ecologically relevant traits, this can increase the adaptive potential of small populations. New alleles brought in via gene flow can alleviate inbreeding depression and cause population growth rate to rebound – this phenomenon is called genetic rescue (reviews by Tallmon *et al.*, 2004; Whiteley *et al.*, 2015). However, gene flow is not a panacea: gene flow can increase within-population diversity, but it homogenizes genetic differences among populations – if these differences are adaptive, then gene flow will have a negative effect on mean fitness. This is called outbreeding depression, defined as a reduction in fitness of progeny produced by the matings of genetically divergent individuals. When gene flow links populations or groups of individuals experiencing different selection pressures, gene flow can counter the effect of natural selection on allele frequencies, and 'swamp' local adaptation. Outbreeding depression may also occur even if populations have experienced similar selective environments, if the populations have evolved different genetic 'solutions' involving multiple interacting loci (i.e., epistasis). Gene flow between populations can break up these coadapted gene complexes, leading to low fitness in the progeny.

There have been several high profile examples of successful genetic rescue in the last decade, perhaps the most famous of which is the Florida panther (*Puma concolor coryi*). The Florida panther is the last surviving subspecies of the puma in eastern North America. By the early 1990s, Florida panthers were reduced to a single population of ~25 individuals suffering from physical complications linked to inbreeding, including heart defects, high loads of infectious diseases, kinked tails, and adult males with low sperm quality and undescended testes (Johnson *et al.*, 2010). After eight female panthers were translocated from Texas into Southern Florida, the frequency of these traits declined, the population tripled in size, and population growth rate went from 5% annual decline to 4% growth (Benson *et al.*, 2011).

There are far fewer empirical examples of outbreeding depression than of inbreeding depression, but the fitness consequences for declining populations can be equally damaging (review by Edmands, 2007); thus active translocation of individuals by humans, or 'assisted gene flow' (Aitken and Whitlock, 2013), must be approached with some caution. This is one of several areas in which genomic methods (i.e., high-throughput, massively parallel sequencing) offer tremendous promise for conservation. Genomics allows the screening of thousands of markers across the entire genome, providing a powerful tool for exploring the genetics of adaptation (Ouborg *et al.*, 2010; Harrisson *et al.*, 2014). Genomic methods can be used to select appropriate source populations for assisted gene flow, and even to identify individuals within those populations that are likely to have the greatest 'rescuing' effect, either because they have highest genome-wide genetic diversity, or because they possess particular alleles associated with fitness (Whiteley *et al.*, 2015).

Concluding Thoughts
