## Kuder–Richardson coefficient

This is used to test the **reliability** of a set of **binary** responses to items in an instrument such as a questionnaire. The Kuder–Richardson (K-R) coefficient measures the consistency of responses from item to item and determines the degree to which all items measure a common characteristic of the respondent. Thus, this is a measure of the **internal consistency** of an instrument. Reliability of the instrument is important for good inferences from the data. If a correct answer is scored as 1 and an incorrect answer is scored as 0, this is given by

$$\text{Kuder–Richardson coefficient: } r_{\text{KR}} = \frac{K}{K-1}\left(1 - \frac{\Sigma_k p_k(1-p_k)}{s^2}\right),$$

where $K$ = number of questions in the instrument, $p_k$ = proportion of subjects in the sample who answered the $k$th ($k$ = 1, 2, …, $K$) question correctly, and $s^2$ = variance of the *total* scores of all the people taking the test. The value of this coefficient ranges from 0 to 1. A high value indicates reliability, while too high a value (in excess of 0.90) indicates a homogeneous test that may not serve the purpose. This coefficient was developed in 1937 [1] and is known to be affected by the difficulty of the test, the variation in scores, and the length of the instrument.

If a 20-item questionnaire ($K$ = 20) is administered to $n$ = 80 subjects, and if 32 of these 80 answer the 7th question correctly, $p_7 = 32/80 = 0.4$. This can be obtained for each question. Suppose the total score of the first subject is 61, the second 78, the third 49, etc., and the variance of these scores is $s^2 = 37.21$ ($s = 6.1$). If the proportion of correct answers is as in Table K.3, $r_{\text{KR}} = \frac{20}{19}\left(1 - \frac{3.0534}{37.21}\right) = 0.97$. This test is highly homogeneous, and possibly not as good in discrimination. The smaller the variance of total scores, the larger the K-R coefficient.

Hiranyatheb et al. [2] used the K-R coefficient for assessing the reliability of the Thai version of the symptom checklist of the Yale–Brown Obsessive Compulsive Scale, and Kesselheim et al. [3] used it for assessing the reliability of a new test of residents' ethics knowledge for pediatrics in the United States.

The popular **Cronbach alpha** is an extension of the K-R coefficient for quantitative responses in place of binary responses.

## kurtosis

Kurtosis in statistics is the peakedness of a unimodal statistical **distribution** of a continuous variable that also affects the tails. Most

**FIGURE K.3** Distribution of PSA level in two groups: (a) sharp peak; (b) flat peak.

continuous medical measurements have a tendency to concentrate around a particular value, which means that this value is the most common. For example, prostate-specific antigen (PSA) in healthy males is mostly around 3 ng/mL. Consequently, when frequency distribution is plotted, the peak will occur around 3 ng/mL. If there are a large number of people with values around 3 ng/mL relative to the adjacent values, the peak will be steep and sharp, but if there are not as many, the peak will be relatively flat. This peakedness is what is called kurtosis.

Figure K.3 presents a contrast between distributions with a sharp peak and a relatively flat peak. Both the distributions have nearly the same variance and the same **skewness**, but the kurtosis is very different. Statistically, a quantity called the fourth moment of a distribution measures the peakedness. Statistical packages will easily compute this for any distribution when you specify either the values or their **frequency distribution**. This, however, will be reliable for a large sample only.

For a Gaussian (normal) distribution, the value of kurtosis is 3. Generally, 3 is subtracted from the value of kurtosis for any distribution so that a comparison with zero value can be made. After this subtraction, the distribution with near-zero kurtosis is called *mesokurtic*, a flat-peaked distribution will have negative kurtosis (called *platykurtic* distribution), and a sharp-peaked distribution will have positive kurtosis (called *leptokurtic* distribution). Platykurtic will generally have light tails and leptokurtic heavy tails. These are assessed in comparison with the peak in the Gaussian distribution, but that is not required physically. Kurtosis can be calculated numerically, as stated in the preceding paragraph. For example, scores on a **Likert scale** from 0 to 9 will have a platykurtic distribution if a large number of responses are of middling type—between 4 and 6—as is the general tendency with this scale. All **uniform distributions** are platykurtic.

It is possible that the two symmetric distributions apparently look **Gaussian** but have very different kurtosis (Figure K.4). When kurtosis is very different from normal, the requirement of Gaussian distribution as for **Student *t*** and **ANOVA *F*** is not met, and the results would not be valid. Thus, it is desirable that kurtosis is also checked along with skewness, particularly for values such as scores on a Likert scale. Practically, this is seldom done since most distributions tend to have nearly normal kurtosis.

Among the many applications of kurtosis in health and medicine, one is in constructing growth curves for children. Many growth parameters (height, weight, head circumference, etc.) have a leptokurtic distribution at each age—thus, an adjustment is needed. The **Box–Cox power exponential (BCPE)** method has been especially devised to take care of this problem in kurtosis.

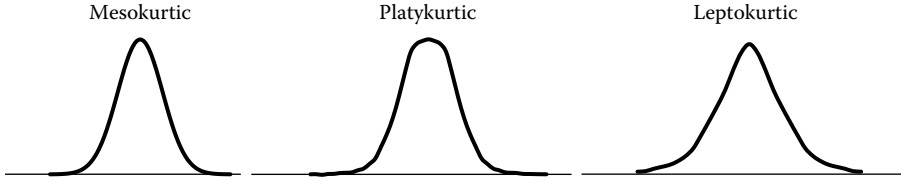

**FIGURE K.4** Symmetric distributions with different kurtosis.

## lag, *see* autocorrelation

## Lan–deMets procedure, *see also* O'Brien–Fleming procedure

The Lan–deMets procedure arises when considering **stopping rules** for clinical trials. An ongoing trial can be stopped for many reasons, two of which are statistical. The first is that the evidence accumulated so far confirms that the regimen has adequate efficacy. The other reason is that the efficacy is found to be too low to go any further. The latter is said to be stopping for futility. Such appraisal has special appeal for phase II trials where the primary aim is to provide proof of concept in the sense that the regimen has minimum efficacy. Stopping for futility will save the researchers from going through the expensive phase III trial. On the other hand, stopping for efficacy can be applied to both phase II and phase III trials but has special appeal to phase III as it can save substantial time and resources.

The procedure for stopping for futility becomes intricate because this is done in a manner that the prefixed **level of significance** and statistical **power** remain unaltered. Software-based intricate calculations are required to ensure this. Stopping for efficacy requires that the level of significance $\alpha$ is judiciously apportioned at each appraisal such that the total **Type I error** does not exceed $\alpha$. A simple but inadequate approach is to spend $\alpha$ in $K$ equal parts if $K$ appraisals are planned, including the final analysis of all the data. This means that the hypothesis at first appraisal is tested at an $\alpha/K$ level of significance, second at a $2\alpha/K$ level of significance, and the last at an $\alpha$ level of significance. Statistically, equal-$\alpha$ spending procedure as just stated is too liberal than required to control Type I error and would relatively easily reject the null. It sounds reasonable to have a procedure that is even more stringent at initial stages. This is done in the group sequential approach to interim statistical testing, but the difficulty is that it includes the number of scheduled analyses. This number must be determined before the onset of the trial, and there should be equal spacing between scheduled analyses with respect to patient accrual. The *alpha-spending function* approach was developed to overcome these problems. One such popular procedure is as follows for a two-tailed test:

$$\alpha\text{-Spending Function: } \alpha(\tau_k) = 2\,[1 - \Phi(z_{\alpha/2}/\sqrt{\tau_k})],$$

where $\Phi$ is the cumulative Gaussian probability at the value specified within the parentheses and $\tau_k$ is the proportion of the information available at the $k$th appraisal. This may appear to be a complex expression but that really is not the case. For example, one-half of the subjects completing one-half of the trial corresponds to $\tau_k = 0.25$, and since $z_{\alpha/2} = 1.96$ for a two-sided Gaussian test at the 0.05 significance level, $z_{\alpha/2}/\sqrt{\tau_k} = 1.96/\sqrt{0.25} = 3.92$ at this $\tau_k$. At this value, $(1 - \Phi) < 0.00005$ from the Gaussian distribution and $\alpha(\tau_k) < 0.0001$. Thus, the critical value of 3.92 for rejecting the null corresponds to a nominal $P$-value of less than 0.0001 at this stage. This is the critical value with this procedure at one-fourth of the trial and assumes that the trend of results later in the trial would be on the same pattern as accrued so far.

**TABLE L.1**
**Lan–deMets α-Spending Function for Unequally Spaced $K = 3$ Appraisals**

| Appraisal No: $k$ | $\tau_k$ | Critical Value | Nominal $P$-Value from Gaussian Table (One-Tailed Test) | Adjusted $P$-Value |
|---|---|---|---|---|
| 1 | 20% | 2.9626 | 0.0015 | 0.0015 |
| 2 | 50% | 2.2682 | 0.0117 | 0.0107 |
| 3 | 100% | 2.0302 | 0.0212 | 0.0128 |
| | | | **Total** | **0.0250** |

A more acceptable procedure is attributed to Lan–deMets [1,2], which is flexible and accommodates unequally spaced appraisals. This can be used for equally spaced sequential designs as well. This preserves the overall Type I error regardless of timing of the appraisals but makes it difficult to stop the trial early unless there is a strong evidence of the desired efficacy. This also imposes a small penalty at the end for interim looks. A suitable software package is needed to find the Lan–deMets critical values for specified appraisals. For example, if there are three appraisals at 20%, 50%, and 100%, the critical values for one-tailed $\alpha = 0.025$ are given in Table L.1. The total of adjusted $P$-values is 0.025, and the critical value at last appraisal at completion of the trial is 2.0302 in place of the usual 1.96, indicating a slight penalty for conducting the previous two appraisals.

No matter which method is used, there is a possibility of bias in early stopping. If you plan $n = 400$ subjects in a trial and stop it after analysis of data on 150 subjects because the data tell you that strict significance has been reached, the question arises as to whether these 150 subjects are as representative of the population as 400 would have been. If the first 150 subjects are not random, further bias is apparent. For details, see Chow et al. [3].

## landmark analysis

This analysis ignores data accruing either before or after a landmark event when full data are anticipated to be highly unreliable because of wavered responses. Thus, this is a conditional analysis. Landmark

analysis is generally applied to durations such as for **Kaplan-Meier** analysis that models any duration from occurrence of an event to occurrence of another event (including termination of follow-up). This duration is generally referred to as duration of survival, but it can be any duration such as duration of hospital stay, time elapsed since the last infarction, or simply the duration of survival after onset of a terminal disease. The model can give unreliable, sometimes erroneous, results if the behavior of patients is too erratic for a part of the duration. For example, patients may show highly variable results initially for some days after a particular surgery, but stable results thereafter. In such cases, it is prudent to model the duration after the response stabilizes. This is called the landmark analysis—the time point of stabilized response being the landmark. Note that stabilizing time point may vary from patient to patient. The duration under landmark modeling could be for something like post-remission survival, relapse after hospital discharge, and the time since the treatment compliance stabilizes after some initial wavering. In some situations, this wavering may mean patient switching group membership such as responders becoming nonresponders, as is quite common in cancer treatment. In the landmark analysis, the data accruing only from a landmark are considered and the data preceding the landmark are ignored. This landmark could be at the end point as well, in which case the data accruing after the landmark are omitted. The method was introduced by Anderson et al. [1] in 1983.

For landmark analysis to provide unbiased results, it is imperative that the landmark is decided before data collection on the basis of clinical considerations since data-driven landmark may produce erroneous results. If the landmark is too early, unreliable observations may still creep in, and if it is too late, a significant proportion of events may be omitted, causing loss of statistical power. Some events occurring early in some patients may be important markers of survival but would not be considered in landmark analysis. If the patients were randomized to begin with, they may not remain randomized after some events are deleted, and follow-up time available for analysis also decreases with this method. In addition, there is always a risk of loss of generalizability of results with this analysis on truncated data since extrapolation of the survival pattern will ignore the omitted time period. On the whole, we can say that this method has promise but is yet to gain maturity, although if the landmark time is early enough, the analysis may provide useful results. For further details and intricacies of the method, see Dafni [2].

The following two examples illustrate situations where landmark analysis could be useful. In comparison of the long-term mortality of acute ST-segment elevation myocardial infarction (STEMI) and non–ST-segment elevation acute coronary syndrome (NSTE-ACS) patients after percutaneous coronary intervention, Ren et al. [3] found no difference in all-cause mortality for both STEMI and NSTE-ACS between 6 months and 4 years of follow-up. This conclusion was based on landmark analysis. With landmark analysis at 12 months, Kumar et al. [4] observed that progression-free survival and overall survival continued to remain superior for patients attaining complete response after autologous stem cell transplant in multiple myeloma.

## LASSO, *see* least absolute shrinkage and selection operator (LASSO)

## latent variables

In contrast to a manifest variable, which can be measured directly, a latent variable cannot be measured directly, such as happiness, satisfaction, racial prejudice, and social class. Depending on the context, latent variables are also referred to as *underlying variables* and sometimes *frailties*. Other kinds of latent variables include hypothetical **constructs** that are tied to less concrete aspects of what is being studied. Sometimes, **random effects** are also considered latent.

In some medical studies, latent variables are an important component that needs to be understood and delineated. Since they are hidden, inference on latent variables has to be indirect, requiring statistical models connecting latent variables with the observed variables. This gives rise to **latent variable models** such as **factor analysis** and **path analysis**.

A latent variable may not be specified because of practical considerations. Since they are difficult to measure, these are sometimes perceived as redundant, or may be considered constants that do not need to be observed. However, in some situations, these variables are essential to draw any inference worthy of execution. They permit us to describe relations among a class of events or variables that share something in common, rather than making concrete statements regarding the relation between specific variables [1].

In a study on adulthood personality correlates of childhood adversity, Carver et al. [2] reduced personality-related scales to four latent variables and termed them anger/aggression, extrinsic focus, agreeableness, and engagement. Note that these are unobservable variables but are useful for this kind of study. Zhao et al. [3] investigated the ability of topic modeling to reduce high dimensionality to a small number of latent variables, which makes it suitable for the clustering of large medical data sets. In this example, latent variables serve as a means to reduce dimensionality without giving them specific names.

A good reference for exploring latent variables is the work of Babones [4].

## latent variables models, *see also* latent variables

These models are developed on observed or manifest variables, relating them to the actual variables of interest that may not be directly observable—referred to as **latent variables**. For example, people are secretive about their income, and housing, cars, amenities, etc., are sometimes observed instead as surrogates to guess their income. Health is also an unobservable characteristic, and indicators such as absence of disease, capacity to lift weight, and lung capacity can be used as indirect measures. Latent variable models can also be used for hardcore statistical issues such as measurement errors, unobserved heterogeneity, and missing data. Methods such as **factor analysis**, **path analysis**, and **structural equation models** are examples of latent variable models that link observable data in the real world to symbolic data in the modeled world. These models seem to have roots in the 1968 book by Lazarsfeld and Henry [1].

Specifics of latent variable models depend on whether the observed and latent variables are **quantitative** (generally continuous) or **qualitative**, and whether there are any **covariates** to be included. For example, the conventional factor analysis is used when both the observed and latent variables are quantitative and there is no covariate. When both the observed and latent variables are categorical, the method called *latent class model* is used. The mathematics underlying this kind of modeling can get rather involved, and best avoided here.

In one of the unusual applications, Ghassemi et al. [2] used latent variable models to decompose free-text hospital notes into meaningful features, and the predictive power of these features for patient mortality was examined. In this example, meaningful features that can possibly predict mortality are the latent variables and the free-text hospital notes are the observed variables. Jackson et al. [3] proposed latent models for ordinal variables and their application in the study of newly licensed teenage drivers. In this study, risky driving behavior during the first 18 months of their licensure was used to predict the occurrence of a crash or a near crash event. You can see in these examples that the predicted variables are latent and not actually observed.

For a comprehensive and unified approach to latent variable modeling from a statistical perspective, see Bartholomew et al. [4]. A word of caution may be in order. Many researchers view latent variable models with suspicion because of unverifiable underlying assumptions and naïve inferences regarding causality. For some, this is a strength as this analysis can be viewed as a type of sensitivity analysis for the robustness of the model.

## laws of probability (addition and multiplication), *see also* probability

Among the most elementary laws of **probability** are the law of multiplication, which helps calculate the probability of *joint* occurrence of two or more events, and the law of addition, which helps calculate the probability of one *or* the other event.

### *Law of Multiplication*

Coronary artery disease (CAD) is more common in diabetic patients than in nondiabetic patients. We say that CAD and diabetes are associated. These are termed statistically dependent diseases although such dependence does not imply any cause–effect type of relationship. On the other hand, blindness and deafness in a person are independent events in the sense that occurrence of one does not increase or decrease the chance of occurrence of the other. For such independent events, the joint probability of the two occurring together in a person can be easily computed as the product of the individual probabilities. Thus,

$$P(\text{blindness AND deafness}) = P(\text{blindness})*P(\text{deafness}),$$

where $P$ is the notation for probability.

Symbolically, "AND" is denoted by $\cap$ and is called an intersection. Thus, for two independent events A and B,

$$P(A \cap B) = P(A)*P(B).$$

This is called the law of multiplication or the product rule of probabilities. A useful feature of this relationship is its inversibility in the sense that if the above equation holds, then events A and B are independent; otherwise, not. Computation of the joint probability $P$(blindness and deafness) directly, without using the above equation, requires knowledge of the percentage of subjects in which these two occur together. In many situations, this might be cumbersome to obtain compared with the two individual probabilities on the right side of the above equation. Note that the individual probability in our example is simply the prevalence rate, which would be easily available. If these are 1 per 1000 and 2 per 10,000, respectively, then the prevalence of blindness and deafness occurring together is $0.001 \times 0.0002 = 0.0000002$ or 2 per 10 million. The law of multiplication is useful for obtaining joint probability for such independent events.

Table L.2 is constructed from the table on the correspondence between body mass index and subscapular-to-triceps skinfold ratio in middle-aged Cretan men given by Aravanis et al. [1].

Cutoff points chosen for each category of BMI are **tertiles**. These divide the subjects into three groups of equal size. Thus, nearly equal numbers in the row totals are not surprising: 109, 111, 111. In this case, $P$(low BMI) = 109/331 = 0.329, and $P$(low skinfold ratio) = 110/331 = 0.332. Thus,

$$P(\text{low BMI}) \times P(\text{low skinfold ratio}) = 0.329 \times 0.332 = 0.109.$$

On the other hand, the following is the joint probability on the basis of the cell frequency: $P$(low BMI and low skinfold ratio) = 56/331 = 0.169. Since these two probabilities are very different, low BMI

**TABLE L.2**
**Correspondence between Skinfold and Body Mass Index (BMI) in Cretan Men**

| | Subscapular-to-Triceps Skinfold Ratio | | | |
|---|---|---|---|---|
| **Body Mass Index** | **Low (<1.77)** | **Medium (1.77–2.33)** | **High (>2.33)** | **Total** |
| Low (<25.3 kg/m$^2$) | 56 | 43 | 10 | **109** |
| Medium (25.3–28.7 kg/m$^2$) | 36 | 40 | 35 | **111** |
| High (>28.7 kg/m$^2$) | 18 | 31 | 62 | **111** |
| **Total** | **110** | **114** | **107** | **331** |

and low skinfold ratio are not independent. The above calculations show that if one is low, there is a greater chance that the other is also low. The same is true for "high." Because 62/331 (i.e., 0.187) is much more than (111/331) × (107/331) (i.e., 0.108), there is a greater chance of one being high when the other is high. However, there is no evidence that middle BMI occurs more frequently with middle skinfold ratio. When BMI is in the middle category, the joint probabilities of low, middle, and high skinfold ratios are 36/331 = 0.109, 40/331 = 0.121, and 35/331 = 0.106, respectively. These are not very different from the product of individual probabilities (111/331) × (110/331) = 0.111, (111/331) × (114/331) = 0.115, and (111/331) × (107/331) = 0.108. Thus, when BMI is in the middle category, skinfold ratio is independent and falls in any of the three categories with almost equal frequency.

Theoretically, even a mild difference in the joint probability from the product of individual probabilities suggests association. Practically, the difference should be *substantial* to conclude **association** because of two considerations. First, $n = 331$ is a sample in the above example and there is a need to be cautious about sampling fluctuation that can easily produce minor deviations. Second, a very mild association may not be medically relevant in many situations.

### Law of Addition

After corrective surgery for residual deformity in multiple injuries, the recovery may be full, partial, or none. Because a patient at any particular instance can belong to only one of these categories, these are called **mutually exclusive** categories. In the case of such categories, the probability of belonging to one or the other is computed by the law of addition. That is,

$$P(\text{full or partial recovery}) = P(\text{full recovery}) + P(\text{partial recovery}).$$

If the probability of full recovery is 0.30 and that of partial recovery is 0.40, then the probability of at least some recovery is 0.70. In notation, the symbol ∪, called union, is used for "or." Thus, for mutually exclusive events,

$$P(\text{A} \cup \text{B}) = P(\text{A}) + P(\text{B}).$$

Note that mutually exclusive events cannot be independent and vice versa. There is no bar on independent events occurring together, whereas mutually exclusive events cannot occur together. Because full, partial, and no recovery are the only possibilities, out of which one has to happen, these are called exhaustive categories but that is not a requirement for using the addition rule. However, if the categories are exhaustive, then the probability of any one of them occurring is 1.

## least absolute shrinkage and selection operator (LASSO)

When there are a large number of predictors under consideration in a **regression** modeling, it is always considered advisable to find a model that uses a small set of predictors so that a parsimonious model can be built. This helps in providing a better handle for control of the outcome and in better understanding the functionality of the system under the model. The LASSO is a method that can help in selecting predictors of a target variable $y$ from a larger set of possible predictors. Developed in 1996 by Tibshirani [1], the LASSO uses the least squares method as usual for estimation of the regression coefficients but puts a restriction that the sum of the absolute values of regression coefficients does not exceed a predefined threshold λ. This threshold is called the tuning parameter. In doing so, the LASSO can drive the coefficients of irrelevant variables down to zero, thus performing automatic variable selection. The method requires that all the predictors are **standardized** since otherwise the regression coefficients depend on the unit of measurement and one variable can outdo others just because the unit of measurement is small.

Incidentally, lasso is also the rope with a loop at one end that is thrown and tightened around the target. This fits well into the nature of the LASSO method that is thrown around the estimates of the regression coefficients to tighten their values. The method is applicable to nonlinear models as well, but we use a linear model in the explanation next for simplicity.

In terms of notations, the linear regression model is

$$\hat{y} = b_1 x_1 + b_2 x_2 + \ldots + b_K x_K,$$

where $(x_1, x_2, \ldots, x_K)$ are the standardized predictors and $(b_1, b_2, \ldots, b_K)$ are the regression coefficients. The usual least squares method chooses regression coefficients $b$'s such that $\Sigma(\hat{y} - y)^2$ is minimum with no other restriction. However, the LASSO method places the restriction that the sum of the absolute values of regression coefficients $\Sigma|b_k| \le \lambda$. When λ is large, the usual regression is obtained but a small λ forces some of the $b$'s to shrink so much so that some even become nearly zero. The predictors' nearly zero coefficient can be excluded from the model. This shrinkage is like penalizing the regression coefficients. This method has been shown to improve the quality of prediction besides increasing the parsimony. For a necessary and sufficient condition for application of LASSO, see Zhao and Yu [2].

Yeh et al. [3] used the LASSO method to identify specific policies of medical schools that are associated with students' reports of interaction with pharmaceutical and medical device industry, and concluded that policy makers should pay greater attention to less research-intensive institutions. Huang et al. [4] developed a computational model for breast cancer prognosis by combining the Pathway Deregulation Score–based pathifier algorithm, using, among others, the LASSO method. This score can help in the more personalized care of breast cancer patients. These examples may give an idea of how and where the LASSO method can be used.

## least significant difference (LSD), *see also* multiple comparisons

The LSD is one of the many methods used for **multiple comparisons** of means in different groups in an **analysis of variance (ANOVA)** setup. Other multiple comparison tests are **Bonferroni**, **Tukey**, **Duncan**, and **Dunnett**, each of which is used under specific conditions. All multiple comparison tests compare a set of means in a way that the experimentwise (Type I) error rate remains under control such as within 5% or at any specified α level. (To understand "experimentwise error rate," see the topic **multiple comparisons**.) The hypothesis that the means are equal is first tested by an α-level ***F*-test** in an ANOVA setup. Should this test turns out not significant, the procedure generally terminates without making any detailed inferences on groupwise differences across the means since this implies that there is no significant difference in means in different groups. When $F$ is significant, the group differences are tested by one of the multiple comparison tests depending on the type of comparisons required for your setup. As just mentioned, these tests adjust the Type I error so that this remains under control. The difference between this and, for example, **Student *t*** for two groups is that LSD uses the **mean square error (MSE)** from ANOVA as the pooled variance in place of the pooled estimate from variances of the two groups under comparison used in the Student $t$-test. The MSE is a better estimate as this is based on a larger sample and considers variation across groups.

$$\text{LSD} = t_{\alpha/2,\nu}\sqrt{\text{MSE}\left(\frac{1}{n_1}+\frac{1}{n_2}\right)},$$

where $t_{\alpha/2,\nu}$ is the critical value from Student $t$ distribution corresponding to an α/2 level of significance and $\nu$ df (these are the df for the MSE) and $n_1$, $n_2$ are the sample sizes of the two groups under comparison. As the name implies, this is the smallest difference between means in the two groups under comparison for it to be considered significant based on Student $t$-test.

The procedure is to calculate one LSD for all the pairwise comparisons and check if the difference in means in any two groups is more than this. The groups with a bigger difference in means are considered statistically significantly different at α level.

Since LSD does not adjust α for multiple comparisons, this test has fallen out of practice. However, this has historical importance as this is the first multiple comparison test ever developed. This was proposed by Ronald Fisher in 1935.

## least squares method

This method is used for fitting a **regression** in a manner that the sum of the squared distances between the observed and fitted values is at a minimum. In terms of notations, this sum is expressed as $\Sigma(y-\hat{y})^2$, where $\hat{y}$ is the notation for the fitted value. The difference between $y$ and $\hat{y}$ is also statistically called the error, although this is not a mistake, just an error in fitting. The better name for samples is **residual**. Some residuals are negative and some are positive, and the method ensures that the sum of these residuals is zero. Because of the square in this method, bigger residuals get a higher weight in minimization compared with the small ones, which means that large residuals, in a way, are tolerated less than small residuals. Two such residuals between the observed and the fitted values are shown in Figure L.1. These are the vertical distances of the observed values of $y$ with the fitted values of $y$. The fitted values of $y$ are represented by the regression curve in this figure.

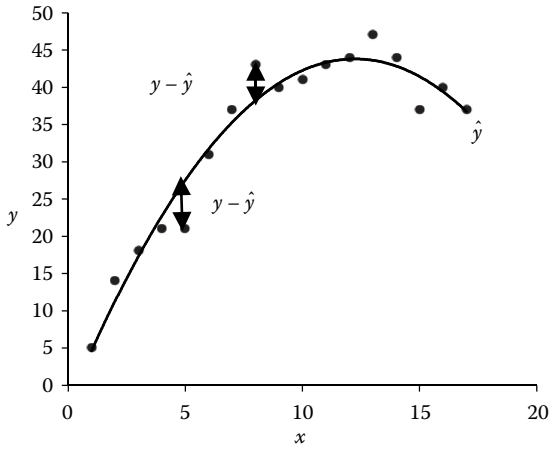

**FIGURE L.1** Differences between the observed and fitted values of $y$.

As explained under the topic **regression**, the data required to fit a regression are the values of the dependent variable $y$ corresponding to different values of the regressor variables $x$'s. The dependent variable must be quantitative. For one set of values of $x$'s, one or many values of $y$ can be observed. The values of $y$ should be available for several distinct values (at least four for the regression to be meaningful) of $x$. The values of the $x$ variables can be *deliberately* chosen to serve the purpose.

The objective of the least squares method is to obtain the **regression coefficients** in a manner that the fitted regression is closest to the observed values. However, the form of the regression—linear, curvilinear, or nonlinear—has to be specified. Square of the differences helps us consider the positive residuals the same way as the negative residuals. The minimization process requires mathematical differential equations that we avoid in this book and are considered not important for our audience. Almost all statistical packages have the facility to provide the estimates of the regression coefficients by the least squares method. The precision of these estimates is best for central values of the regressors and imprecise for larger or smaller values. The method of least squares works well when the variance of the residuals is the same for different values of the regressors. When this does not hold, a **weighted least squares method** is used. When the regression is linear and the $y$ values are independent of one another, the inverse of the variances is chosen as the weights. This may require an iterative process.

The other method generally used for obtaining the estimates of the regression coefficients is the **maximum likelihood**. When the regression equation is $\hat{y} = b_0 + b_1x_1 + b_2x_2 + \ldots + b_Kx_K$, this method finds those values of ($b_0$, $b_1$, …, $b_K$) that make our observed sample most likely to happen. In case the residuals follow the **Gaussian** pattern, this method gives the same estimates as the method of least squares. The method of least squares is more popular as it does not require any particular pattern of the data.

## level of significance, *see also* *P*-values

Level of significance is the prefixed maximum threshold of the chance of **Type I error** in statistical testing of hypothesis. Type I error is explained in the next paragraph. In brief, this is the probability of wrongly rejecting a **null hypothesis** ($H_0$).When performing a hypothesis test, the values observed in the sample serve as evidence, and they are used either to reject or not to reject an $H_0$. However, these values are subject to sampling fluctuation and may or may not lead to a correct conclusion. Errors do occur, which are classified as

Type I and Type II errors. To understand why we need to put a cap on Type I error and give it a new name as level of significance, a detailed account of Type I error is necessary in this section. **Type II error** is explained separately.

### *Type I Error*

This error is best explained with the help of court analogy. It is quite common in court that a real offender is acquitted because of weak evidence. This is not considered a serious error, but the other error also occurs. An innocent is pronounced guilty because there is strong circumstantial evidence. This is serious, and is an example of Type I error.

In a testing of hypothesis setup, if there is no real difference between the test and control groups in a clinical trial, but the data strongly disagree, the true null hypothesis of equality has to be undesirably rejected. A false-positive conclusion is reached. This is serious, and is thus called Type I error, or alpha error.

The seriousness of this error can also be understood from the setup of a trial on a new drug. This type of error occurs when an ineffective drug is declared effective. This gives false assurance, and the ineffective drug is unnecessarily marketed, prescribed, and ingested, and side effects are tolerated. Imagine the cost and inconvenience caused by this error. Statistical procedure requires that the probability of this type of error be kept low, generally within 5%. The actual probability of Type I error in the observed sample is called the ***P*-value**. It can also be understood as the probability that a true null hypothesis is wrongly discarded because the sample values so indicate. In the case of trials, this could occur if the patients included in the trial by chance happen to exhibit a difference between the groups when actually none exists.

The seriousness of a Type I error requires that a threshold of *P*-value is fixed *in advance*, beyond which it would not be tolerated. This is called the significance level and is denoted by α. This is also called the alpha level. This specifies the criterion of doubt, beyond which a null hypothesis is rejected. Statisticians—almost all empirical scientists—generally use a threshold of 5% chance of error. Five percent is an internationally accepted norm for significance level that is rarely breached in medical literature. In situations where 5% chance of error can translate into serious consequences such as death, a lower level can be fixed.

A null hypothesis is generally a statement of the status quo, and the **alternative hypothesis** signifies a change. If it were very costly to make changes from the status quo, you would want to be very sure that the change would be beneficial. The threshold of risk of Type I error is then kept very low, say less than 1%. This may be needed when, for example, a drug presently in extensive use or an existing lifesaving drug is sought to be replaced. In most medical situations, $\alpha = 0.05$ is considered adequate.

To theorists, a 5% chance of error may look high but that is not so as humans and animals vary much more than chemical reactions or electron motion in physics. Medical theories are hard to evolve, and all medical professionals are expected to be well informed about the pros and cons of various errors so that they can be judicious in their decisions despite a 5% chance of Type I error.

When the *P*-value in any study is less than the prefixed level of significance, the presence of difference or relationship is concluded. When $P$ is more than or equal to, say, 0.05, sampling fluctuation cannot be excluded as a likely explanation of the observed difference. There is a convention to call a result statistically significant when $P < 0.05$ and to call a result highly significant when $P < 0.01$. A probability of less than 0.01 is considered exceedingly small in most medical contexts.

It is important to distinguish between a *P*-value and an α level. Both measure the probability of Type I error. The first is obtained for the data set in hand whereas the second is fixed in advance. You may say for a problem that not more than 3% chance of Type I error can be tolerated by setting $\alpha = 0.03$. The calculations later on may reveal that the *P*-value for your data set is only 0.012, 0.362, or any other number. A decision regarding rejecting or not rejecting a null hypothesis is reached according to the *P*-value being higher or lower than the predetermined level of significance.

## Levene test

This test is used to check whether the **variances** in two or more groups are the same or not. Equality, also called homogeneity, of variances across groups is an important prerequisite for many statistical procedures such as the Student *t*-test and analysis of variance (ANOVA) and for residuals in regression. The Levene test helps in finding violations of this requirement. Since procedures such as ANOVA are for testing equality of means, intuitively, this equality has clear meaning when the variances are equal and loses relevance when variances greatly differ from group to group.

The conventional test for equality of variances in two groups is $F = s_1^2/s_2^2$, where $s_1$ and $s_2$ are the sample standard deviations. This is referred to as *F*-distribution for finding the *P*-value. For more than two groups, the **Bartlett test** is conventionally used. Both these tests are heavily dependent on the Gaussian distribution because the sample variances themselves (with numerator involving $(y - \bar{y})^2$) are distorted by outliers, and these outliers can substantially change the mean, thus affecting the deviations from mean, and the use of the square, amplifying the effect. The Levene test, on the other hand, is relatively independent of this requirement. This test was developed by Howard Levene in 1960 [1] using means as explained next but was later extended by Brown and Forsythe [2] using medians. This extension made the Levene test independent of the requirement of Gaussian distribution of the data.

Howard Levene

The Levene test criterion is

$$W = \frac{(n-K)\Sigma_{k=1}^{K} n_k (\bar{y}_k - \bar{y})^2}{(K-1)\Sigma_{k=1}^{K}\Sigma_{i=1}^{n_k} (y_{ik} - \bar{y}_k)^2},$$

where $K$ is the number of groups and the sample size of group $k$ is $n_k$ ($k = 1, 2, \ldots, K$), and $y_{ik} = \left|x_{ik} - \bar{x}_k\right|$. With the Brown and Forsythe extension, the mean in the last expression can be replaced by median. In this case, the means appearing in the formula for $W$ can also be replaced by medians and the criterion is then called the **Brown–Forsythe test**. The test is essentially based on the absolute values of the deviations $y_{ik}$'s. The criterion $W$ approximately follows an *F*-distribution with ($K - 1$, $n - K$) df, which would allow one to obtain the *P*-value.

The Levene test is just about the most popular test for checking the homogeneity of variances, and it is available in almost all

statistical software packages. When the Levene test indicates that the variances across groups are not significantly different, procedures such as ANOVA *F*-test can be confidently used provided other conditions are met. However, when the Levene test is significant, the variances are not equal and the subsequent test for equality of means is the **Welch test** instead of the regular *F*-test.

## Lexis diagram

A Lexis diagram is a two-dimensional representation of three-dimensional data; it is used more commonly in demographics for age at death, year of death, and year of birth for a cohort of population. An initial version of this diagram was first proposed by Zeuner in 1869, to which Wilhelm Lexis just added a network of parallel lines, but the name "Lexis diagram" has imposed itself in a seemingly invincible way [1]. The diagram could be a useful tool in **age–period–cohort analysis** as explained by Carstensen [2].

A very typical Lexis diagram that shows age-specific mortality in different birth cohorts is a contour-like diagram as shown in Figure L.2a. This figure shows the lung cancer mortality in Australian males in 1950–1985 by age at death and year of death [3]. Note how the dashed lines connect the age, year of birth, and year of death. The authors of the article called it a **synoptic chart**. Displayed along the contours is the number of deaths. The data displayed in Figure L.2a can also be shown in three dimensions by a **surface chart** (Figure L.2b). Perhaps easier to understand is the surface in Figure L.2b. It can be easily seen, for example, that the mortality rate at age around 70 years steeply increased during the period 1970–1980 and showed a slight decline thereafter.

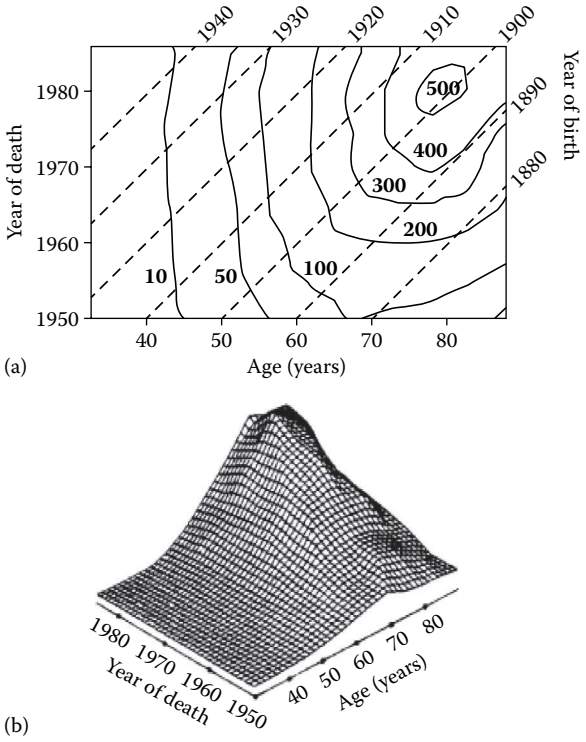

**FIGURE L.2** Mortality from lung cancer in Australian males during 1950–1985: (a) Lexis diagram; (b) surface chart. (From Jolley D, Giles GG. *Int J Epidemiol* 1992; 21:178–82. http://ije.oxfordjournals.org/content/21/1/178.full.pdf. With permission.)

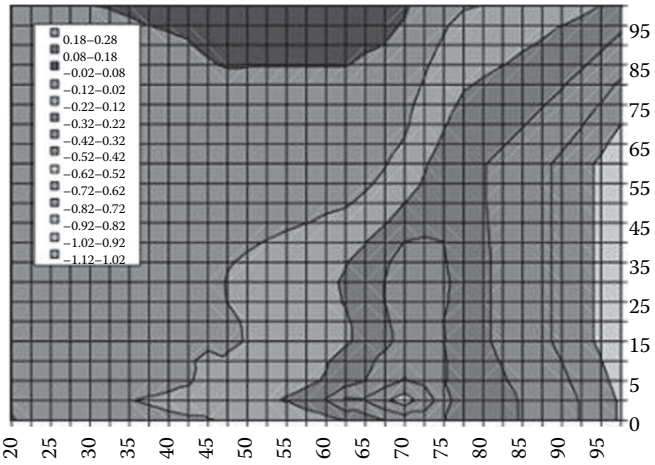

**FIGURE L.3** Log of ratios of death rates between adjacent levels of life expectancy. (From Gerland P, Li N. Modifying the Lee–Carter method to project mortality changes up to 2100. Paper presented at the *Population Association of America Annual General Meeting, 2011.* http://esa.un.org/unpd/wpp/publications/Files/Li_2011_Modifying%20the%20Lee-Carter%20method%20to%20project%20mortality%20changes%20up%20to%202100.pdf.)

Gerland and Li [4] have presented several Lexis diagrams on projected changes in mortality up to 2100 in some parts of the world. One of these is in Figure L.3, where log of ratios of death rates between adjacent levels of life expectancy are shown. Brinks et al. [5] used a Lexis diagram to track different timescales for birth rates, incidence, and mortality rates of chronic diseases.

Vandeschrick [1] has explained each step of the construction of a Lexis diagram in case you are interested to draw one yourself.

## life expectancy (types of), *see also* expectation of life and life table method

The term *life expectancy* is used for **expectation of life**—a term separately explained. However, there are many variants of life expectancy, namely, active life expectancy, disability-free life expectancy, and health-adjusted life expectancy or healthy life expectancy, and we explain all these in this section. Broadly, these terms are used for that part of life expectancy that is expected to be lived in good health as per the current trend. Minor differences in them are as follows.

It was realized a long time ago that increased longevity beyond a point does not generally translate into overall physical well-being of individuals. The advanced technology now available can delay death and prolong life in many cases. However, many of these added years can be more painful or of increasingly restricted activity. Years are added to life, but life not added to years. Thus, the concept of *healthy life expectancy* was evolved. This is the average number of years that a person is expected to live in good health. Good health is subjective and defined variously by different workers, which has caused usage of different terms.

In the context of old age, this can be *active life expectancy*, that is, the period when a person can independently carry out the daily chores of life—walking, bathing, toileting, dressing, and so on. Active life expectancy would be obviously lower in old age than the usual life expectancy. This would include periods of those sicknesses that do not affect the daily activities of life but would exclude the dependent period. One variation is *disability-free life expectancy* (DFLE) that excludes the period of disease and infirmity. This period can arise from acute diseases that occasionally occur for a short duration such as cough and cold, diarrhea, cholera, typhoid, and malaria, as well as from chronic diseases such as ischemias, malignancies, tuberculosis, and ulcers that cause long-term sickness. Disabilities such as of vision, hearing, and movements are also counted. After such exclusion, the procedure to calculate DFLE is basically the same as for calculating life expectancy. However, estimating the duration of disease and infirmity in a lifetime is a big challenge.

A more popular version is the *health-adjusted life expectancy* (HALE), where the period of ill health is adjusted according to the severity of condition, and equivalent years in good health lost are computed in a way similar to the years of disability calculated for **disability-adjusted life years** (DALYs) lost. The process though is somewhat reversed in the sense that our interest now is in equivalent healthy years lived in place of healthy years lost. This is also popularly known as *healthy life expectancy*. According to World Health Organization (WHO) estimates, global HALE at birth in 2012 for males and females combined was 62 years in the world. This is 8 years lower than total life expectancy at birth. These are the equivalent years lost due to poor health. HALE at birth ranged from a low of 49 years for African males to almost 70 years for females in the WHO Western Pacific Region. Approximately 10% to 15% life is lost due to ill health in different parts of the world [1]. For complete methodology for calculating HALE, see the WHO document [2] on this topic.

## life table method, *see* survival curve/function

## likelihood, log-likelihood, and maximum likelihood estimates

We first explain what do we mean by likelihood and then describe log-likelihood and maximum likelihood estimates.

### *Likelihood*

Likelihood is the chance of occurrence, but it looks at an event that has already occurred. If you have three randomly selected persons in the sample and the first two are obese while the third is not, what is the chance of this happening when the chance of one being obese is 0.2? If the subjects are independent, this chance is $0.2 \times 0.2 \times 0.8 = 0.032$. This is the likelihood of this sample and depends on the value of the parameter—in this case, the probability 0.2 of occurrence in a single subject. Likelihood refers to the past events with known outcomes, whereas probability refers to the occurrence of future events.

In statistics, likelihood is a function of the **parameters** of the **distribution** from which the sample is drawn in the sense that the likelihood depends on what the value of each parameter is. For example, if the sample is drawn from a population where the values follow a Gaussian (Normal) distribution, the likelihood would depend on the values of the population mean $\mu$ and population standard deviation $\sigma$. Thus, the full name is *likelihood function* of the sample that signifies that it depends on the values of the parameters. The sample values $(x_1, x_2, \ldots, x_n)$ are considered known as just explained and the likelihood is obtained after these values are obtained. The values of the parameters are considered unknown as almost always is the case. Thus, likelihood is a function of the parameters with a fixed sample. For mathematical derivation, these sample values can continue to be denoted by $(x_1, x_2, \ldots, x_n)$, but these are no longer variables in a likelihood function; instead, they are fixed values. When the sample values are independent of one another, the likelihood function is the product of the individual probabilities of the values in the sample in accordance with the product rule of probabilities. In short, this is the probability of occurrence of the values obtained in the sample and is, thus, calculated after the sample values are available. If you have $n$ independent subjects in your sample with values $x_1, x_2, \ldots, x_n$, the likelihood is $L = P(x_1) \times P(x_2) \times \ldots \times P(x_n)$, where $P$ stands for probability.

The primary use of likelihood function in statistics is in finding those estimates of the parameters of the distribution that make the sample values most likely to happen. These are called the maximum likelihood estimates as explained in a short while. The second use of likelihoods is in the **likelihood ratio test** for which the following may be useful.

### *Log-Likelihood*

The product of probabilities in likelihood may have made it clear why taking the logarithm is useful. Since $L = P(x_1) \times P(x_2) \times \ldots \times P(x_n)$, $\ln L = \Sigma_i \ln P(x_i)$, which is now additive. Logarithm converts multiplications to additions. On top of this, many probabilities based on statistical distributions involve exponents, and taking log converts them to algebraically simple expressions. For example,

the likelihood when 3 deaths occur out of 9 cases is (by **binomial distribution**)

$$L = \frac{9!}{3!6!}\pi^3(1-\pi)^6,$$

where $\pi$ is the probability of death of a case. This gives $\ln L$ = constant + $3\ln\pi + 6\ln(1-\pi)$, which is linear and much easier to handle. However $L$, being the probability, is almost always less than 1 and $\ln L$ is negative. Thus, instead of $\ln L$, $-2\ln L$ is used, which not only makes it positive but also allows us to use the chi-square criterion for large $n$. This property is extensively used in statistical tests such as in the **likelihood ratio test**.

### *Maximum Likelihood Estimates*

Maximum likelihood can be easily explained by considering an example of a **binary variable**. Suppose 3 die out of 9 patients with the Ebola virus. The probability of death is unknown: let us denote this by $\pi$. As before, the **binomial distribution** tells us that the likelihood of 3 deaths out of 9 cases (if independent) is

$$L = \frac{9!}{3!6!}\pi^3(1-\pi)^6.$$

At what value of $\pi$ is this likelihood at a maximum? At $\pi = 0.1$, $L = 0.0446$; at $\pi = 0.2$, $L = 0.1762$; at $\pi = 0.3$, $L = 0.2668$; at $\pi = 0.33$, $L = 0.2731$, at $\pi = 0.35$, $L = 0.2716$; at $\pi = 0.4$, $L = 0.2508$. You can see that the value of $L$ is maximum when $\pi = 0.33$ and all other values of $\pi$ give a lower value of $L$. Thus, the maximum likelihood estimate of $\pi$ is 0.33. This incidentally is the same as the proportion of deaths observed in the sample (3 out of 9).

The method of maximum likelihood provides those estimates of the parameters of a model that make the sample values most likely. Since we cannot change the data, we change the estimate to see what estimate makes the likelihood maximum. For computational convenience, log-likelihood is maximized in place of the likelihood itself. Taking the logarithm tends to linearize the likelihood function as explained earlier. Instead of log-likelihood, $-2\ln L$ is used, which not only makes it positive but also is easy to handle as the distribution of $-2\ln L$ is known (chi-square) for many situations as also explained earlier. Because of the minus sign in this, those estimates are chosen in a model that minimizes $-2\ln L$, which is the same as maximizing $L$.

Maximizing involves differential calculus: maximum likelihood estimates are easily and exclusively obtained for distributions such as Gaussian; this is not so easy for some other distributions. Logistic regression is an example where the estimates of parameters that maximize the likelihood of such distributions are obtained by iteration. This is a trial-and-error method starting with some plausible estimates.

## likelihood ratio of a diagnostic test

Likelihood ratio of a diagnostic test is a measure of its utility in increasing or decreasing our confidence in the presence or absence of disease in a suspected case. Realize first that medical science is based on observations and a diagnosis can seldom be established with 100% confidence. Some uncertainty remains. Suppose the clinical picture in a patient gives you a confidence of 60% that a particular disease X is present in that patient. This is the *pretest probability* of that disease in that patient. A diagnostic test such as prostatic specific antigen is ordered for confirming or ruling out cancer of the prostate. If the result of this test is positive, your confidence in the presence of disease increases, although the confidence level still does not reach 100%, and if the result is negative, the confidence decreases. Likelihood ratio tells how much the confidence will increase or decrease after the result of the test is available.

The likelihood ratio is the ratio of the probability of a test result in those with disease and the probability in those without disease (this is not the same as used in a statistical likelihood ratio test). Since the test can be negative or positive, the likelihood ratio is also of two types—positive likelihood ratio denoted by LR+ and negative likelihood ratio denoted by LR–. These are defined as follows:

$$\text{LR}+ = \frac{\text{probability of positive test in persons with disease}}{\text{probability of positive test in those without disease}}$$

$$= \frac{\text{sensitivity}}{1-\text{specificity}};$$

$$\text{LR}- = \frac{\text{probability of negative test in persons with disease}}{\text{probability of negative test in those without disease}}$$

$$= \frac{1-\text{sensitivity}}{\text{specificity}}.$$

Sensitivity and specificity should be clear from these equations; otherwise, they are explained under the topic **sensitivity and specificity**. If sensitivity is 90% and specificity is 80%, then LR+ = 0.90/(1 − 0.80) = 4.5 and LR– = (1 − 0.90)/0.80 = 0.125. Note that LR+ is more than 1 in this example and LR– is less than 1. This would be the case in most situations. The interpretation of these ratios is something like this: A value of 10 or more of LR+ and 0.1 or less of LR– indicates that the test is extremely good in those whose disease status is known, a value of 5–10 of LR+ and 0.1–0.2 of LR– indicates moderate utility of the test, and all other values are regarded as not helpful. A value of 1 means that the test is not helpful at all, and a test with LRs around 1 should not be ordered as it does not help in enhancing your confidence in the presence or absence of disease in a suspected patient.

Since sensitivity and specificity are indicators of the inherent validity of the test, likelihood ratios are indicators of the inherent validity of the test as well. Despite this, the interpretation is mostly in terms of the likelihood of presence or absence of disease. LR is multiplicative for odds of disease but not for the probability of disease. For distinction between odds and probability, see the topic **odds** on this volume. LR+ measures the increased factor of odds of disease when the test is positive, and LR– measures the decreased factor of odds of no disease when the test is negative. In other words,

$$\text{posttest odds} = \text{pretest odds}*\text{LR}.$$

If the pretest probability of disease is 10%, the odds are 1:9 or 1/9, and if LR+ = 6, posttest odds = 6/9 by the equation just mentioned, or the probability is 6/(6 + 9) = 0.4. That is, the chances of disease being present after testing positive increase from 10% to 40%. Thus, LRs provide further insight into the inherent quality of the test. The procedure is to first covert the pretest probability to odds, multiply it with LR to get posttest odds, and finally convert the posttest odds back to probability.

## likelihood ratio test, *see also* likelihood, log-likelihood, and maximum likelihood estimates

Let us first understand likelihood ratio (LR) as used in this test. Consider a simple example of 3 deaths out of 9 cases of Ebola virus. Let the unknown probability of death be denoted by $\pi$, so that the **likelihood** of 3 deaths out of 9 by **binomial distribution** is

$$L = \frac{9!}{3!6!}\pi^3(1-\pi)^6.$$

If $\pi = 0.1$, this likelihood is 0.0446, and for $\pi = 0.2$, this is 0.1762, giving an LR of 0.1762/0.0446 = 3.95. Thus, the likelihood of $\pi = 0.2$ is just about four times as much as of $\pi = 0.1$ when the number of deaths is 3 out of 9 cases. You can see how LR tells us which value of the parameter is more plausible out of those that we have under comparison.

The LR test uses a similar argument but in a different context. This test is mostly used to check the statistical significance of the loss when some parameters of the model are deleted to achieve a relatively simple model. Since the parameters of a model are seldom known, we must estimate them, and the estimation of less number of parameters is easier. The estimates will be more reliable also because of the smaller number of parameters, and the model becomes simple that it could be easily expressed and easily used.

Although the LR test can be used in a variety of situations, it should be clear from the preceding explanation that it is best used for nested models; that is, the simpler model is part of the more complex model—the only difference being that the complex model has additional parameters. Removing one or more predictor variables will always reduce the likelihood (model will fit less well), but whether or not the loss is statistically significant is tested by the LR test. It is customary to call the more complex model as the full model and the simpler model as the reduced model. What is not clear from our explanation is that the LR test is an approximate test and valid only for large $n$ because of the use of chi-square as explained in a short while.

Suppose the full model has $M$ parameters and the reduced model has $K$ parameters ($K < M$). Thus, the null hypothesis under test is that the remaining $M - K$ parameters, which are examined for deletion, are equal to zero. If our data fail to reject this null, the conclusion is that the reduced model is not significantly different from the full model. That is, the loss in likelihood by deleting $M - K$ parameters is not statistically significant. In that case, we can go ahead with the reduced model. In a special case, $K$ could be zero, in which case the null is that all $M$ parameters in the full model are equal to zero. Now proceed as follows.

Replace the values of the parameters by their **maximum likelihood estimates** and obtain the value of the likelihoods for the full model as well as for the reduced model. Denote these likelihoods respectively by $L_1$ and $L_0$. Since the full model has more parameters, $L_1$ will be more than $L_0$. Calculate the ratio $\lambda = L_0/L_1$. This ratio will always be between 0 and 1. The smaller the value of $\lambda$, the higher is the loss in likelihood due to fewer parameters in the reduced model, and the reduced model becomes less plausible. It may look amazing, but it has been theoretically established that $-2\ln\lambda$ follows approximately a chi-square distribution with $(M - K)$ degrees of freedom for large $n$. Since $\lambda$ is less than 1, $\ln\lambda$ will be negative and $-2\ln\lambda$, called **deviance**, will be positive. The smaller the value of the LR, the larger will be the value of $-2\ln\lambda$. Thus, a large value of $-2\ln\lambda$ will reject the null hypothesis and will indicate that the reduced model is causing significant loss in likelihood—thus, the concerned parameters should not be deleted. Just as a reminder,

$$\text{Deviance: } -2\ln\lambda = -2\ln(L_0/L_1) = -2(\ln L_0 - \ln L_1) \sim \chi^2 \text{ with } (M - K) \text{ df.}$$

Also, recollect that the likelihoods are obtained by multiplication of the probabilities of individual values, the logarithm of which will be a sum. Thus, this transformation helps not only in achieving chi-square distribution but also in converting the ratio to a linear function. The ***P*-value** will be obtained by the chi-square distribution that will determine the statistical significance.

Consider a **logistic model** that predicts the probability of death of patients admitted in the intensive care unit (ICU) on the basis of age, sex, and severity score. This model will be of the type

$$\text{logit}(\pi) = \beta_0 + \beta_1\text{*age} + \beta_2\text{*Sex} + \beta_3\text{*(severity score)} + \varepsilon,$$

where $\pi$ is the probability of death of an ICU patient. If the interest is in finding whether sex has any significant effect on the probability of death, the null hypothesis is $H_0$: $\beta_2 = 0$. In this case, the full model is as stated above and the reduced model will be $\text{logit}(\pi) = \beta_0 + \beta_1\text{*age} + \beta_3\text{*(severity score)} + \varepsilon$. The $\beta$'s and their estimates in the reduced model will be different from the estimates in the full model although we are using the same notation. The full model has $M = 4$ parameters (including $\beta_0$), and the reduced model has $K = 3$ parameters. To test this null, obtain the likelihood $L_1$ of the full model and the likelihood $L_0$ of the reduced model, calculate $-2\ln\lambda$ as per the procedure just mentioned, and compare using chi-square with $(M - K) = 1$ df for finding the $P$-value. If this is less than the preset level of significance such as 0.05, reject the null; otherwise, not. When this null is rejected, the conclusion would be that sex does have a significant influence on the probability of death or, in other words, probability of death is different in males and females even when age and severity score are the same.

## Likert scale

This is a specific kind of tool for psychometric assessment of opinion, belief, and attitude. For a particular construct such as satisfaction from hospital services, a set of items is developed so that all aspects of that construct can be assessed. For hospital services, these items could be on competence of doctors, humanitarian nursing services, proper diagnostic facilities, and so on. A declarative statement such as "I am happy with the nursing services in this hospital" is made in each item and the respondent is asked to specify his level of agreement on generally a 5-point scale such as strongly disagree, disagree, indifferent (neutral), agree, and strongly agree. This is called a Likert scale.

You can have as many items in your questionnaire as is necessary, but a 10-item assessment looks enough to cover different aspects of a construct without burdening the respondent. Sometimes, many more items are devised for discussion by the group of stakeholders who selects "good" items. If the survey is repetitive, **item-analysis** of the responses of a previous survey is done to delete the redundant items and, possibly, to replace them with new ones. Internal consistency can be assessed by a measure such as **Cronbach alpha**. The construct validity of the items is assessed by **factor analysis**.

Response for each item is graded on the same scale—not necessarily 5-point—it could be 7-point, 9-point, or any other scale. Attempts should be made to ensure that the options from strongly disagree to strongly agree are equally spaced so that they can be legitimately assigned scores 0 to 4, 0 to 6, or 0 to 8 depending on the number of options. Instead, these scores can be scaled from −2 to +2, −3 to +3, −4 to +4, and so on. You may like to prefer 1 to 5, 1 to 7, 1 to 9, and so on. Various scoring patterns can give different results and the choice is yours as long as you can justify it.

Options for some items are reversed so that "strongly agree" is the first option and "strongly disagree" is the last option. Some items are negatively framed. This helps in eliciting a well-thought response instead of consistently selecting the same response such as "agree" for most items. At the time of analysis, such reversed items and corresponding scores are rearranged in the proper order.

Add the scores of all the items and get a total score for each respondent. This total is called the Likert score of that respondent for the construct under study. For a 10-item questionnaire and each item on a 5-point scale (0 to 4), the total score for each respondent will range from 0 to 40, which can be analyzed just as any other numerical measurement. Second, the analysis can be focused on each item. If item 3 is on satisfaction with diagnostic facilities, and these are $n = 50$ responses on a 0-to-4 scale for this item, you can calculate the median score to get an assessment of satisfaction with diagnostic facilities, or to compare it with, say, nursing services. Thus, an assessment regarding which component of the construct is adequate in the hospital and which needs strengthening can be made.

Rodriguez et al. [1] used a 1-to-5 Likert scale for assessing satisfaction of the patients, primary care providers, and specialty physicians with electronic consultation in a veteran setting in the United States. Wong et al. [2] used the same scale for patients' beliefs about generic medicines in Malaysia. These examples may give you an idea how Likert scale is used in practice.

## limits of agreement, *see* Bland-Altman method of agreement

## linear effect, *see also* linearity (test for)

First, the meaning of linear should be clear. Statisticians know it well, but some medical professionals may not be very clear. The term *linear* comes from line. If a relationship between $x$ and $y$ is linear, it really implies that as $x$ increases from $x$ to $x + 1$, the value of $y$ increases by the same quantity, no matter what the value of $x$ is within the values observed. The mathematical equation of a line is

$$\text{Line: } y = a + b*x.$$

In this equation, as $x$ becomes $x + 1$, $y$ becomes $y + b$; that is, $y$ always increases by $b$ whatever $x$ is. This is essentially interpreted as the same effect of $x$ on $y$ over the entire range of values of $x$ under observations, and not that $y$ values increase at a faster rate for some values of $x$ and at a slower rate for other values, or increase for some values of $x$ and decline for other values of $x$. If the risk of myocardial infarction (MI) increases by 1% as diastolic pressure increases by 5 mmHg, beyond 90 mmHg, it would be called linear when this rise in risk remains the same 1% whether the diastolic pressure increases from 100 to 105 mmHg or from 130 to 135 mmHg. If the risk of MI rises by 2% when the diastolic pressure increases from 130 to 135 mmHg but by only by 1% when it increases from 100 to 105 mmHg, the effect is not linear.

To understand linearity more clearly, consider Figure L.4a. This contains a graphical depiction of three linear equations: $y = -x$, $y = 5 + 2x$, and $y = 5 + 3x$. In the first equation, $a = 0$ and $b = -1$; in the second, $a = 5$ and $b = 2$; and in the third, $a = 5$ and $b = 3$. All these three are lines. The gradient or slope of the line is determined by the coefficient $b$ of $x$ and the intercept on the $y$ axis is the constant $a$ in the equation.

The steepest slope among these three lines is in the equation $y = 5 + 3x$. For this equation, if $x = 0$, $y = 5$; if $x = 1$, $y = 8$; if $x = 2$, $y = 11$; and if $x = 3$, $y = 14$. As $x$ increases by 1, $y$ always increases by the same quantity—in this case by 3. This is what defines line. The line $y = -x$ has a negative slope: as $x$ increases by 1, $y$ decreases by 1.

For more clarity, let us give it a twist and introduce a square term to the equation. This is called a *quadratic equation* and plots into a curve. Thus,

$$\text{Quadratic curve: } y = a + b*x + c*x^2.$$

For example, the graphical depiction of the equation $y = 5 + 3x - \frac{1}{3}x^2$ is shown as a dark curve in Figure L.4b. This is no longer a line because of the square term. Technically, this is called a *parabola*. The values of $y$ increase for $x$ values between –1 and 5 and decrease thereafter. This contradicts linearity. The variable $x$ has a nonlinear effect on $y$ in this case.

The linear effect of a characteristic on the outcome can also be understood as that part of the effect that can be explained by a line. In other words, this is the *component* that remains the same for each unit increase in the value of the characteristic. The linear effect from the just mentioned quadratic curve can be extracted in two different ways: (i) Best line that can represent the trend in the curve as shown in Figure L.4b. The linear component of the curve is best

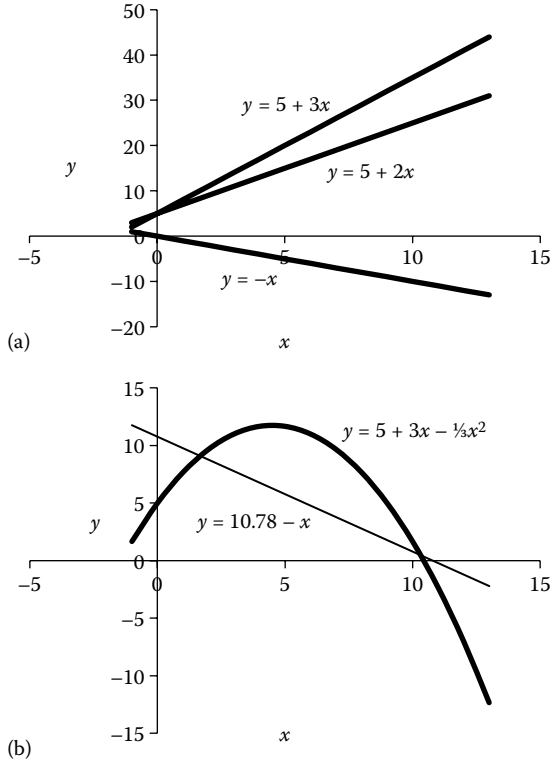

**FIGURE L.4** (a) Three lines and their equation. (b) Quadratic curve and best line.

represented by the line $y = 10.78 - x$, which shows that the linear component of the curve on the whole over the range ($x = -1$ to $+13$) is declining $y$ as $x$ increases. (ii) Although rarely used, the second is to ignore the quadratic term in the equation and say that the linear component of this curve is $y = 5 + 3x$ (deleting the term $-\frac{1}{3}x^2$). This would be difficult to interpret and not valid.

We have used easy examples of two variables $x$ and $y$ to explain linear effect, but the concept can be easily extended to many variables. The multiple linear regression model

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_3 x_K + \varepsilon$$

is a popular example. This model has $K$ regressor variables and each is considered to have a linear effect on $y$. This graphically depicts a hyperplane in multidimensions, which, in three dimensions (two variables on the left-hand side), is reduced to a plane sheet. Such a linear regression model is not without limitations as most medical parameters have a nonlinear effect, but it does capture the linear effect of the $x$'s on $y$. In the context of regression models, the term *linear* does not have this narrow sense as made out in this section but has a wider meaning since linearity in regression refers to linearity in parameters. This linearity includes curvilinear models such as quadratic curve discussed in this section. For a brief on this, see the topic **linearity (test for)**.

## linearity (test for), *see also* linear effect

For the meaning of linear, see the topic **linear effect**. There is no doubt that hardly any relationship in medicine is truly linear. Yet, a linear relationship is the most commonly studied form of relationship in health and medicine. This simplification seems to work fairly well in many situations but can destroy an otherwise very clear relationship in others. Square or such other terms of the regressors are rarely included in medical investigations and this can cause fallacies in some situations. Such terms should be included where needed.

In a narrow sense of linearity, it defines a line (or a hyperplane in multiple dimensions), but broadly, and strangely, statistical linearity also includes a curve such as a parabola. This is so when the square term is considered just another variable; that is, $x^2$ is denoted by $x_2$. For example, the quadratic equation $y = 5 + 3x - \frac{1}{3}x^2$ that is graphically a parabola (see Figure L.4b) can also be written as $y = 5 + 3x_1 - \frac{1}{3}x_2$, where $x_2$ is $x^2$, and this is linear in $x_1$ and $x_2$. This is categorized as curvilinear instead of nonlinear. Statistically, a relationship is nonlinear when any coefficient of the regression equation is nonlinear. Thus, the equation $y = a + bx_1 + b^2x_2$ is statistically nonlinear since the coefficient $b^2$ is nonlinear. This equation puts the restriction that the coefficient of $x_2$ is the square of the coefficient of $x_1$.

Researchers tend to look for one equation—either linear, curvilinear, or whatever—for the entire range of a measurement. Left ventricular ejection fraction (LVEF) ranges from 10% to 90%—less than 50% is considered a coronary risk and more than 60% does not provide any benefit. If coronary risk is plotted against LVEF, it will be flat after 60%. One model over the entire range 10% to 90% would not capture this phenomenon. For measurements that show one pattern for $x \le a$ and another for $x > a$, a **spline** function is needed. Without this, the results could be fallacious. Realize however that this could be used only if you know, or at least suspect, that the patterns could be different over different ranges of $x$. If this is not known, the fallacy can continue for a long time.

How do you find out whether the relationship between two or more medical variables can be considered linear or not? In the case of two variables, you can plot the scatter diagram of $y$ versus $x$, overlay a trend if needed, and examine if this trend is close to a straight line. However, this is inexact and can be subjective. Other methods can be used depending on the context. In a simple case when there are only two variables and the model has a square or any other term, just test the statistical significance of such a term. This can be done by the **Wald test** just as for any **regression coefficient**. If this is statistically significant, conclude that the relationship is not linear (in the narrow sense as earlier mentioned) but is curvilinear or nonlinear. In this case, the usual (Pearsonian) **correlation coefficient** would be low since this measures the strength of a *linear* relationship. If the correlation coefficient between $y$ and $x$ is high, you can be fairly confident that the relationship is mostly linear. Some statisticians may advise testing the statistical significance of the correlation coefficient but that is not a right procedure in this case since a low correlation in a clearly nonlinear relationship could also be statistically significant when the sample size is large. Another method is to divide the range of $x$ into three or four plausible categories and see if the regression coefficient for each range is nearly the same.

In the broad statistical sense, and when many variables are involved, an easy method to check linearity is to look at the value of the square of the **multiple correlation** coefficient ($R^2$). Note that this is calculated by using a multiple linear regression in the broad sense that all regression coefficients are linear. If the value of $R^2$ is high, say, exceeding 0.7, you can be quite confident that the relationship is approximately linear. Examples are available where this is not true, but those are exceptions. The other is to construct a model with whatever nonlinearity you suspect and compare the **coefficient of determination** ($\eta^2$) from this model with the $R^2$ obtained from the corresponding linear model and consider that the relationship is approximately linear if the difference is minor. For a formal statistical test, use the **likelihood ratio test** by using likelihoods of the two models.

A continuous regressor is generally entered as such in a **logistic regression** that implies that the effect of this continuous $x$ is linear on the **logit** of the outcome. Few researchers care to test if this is really so. Minor deviations do not matter, but U-shaped or J-shaped relationships can drastically affect the regression equation. For example, the regression between logit of incidence of coronary heart disease with post-glucose insulin in the general population is J-shaped in the sense that the incidence is high (even when converted to logit) both at low values of insulin and at very high and high values of insulin. To test linearity, check the plot of residuals against the regressor $x$. If the relationship is genuinely nonlinear, divide the values of $x$ into few rational categories and use appropriate scores, or use splines as already advised and fit separate regression for low values, middle values, and high values.

If you have proportions of "positive" response in different categories, such as percentage anemic in various parity women, linearity of trend in proportions with increasing parity can be tested by the **Cochran test for linear trend**.

## linear models, *see* general linear models

## linear regression, *see also* simple linear regression, multiple linear regression

Prediction of a dependent variable $y$ by a set of regressors (or independent variables) may take any of several different forms. One that is relatively simple to comprehend and most commonly studied is the linear form. For $K$ regressors, this is expressed as

$$\hat{y} = b_0 + b_1 x_1 + b_2 x_2 + \cdots + b_K x_K,$$

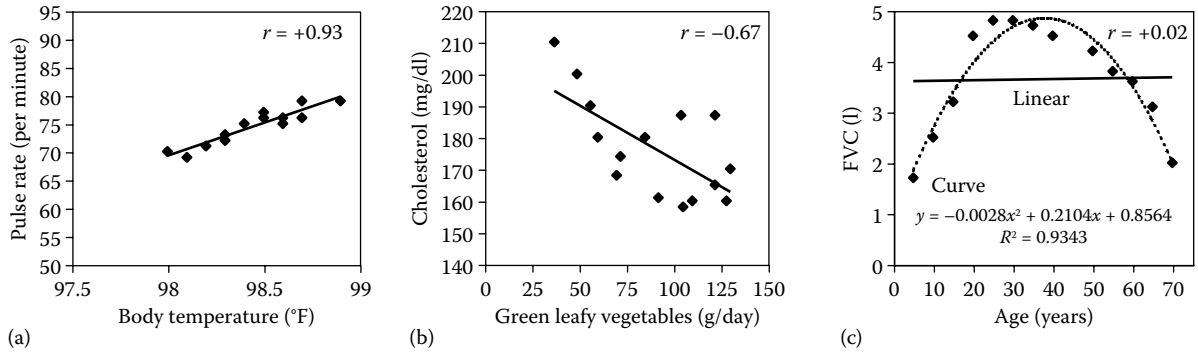

**FIGURE L.5** (a) Good linear regression of pulse rate on body temperature; (b) linear regression of cholesterol level on intake of green leafy vegetables due to two specific points; and (c) inappropriate linear regression of forced vital capacity (FVC) on age.

where $\hat{y}$ is the predicted value. This is linear in the coefficients $b_1$, $b_2$, …, $b_K$. Geometrically, this equation defines a hyperplane in $(K + 1)$-dimensional space and reduces to a line when $K = 1$. When there is only one independent variable $x_1$, the equation is $\hat{y} = b_0 + b_1 x_1$, which depicts a line. It is more convenient to write it as $\hat{y} = a + bx$, which is the usual equation for a **simple linear regression**. With $K$ independents, this defines **multiple linear regression**. The constants $b_1$, $b_2$, …, $b_K$ in this equation are called regression coefficients, and $b_0$ is called the intercept. These in fact are estimates of actual regression coefficients in the target population. The corresponding regression parameters in the population are denoted by $\beta_0$, $\beta_1$, $\beta_2$, …, $\beta_K$, respectively. It is important to realize that a linear model is linear in parameters and not necessarily linear in $x$'s. For details, see the topic **linear effect**. In the conventional regression setting, both the dependent set and the set of independents are quantitative, but that is not necessary for independents. Consider the following two examples that illustrate how simple and multiple linear regressions are used in practice.

Body surface area (BSA) determination is useful in several applications related to the body's metabolism such as ventilation, fluid requirements, extracorporeal circulation, and drug dosages. Current [1] found that this could be adequately estimated by using weight (Wt) in well-proportioned infants and children of weight between 3 and 30 kg. The regression equation obtained is

$$\text{BSA} = 1321 + 0.3433(\text{Wt}),$$

where BSA is in square centimeters and Wt is in grams. This is a simple linear regression and shows that as weight increases by 1 g, BSA increases on average by 0.3433 cm. The left-hand side is in fact an estimate, although the hat (^) sign is removed for simplicity. Here, $b_0 = 1321$ and $b_1 = 0.3433$. As a side note: according to the authors, a simplified version of this regression is BSA = (Wt + 4)/30, where BSA now is in square meters and Wt is in kilograms.

Marquis et al. [2] studied length (in centimeters) of 15-month-old (L15m) Peruvian toddlers living in a shantytown of Lima. This length was studied in relation to length at 12 months (L12m), time interval (TI) in months between 12- and 15-month measurements (as per the authors), breast-feedings (BFs) per day between 12 and 15 months of age, and its interaction with a low diet/high diarrhea (LDHD) combination if present. The following equation was obtained:

$$\text{L15m} = 74.674 + 0.976(\text{L12m}) + 0.860(\text{TI}) + 0.043(\text{BF}) - 0.157(\text{BF}*\text{LDHD}),$$

where the last term represents an **interaction**. This also is a linear regression. The authors also studied other regressors, but this equation includes only those that are relevant for our illustration. Of these, BF was not significant ($P > 0.3$). The associated signs show that L12m, TI, and BF had a positive contribution to L15m, but the interaction BF*LDHD had a negative contribution; that is, when low diet/high diarrhea is present with a high number of breast-feedings, the length of the child is less. This was part of an investigation to show that increased breast-feeding did not lead to poor growth but poor health led to increased breast-feeding—an example of what authors called **reverse causality**.

Linear regression is an overused model in health and medical setups. Whereas the relationship between pulse rate and body temperature is indeed linear (Figure L.5a), this may not be so for other measurements. In Figure L.5b, the trend looks like a decline in cholesterol with increased intake of green leafy vegetables just because of the first two points in the scatter. If these two points are ignored, the other points are randomly scattered with no visible trend. This highlights the need to critically examine statistically obtained relationships and not take on its face value. Even more daunting is the relationship between forced vital capacity (FVC) and age from 5 to 70 years (Figure L.5c). FVC increases up to the age of 35–40 years in this figure and declines thereafter. If you try to fit a linear regression of FVC on age 5 to 70 years, it will have a nearly zero slope, indicating that as age increases, FVC remains constant. This absurd result is due to a completely inappropriate application of linear regression. The scatterplot clearly indicates that a curve should be fitted to these data instead of a line. This comes under the rubrics of **curvilinear regression**. This illustrates why there is a need to distinguish between linear models in a narrow sense (linear in $x$'s) and linear models in a broad sense, which includes curvilinear relationships (linear in parameters).

## line diagrams

A line diagram is used to show the trend of one variable over another by means of a line or a set of lines. For example, Figure L.6a shows the trend of infant mortality rate against the socioeconomic status of

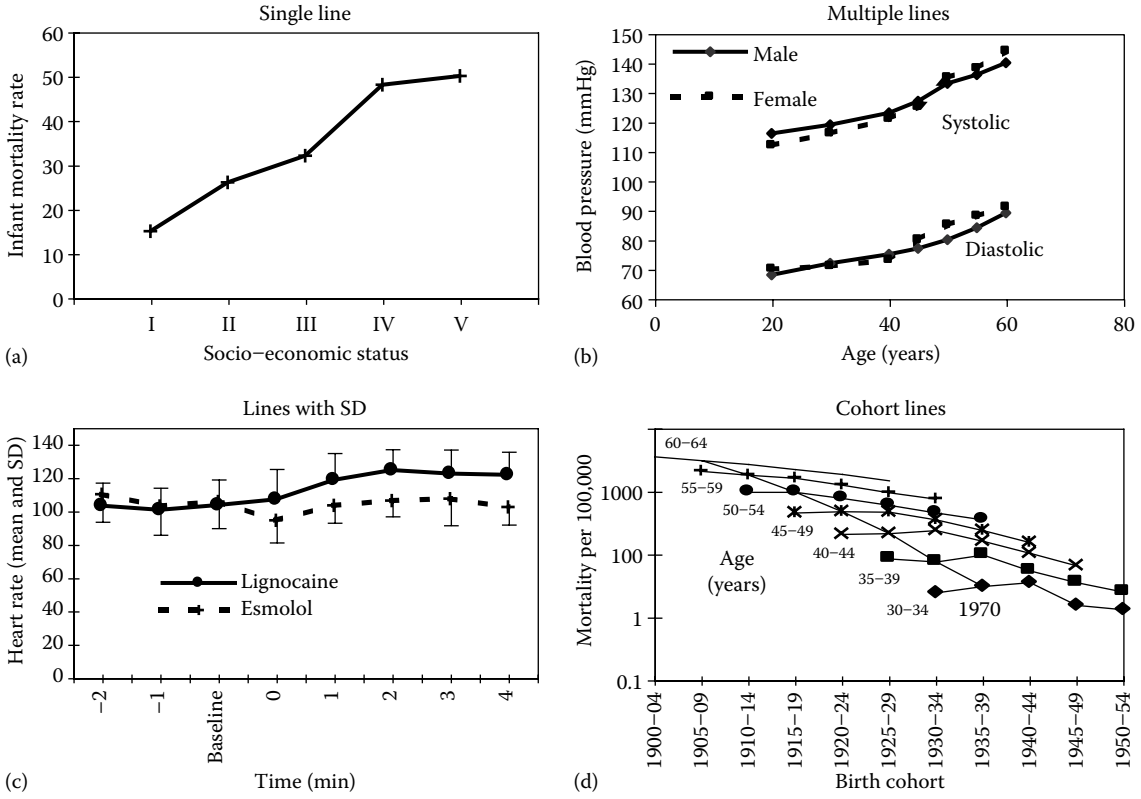

**FIGURE L.6** Different types of line diagram: (a) Infant mortality rate per 1000 live births by socioeconomic status in an area. (b) Trend of average systolic and diastolic BP over age in males and females in a general population of adults. (c) Heart rate in women with pregnancy-induced hypertension undergoing cesarean section—esmolol and lignocaine groups. (d) Trend in age-specific coronary heart disease mortality per 100,000 in Australia from 1960 to 1992 within 5-year birth cohorts for females aged 30–64 years (*y* axis is on logarithmic scale). (From Wilson A, Siskind V. *Int J Epidemiol* 1995;24:678–84. http://ije.oxfordjournals.org/content/24/4/678.full.pdf. Permission to be obtained from Oxford University Press.)

families in a developing country. The plotted points are joined by a line. It can be called a time plot when the *x*-axis is time. It continues to be called a line diagram even when the representation is by a curve instead of a straight line. The variable on the *y*-axis could be an average as in Figure L.6b between age and mean blood pressure. Although not clearly brought out in this diagram, a line diagram can plot the points for unequally spaced values on the *x*-axis. This facility is not available in a **bar diagram**. Such adjustment can be done when the *x*-axis is on a metric scale but not when it is on an ordinal scale. The question of trend does not arise in the case of the nominal scale because then the categories do not have any particular order.

Two or more lines can be drawn in one diagram (Figure L.6b), but more than five lines make it cluttered and difficult to understand. Another complexity arises when the standard deviation (SD) of the variable for each point on the *x*-axis is shown on the *y*-axis by vertical lines on either side as in Figure L.6c. This gives an indication of the variation present in the data. Realize for this that representation of 1*SD on either side can be fallacious because the actual variation is much more.

An interesting representation by line diagram could be of mortality in several cohorts. Figure L.6d shows the age-specific coronary heart disease mortality rate in different 5-year birth cohorts for females in Australia from 1910–1914 to 1950–1954 [1]. Note that the cross-sectional lines can be used to show the age trend in mortality in a particular group of years. One such line is drawn for the years 1970 ± 5. This is because various cohorts attain different ages in the same calendar year.

## linkage, *see* record linkage

## link functions

This topic is directly related to **generalized linear models**. You may be aware that ordinary quantitative regression covered by **general linear regression** models (which includes regression, analysis of variance, and analysis of covariance) requires that the residuals have a Gaussian (Normal) distribution. This requirement is dispensed with in generalized linear models where most other distributions can be studied through the link functions that tend to convert the residuals to a Gaussian form, at least approximately. These link functions also tend to make linear relationship more plausible and also help in stabilizing variances.

Consider, for example, the number of deaths in a critical care unit of a large hospital in a day, which is a discrete variable with a small number of possible values and is likely to have a highly skewed distribution in the sense that the number of deaths would be 0, 1, or 2 on most days but can even go up to 5 or 6 on isolated days. If this is the dependent variable in a regression, the residuals are not likely to follow a Gaussian distribution. This kind of count quite often follows a

**TABLE L.3**
**Link Functions for Various Distributions**

| Distribution | Type and Range of $y$ | Name of Link Function | Link Function |
|---|---|---|---|
| Normal | Real $-\infty < y < \infty$ | Identity | $\mu$ (No transformation) |
| Poisson | Positive integer 0, 1, 2, … Or, rate ($y/t$) | Log | $\ln(\mu)$, $\sqrt{n}$ |
| Binomial | Binary 0,1 | Logit | $\ln\left(\frac{\pi}{1-\pi}\right)$ |
| | Binary $<a$, $\geq a$ (underlying Gaussian) | Probit | $\Phi^{-1}(\pi)$ |
| | Binary 0,1 (highly skewed) | Complementary log–log | $\ln(-\ln(1-\pi))$ |
| Multinomial | Nominal | Logit | $\ln\left(\frac{\pi}{1-\pi}\right)$ |
| Gamma | Real but positive $0 < y < \infty$ | Inverse | $\mu^{-1}$ |

*Note:* Link functions are expressed for the population mean of the dependent variable instead of the variable itself.
$\pi$ is the probability of "success."
$\Phi$ is the notation for the Gaussian probability.

Poisson distribution with the variance nearly the same as the mean. When this is so, use transformation ln($y$), where $y$ is the number of deaths in a day. You can obtain $y$ for several hospitals or several days in a hospital, but the condition of independence must be fulfilled for regression model to be valid. Suppose the regressor of interest is the severity of the condition at the time of admission. The objective is to find how much the number of deaths is affected by the different combination of severities of the patients. On any day, there might be $x_1$% serious cases, $x_2$% critical cases, and $x_3$% gravely critical cases. This relationship can be examined by ln (natural logarithm) link as just stated. Similar links are available for many other distributions (Table L.3). While all other links may be readily clear, a word about probit link will help. This link is used when the underlying variable is continuous and has a Gaussian distribution but is observed in two exclusive categories. This may be like the bilirubin level in healthy subjects and the cutoff such as 20 mg/dL is used to dichotomize the subjects. Complementary log–log is used for highly skewed binary variables such as smokers and nonsmokers among adolescents where nonsmokers hugely outscore smokers.

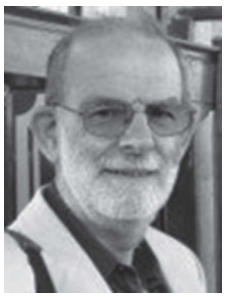
## LMS method

Lambda–Mu–Sigma (LMS) is a popular method of constructing smooth **centile** curves describing growth in children and such other parameters that change with time. The LMS method was initially developed by Tim Cole in 1990 [1]. We explain this for growth curves. Application to other setups such as bone mineral density at different ages is similar.



Tim Cole

The construction of **growth charts** involves two distinct steps: (i) correctly finding various percentiles at different ages and (ii) converting the plot of percentiles versus age to a smooth curve. The first becomes difficult because most growth parameters (such as weight and height) rarely follow a Gaussian pattern; thus, finding the correct percentile is complicated. The second is challenging because smoothing can lose the real points of troughs and peaks that define children's growth pattern. The LMS method is designed to overcome most of these problems. "Most," first because this method fails to address the problem of deviations in **kurtosis** that also occurs in the distribution of many growth parameters, and second because now better methods are available for the smoothing than used in the LMS method. For these, an improvement called the **BCPE method** is used as separately described. Indrayan [2] has written a seminal paper on the LMS and BCPE methods and how they are used, with the aim of demystifying the statistics around these methods.

A large number of other methods are also available for constructing centile curves. Borghi et al. [3] have reviewed 30 such methods, but the LMS methods became kind of the standard method until the BCPE method appeared. The BCPE method is more complicated and many researchers continue to use the LMS method because of its relative simplicity.

The fundamental quantity in finding the centiles is the ***Z*-score**. This is the deviation of the value from its mean in standard deviation units. In notations, this is $Z = (y - \mu)/\sigma$. If the distribution is **Gaussian** (Normal), $Z = 1.96$ corresponds to the 97.5th percentile and $Z = 1.28$ corresponds to the 90th percentile. Software packages give these percentiles easily for any value of $Z$. The difficulty arises when the distribution is non-Gaussian. Several types of deviations from Gaussianity can occur, but most growth parameters are nice to follow a unimodal pattern for each age. That is, if you measure the weight of 400 healthy children of age 3 years, the distribution will have one peak. However, the distribution is not likely to be symmetric and it may not have normal kurtosis. Generally speaking, **skewness** |Sk| > 0.5 and kurtosis |Kurt| > 1.0 are considered high. The statistical significance of these values can also be tested. In these situations, $Z$-scores do not have a valid interpretation. The LMS method takes care of the skewness but not of the kurtosis.

The conventional method that deals with skewness is the use of transformations such as square root or square, generally after dividing each value $y$ of the measurement under consideration by its central value $\mu$, that is, after calculating $y/\mu$. This central value could be mean or median or any other value. Now, the square-root transformation is $(y/\mu)^{0.5}$ and the square transformation is $(y/\mu)^2$. In general, the power transformation is $(y/\mu)^\lambda$, $\lambda > 1$ is for correcting left skewness, and $\lambda < 1$ is for correcting right skewness; the exact value of $\lambda$ depends on the extent of skewness. If the distribution is already Gaussian, no correction is required, and then $\lambda = 1$.

The LMS method is an improvement over these transformations and uses the following:

$$\text{(A)} \quad Z_{\text{LMS}} = \frac{1}{\sigma_L \lambda}\left[\left(\frac{y}{\mu}\right)^{\lambda} - 1\right], \ (y, \lambda, \mu, \sigma L \neq 0),$$

where $\sigma_L$ is a measure of dispersion ($\sigma_L$ is generally the **coefficient of variation**: $\sigma/\mu$). The original measurements such as weight in our child growth example may have any skewed distribution with single mode; the distribution of $Z_{\text{LMS}}$ with this transformation will be standard normal and this will give the correct $Z$-score for calculating the percentile provided the kurtosis is already zero. Note the involvement of **l**ambda ($\lambda$), **m**u ($\mu$), and **s**igma ($\sigma_L$), making it an LMS method. The rationale of $(y/\mu)^{\lambda}$ is already explained and $\sigma_L$ is in the denominator just as is $\sigma$ in $z = (y - \mu)/\sigma$. Note that when $\sigma_L = \sigma/\mu$, and $\lambda = 1$, the equation above reduces to the usual $Z$-score $(y - \mu)/\sigma$. The reason that coefficient of variation (CV) is used in place of the usual $\sigma$ is that $\sigma$ tends to rise with age for many measurements, whereas CV remains nearly constant for different age-groups.

The first difficult part is to estimate the values of $\lambda$, $\mu$, and $\sigma_L$. Explicit forms for estimating these parameters do not exist, and special software (LMSchartmaker of the Medical Research Council, UK, is the software package of choice for this purpose) is used to find the values of these parameters that maximize the likelihood of the transformed values of the sample that have come from a standard Gaussian distribution with mean = 0, SD = 1, and skewness = 0. Software will find those values of $\lambda$, $\mu$, and $\sigma_L$ that make the distribution of $Z_{\text{LMS}}$ closest to standard normal. However, the estimates of $\lambda$, $\mu$, and $\sigma_L$ are iteratively revised by the method of penalized likelihood proposed by Cole and Green [4] so that the curves for these estimates against age are smooth. The **Akaike information criterion** is used to test goodness of fit so that a higher number of parameters are penalized and the model can remain relatively simple. Sometimes, age is also transformed into $\sqrt{\text{age}}$, which stretches younger (<1 year) and shrinks older (>1 year) age and takes care of the steep rise in growth parameters during the infantile period. The software LMSchartmaker also has provision for this and to provide curves for different percentiles.

There is a mathematical relationship between usual $Z$ and LMS percentile:

$$\text{(B)} \quad p\text{th percentile of } y = \mu(1 + \lambda\sigma_L Z_p)^{1/\lambda},$$

where $Z_p$ is the usual value from Gaussian distribution corresponding to the $p$th percentile. For example, for the 75th percentile, $Z_p = 0.675$. If the mean weight of children of age 2 years is 13.6 kg, and if $\sigma_L = 0.147$ and $\lambda = 0.30$ from the LMSchartmaker, then the 75th LMS percentile = $13.6 \times (1 + 0.30 \times 0.147 \times 0.675)^{1/0.30} = 13.6 \times 1.103 = 15.0$ kg. Once estimates of $\lambda$, $\mu$, and $\sigma_L$ are obtained, Equation B shows that calculating percentiles at any particular age for a skewed distribution is very easy. Since the curves of the estimates of $\lambda$, $\mu$, and $\sigma_L$ are already smoothed, the percentiles so obtained are likely to follow a smooth curve. To overcome the possibility of having not-so-smooth growth curves via the LMS method, Centers for Disease Control and Prevention of the United States used a type of inverse method. They first obtained the agewise percentiles, smoothed these curves, and then estimated the LMS parameters based on the smoothed percentile curves [5].

## LMSP method, *see* Box-Cox power exponential (BCPE) method

## loadings, factor

The concept of loadings arises while performing **factor analysis**. The statistical purpose of factor analysis is to obtain each observed variable as a combination of a few unobservable factors, that is,

observed value of a variable = linear combination of factors + error.

If the observed variables are $x_1, x_2, \ldots, x_K$, the factor analysis seeks the following:

$$\left.\begin{aligned} x_1 &= a_{11}F_1 + a_{12}F_2 + \cdots + a_{1M}F_M + U_1, \\ x_2 &= a_{21}F_1 + a_{22}F_2 + \cdots + a_{2M}F_M + U_2, \\ &\vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \\ &\vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \\ x_K &= a_{K1}F_1 + a_{K2}F_2 + \cdots + a_{KM}F_M + U_K, \end{aligned}\right\},$$

where $F_1, F_2, \ldots, F_M$ are the $M$ unobservable factors common to $x_k$'s, and $U_k$'s ($k = 1, 2, \ldots, K$) are called unique factors. Unobservable common factors are also called *constructs*.

The coefficients $a_{km}$ ($k = 1, 2, \ldots, K$; $m = 1, 2, \ldots, M$; $M << K$) are estimated by the factor analysis procedure. These coefficients are called loadings and measure the importance of the factor $F_m$ in the variable $x_k$ on a scale zero to one when sign is ignored. The loadings close to −1 or +1 indicate that the factor strongly affects the variable, and the loadings close to zero indicate that the factor has a weak effect on the variable. When a loading is very small, say less than 0.20, the corresponding factor can be dropped from the above equation. Thus, different variables may contain different sets of factors. Some factors would overlap and would be present in two or more variables.

The factor's equations differ from the usual multiple regression equations because the $F_m$'s are not single independent variables. Instead, they are labels for a combination of variables that characterize these constructs. They are obtained in such a manner that they are uncorrelated with one another. The statistical method of **principal components** is generally used for this purpose. You may like to see Kline [1] for details. A relevant statistical software package would easily provide an output, but the software package may ask you to specify different aspects of the methodology. This exercise should be undertaken by only those who understand the intricacies. Do not hesitate to obtain the help of a biostatistician when needed.

Kim et al. [2] studied reliability and validity of the Korean version of the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire to assess chemotherapy-induced peripheral neuropathy (CIPN). This questionnaire had 20 items, but the factor analysis confirmed three dimensions of CIPN, namely, the sensory, motor, and autonomic. These are the factors in this example. The factor loadings in these 20 items ranged from 0.38 to 0.85. Thus, none of the factors was unimportant for any item in this questionnaire.

## location (measures of)

In statistics, location refers to the physical location of the **distribution** of the variable under consideration on the *x* axis. In a statistical distribution, the *x*-axis is the one that plots the values of the characteristic. For example, direct bilirubin is lower than indirect bilirubin; thus, the distribution of direct bilirubin would be located to the left of the distribution of indirect bilirubin. Figure L.7 shows two distributions that differ in location but are otherwise identical.

Measurement of location requires that we concentrate on some specific values or some representative value. If we restrict ourselves to central values, the statistical measures are **mean, median, and mode**. **Geometric mean** and **harmonic mean** are also measures of central location, which are separately explained. However, the interest sometimes is not in any central value but in a threshold below which, say, 90% of values lie. This is the 90th **percentile** and is also a measure of location, though not of central location. Similarly, tertiles, quartiles, and deciles also are measures of location of a distribution. All these are explained under the topic **quantiles**. Figure L.7 shows how 90th percentiles of the two distributions differ when they differ in location and not in any other feature.

## logarithmic scale/transformation

In case you are not aware, logarithm (abbreviated as log) is a mathematical function that converts a very large number to a very small number. It depends on the "base" used for this conversion. If nothing is stated, base is taken as 10. If $y = 10^x$ then $\log y = x$. This is the definition of logarithm. Thus, log of 100 is 2, log of 1000 is 3, and log of 1,000,000 is 6. See how logarithm sharply attenuates the number as the number becomes large. Also note that log of 1 is zero and the log of values less than 1 is negative, reaching $-\infty$ for log of zero. Thus, values between 0.001 and, say, 1000 are converted to –3 to +3. Also, $\log(a \times b) = \log a + \log b$. Thus, multiplicative values become additive—a great mathematical convenience. The other log required in biostatistics is to the base *e*. This is called the Naperian base and the log taken with this base is called the *natural log*, denoted by ln. This base helps in mathematical manipulations such as integration and differentiation that base 10 does not do. This also has similar properties, and neither of them can be used for negative values. If you have negative values and you think that log transformation would help, add slightly more than the maximum negative value (minimum value in mathematical language) to all the values so that none is zero or negative. This is readjusted to the original values at the time of making inference.

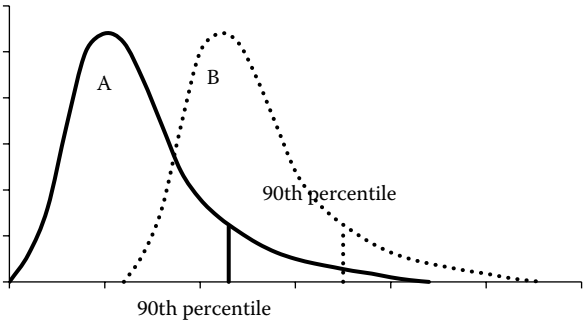

**FIGURE L.7** Different locations of two distributions.

Where do we use log-scale in health and medicine? It is used for any characteristic that is multiplicative in nature. Radiation dose is a common example. This is just approximately 5 μSv for dental x-ray, 100 μSv for chest x-ray, 4000 μSv for mammogram, and 10,000 μSv for average computed tomography scan. In conventional radiotherapy, this can go up to 2,000,000 μSv. Acidity measured in pH (e.g., in blood) also has this feature. Each whole pH value below 7 is 10 times more acidic than the next higher value; for example, a pH of 6 is 10 times more acidic than a pH of 7. The same holds true for pH values above 7, each of which is 10 times more alkaline than the next lower whole value; for example, a pH of 9 is 100 times more alkaline than a pH of 7. Titers also have a similar feature. All these are expressed in log units.

In biostatistics, log-scale is used for values that have an extremely wide range. Generally, these are those values that steeply go up or steeply go down in different subjects or in different situations. Logarithmic transformation in these setups reduces very large numbers to smaller numbers that can be easily represented or talked about. See the figure in the topic **line diagram** where mortality rate on the vertical axis is shown in log-scale. This rate in that figure has steeply come down from what it was in 1900. In this kind of figure, if we have to show a mortality rate of 1000 (per 100,000) and also of 1 by the usual (linear) scale, we need an extremely long vertical axis that may not even fit a page. Log-scale is a great convenience in such cases. This is illustrated in Figure L.8 that shows Ebola virus cases in West Africa in the first 9 months of epidemic on the usual (linear) scale in the left panel and on logarithmic scale in the right panel. The exponential rise is clear. If the same trend continued, the number of cases after 1 year of epidemic was projected to be nearly 80,000 [1]. To show this, the vertical axis on the linear scale in the left panel will have to be extended to a steep height but is easily shown on log-scale in the right panel. Although the log-scale conceals the high speed with which the cases were growing and expected to grow, the shape becomes amenable to modeling.

Suh et al. [2] used logarithmic transformation of the thickness of the retinal nerve fiber layer to study relationship with visual field indices. In this case, log-scale helped to linearize the relationship. Tomitaka and Furukawa [3] also used log-scale for major depressive disorder durations that ranged from a month to several years—again to get a linear relationship. There are many such examples in the literature.

There are several other statistical uses of log-scale. The variables that have highly **skewed** distribution on the positive side are transformed on log-scale to achieve relative symmetry, possibly Gaussian distribution. This helps in using usual statistical methods on the transformed values. The second common use is in studying ratios and proportions. Log of odds ratio and log of relative risk linearize them and make them additive—thus raising the specter of applicability of the **central limit theorem**. This theorem is for additive indices

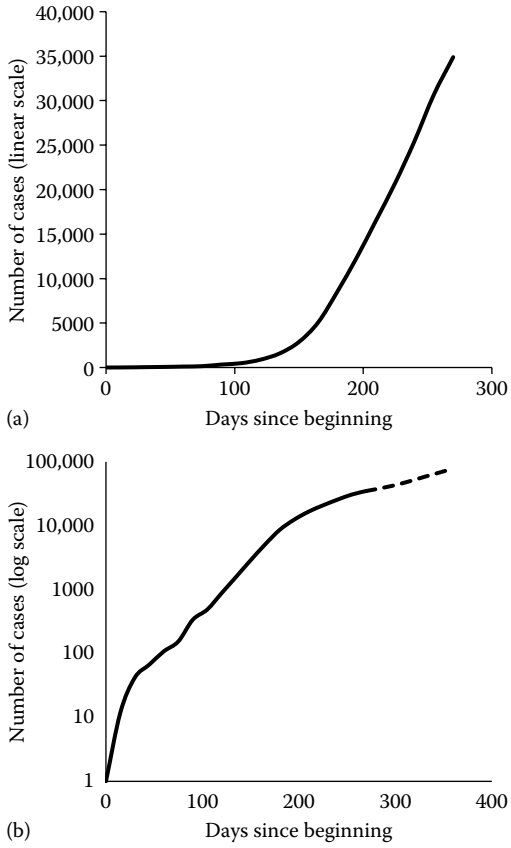

**FIGURE L.8** Ebola virus cases in the first 9 months in West Africa: (a) linear scale (smoothened curve); (b) log-scale with projection at 1 year since inception.

and helps us to legitimately fall back on Gaussian distribution. Third, proportional hazards such as in a **Cox regression** can be studied as difference (in place of ratio) after log transformation. Fourth, the Cox regression also assumes that the covariates affect the hazard in a multiplicative manner. This means that when two factors are simultaneously present, the hazard multiplies instead of adding. This property (multiplication) amounts to additivity in logarithm terms.

The following precautions are required when interpreting the log-transformed data:

- If $\ln(y)$ has a Gaussian distribution, its mean is $\ln(\mu + \frac{1}{2}\sigma^2)$ and not $\ln(\mu)$. Thus, antilog of the mean of $\ln(y)$ will not give you the mean of $y$. For log-transformed values, use geometric mean (GM) in place of arithmetic mean; that is, the arithmetic mean of log values is the log of GM. If the interest in arithmetic mean persists, correct the mean by adding $\frac{1}{2}\sigma^2$.
- When the dependent variable in a regression is log-transformed, the regression coefficient $\beta$ measures approximate *proportionate* change (better understood as percentage change when multiplied by 100) in $y$ per unit change in $x$. This can be seen as follows: When $y$ is log-transformed, the simple linear regression equation is $\ln(y) = a + bx$. When 1 is added to $x$, that is, $x_1 = x_0 + 1$, then $\ln(y_0) = a + bx_0$ becomes $\ln(y_1) = a + bx_0 + b = \ln(y_0) + b$, and $\exp(b) = y_1/y_0$.
- If interested in percentage change in $y$ when $x$ increases by 1, this is $100*(y_1 - y_0)/y_0 = 100*y_1/y_0 - 1 = 100*[\exp(b) - 1]$. Thus, it is not directly obtained by the regression coefficient $b$. However, in most situations, the coefficient $b$ would be extremely small because of log transformation, and in that case, $\exp(b) - 1 = b$ approximately, and you would be safe in making the usual conclusion.
- If both $x$ and $y$ are log-transformed, the regression will give an approximate percentage change in $y$ for a percentage change in $x$.
- All these arguments can be extended to multiple linear regression while considering individual variables.

## logistic coefficients (CI and test of $H_0$)

This section presumes familiarity with the basics of **logistic regression**. If not, review that topic in this volume. For $K$ regressors, this regression takes the form

$$\hat{\lambda} = b_0 + b_1 x_1 + b_2 x_2 + \ldots + b_K x_K,$$

where $\hat{\lambda} = \ln[p/(1-p)]$, and $p$ is the observed proportion of occurrence of the event of interest in the sample. Statistical software packages easily provide the values of $b_0$, $b_1$, $b_2$, …, $b_K$, which are the estimates of the corresponding parameters $\beta_0$, $\beta_1$, $\beta_2$, …, $\beta_K$, respectively. These are called logistic coefficients. You may also like to review the topic **logistic coefficients (interpretation of)** to understand the meaning of these coefficients. Since the $b$'s are estimates, we can find the confidence interval (CI) for the corresponding $\beta$'s and can also test hypothesis on them. The CIs and $P$-values for significance of the logistic coefficients are standard features in reporting the results of a logistic regression.

When all of the specified regressor variables are forced into the model and not selected by any of the **stepwise** algorithms, there is a need to test the statistical significance of each logistic coefficient. For this, one method is to refer the difference between $-2\ln L$ without and with the variable in question to **chi-square** with one df (see **likelihood ratio test**). The other method is to refer $z = b/\mathrm{SE}(b)$ to the Gaussian distribution, where $\mathrm{SE}(b)$ is the standard error of $b$. $\mathrm{SE}(b)$ has a complex expression, but its value is routinely provided by the statistical software. Both chi-square and Gaussian $z$ require large $n$. Most statistical software perform the Gaussian test; its square, called the **Wald** statistic, is referenced to chi-square with one df for testing significance. Consider the following elaborate example that illustrates some of these facets of logistic regression.

Among a group of Peruvian children studied by Marquis et al. [1], 127 were still breast-feeding at the end of their 13th month of age. These children were thus at *risk* of being weaned. The objective was to find support for the contention that poor health of the child determined maternal breast-feeding practice and maternal breast-feeding is not a precursor to poor health. The following variables were investigated for their role in determining the weaning: (i) $Z$-score

of 12-month weight-for-age (WA), (ii) complementary food intake (FOOD) between 9 and 12 months of age in terms of number of foods (out of 27 groups), and (iii) change (CH) in diarrheal incidence from 9–12 months to 12–15 months of age. As these are to be considered precursors for weaning during the 14th month, consider CH from 9–11 to 11–13 months for our example. The response variable is the probability of weaning during the 14th month of age. All variables were centered on the mean, and the results so obtained by logistic regression are summarized in Table L.4. The table contains the estimated logistic coefficients, their SE values, and the two-tailed *P*-values for assessing their statistical significance. All these easily come from a statistical software package.

The aim of a logistic model is to predict or explain $\lambda = \ln[\pi/(1-\pi)]$, and thereby $\pi$, by a linear combination of the regressor variables. In this example, $\lambda$ is the logarithm of odds of weaning. Using the regression coefficient in Table L.5, the logistic equation obtained is

$$\ln\frac{p}{1-p} = -3.303 - 0.024(\text{WA}) + 0.093(\text{FOOD}) + 0.542(\text{CH}) + 0.046(\text{WA}\times\text{FOOD}) + 0.336(\text{WA}\times\text{CH}) - 0.143(\text{CH}\times\text{FOOD}) - 0.202(\text{WA}\times\text{CH}\times\text{FOOD}).$$

A coefficient *b* close to 0 implies that the corresponding explanatory variable is not a good predictor. Whether it is significantly different from 0 can be tested by referring [*b*/SE(*b*)] to the standard Gaussian or its square to the Wald statistic as mentioned earlier. The *P*-values thus obtained are given in the last column of the table. Diarrheal change (CH) is statistically significant at $\alpha = 0.10$ but not at the conventional $\alpha = 0.05$, where $\alpha$ is the **level of significance**. The only regressor variable that shows significance ($P < 0.05$) in this case is in the last row. This is the **interaction** between WA, FOOD, and CH. The coefficient *b* is negative for this interaction, which indicates that logarithm of odds of weaning *declines* as WA, FOOD, and CH change *together* such that WA × FOOD × CH increases. When log-odds decreases, the corresponding probability also decreases. The authors of this investigation explained that the probability of weaning decreases especially when low FOOD and low WA are accompanied by an increase in diarrheal incidence. These three together indicate poor health of the child. Thus, the inference is that a child who is breast-fed until 13 months of age is less likely to be weaned during the 14th month if its health condition is poor, hence the conclusion that health condition determines maternal breast-feeding practice.

**TABLE L.4**
**Results of Logistic Regression of Weaning on Health of the Children**

| Variable | *b* | SE(*b*) | *P*-Value |
|---|---|---|---|
| Constant | –3.303 | 0.644 | 0.000 |
| 12-month *Z*-score—WA | –0.024 | 0.446 | 0.958 |
| 9–12 months—FOOD | 0.093 | 0.267 | 0.733 |
| Diarrheal change—CH | 0.542 | 0.322 | 0.095 |
| Interaction 1—WA × FOOD | 0.046 | 0.211 | 0.833 |
| Interaction 2—WA × CH | 0.336 | 0.179 | 0.064 |
| Interaction 3—FOOD × CH | –0.143 | 0.144 | 0.323 |
| Three-factor interaction—WA × FOOD × CH | –0.202 | 0.096 | 0.038 |

**TABLE L.5**
**Classification Table for the Subjects**

| Observed Group | Predicted by Logistic Model | | | |
|---|---|---|---|---|
| | Control | Case | Total | Percent Correct |
| Control | 23 | 7 | **30** | 100 × 23/30 = 76.7 |
| Case | 8 | 22 | **30** | 100 × 22/30 = 73.3 |
| | | | **Overall** | **100 × 45/60 = 75.0** |

The example illustrates the method to test the significance of individual coefficients. If there are many regressors as in this example, an alpha level of 0.05 for each individual predictor may be too high because all tests are based on the same data. Exercise caution and see if you would like to use a **Bonferroni** type of procedure to adjust the alpha level instead of the one used in Table L.5.

Some researchers prefer providing results of logistic regression for only those regressors that turn out to be statistically significant. However, the results of logistic regression must also contain a list of other regressors that were considered but were not found statistically significant so that a comprehensive view is available to the reader.

Ninety-five percent **confidence interval (CI)** for each logistic coefficient is obtained as $b \pm 1.96\text{SE}(b)$ using Gaussian approximation. This is converted to OR by computing its exponent. This procedure is valid only for large *n*. When such a CI is obtained, there is no need to perform the test of hypothesis $H_0$: $\beta = 0$ on individual coefficients since CI for any regressor containing zero indicates that the regressor is not significantly affecting the odds of the dependent variable when the values of other regressors are fixed. Thus, that factor is not a useful predictor or as explanatory. When there are a large number of regressors, CIs on individual coefficients may not be very useful for any *joint* conclusion because joint probability may be very different.

## logistic coefficients (interpretation of), *see also* logistic coefficients (CI and test of $H_0$)

To understand this section, we presume that you are aware of **logistic regression**. Briefly, logistic regression is the regression between logit of *p* defined as $\lambda = \ln[p/(1-p)]$, where *p* is the observed proportion of occurrence of the event of interest in the sample and the regressors. This takes the form

$$\hat{\lambda} = b_0 + b_1x_1 + b_2x_2 + \ldots + b_Kx_K$$

for *K* regressors. This is also called the logistic regression equation. Your software easily provides the values of $b_0, b_1, b_2, \ldots, b_K$, which are the estimates of the corresponding parameters $\beta_0, \beta_1, \beta_2, \ldots, \beta_K$, respectively. These are now called logistic coefficients. Note that logit in the above equation is actually log of **odds**.

The coefficients $b_1, b_2, \ldots, b_K$ in the logistic regression formula given in the above equation have an extremely useful interpretation in terms of odds ratios (ORs). Guard against the temptation to interpret an OR as relative risk. The two are not the same, but OR is nearly equal to relative risk when the prevalence of disease, *p*, is small, say less than 5%. Other precautions as mentioned under the topic **odds ratio** should also be observed.

The meaning of logistic coefficients in the case of a dichotomous regressor is slightly different from the meaning in the case of a polytomous or continuous regressor.

### *Dichotomous Regressors*

Consider a simple logistic equation with only one regressor, $x_1$. Then, $\hat{\lambda} = b_0 + b_1 x_1$. Since $p/(1-p) = e^{\hat{\lambda}}$, it implies that $p/(1-p) = e^{b_0 + b_1 x_1}$. Suppose $x_1$ is a *binary* regressor with value 1 when present and value 0 when absent. Refer to these as exposure present and exposure absent. Since $p/(1-p)$ is odds for positive response, odds for exposed subjects $(x_1 = 1) = e^{b_0 + b_1}$ and odds for unexposed subjects $(x_1 = 0) = e^{b_0}$. Thus,

$$\text{odds ratio (OR)} = \frac{e^{b_0 + b_1}}{e^{b_0}} = e^{b_1} \text{ and } \ln(\text{OR}) = b_1.$$

It is now clear that $b_1$ is the log of the OR corresponding to the variable $x_1$ when $x_1$ is binary. This is the OR with respect to $x_1 = 0$, which is called the reference category.

In general, when several regressors are present in the logistic model, $e^{b_1}$ is an *independent* contribution of one unit of $x_1$ to the OR when other $x$'s remain the same. Then, this is also called the **adjusted odds ratio**. While reporting results of a logistic regression, many researchers give both adjusted and unadjusted ORs, where unadjusted ORs are based on logistic regression with only one regressor at a time and adjusted when all the regressors are considered together.

Consider a case–control study of adult males to assess the relative importance of various risk factors of benign prostate hyperplasia (BPH). For convenience of illustration, restrict risk factors to only three: $x_1$ for age, categorized as 50–59, 60–69, or 70+; $x_2$ for self-reported sexual activity, categorized as mild, moderate, or heavy; and $x_3$ for diet, categorized as vegetarian or nonvegetarian. These are coded as (0, 1, 2), (0, 1, 2), and (0, 1), respectively. The controls in this study are non-BPH males from the same social milieu, and let there be 30 subjects in each group.

The data are entered into a computer and the logistic regression is obtained. Suppose the estimated value of the intercept (sometimes called constant) is –2.65 and the regression coefficients are +0.50, +0.78, and +0.22 for $x_1$, $x_2$, and $x_3$, respectively. Thus, the following logistic regression is obtained:

$$\hat{\lambda} = -2.65 + 0.50x_1 + 0.78x_2 + 0.22x_3.$$

For a person with the highest risk factors, $x_1 = 2$ (age 70+ years), $x_2 = 2$ (heavy sexual activity), and $x_3 = 1$ (nonvegetarian diet). Thus, for this person,

$$\hat{\lambda} = -2.65 + 0.50 \times 2 + 0.78 \times 2 + 0.22 \times 1 = 0.13.$$

Since $\hat{\lambda} = \ln[p/(1-p)]$, the estimate of the odds for this person with highest rank is $p/(1-p) = e^{0.13} = 1.1388$. For a person with the lowest risk, $x_1 = 0$, $x_2 = 0$, and $x_3 = 0$, $\hat{\lambda}$ is –2.65. This gives odds $e^{-2.65} = 0.0707$. Therefore, the **odds ratio (OR)** is 1.1388/0.0707 = 16. Thus, the odds of BPH for the first person with all the three risk factors are nearly 16 times compared with a person with least risk (of age 50–59 years, with mild sexual activity, and on vegetarian diet). ORs are not probabilities, for example, for the first odds, $p/(1-p) = 1.1388$ gives $p = 0.5325$, and for the second odds, $p/(1-p) = 0.0707$ gives $p = 0.0660$. The first probability is about 8 times the second, whereas the OR was nearly 16 times. Thus, do not interpret odds as probabilities.

How do you interpret the other logistic coefficients such as 0.22 for $x_3$ in this equation? In our example, for a person with $x_1 = 0$, $x_2 = 0$, and $x_3 = 0$, odds $= e^{-2.65} = 0.0707$. If the person is nonvegetarian ($x_3 = 1$) with other $x$'s same, then $x_1 = 0$, $x_2 = 0$, and $x_3 = 1$, and odds $= e^{-2.65+0.22} = 0.0880$. These values give an OR for BPH for a nonvegetarian against a vegetarian of 0.0880/0.0707 = 1.25, which means that a nonvegetarian diet increases odds by 25%. This is the adjusted OR and measures the independent contribution of $x_3$ when $x_1$ and $x_2$ are in the model. Again, since ln(1.25) = 0.22, the logistic coefficient ($b_3 = 0.22$ in this case) is the logarithm of the OR for $x_3$. When logistic coefficients are available, the corresponding OR relative to a reference can be immediately computed. It is this property of the logistic regression that has made this method so popular. The category coded as $x = 0$ serves as reference and $e^b$ is the ratio of odds for category $x = 1$ relative to the reference category. As another example, if $b = 1.3$ for a positive family history in case of breast cancer, OR $= e^{1.3} = 3.67$. This means that the odds of breast cancer in those with a positive family history are 3.67 times the odds in those without a positive family history. (This statement is not for chance: chance has to be worked out separately as illustrated earlier.) Thus, $e^b$ is the predicted change in odds of the dependent for a unit increase in the corresponding predictor. An OR of less than one for any $x$ corresponds to a decrease in odds and an OR of more than one corresponds to an increase. An OR close to one indicates that the change in the regressor does not affect the response, and thus the regressor has no predictive utility.

The preceding explanation is in terms of OR because this is how a logistic regression is widely understood. However, in the case of prospective studies, the interpretation is in terms of **relative risk** and not OR. Also, realize that $\pi$ ranges between (0, 1), OR ranges between (0, ∞), and logit ranges between (–∞, +∞).

### *Polytomous and Continuous Regressors*

There is no restriction in logistic regression for any predictor to be binary and can be polytomous or continuous. Interpretation of logistic coefficients for regressors with three or more categories depends on the coding system adopted. If a particular regressor is polytomous ordinal such as disease severity categorized as none, mild, moderate, serious, or critical, many types of coding can be done. The simplest can be 0, 1, 2, 3, 4 when the number of categories is five. We have used this kind of coding for age-group and sexual activity in our BPH example, which quantifies the regressor values and works like a score. In this case, the corresponding $e^b$ is the factor by which OR multiplies when the category moves one up in terms of this score. If $e^b = 1.15$, this means that the odds for category $x = 1$ (mild disease) are 1.15 times the odds for category with $x = 0$ (no disease), and the odds for category $x = 2$ (moderate disease) are 1.15 times the odds for category $x = 1$ and $1.15 \times 1.15 = 1.32$ times the odds for $x = 0$ (no disease). This will change if the scoring is not 0, 1, 2, 3, 4, but something else.

This interpretation of the logistic coefficient is valid for ordinal $x$, which can be given scores. For real nominal categories, suitable contrasts of interest should be defined. They are generally defined in terms of the difference of one group from one or more of the others. If the objective is to examine 5-year survival with site of malignancy, you can have one particular site, say lung, as the reference category and compare this with oral, prostate, esophagus, and so on, by forming contrasts such as (lung–oral), (lung–prostate), and so on. Each of these contrasts would appear in the predictor set of the logistic model. If "prostate cancer" is the reference category, all other sites will be compared with this cancer with suitable coding. The advantage with these kinds of contrasts is that each contrast

will have its own logistic coefficient, and the coefficient for one contrast can differ from that of another contrast. Thus, differential effects of the categories on the response, if present, will emerge. It is possible to find out if one particular category, say category 2, is a significantly higher contributor to the response than category 3 or category 1. The serial coding 0, 1, 2, 3, 4 mentioned in the preceding paragraph does not have this feature because this works as a score.

If $x_1$ is *continuous*, odds $(x_1 = a+1) = e^{b_0+b_1a+b_1}$, and odds $(x_1 = a) = e^{b_0+b_1a}$. Thus,

$$\text{odds ratio} = \frac{e^{b_0+b_1a+b_1}}{e^{b_0+b_1a}} = e^{b_1}.$$

Again, $b_1$ is the log of the odds ratio. Whether $x_1$ is binary or continuous, $b_1$ is the log of OR when $x_1$ is increased by one.

If a predictor is continuous such as age in years, a logistic coefficient of 0.15 would imply OR = $e^{0.15}$ = 1.16, indicating that each year increase in age increases OR by a factor of 1.16. A 10-year increase in age would increase OR by a factor of $(1.16)^{10}$ = 4.41, and you can say that a 10-year increase in age increases OR by 341%. In this case, the OR that may look only slightly more than 1.0 can translate into an enormous effect.

For some predictors, a unit change can mean enormous change—even impossible in practice. Waist–hip ratio (WHR) is a variable that generally varies from 0.7 to 1.5. It looks preposterous to think of a unit change in WHR such as from 1.2 to 2.2. For this kind of variable, it is prudent to consider 0.1 as the unit while running the regression.

Logistic regression is linear, and interpretation of logistic coefficients for a metric (continuous or not) predictor assumes that the effect of increase from, say, 5 to 10 in the value of $x$ is the same on the outcome as an increase from 70 to 75. This should be tested for its validity as per the procedure laid down under the topic **linearity (test for)** in this volume. This may not be valid for many clinical variables. For example, a blood pressure rise from 120 to 130 mmHg may not have the same effect on outcome as an increase from 170 to 180 mmHg. In such a situation, you may like to include square or any other term that can realistically depict the relationship.

## logistic discriminant functions

If needed, see the topic **discriminant function** to understand what this is and where this can be used. Briefly, this is used to find functions (generally linear) of the predictor variables that can adequately classify the subjects into known groups. The procedure mentioned in that topic is for quantitative predictors and is best suited for the variables that have a Gaussian distribution. Logistic discriminant function is the counterpart used when classification decision is to be based on qualitative or categorical variables, although this can include quantitative predictors as well.

For outcome in two categories, the preferable method is **logistic regression**, where predictors could be quantitative or qualitative. We have a **polytomous** extension of logistic, which answers the same research question for multiple categories, but the logistic discriminant function is simpler, is more practical, and considers all categories together. Also, it does not require as big a sample as polytomous logistic regression does. As in the case of the usual discriminant functions, the logistic discriminant functions help in predicting the category of the new set of values of the predictors, for example, to predict the type of liver disease (cirrhosis, malignancy, or hepatitis) on the basis of signs–symptoms and laboratory investigations.

The only requirement for logistic discriminant functions is that the logarithms of **likelihood ratios** of all pairs of categories are **linear** in the observed values. This helps in using a known algorithm for finding the discriminant functions that maximize the chance of correct classification. The number of discriminant functions is one less than the number of categories under prediction just as in the case of the usual discriminant function. For predicting that a patient has liver cirrhosis, malignancy, or hepatitis on the basis of various clinical features and investigations, only two discriminant functions are needed since there are three categories. Also, as in the case of the usual discriminant functions, you can use a variable selection method such as **stepwise** so that the discriminant functions do not use the variables that do not contribute significantly to the discrimination, which can help in obtaining simpler discriminant functions. For further details, see Albert [1] and Anderson [2].

Rossi et al. [3] used logistic discriminant functions to conclusively diagnose primary aldosteronism or idiopathic hyperaldosteronism in hypertensive patients in Italy. The predictors they used are measurement of Na+ and K+ in serum and 24-h urine, sitting plasma renin activity, and aldosterone at baseline and after 50 mg of captopril. Mwangi et al. [4] used logistic discriminant analysis to assess the diagnostic performance of zinc protoporphyrin, alone and in combination with hemoglobin concentration in those without inflammation, *Plasmodium* infection, or HIV infection in rural Kenyan women.

## logistic models/regression (adequacy of)

This section presumes that you are familiar with the basics of logistic models. If not, review the topic **logistic models (basics of)**.

Before using any model for inferential purpose, it is necessary to be convinced of the statistical adequacy of the model in addition to the biological plausibility, which is assessed separately as a prime consideration. Statistical adequacy means whether the model is able to explain the data adequately. Although several criteria such as generalized $R^2$, likelihood ratio, and Wald statistic are available to check the statistical adequacy of a logistic model, **log-likelihood** seems to have better appeal and wider applicability. The other commonly used criteria are the classification accuracy and the area under the receiver operating characteristic curve. Each of these three is explained below. The **Hosmer–Lemeshow test** can also be used as described separately under that topic. For other criteria, see the book by Hosmer et al. [1]. All these methods assess adequacy for the data on which the model was developed, but for real applicability, the model should be assessed on new set of data.

### *Log-Likelihood Method for Assessing Overall Adequacy of a Logistic Model*

The **likelihood**, $L$, is the probability of obtaining the values observed in the sample when the model is correct. Since a probability is necessarily a small number, that is, less than 1, and your high school math tells you that the logarithm of a number less than one is negative, it is helpful to use $-L$, in fact $-2\ln L$ instead, because the distribution of $-2\ln L$ for large $n$ has been found to follow chi-square under $H_0$ in fairly general conditions. The $H_0$ in the case of logistic is that there is no relationship between the dependent and regressor variables. If $H_0$ is true, then all the regression coefficients $\beta_1, \beta_2, \ldots, \beta_K$ are zero, and

$$\hat{\lambda} = b_0'.$$

This is the reduced model. Compare this with the fitted model to determine if this is adequate or not.

Denote likelihood for the reduced model by $L_0$ and for the fitted model by $L_1$. The value of $-2\ln L_0$ for the reduced model would invariably be more than $-2\ln L_1$ for the fitted model. The difference between these two also follows a chi-square distribution with $K$ degrees of freedom, where $K$ is the number of parameters in the fitted model. This deviance is called the model chi-square. Most standard statistical software packages give the value of $-2\ln L$ for the model under consideration. For example, if $-2\ln L_0 = 83.18$ for the reduced model and $-2\ln L_1 = 61.01$ for the fitted model (with, say, $K = 3$ regressors), then model chi-square = 83.18 − 61.01 = 22.17. At $K = 3$ df, this is highly significant ($P < 0.001$). This shows that $x_1$, $x_2$, and $x_3$ (together) in this example are useful in predicting the outcome.

The following comments explain some of the implications:

- If the model is a perfect fit, then the likelihood is 1 and $-2\ln L = 0$. Note that since probability $L < 1$, $\ln L$ is always negative and the deviance $-2\ln L$ is always positive.
- One measure of the adequacy of a fitted logistic model is the extent of decrease in the value of $-2\ln L$ relative to the value for the reduced model. This can be calculated as follows:

$$\text{Contribution of the model: } C = \frac{(-2\ln L_0) - (-2\ln L_1)}{-2\ln L_0},$$

  where $L_0$ corresponds to the reduced model and $L_1$ corresponds to the fitted model as before. The role of $-2\ln L$ is similar to that of $\boldsymbol{R^2}$ in the ordinary linear regression but has a negative meaning. In the case of $R^2$, a larger value is better, but in the case of $-2\ln L$, a smaller value is better. Also $-2\ln L$ does not fall between 0 and 1 as $R^2$ does. For the purpose of $C$ in the formula just given, $\ln L$ can be used if your software provides log-likelihood instead of $-2\ln L$.
- All models can be improved by adding more regressor variables. This will invariably decrease the value of $-2\ln L$, but this decrease may or may not be statistically significant. To test this, the decrease in $-2\ln L$ is again referred to chi-square to obtain a $P$-value. A nonsignificant decrease indicates that adding those regressors is not helpful. Similarly one or more regressors can be dropped in search of a more parsimonious model. A nonsignificant increase in $-2\ln L$ justifies dropping because the model still works almost just as well without those predictors. Also, as always in a regression setup, an increase in number of parameters decreases $-2\ln L$ and improves fit in absolute terms, but sometimes the df's increase relatively faster and statistical significance declines.
- Beware of outliers since these can vitiate any model, and logistic is no exception. Parameter estimates generally incorporate all values but are affected disproportionately by such extreme values. In the process, the whole model can shift its position. As a result, the likelihood $L$ and the deviance may be substantially affected. At the time of scrutiny of data, try to locate outliers and take a conscientious decision to include or exclude some or all of them from the analysis. This should not be done after you have seen the final results.
- All statistical tests, including the one described here, are heavily dependent on sample size. A large sample will almost invariably yield statistical significance whether the model is good or not. Thus, use this method for checking overall adequacy only as a preliminary test. If the overall adequacy is not significant on the basis of this test, there is no need to proceed further, but if it is significant, assess its actual utility by one or more of the methods subsequently described in this section.
- The logistic method for small $n$ in case of categorical dependent variables is too complex—interested readers may see Mehta and Patel [2] for an exact logistic regression valid for any $n$, including small $n$.

When the number of possible regressor variables is large, the computer program can be asked to identify and include only the significant variables in the logistic model. This can be done by one of the following three **variable selection** algorithms: (i) forward selection, (ii) backward elimination, and (iii) stepwise algorithms. These are the same as for ordinary quantitative regression, the only difference being that instead of $R^2$, $-2\ln L$ is now used as the criterion for selection. However, these algorithms are not as well defined for logistic regression as they are for ordinary quantitative regression. None of these algorithms may yield the best model, and this may lead to three different models. It is a good idea to examine several possible models and choose on the basis of interpretability, parsimony, and convenience in obtaining the data.

### *Classification Accuracy Method for Assessing Overall Adequacy of a Logistic Model*

Another way of assessing the adequacy of a logistic model is by finding what percentage of subjects is correctly classified. For this, the model is used on the same set of data on which the model was built, and an estimated probability $p$ is obtained for each subject. A subject is predicted to belong to the "control" if $p < 0.5$ and to the "case" if $p > 0.5$. Any other cutoff point can be used if that is more justified; otherwise, 0.5 seems like a reasonable cutoff. The terms *case* and *control* used here are in a very general sense for the dichotomous group—a case could be either a subject with disease or the one with exposure. The probability $p$ is calculated to several decimal places and $p = 0.5$ is unlikely to occur. If it does, the subject is not classified into either group. The actual status of all the subjects is already known; thus, the predicted grouping can be compared with the observed grouping, and a table similar to Table L.5 can be constructed.

Consider 30 cases with benign prostatic hyperplasia (BPH) and 30 non-BPH controls as shown in Table L.5. When the probability of BPH is estimated for these subjects based on the fitted logit model, suppose 23 out of 30 controls have $p < 0.5$ and 22 out of 30 cases have $p > 0.5$. This information can be used to calculate both positive

and negative **predictivity** type of measures; the two are generally considered together. In Table L.5, a total of 45 out of 60 subjects (75%) were correctly classified by the model, which is not high, indicating a room for improvement. This can be done either by including more regressors in the model or by considering an alternative set of variables as regressors that can really predict BPH status. The higher the correct classification, the better the model. Generally, a correct classification between 80% and 89% is considered good and 90% or more is considered excellent.

One difficulty with this procedure is that the middling probability 0.51 is treated the same way as the high probability 0.97. Also, a subject with a probability of 0.49 goes to another group compared to a subject with a probability of 0.51 despite the minimal difference. The classification is strictly with respect to the cutoff point 0.5 and ignores the magnitude of the difference from 0.5. Another difficulty arises when one group is extremely large and the other group is too small. Suppose 600 pregnant women are followed for eclampsia, and only 30 of them develop this complication. The model may be able to correctly classify 560 of the 570 who did not develop eclampsia and only 2 out of 30 who develop eclampsia. The overall correct classification is 562/600 = 93.7%, which may give an impression that the model is good, ignoring that it actually is good for ruling out the disease but not for confirming. It has correctly classified only 2 out of 30 (6.7%) with eclampsia, and these are crucial for the success of the model. Thus, classification accuracy should be correctly interpreted.

### *ROC Method for Assessing the Overall Adequacy of a Logistic Model*

A popular method for checking the adequacy of a logistic model is by drawing a **receiver operating characteristic (ROC)** curve. This is typically used when the logistic model is used to develop a scoring system. This curve is drawn between **sensitivity** and (1 − **specificity**) for various cutoffs by considering positives and negatives in the sample as "gold" and by working out the sensitivity–specificity of the model by comparing the predicted categories with the actually observed ones in the sample. Sensitivity and specificity are obtained for different values of the regressors so that a range of values is available for drawing the ROC curve. The area under this curve provides a measure of the adequacy of the model; if it exceeds, say, 0.80 out of possible 1.0, the model is usually considered adequate.

Wang et al. [3] used multiple logistic regression to develop a scoring system for identifying individuals with impaired fasting glucose tolerance in the southern Chinese population, with age, waist circumference, body mass index, family history of diabetes, and so on as regressors. They evaluated the adequacy of the scoring system by the area under the ROC curve, which was 0.70 in their subjects. This is not particularly high to inspire confidence in the logistic model–based scoring system developed by them.

## logistic models/regression (basics of)

A logistic model is typically suitable in situations where the response or the **dependent variable** is dichotomously observed; that is, the response is **binary** and the objective is to determine how the response is affected by a set of given **regressors** or to assess the net effect of one particular regressor when all others are fixed. The ordinary regression is for quantitative outcomes and cannot be used for binary outcomes. As explained for **models**, the logistic model can be causal, predictive, or explanatory depending on the objective. It can also be used for developing scores such as **APACHE** that classify the subjects into severity groups as per the details given for **scoring system**.

Consider occurrence of prostate cancer in males of age 60 years or more. This is dichotomous (yes or no) and may be investigated to depend on, say, vasectomy status (yes or no) and dietary habits as the primary variables of interest. Possible **confounders** such as smoking and covariates such as age at vasectomy can be the other regressors in the model. In another setup, hypothyroidism versus euthyroidism can be investigated for dependence upon the presence or absence of signs or symptoms such as lethargy, constipation, cold intolerance, or hoarseness of voice, and upon serum levels of thyroid-stimulating hormone, triiodothyronine, and thyroxine. A binary variable is also obtained when a continuous variable is dichotomized, such as diastolic BP <90 and ≥90 mmHg with names such as normotension and hypertension. However, there are extensions of logistic regression for polytomous and ordinal data. For these, refer to **logistic models/regression (multinomial, ordinal, and conditional)**. The present section is for dichotomous outcomes.

In all dichotomous situations, the dependent variable $y$ is given a value 0 for a negative response or 1 for a positive response, and nothing in between. Statistically, the dependent variable is the proportion $p$ of subjects providing a positive response. This proportion is converted to $\text{logit}(p) = \ln[p/(1-p)]$ for fitting a logistic model. This is denoted by $\hat{\lambda}$ as this is the estimate of $\lambda = \text{logit}(\pi) = \ln[\pi/(1-\pi)]$, where $\pi$ is the probability of the positive response in the target population. Justification and other details of this transformation are in the topic **logit**. It has been observed that the results not only lend themselves to easy and useful interpretation in terms of **odds ratio** when the binary dependent variable is transformed to logit but also help retain the sigmoid shape of the probabilities that are bound by 0 and 1, thus doing away with the requirement of the Gaussian pattern of the responses and homoscedasticity that do not hold in this setup. The logistic model takes the form

$$\hat{\lambda} = b_0 + b_1 x_1 + b_2 x_2 + \ldots + b_K x_K$$

for $K$ regressors. The regressors can be quantitative or qualitative—there is no restriction. This is also called the logistic regression equation. Statistical software easily provides the values of $b_0$, $b_1$, $b_2$, …, $b_K$, which are the estimates of the corresponding parameters $\beta_0$, $\beta_1$, $\beta_2$, …, $\beta_K$, respectively, in the population. These are now called logistic coefficients. See the topic **logistic coefficients (interpretation of)** to understand their practical utility and interpretation in terms of odds ratio. The software obtains the estimates by using a re-weighted **least squares method** that requires iterations.

There are several advantages of logistic regression compared with the ordinary quantitative regression:

1. There is no need to worry about Gaussian pattern, even for testing of hypothesis. It is a nonparametric procedure.
2. **Homoscedasticity** is not a requirement.

3. $\pi/(1-\pi)$ represents the odds for positive response in the subjects, which is a useful statistical quantity. Logit mentioned earlier is actually log of odds.
4. Logistic regression does not explicitly require a *linear* relationship between the dependent $\pi$ and the regressors. However, logistic regression does require a linear relationship between the predictors and the log of odds of the dependent variable, as should be clear from the logistic equation given earlier. This is especially important for quantitative regressors.

However, independence of various values of the dependent variable is still needed. This is fulfilled when the response is assessed for different subjects, and where response of one does not affect the response of another subject. It may be violated in repeated measures such as in placental abruption or placenta previa in pregnancies in the same set of women, which are known to recur with greater frequency in subsequent pregnancies. Exercise due caution in such cases.

Although the real objective is to estimate the probability $\pi$ on the basis of a set of predictors, $\lambda$ is predicted instead. The logistic relationship recognizes that the probability $\pi$ is always between 0 and 1, and this probability is given by

$$\pi = \frac{1}{1+e^{-\lambda}}.$$

In practice, $\pi$ is replaced by its estimate $p$ in logit function, and correspondingly in the formula just mentioned where $\lambda$ is replaced by $\hat{\lambda}$.

A useful application of logistic regression is in **case–control studies**. Such studies have a retrospective design, but for the purpose of the logistic model, case–control studies are considered a binary response of the subjects. The case group may comprise those who have the disease and the control group may comprise those who do not have the disease. When the cases and controls are one-to-one matched, a modification called *conditional logistic* is used.

As in the case of the ordinary quantitative regression, the regressor could be one variable $x$, providing a simple logistic setup, or a set of many predictors providing a multiple logistic setup. This is also called *multivariable logistic regression*, although the term *multiple* looks better. Many such similarities are present between the logistic regression and the usual quantitative regression. For example, interaction can be considered by including the product of the values of the concerned predictors, **multicollinearity** affects the reliability of the estimates in the case of logistic as well, and outliers can throw this out of gear. The logistic model is connected with **generalized linear models** through the logit **link function**. In the literature, multivariable logistic is sometimes described as multivariate logistic, but that is not an adequate description.

One basic difficulty with logistic regression is that it demands a large sample. The tests of significance of the regression coefficients and confidence intervals (see the topic **logistic coefficients (CI and test of $H_0$)**) are based on Gaussian distribution: a condition fulfilled with large sample only. Simulation results show that at least 10 positive and 10 negative responses (called the limiting sample size) are required per regressor. If there are 6 regressors, and if only 5% are positive responses, a sample of 1200 subjects is needed to give 60 positive responses. Our experience suggests that this requirement is even more for few regressors but less when the number of regressors is large.

## logistic models/regression (multinomial, ordinal, and conditional), *see also* logistic models/regression (basics of)

The conventional regression models are for binary outcome as described under the topic **logistic models/regression (basics of)**. However, there are extensions for the setups where the outcome is **polytomous** or **ordinal**.

### *Multinomial Logistic Models*

**Nominal** categories cannot be ordered, and each category must be studied as stand-alone. Logistic regression is straightforward if a category is to be compared with the rest since, in this case, the probability $\pi$ is for the category of interest and $(1-\pi)$ is for the rest. In the case of liver diseases, compare hepatitis with (cirrhosis + malignancy), cirrhosis with (hepatitis + malignancy), and malignancy with (hepatitis + cirrhosis) by separate logistics when these are the only possibilities under consideration. A joint model can be made for studying all three comparisons together that will reduce the number of parameters, but the interpretation of the logistic coefficients becomes complex. Calculations also become more complex although appropriate software can help.

Methods that compare one category with the other without the restriction of two probabilities adding to one are available. Thus, category 1 can be compared with category 3, and category 2 can be compared with category 3 by running two separate logistic regressions. In this case, it is helpful to consider one particular category as reference just as is done for regressors. For the comparisons just cited, since both comparisons are with category 3, this serves as the reference. In our example on liver disease, any one category can be considered the reference. If cirrhosis were the reference, both hepatitis and malignancy would be compared with cirrhosis, and there will be two logistics—one for hepatitis and one for malignancy. For a practical example, see Mohaghegh et al. [1] who used this for breast cancer staging in Iran. Breast cancer stages are the multiple categories of the response in this example.

### *Ordinal Logistic Models*

Several possibilities exist in the case of ordinal dependent categories.

- Compare each category with each of the others. If the dependent variable is severity of illness categorized as none, mild, moderate, and serious, the possible comparisons are mild, moderate, and serious each with none; moderate and serious each with mild; and serious with moderate. This would require six different logistic runs. This is the same as considering them nominal.
- Compare each category with the preceding or succeeding category—mild with none, moderate with mild, and serious with moderate. These can be called *adjacent categories logits*. This is one of the **logit models** used in ordinal categories.
- Compare each with the combination of the others. This means comparing none with (mild + moderate + serious), mild with (none + moderate + serious), and so on. This is the easiest but may not be sensible in some cases.
- Compare each category with the combination of the preceding or succeeding categories. This means comparing mild with none, moderate with (none + mild), and serious with (none + mild + moderate). Similarly, comparison with the succeeding categories can also be done if it is considered more meaningful. This uses what is called

*cumulative logit* and is one of the other logit models used for ordinal categories.
- Compare each with a reference. If "no disease" is considered the reference, compare mild with no disease, moderate with no disease, and serious with no disease category.

Perhaps some other comparisons can also be thought of. In all these cases, it is possible again to prepare a joint model, although this may make the model too complex for interpretation. A joint model is relatively easy for cumulative logits when odds for successive categories are proportional. That is, the coefficient that describes the relationship between one category versus all higher categories of the dependent variable is the same as the one that describes the relationship between the next category versus all its higher categories. All such possibilities should be considered only for a small number of categories of the response variable. If the number of ordinal categories is large, say, more than four, consider running the usual quantitative regression (instead of logistic) after giving suitable scores to the categories.

For ordinal logistic in action, see Sharma et al. [2].

### *Conditional Logistic*

**Before–after studies** always provide matched data but one-to-one matching can also happen in case–control studies where the subjects are matched for background characteristics such as age-group, sex, and body mass index (BMI). You may be aware that matching is done only for those characteristics that are not under investigation for their influence of the outcome: that is, only the unmatched characteristics can be the regressors. Matching obviously produces a high degree of correlation and special methods are needed to analyze data from such studies. The **McNemar test** for matched data cannot be used here because the aim of logistic is to study the form of relationship of regressors with the outcome, and not just for presence or absence of relationship. One-to-one matching gives rise to $n$ strata corresponding to $n$ matched pairs, each comprising only two individuals. This requires generation of $(n - 1)$ **dummy variables**, and each will have a corresponding logistic coefficient. Thus, the number of parameters for estimation becomes too many for $n$ pairs of subjects. Increasing the sample size does not help in this case because the number of dummy variables also correspondingly increases as the number of pairs increases. Each stratum will have a parameter dedicated to the stratum that statisticians call **nuisance parameter** because it does not help but instead hurts the interpretation.

A conditional logistic method eliminates this nuisance parameter, which is the intercept $b_0$ in this case, and thus simplifies the estimation method and protects against potential bias that arises in the regular unconditional logistic model when used for matched data. Only the parameters corresponding to the predictors are estimated, and "no intercept" is specified so that a logistic model is fitted with no $b_0$. In conditional logistic, matching variables are not included in the model, and the entire pair is discarded when information on one part of the pair is missing.

Many statistical software packages provide option for running the conditional logistic, and some allow even more than one matched control per case. You must ensure that a suitable package and the correct option in the package are used for analyzing matched data.

## logistic regression (requirements for)

This section presumes familiarity with the basics of **logistic models**. These models are obtained by running the regression of a function of probability of occurrence of an event on a set of regressors. Thus, the **dependent** variable is **qualitative**, mostly **binary**. The regressors can be binary, polytomous or quantitative—there is no restriction.

Logistic regression is among the most commonly used statistical methods in health and medicine. Because of the easy and useful interpretation of **logistic coefficients** and the extensive availability of the software packages, the method has been indiscriminately used forgetting that the results of logistic regression are valid only under some regularity conditions. Logistic regression does not require Gaussianity or **homogeneity of variances** for the variables, but it does require the following.

The first is regarding the selection of the regressors both in terms of number and in terms of relevance. You should have a clear idea of what might be influencing the chance of occurrence of the event of interest (the dependent variable). For this, use your experience, review the literature, and consult the experts. If the potential number of regressors is large, examine how to reduce them, since the large number of regressors compromises the parsimony of the model and the computation time and computer memory requirement also become enormous. Remember that the estimation of the logistic coefficients is computation-intensive. If good biological reasons are not available to reduce the number of regressors, use a statistical method such as **stepwise** to select the significant variables. Also ensure that the regressors included in a logistic regression do not have much **collinearity** among them because that can produce very unreliable estimates.

The second requirement is for sample size and is intimately related to the number of regressors. The requirement is in terms of the number of rarest responses, called the *limiting sample size*. The norm for logistic regression is that the limiting sample size should be at least 10 times the number of regressors. If you are investigating the relationship of the chance of eclampsia in pregnant women, which is supposedly seen in 10% of women, on 6 regressors, you need a minimum sample size of 600 women so that at least 60 women with eclampsia are available in your data set. Our experience suggests that you need higher than 10 times when the number of regressors is small and lower than 10 times when the number of regressors is large, but a substantial sample size is needed in any case.

The third requirement is with regard to the coding of the qualitative regressors. Whereas dichotomous regressors are invariably coded as 0 for absent and 1 for present, care is required for **polytomous** regressors. These could be nominal or ordinal. For ordinal categories such as disease severity into none, mild, moderate, serious, and critical, you can think of using codes 0, 1, 2, 3, and 4 as quantitative variables but with precaution that such coding actually is scoring and implies that a moderate disease with code 2 is twice of a mild disease with code 1, and so on. If these do not reflect the actual situation, any other appropriate scores can be used. For nominal categories such as blood group O, A, B, and AB, such codes cannot be used and the representation should be in terms of indicator variables: (0, 0, 0), say, for blood group O, (1, 0, 0) for blood group A, (0, 1, 0) for blood group B, and (0, 0, 1) for blood group AB. This

coding is valid when blood group O is the reference category since this is coded as (0, 0, 0). The regression coefficients for all others will give log of odds with this category as the reference.

The fourth requirement is linearity of relationship of log of odds with the quantitative regressor ($x$) if that is included in your model. Note that this linearity is not between the regressor and the chance of outcome but with the logarithm of odds. To check this, plot the log of odds versus the values of $x$ and see if it is close to a line, although this can be done only when many observations for each of several values of $x$ are available. If the plot is not nearly linear, this can give an idea of whether to include a square term, a square-root term, or any other term. The second method is to divide the range of quantitative $x$ into three or four appropriate intervals, fit a logistic to each interval separately, and check whether or not nearly the same logistic coefficient is obtained for each interval of $x$. This is possible when sufficient data are available in each interval of $x$ values. If the relationship is not linear, it is advisable to divide range of $x$ into as many plausible intervals as required (generally three or four) and use these as categories in the logistic regression.

Last is the most important requirement of independence of errors. In effect, this means that the subjects of research should be such that one does not influence the values in any other. That is, for example, they should not belong to the same family where the values tend to be similar.

For further details of requirements of logistic regression, see Kumar et al. [1].

## logit, *see also* logistic models/regression (basics of)

For a probability $\pi$ of occurrence of an event, the logit in statistics is defined as

$$\text{Logit: } \lambda = \ln \frac{\pi}{1-\pi}.$$

Note that $\pi/(1-\pi)$ is the **odds** of the occurrence of the event, and logit is the logarithm of odds. This is an acronym for *logistic integral transformation*.

Why do we need this kind of weird transformation? The need arises from the fact that any probability necessarily lies between 0 and 1—and this is highly restrictive for statistical modeling. Probabilities cannot go in a straight line forever. If the probability increases with value of a variable, such as probability of death of a critical patient within a week increasing with increasing severity of the condition, the relationship generally takes the form of an S-shaped (called **sigmoidal**) curve (Figure L.9a). The probability of death is almost zero in patients with no disease, increases slightly when the disease is mild, but shows a sharp increase as the severity increases. After the probability reaches something like 90% for critical disease, increase in chance of death is slow even when the disease is more severe than critical. This is because the probability cannot exceed 1 and has to flatten. This shape is natural because of restriction of (0,1) on $\pi$. It should be clear from this figure that very small values of $x$ make little contribution to the probability and so do the very large values, whereas an increase in value of $x$ toward the middle steeply increases the probability in a pretty straightforward fashion. This is typical for most medical events.

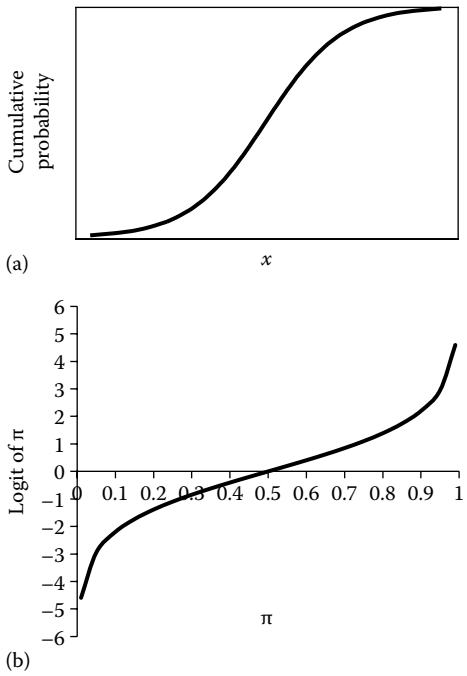

**FIGURE L.9** (a) S-shape of the relationship of cumulative probability with the value of the variable positively affecting the probability. (b) Plot of logit($\pi$) for $\pi = 0.01$ to 0.99.

The logit transformation removes the (0, 1) restriction since $\lambda$ can now be between $-\infty$ for $\pi = 0$ to $+\infty$ for $\pi = 1$ (Figure L.9b). It is nice to note that $\lambda = 0$ for $\pi = ½$, logit is negative for $\pi < ½$, and this is positive for $\pi > ½$. Thus, $\lambda$ is statistically more suitable for studying the relationship with the regressors. The most important use of this transformation is in **logistic regression**, where logit of probability of occurrence of an event such as death is expressed as a linear combination of the regressors. This helps in delineating the role of each regressor in determining or explaining the chance of occurrence of the event. Luckily, in this case, logit helps in a very useful interpretation of the **logistic coefficients** in terms of logarithm of **odds ratio**. The odds ratio is estimated as $\text{OR} = \frac{p_1/(1-p_1)}{p_2/(1-p_2)}$, and $\ln(\text{OR}) = \text{logit}(p_1) - \text{logit}(p_2)$. Thus, a ratio of ratios is converted to a linear function that can be easily handled.

The inverse of logit is $\pi = 1/(1 + e^{-\lambda})$, and this is called *logistic* of $\pi$. Thus, if the log of odds for any probability is known, the corresponding probability can be obtained.

In some isolated cases where the binary dependent variable has underlying continuum that follows Gaussian (Normal) distribution, **probit transformation** may perform better than logit transformation, especially when the variable values are divided as $<a$ and $\geq a$ categories. For example, diastolic level can be divided as <90 mmHg and ≥90 mmHg, and if the diastolic level in the subjects has a Gaussian distribution, probit may be more appropriate.

## log-likelihood, *see* likelihood, log-likelihood, and maximum likelihood

## log-linear models

Log-linear models use the linearizing property of logarithm on the expected frequencies (see **cell frequency**), which otherwise

are multiplicative, in a contingency table, and help in finding how cell counts are affected by the levels of factors. A unique feature of these models is that there is no dependent or independent variable. All characteristics are treated statistically the same way and no distinction is made between an antecedent and outcome. This is the basic distinction between log-linear models and logistic models. These models are best suited for data obtained from **cross-sectional studies** divided by three or more qualitative characteristics and are applicable to **categorical data** only. When male cancer cases are divided by site of cancer and age-group, the interest may be to know which site is more common in which age-group, without antecedent–outcome implications. Biologically, one characteristic can be dependent on the other but log-linear models accord them the same status. In the usual log-linear setup, the variables are treated on a nominal scale—thus, order in age-groups in our example is ignored. The subjects must be independent and randomly selected as in most statistical setups. Just as for almost any categorical data, the test of hypothesis in the case of log-linear models is also based on **chi-square**, and this requires a large sample. The historical account given by Fienberg and Rinaldo [1] attributes the development of log-linear models to a series of efforts of Goodman and others.

As explained next, the logarithm of expected frequencies in a contingency table can be expressed in terms of additive factors relating to the variables under study, hence the term *log-linear*. The objective is to find whether the categories of different variables, individually or jointly, are especially contributing to determining the cell frequency.

## Log-Linear Model for Two-Way Tables

Log-linear models are easily understood with the help of two-way tables, although their application is more useful for higher-order tables. Suppose the number of rows in this table is $R$ and the number of columns is $C$. The expected frequency under $H_0$ of independence in case of two-way tables is

$$E_{rc} = (O_{r\bullet}O_{\bullet c})/n; \quad r = 1, 2, \ldots, R; \quad c = 1, 2, \ldots, C,$$

where $O_{r\bullet}$ And $O_{\bullet c}$ are the totals in the $r$th row and $c$th column, respectively, in the contingency table and $n$ is the grand total. This gives

$$\ln(E_{rc}) = -\ln(n) + \ln(O_{r\bullet}) + \ln(O_{\bullet c})$$

$$= \mu + \alpha_r + \beta_c,$$

where $\mu = -\ln(n)$, $\alpha_r = \ln(O_{r\bullet})$, and $\beta_c = \ln(O_{\bullet c})$. These are interpreted as the general mean and the main effects of rows and columns, respectively, just as we do for ANOVA. They can be redefined to satisfy conditions such as $\Sigma_r\alpha_r = 0$ and $\Sigma_c\beta_c = 0$ that can help make the quantities $\alpha_r$ and $\beta_c$ more interpretable as deviation from the average. The model in the last equation describes the logarithm of expected cell frequency as a linear combination of an overall effect, the effect of the $r$th category of the first variable, and the effect of the $c$th category of the second variable. It is this feature of log-linear models that has made these so popular.

The actually observed frequency $O_{rc}$ will not be the same as expected from this equation but will be something else. Let the difference be denoted by $\theta_{rc}$. Thus, in general,

$$\text{Log-linear model (two-way): } \ln(O_{rc}) = \mu + \alpha_r + \beta_c + \theta_{rc},$$

provided the observed cell frequency is not zero. Log-linear is essentially a large sample procedure where no $O_{rc}$ is likely to be zero.

The component $\theta_{rc}$ measures **interaction** and $\theta_{rc} = 0$ for all $(r, c)$ implies that the observed frequencies conform to the hypothesis of independence. The higher the value of $\theta_{rc}$, the stronger the interaction or dependence. The test of the hypothesis of no interaction ($\theta_{rc} = 0$ for all $r$, $c$) is the usual chi-square, but it is customary in the case of log-linear models to use another criterion called $G^2$ that maximizes the likelihood. For a two-way table, this is defined as

$$G^2 = 2\Sigma_{rc}O_{rc}\ln(O_{rc}/E_{rc}).$$

This also follows a chi-square distribution with $(R - 1)(C - 1)$ df when expected frequencies in at least four-fifths cells of the contingency table are 5 or more and $n$ is large. In other words, $\chi^2$ and $G^2$ are equivalent for large $n$. $G^2$ is called the likelihood ratio chi-square test.

## Log-Linear Model for Three-Way Tables

The preceding discussion for two-way tables was just to explain the concept of log-linear models, but these models are more effective for three-way or higher-way tables. An explanation similar to that for a two-way table can also be given for a three-way table. In this case,

$$\text{Log-linear model (three-way): } \ln(O_{rcl}) = \mu + \alpha_r + \beta_c + \gamma_l + \theta_{rc} + \omega_{rl} + \delta_{cl} + \phi_{rcl},$$
$$r = 1, 2, \ldots, R; \; c = 1, 2, \ldots, C; \; l = 1, 2, \ldots, L,$$

where $\mu$ is the general mean, $\alpha_r$, $\beta_c$, and $\gamma_l$ are the main effects, $\theta_{rc}$, $\omega_{rl}$, and $\delta_{cl}$ are the two-factor interactions, and $\phi_{rcl}$ is the three-factor interaction. Thus, it contains all possible interactions for a three-way table, which will always be an exact fit, called a *saturated model*. The adequacy of fit under the null, or its lack, is tested by $G^2$ in the equation above. The primary interest in log-linear models is to test significance of interaction terms because those indicate dependence. In the site of cancer and age-group example, the third variable could be type of diet (veg/nonveg), and the interest among others could be to find if diet and site of cancer are related. In terms of notation, this transforms to $H_0$: $\omega_{rl} = 0$. If this null is not rejected, this interaction term can be deleted from the model without significantly affecting the utility of the model. The less the number of interaction terms, the more is the parsimony of the model.

The procedure is to calculate the expected cell frequencies under $H_0$ and obtain $G^2$ by a three-way analog of the formula given earlier, and use the chi-square distribution to check whether or not $P < 0.05$. If it is, reject $H_0$ and conclude that $\omega_{rl} \neq 0$, or that age-groups and site of cancer are related in our example. The category actually dominating is identified by further analysis. Interested readers may consult Knoke and Burke [2] for details of this kind of analysis. The model can be easily extended to four or more variables although the interpretation becomes increasingly complex as the number of variables increases. However, log-linear may still turn out to be the method of choice for multidimensional tables because the row effects and column effects can be expressed in terms of marginal totals.

## Issues with Log-Linear Models

Different statistical software packages give different types of output, but everything starts to make sense after some experience. A log-linear model is generally specified by leaving out the interaction or the main effect under test from the model given in the equation just mentioned and the $P$-value corresponding to the value of $G^2$ obtained from the data. A series of models may have to be fitted to come to a focused conclusion. The software may also help in identifying particular cells that are most divergent and cause the significance.

Among many uses of log-linear models, one is to evaluate the net association between two variables after removing the effect of the others. Tiensuwan et al. [3] used log-linear models to conclude that the site of cancer is related to marital status, diagnostic evidence, and treatment in males as well as in females. This example illustrates the use of log-linear models but does not demonstrate the utility. The following remarks may be helpful in understanding the implications of log-linear models:

- Simultaneous consideration of three or more factors raises the question of mutual independence, partial independence, and conditional independence. For details, see Le [4].
- Log-linear models can be adjusted for structural zeroes in cells of the contingency tables if present. These are not zero frequencies by chance in the sample but present by design. In such a case, fit a model to the subset of cells that remains.
- Just as in the case of classical $\chi^2 = \Sigma[(O-E)^2/E]$, log-linear models disregard the order, if any, in the categories of the variables. Each variable is considered to be on a nominal scale. If an ordinal scale is present and is to be given due consideration, different models are required. Ordinal and metric categories allow investigation of the presence or absence of a trend or a gradient in proportion as well as its nature similar to the one discussed under chi-square for trend. See Agresti [5] for details of these models.
- One way to assess the goodness of fit of log-linear models is to compute the standardized deviate $z = (O-E)/\sqrt{E}$ for each cell, where $O$ is the observed frequency and $E$ is the expected frequency under the model. When the cell frequency is large, this $z$ follows an approximately Gaussian pattern. If almost all values of $z$ are between –2 and +2, the fit can be considered good. When the value of $z$ is large for one or more cells, those cells can be considered to contribute significantly to the association. If there are many such cells, the value of each $|z|$ should be more than 3 as is generally required on **Bonferroni** considerations.

## log-normal distribution

As the name implies, a log-normal distribution is an attempt to Gaussianize a highly **skewed** distribution on the positive side by taking logarithm of the variable under study. As explained for **logarithmic scale/transformation**, with base 10, logarithm of 1 is 0, that 10 is 1, that of 100 is 2, that of 1000 is 3, and so on. Also, logarithm of 0.1 is –1, that of 0.01 is –2, that of 0.001 is –3, and so on. Thus, log transformation drastically attenuates the large values and inflates values less than 1 with a negative sign. Thus, a highly skewed distribution tends to become symmetric. We have explained this with base 10 for simplicity but log-normal distribution uses Naperian base $e$, which is also called *natural log* (written as ln), because of its nice mathematical properties. Also note that log-normal distribution is applicable to only those variables that cannot be negative. Luckily, hardly any medical measurement has negative value. However, while dealing with differences, such as change in cholesterol level before and after a treatment, be careful since some of these changes can be negative. In case negative values are present in the data and log-normal still looks like a plausible distribution, add slightly more than the highest negative value (in absolute value) to all the values in the data set so that none is zero or negative, and readjust the results to account for this transformation.

Figure L.10a shows the distribution of fasting blood glucose (FBG) level in a general population of adults. In this population, most have FBG between 80 and 140 mg/dL but some have a high level and a few have a very high level of FBG. These are the people who are not on any treatment or have a high level despite treatment. This distribution is highly skewed on the positive side and has a sharp peak. When we plot the same values after taking the natural logarithm of FBG values, the distribution tends to become symmetrical and the peak becomes close to what we expect in a Gaussian distribution (Figure L.10b). The right tail remains but is now much shorter and the skewness is mild. Most statistical methods are robust to this kind of mild skewness and they can be safely used for this transformed distribution. Since ln(FBG) has close to Gaussian distribution, the distribution of FBG itself is log-normal.

The most common medical example of the variable with log-normal distribution is the duration—the duration of survival after detection of a terminal disease, the duration of hospital stay after a particular surgery, latent period of infectious diseases, and so on. Almost all durations concentrate at around a specific value, but the duration for some subjects tends to become long, and for some others, it tends to become very long because of complications or otherwise. Because of this feature, the duration usually will have a log-normal distribution. However, there are other applications as well. Karulin et al. [1] found it useful in counting ELISPOTs produced by CD8 and CD4 cells as the size of the spots follows a log-normal distribution ranging from micrometers up to a millimeter

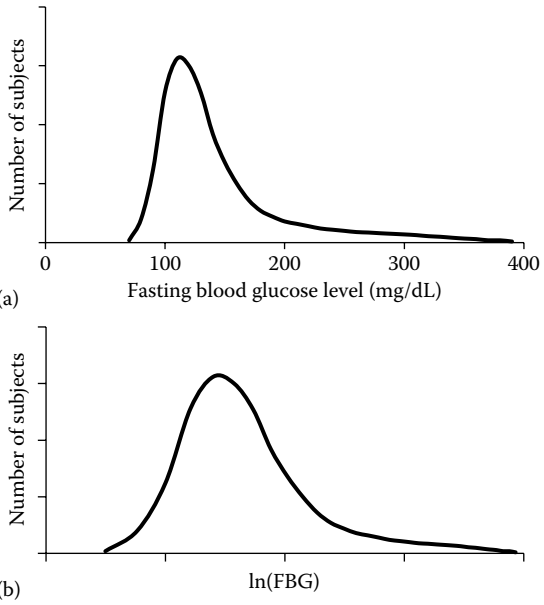

**FIGURE L.10** (a) Distribution of fasting blood glucose (FBG) level in a general population of adults. (b) The same distribution after log transformation of FBG level.

in diameter. Tomitaka et al. [2] observed that depression score in a Japanese population has a log-normal distribution. They used this feature to compare depression scores in various age-groups.

When $y = \ln(x)$ has a log-normal distribution, the mean of $y$ is $\ln(\mu + \frac{1}{2}\sigma^2)$, where $\mu$ is the mean of $x$ and $\sigma^2$ is the variance of $x$. Thus, the antilog of the mean of $y$ does not give you the mean of $x$ but a correction by $\frac{1}{2}\sigma^2$ is needed.

## log-rank test (Mantel–Cox test)

First proposed by Nathan Mental in 1966 [1], the log-rank test is designed to compare the overall pattern of two **survival curves** without reference to any particular point of time. This is a large sample test and uses chi-square criterion to arrive at significance or nonsignificance of the difference. Being a nonparametric test, this is not affected by the shape of the survival curves or distribution of survival times. It requires that any **censoring** in both the groups is independent of the survival process. If patients getting two treatments are under comparison, the patients getting the worse or the better treatment should not drop out quicker than others. Also, the log-rank method is valid when all time points are equally important. If the time points with a higher number of subjects at risk are given more weight, another method such as the **Breslow test** should be used. As a middle path between log-rank and Breslow, some prefer the **Tarone–Ware test** that gives weight proportional to $\sqrt{n_t}$, where $n_t$ is the number at risk at time point $t$.

Nathan Mantel

The null hypothesis for the log-rank test is that the survival curves are identical in the two populations under comparison. This implies that the probability of survival (or of death) at *each* point of time is the same in one group as in the other. Under this null hypothesis, the expected number of deaths is calculated for each time using the combined experience in the two groups.

$$E_{1t} = \frac{n_{1t}}{n_{1t} + n_{2t}}(d_{1t} + d_{2t}) \quad \text{and} \quad E_{2t} = \frac{n_{2t}}{n_{1t} + n_{2t}}(d_{1t} + d_{2t}); t = 1, 2, \ldots, T,$$

where $n_{1t}$ is the number of subjects at risk at the $t$th time point in the first group, $n_{2t}$ is the number of subjects at risk at the $t$th time point in the second group, and $d_{1t}$ and $d_{2t}$ are the observed number of deaths at the $t$th time point in the first and the second group, respectively.

When any survival time is censored, that individual is considered to be at risk of dying in the time of censoring but is ignored for subsequent time points as done for obtaining the **Kaplan–Meier** curve. The sums $\Sigma E_{1t}$ and $\Sigma E_{2t}$ give the expected frequencies for use in chi-square as illustrated in the following example.

In a study of early posttransplant phase of renal allografts, peak antibody level was recorded to assess if it affects survival in the first 2 years [2]. Out of a total of 216 patients, the peak antibody level did not reach 15% in 137 patients (group I). In the other 79 patients (group II), the antibody level exceeded 15%.

Table L.6 contains calculations for the two groups. Note how subjects with censored observations are excluded from the calculations. For the purpose of completeness, time = 16 months is shown, but it does not contribute to the calculation as all the three subjects are censored at this time. A relevant software package will automatically do this for you. Under the null, the expected frequency (number of deaths) for group I is 12.39 and that for group II is 6.61. The observed frequencies for groups I and II are 3 and 16, respectively. Subtract the expected frequencies from the observed frequencies for the two groups and get

$$(O_1 - E_1) = -9.39 \text{ and } (O_2 - E_2) = +9.39$$

$$\chi^2 = \frac{(-9.39)^2}{12.39} + \frac{(+9.39)^2}{6.61}$$

$$= 20.46.$$

This has one df and a software gives $P < 0.001$ for this value of $\chi^2$, leading to the conclusion that the difference in the survival pattern in the two groups is highly significant. The two survival curves are shown in Figure L.11 and the difference is easily seen.

The test can be easily extended to more than two groups. The validity conditions of the log-rank test are the same as for the Kaplan–Meier curve as follows:

- Censored values have the same pattern of survival as the uncensored values; that is, they have the same prognosis.
- In case the subjects are enrolled sequentially over a period, those enrolled later have the same survival pattern as those enrolled early. This means that no innovation has occurred during the period of enrollment that may have a case-mix.
- The time of occurrence of events is exactly recorded and not in intervals.

The log-rank test is most likely to succeed in detecting a difference between survival patterns in two groups when the chance of survival in one group is consistently higher or consistently lower at each time point than the other. If the survival curves cross one another, as can happen while comparing medical treatment with surgical operation, then the difference in the overall pattern may be masked. Also, this test only reveals whether the curves are different, without any implication regarding the magnitude of difference. One method for assessing the magnitude of difference is to compute the ratio of the **hazards** in the two groups at the time point of interest.

For further details of the log-rank test, see Hosmer et al. [3].

## longitudinal data (analysis of)

Longitudinal data arise from **longitudinal studies** where a characteristic is measured on a number of occasions for each subject. The measurements can be qualitative or quantitative, but for simplicity, most of what we state in this section applies to quantitative data for one variable. Among many issues that make analysis of longitudinal data complicated, the most important is correlation among the serial values. This violates the basic requirement of independence that we need for using ordinary regression, ANOVA, and most other statistical methods. Ignoring this correlation provides invalid results of estimation and hypothesis testing.

When the data are obtained for the same fixed points of time for each subject, the analysis can be done in many situations by using **repeated measures ANOVA** as explained for that topic. This requires that if you are measuring the creatinine level of kidney transplant patients, this should be measured at the same time points, say, 1 week, 1 month, 3 months, and 6 months for each patient. The time intervals may or may not be equal; that does not matter, but the time points should remain the same. However, this method is only able to provide statistical significance or nonsignificance of differences in means across groups and not about trend. Also, there must not be many missing values—a common malady of longitudinal studies—for repeated measures ANOVA to be valid.

The longitudinal data are generally obtained from studies that measure different subjects at different points in time. For example, child 1 may have measurements at 0, 7, 10, 18, and 23 months and child 2 may have measurements at 0, 3, 8, 14, and 19 months depending on when they visit the well-baby clinic. The objective in this case is generally to find the time trend such as growth curves for children and bioavailability of drugs in pharmacokinetic studies. The observations are not necessarily forward in time and can also be from past records.

If the objective of longitudinal measurements is in finding the time point that reaches a predefined end point, such as the time taken by body functions to reach the normal physiological levels, **survival analysis** may be the right procedure to use. Some subjects will reach the end point at 15 days, some at 2 months, some at 4½ months, and so on, and these data can be modeled as survival function. Survival pattern in two or more groups can be compared by the **log-rank test** or its extension. If the interest is in finding the effect of various correlates on the duration (of reaching to the predefined end point), you can use the **Cox model**. This can incorporate both time-invariant (e.g., sex and blood group) and time-dependent (e.g., blood pressure, liver functions, etc., that can vary at different points in time under observation) covariates.

If the objective is to look at the mean values at different time points for the entire follow-up, consider whether **area under the concentration curve** is an appropriate measure for the comparison of pattern in different groups. This will work well when the values in one group are generally lower than the other. If they crisscross, this area can be misleading. Concentration curves do not require that the same time points are observed for each subject. If the objective is to compare peak (or lowest) value obtained, the method used in **pharmacokinetic studies** can be used. Both these will be based on average at different time points, and these averages can be problematic in some situations as anywhere else.

If the series is long, something like observations at 50 time points on each subject, **time series** methods can be used for analysis of data. Typically, though, in the present context, longitudinal data pertain to four to six repeated measurements where time series methods will not apply.

**Mixed effects models** that include random effects are particularly suitable for analyzing correlated continuous outcomes in longitudinal studies. These model group effect as fixed and individual effects as random. Several observations for the same individual at different time points or otherwise will constitute within-subject values. Mixed models can be used even when the observation time points vary from subject to subject. This might be the method of choice if many repeated measures are missing, which makes uneven observation points for different subjects, provided the missing values are random and do not create a biased set of data. Mixed model is a fairly general method but confidence intervals and test of hypotheses generally require that the error term follows a Gaussian distribution. Other distributions can also be studied through **link functions** available in **generalized linear models**. This includes categorical responses and count data. However, the computations are complex in this case and setting up the analysis properly in statistical software requires considerable expertise. This should be done only by competent statisticians.

There are several other approaches such as those based on serial differences or differences from base value, but none is simple. For details, see Diggle and Heagerty [1].

## lot quality assurance scheme

Hospital officials look for assurance that the incoming material such as drugs, chemicals, and blood products is of good quality. When purchased from a reputable company, these may have already been subjected to a rigorous quality check, yet it is sometimes desirable to also check their quality at the time of receiving them. This can be done by using a lot quality assurance scheme (LQAS) when bulk purchases are made. Blood testing strips and skin patches are the other examples where this can be used. This scheme is also applied to the assessment of health services and to disease surveillance. Details of LQAS have been provided by Montgomery [1]. A brief is as follows.

### *LQAS in a Laboratory Setup*

The total material to be inspected for quality is first divided into lots of nearly equal size, and a small sample of units from each lot is checked for quality. If the number of defective units exceeds a predetermined tolerance threshold, the whole lot is rejected; otherwise, it is accepted.

Suppose a hospital received 80 boxes, each box containing 10 laboratory kits. These can be divided into five lots of 16 boxes each. Each lot will now have 160 kits. Take a random sample of, say, $n$ = 15 kits from each lot, and check these for a predetermined quality standard. All kits cannot be inspected as that can render them unusable, or it may be too expensive to do 100% checking. If the number of kits not meeting the standard exceeds the tolerance level, reject the whole lot. The tolerance level for large $n$ (based on Gaussian approximation) is determined by an expression similar to the following equation depending on the acceptable rate of error.

$$\text{upper limit of tolerance} = n\pi + 1.645*\text{SE},$$

where $\text{SE} = \sqrt{n\pi(1-\pi)}$ and $\pi$ is the proportion defective. If the proportion defective is expected to be at most $\pi = 0.2$, that is, 2%, the upper limit of tolerance for $n$ = 15 is $15 \times 0.02 + 1.645 \times \sqrt{(15 \times 0.02 \times 0.98)} = 1.19$. Thus, if the number of defectives is more than 1 in a sample of 15, you can be confident that the percentage of defectives is more than 2% and the lot can be rejected. We have illustrated this using Gaussian approximation, but for small $n$ and small $p$ such as this example, an exact threshold [1] based on the **binomial distribution** should be used.

### *LQAS in Health Assessment*

The lot quality method has been used in disease surveillance, nutrition programs, assessing women's health services, and, most of all, immunization coverage assessment [2].

Suppose coverage of at least 90% by polio vaccine is required to build herd immunity so that the transmission is throttled and the disease is not able to propagate itself. Thus, not more than 10% of children should remain uncovered ($\pi = 0.10$). Let the target population be children below the age of 3 years in a district. The area of the district is divided into, say, 20 zones that will serve as "lots" in LQAS. Within each zone, suppose a random sample of $n$ = 80 children is examined for noncoverage by polio vaccine. The tolerance threshold in this case is

$$80 \times 0.10 + 1.645\sqrt{80 \times 0.10 \times 0.90} = 12.4.$$

If the number of nonimmunized children is 13 or more in any sample of size 80, reject that lot. That lot—zone in this case—can be considered to have almost surely not reached the level of 90% coverage required for herd immunity. This is because the probability of 13 or more nonimmunized out of 80 is less than 0.05 when the coverage is 90%. When the problem is stated this way, the conclusion is that 90% (or more) coverage is unlikely. For more assurance, the problem can be stated in a reverse manner with threshold $y = n\pi - 1.645*\sqrt{n\pi(1-\pi)}$ for the maximum nonimmunized. In this example, this is 8.0 − 4.4 = 3.6; that is, if there are 3 or less unimmunized in a lot of 80, you are confident that the level of immunization is at least 90%. Note the reverse nature of this conclusion.

The following comments regarding LQAS may be helpful:

- The division of the total material into lots should preferably be such that each lot is homogeneous while the lots themselves are different from one another. In the example above, the zones may be such that one consists mostly of a slum or underprivileged population and another consists of a population of high socioeconomic status. LQAS can then better identify the zones with low coverage.
- Sometimes, lots with a high proportion of defectives can also be wrongly accepted under this scheme (for that matter, in any statistical decision). This is the same as **Type II error** under the testing of hypothesis procedure. Methods are available to devise an LQAS such that the probability Type II error is under control. For details, see Robertson et al. [2].

## LOWESS plot

This is an acronym for "LOcally WEighted Smooth Scatter" plot. This method finds smoothed predicted value for each point on the basis of **linear regression** fit to the points in the neighborhood, giving more weight to the closer points and less weight to the farther points. Thus, the predicted value of dependent $y$ for any $x_i$ is based on linear regression that gives higher weight to $x_{i-1}$ and $x_{i+1}$ and less weight to the distant values. Higher weight to the immediate neighbor and lower weight to the farther values make it a locally weighted method. This differential weighting requires the weighted least square method in place of the regular **least square method**. The procedure is repeated to obtain the smoothed predicted values for each value of the regressor $x$, which means that a separate weighted regression is performed for every point in the data. When quadratic or other regression is used in place of linear regression for each $x$, the method is called *LOESS* (Local regrESSion) instead of LOWESS.

Figure L.12 shows our version of a LOWESS plot between increasing 25-hydroxyvitamin D levels and the cumulative frequency of community-acquired pneumonia [1]. The straight lines (linear regression) at different points can be distinctly seen. This

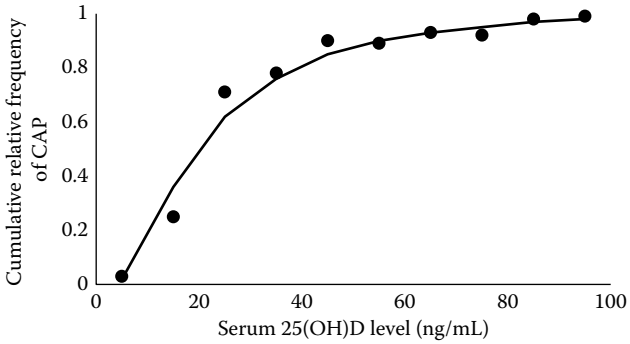

**FIGURE L.12** Locally weighted scatterplot smoothing (LOWESS) plot between increasing 25-hydroxyvitamin D levels and the cumulative frequency of community-acquired pneumonia. (Adapted from Quraishi SA, Bittner EA, Christopher KB, Camargo CA Jr. *PLoS One* 2013 Nov 15;8(11):e81120. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3829945/.)

lacks smoothness that we generally expect in a LOWESS plot. Smoothness is achieved when the number of $x$ values is large.

Consider the regression of bone mineral density (BMD) on age in apparently healthy females of age 40 to 80 years. The objective may be to establish normal values for your population. Under the LOWESS method, the predicted value of BMD for age, say, 52 years will be based on linear regression of BMD on age between, say, 47 and 57 years, giving more weight to the BMD values at age 51 and 53 years (which are close to 52 years) but less weight to the BMD values at age 47 and 57 years. Predicted BMD at 53 years will be based on linear regression of BMD values at age 48 and 58 years by giving more weight to the values at age 52 and 54 years and less weight to the ages far from 53 years. Note how the weight shifts from one value of $x$ (age in this example) and also note that many linear regressions are obtained. This is what makes this method computation intensive. Such a method can be conceived now with computer to our assistance but was unthinkable a few decades ago.

Important features of this method are as follows. (i) It requires that the span of values to be considered for each fit is specified. In our BMD example, this is 10 years—from 47 to 57 years for predicting the BMD at age 52 years, from 48 to 58 years for predicting BMD at age 53 years, and so on. Each smoothed value is determined by neighboring data points defined within this span. Another term for this span is bandwidth. (ii) Because of local weights, the values farther away do not influence the regression as much, and the possibility of some unusual values at the extremes distorting the regression is minimized. (iii) The method would give valid results only when a big series of data points is available with diverse values of the regressor $x$. In our BMD example, if the age is restricted to the narrow range of 40 to 49 years in place of 40 to 80 years, the LOWESS method will not succeed. (iv) The method is easily affected by outliers. If BMD values at the hip for age 65 years are mostly 0.7 to 0.9 g/cm$^2$ and one value is 1.2 g/cm$^2$, the regression could be severely affected. Smoothing is likely to take care of any aberration that might occur somewhere in the middle, but for end point outliers, a robust weight function is available [2]. (v) The method does not produce a regression function that can be represented by a mathematical equation; instead, the plot itself is utilized as the output in most cases.

LOWESS has overriding advantages in some situations, not just in correctly fitting a complex trend that can go up and down, but because it does not require the specification of the equation to fit a trend. That, however, is also a disadvantage since an equation is very helpful in understanding the features of the trend.

## Mahalanobis distance

Mahalanobis distance is the usual **Euclidean distance** between two **multivariate** observations but adjusted for variances and covariances. This does not answer the question whether the two observations are sufficiently different or not; it answers how much is the difference. This distance was developed by Prasanta Mahalanobis in 1930 [1] and further explained in 1936 [2]. A simple explanation has been provided by McLachlan [3].

Prasanta Mahalanobis

In a simple situation, the Euclidean distance between two multivariate observations of $K$ component is measured by $\sqrt{\Sigma_k (x_k - y_k)^2}$, where $k = 1, 2, \ldots, K$; and

$$\text{Mahalanobis distance: } d = \sqrt{\sum_k \left( \frac{x_k - y_k}{s_k} \right)^2},$$

where $s_k$ is the standard deviation (SD) of the $k$th component, provided that the components are independent. In a multivariate setup, this will seldom be the case, and we will come back to this setup.

Consider values of hemoglobin level (Hb) (g/dL), body mass index (BMI) (kg/m$^2$), total cholesterol level (TCL) (mg/dL), and plasma creatinine level (PCL) (mg/dL). Let these be (12.4, 23.7, 189, 0.6) for one person and (13.6, 21.8, 211, 0.8) for another person. How much different are these values? The Euclidean distance between these two is $\sqrt{(12.4-13.6)^2 + (23.7-21.8)^2 + (189-211)^2 + (0.6-0.8)^2} = \sqrt{489.09} = 22.12$. If SD of Hb is 1.7 mg/dL, of BMI 2.4 kg/m$^2$, of TCL 15.2 mg/dL, and of PCL 0.15 mg/dL, the Mahalanobis distance between these two persons (assuming independence) is

$$\sqrt{\frac{(12.4-13.6)^2}{(1.7)^2} + \frac{(23.7-21.8)^2}{(2.4)^2} + \frac{(189-211)^2}{(15.2)^2} + \frac{(0.6-0.8)^2}{(0.15)^2}} = 2.23.$$

Large values in absolute sense such as TCL in our example are divided by the corresponding SD that will also be large, and small values such as PCL in our example are divided by the corresponding small SD. Dividing by the respective SDs tends to equalize the weight of the variables irrespective of the unit of measurement and the extent of variability.

The calculation of Mahalanobis distance just mentioned is valid when the Hb level, BMI, TCL, and PCL are independent of one another. Since this would seldom be the case in a multivariate setup, we need to consider the **covariances** among these variables. Whereas exact formula for Mahalanobis distance will be in terms of matrix notations that we wish to avoid, suffice it to say that it will involve inverse of the **covariance matrix** of the variables. Inverse of the covariance matrix corresponds to the division by the respective SDs in the independent variables setup.

Mahalanobis distance can be used to answer the questions of the type whether average metabolic characteristics of male diabetics are more different from normal than of female diabetics. It is mainly used in classification problems where there are several groups and the concern is with affinity among groups [3]. This distance is also used in **discriminant analysis**.

## main effects and interaction effects in ANOVA

We explain these two in separate subsections.

### *Main Effects*

Main effect is the average effect of a level of **factor** in **analysis of variance (ANOVA)**. This is generally measured as the difference from the overall mean but can also be measured in other manners such as the difference from the control or from the group with minimum level. Suppose the mean increase in hemoglobin (Hb) level in anemic after regimen A is 2.3 g/dL, after regimen B is 4.1 g/dL, and after regimen C is 1.7 g/dL. The average of these three is 2.7 g/dL. Thus, the main effect of regimen A can be considered to be (2.3 – 2.7 =) –0.4 g/dL, of regimen B (4.1 – 2.7 =) +1.4 g/dL, and of regimen C (1.7 – 2.7 =) –1.0 g/dL. Under this formulation of the main effects, their sum is zero and that is a convenience in interpretation and calculations. However, if there is a control group and the mean increase in this group is –0.1 g/dL, the main effect can be measured from this value as 2.4 g/dL for regimen A, 4.2 g/dl for regimen B, and 1.8 g/dL for regimen C.

Similar explanations can be given for the main effects of the levels of two or more factors in an ANOVA setup. Consider the following example of two factors that will also help us in explaining interactions later in this section. A study was done by Wang et al. [1] on the effect of maternal smoking on birth weight in the United States. For our purpose, vary this study and assume that some women, who are otherwise habitual smokers, give up smoking off and on during pregnancy but could not give up altogether. Nonsmokers are excluded in this example. Suppose that such women are asked at the time of their last antenatal visit just before birth about the duration of smoking (factor 1) and the amount of smoking (factor 2). At the end of the

pregnancy, the former is categorized as <18, 18–31, and ≥32 weeks. These are the three levels of factor 1. The amount of smoking is categorized as mild (1–9 cigarettes per day), moderate (10–19 cigarettes per day), and heavy (20+ cigarettes per day). The days in this calculation are only those when at least some smoking was done, and the amount of smoking is average per smoking day. These are the three levels of factor 2. The outcome of interest (response variable) is birth weight of the children born to these women. Let the mean birth weight in different groups be as given in Table M.1.

There are, for instance, 15 women who smoked an average of 1–9 cigarettes per day for a total of less than 18 weeks during the entire pregnancy. Average birth weight of their babies was 3.45 kg. There are 8 women who smoked on average of 1–9 cigarettes per day for a total of 18–31 weeks, and the average birth weight of their babies was 3.38 kg, and so on. Because of unequal $n$, the design is unbalanced. Although in our example, factors 1 and 2 are both ordinal, this feature is overlooked in the present analysis since ANOVA considers all categories nominal.

Main effects and interactions are easy to explain with the help of notations. Let the levels of factor 1 be identified by subscript $j$ ($j$ = 1, 2, …, $J$), of factor 2 by subscript $k$ ($k$ = 1, 2, …, $K$), and subjects within each group by subscript $i$ ($i$ = 1, 2, …, $n$). In our example, $J = 3$ and $K = 3$, but $n$ in different groups is not equal. For the purpose of explaining the concepts, it is useful to keep the notation relatively simple and assume that all groups have the same number $n$ of subjects. The response of the $i$th subject belonging to the $j$th level of factor 1 and the $k$th level of factor 2 is denoted by $y_{ijk}$. If birth weight of the child born to the fourth woman in the group comprising those smoking mildly (first group of amount of smoking) for 18–31 weeks (second group of duration of smoking) is 3.49 kg, then $y_{421} = 3.49$ kg. With these notations, the mean for the $j$th level of factor 1 is $\bar{y}_{.j.}$, and that for the $k$th level of factor 2 is $\bar{y}_{..k}$; the overall mean of all $nJK$ observations is $\bar{y}_{...}$. When measured from the overall mean,

estimated main effect of the $j$th level of factor 1:

$$\hat{\alpha}_j = (\bar{y}_{.j.} - \bar{y}_{...}); \quad j = 1, 2, \ldots, J;$$

and estimated main effect of the $k$th level of factor 2:

$$\hat{\beta}_k = (\bar{y}_{..k} - \bar{y}_{...}); \quad k = 1, 2, \ldots, K.$$

The main effect of smoking for less than 18 weeks in our example is 3.44 – 3.38 = +0.06 kg, and that of moderate smoking is 3.40 – 3.38 = +0.02 kg. The positive effect is not surprising since these are the effects of those categories on the birth weight *compared with the overall mean* of all categories that include the heavy and long-duration smokers. It is easy to show by some algebra that under this definition of main effects, $\Sigma_j \alpha_j = 0$ and $\Sigma_j \beta_j = 0$. Consequently, only $(J - 1)$ α's and $(K - 1)$ β's are independently determined. One each is automatically determined by these conditions.

### Interaction Effect

Variation in the effect of one level of a factor with the levels of the other factor is called **interaction**. The amount of this variation is measured by interaction effect. This is obtained separately for each combination of the levels of the two factors. This is the excess mean after adjustment for the main effects of the concerned level of factors 1 and 2. Thus, the estimated interaction effect between the $j$th level of factor l and the $k$th level of factor 2 is

$$\hat{\theta}_{jk} = (\bar{y}_{.jk} - \bar{y}_{...}) - (\bar{y}_{.j.} - \bar{y}_{...}) - (\bar{y}_{..k} - \bar{y}_{...}) = (\bar{y}_{.jk} - \bar{y}_{.j.} - \bar{y}_{..k} + \bar{y}_{...}),$$

where $\bar{y}_{.jk}$ is the mean of $n$ subjects in the $(j, k)$th group. For example, the estimate of the interaction effect between moderate smoking and smoking for 32+ weeks in Table M.1 is 3.30 – 3.25 – 3.40 + 3.38 = +0.03 kg. Thus, this combination of duration and amount of smoking increases birth weight by 30 g on average in this sample *relative to the means in respective categories*. Note, again, that the overall mean is based on all women including those who are heavy smokers and long-duration smokers. Mathematically, relative to the respective means implies $\Sigma_j \theta_{jk} = 0$ and $\Sigma_k \theta_{jk} = 0$. As always, lack of statistical significance of interaction does not mean interaction is absent. It only means that this could not be detected from the available data. This might be more so in case of ANOVA since the sample size is generally planned to detect main effects, whereas a higher sample size is required for detection of interaction.

The calculations are done on the original values of birth weight in 75 children in our example. Statistical significance of the main and interaction effects is tested by ***F*-test**. Suppose a software package reveals $P > 0.05$ for $F$ when calculated for amount of smoking (factor 2) and $P < 0.01$ for $F$ when calculated for duration of smoking (factor 1). The first is not statistically significant, but the second is. The conclusion then is that this sample of women does not provide sufficient evidence to conclude that the amount of smoking makes a difference in birth weight, but the duration of smoking in the pregnancy does make a difference. Let $P < 0.05$ for $F$ for interaction. This indicates that an interaction between amount of smoking and duration of smoking is present and implies that the effect of duration of smoking on birth weight is not uniform in the three categories of amount of smoking. This can also be easily seen in Figure M.1, which is drawn from

**TABLE M.1**
**Average Birth Weight (kg) of Children Born to Women with Different Amounts and Duration of Smoking**

| Duration of Smoking in Pregnancy | Amount of Smoking | | | |
|---|---|---|---|---|
| | Mild | Moderate | Heavy | All[a] |
| –18 weeks | 3.45 ($n$ = 15) | 3.42 ($n$ = 12) | 3.43 ($n$ = 7) | 3.44 ($n$ = 34) |
| 18–31 weeks | 3.38 ($n$ = 8) | 3.40 ($n$ = 10) | 3.39 ($n$ = 6) | 3.39 ($n$ = 24) |
| 32+ weeks | 3.35 ($n$ = 25) | 3.30 ($n$ = 23) | 3.18 ($n$ = 29) | 3.27 ($n$ = 77) |
| All | 3.39 ($n$ = 48) | 3.35 ($n$ = 45) | 3.25 ($n$ = 42) | 3.33 ($n$ = 135) |

*Note:* Entries are average birth weight in kilograms.

[a] Weighted average because of varying $n$.

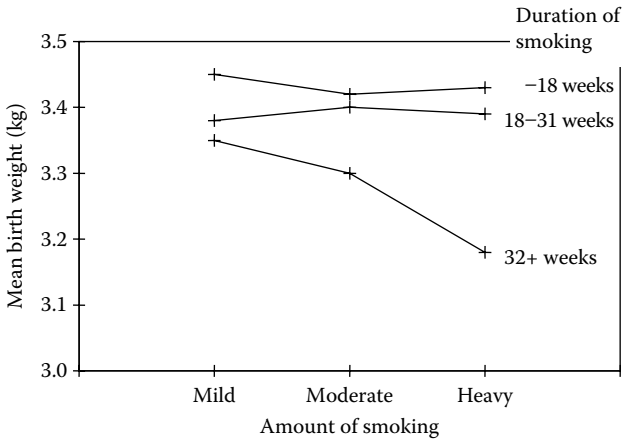

**FIGURE M.1** Interaction between duration and amount of smoking.

the data in Table M.1. If the lines for the three duration groups are parallel, an interaction is said to be absent. In this example, the line is flatter for –18 and 18–31 weeks but shows an unusual dip for smoking heavily for 32+ weeks. This indicates that an interaction is present. Smoking heavily for 32+ weeks steeply reduced the mean birth weight compared with, for example, heavy smoking for 18–31 weeks or moderate smoking for 32+ weeks. This example also illustrates that if the interaction is significant, you should condition your conclusion about one factor's effect on the level of the other factor. When the interaction is not significant, the focus is on main effects. In that case, factor 1 levels should not be compared within factor 2 levels because factor 1 effects are not significantly different. Only the average is adequate.

The equations we have mentioned define the main effects and the interaction effects relative to the overall mean. This is the most commonly used definition, but main effects and interactions can also be defined relative to any other base value. In our example, the base can be changed to the category with least smoking where the mean birth weight is 3.45 kg. In that case, for example, the estimated main effect of heavy smoking would be 3.32 – 3.45 = –0.13 kg. That is, heavy smoking reduces birth weight by 0.13 kg on average compared with the mild smokers for less than 18 weeks. A similar interpretation can be given for the other main effects and interactions when measured from a base value.

## Mantel–Haenszel procedure

This is a procedure for combined inference from the stratified **categorical data** in observational studies that have done stratification of the subjects to control confounding or for some other reason. Strata could be different subgroups but can also be different times, different places, etc. Mantel–Haenszel (M-H) procedure is most commonly used for testing the hypothesis of association in stratified data and for obtaining pooled estimate of **odds ratio** (OR) and **relative risk** (RR) in this setup. A prominent application of this procedure is in **meta-analysis** where results from different studies are combined to get firmer evidence. This is also referred to as *Cochran–Mantel–Haenszel (CMH) procedure*.

Consider recurrence of eclampsia in second or subsequent pregnancies when it once occurred at primigravida stage. It is widely suspected that occurrence at the time of first pregnancy is related to a positive family history of eclampsia, and so is the recurrence. But the risk of recurrence could differentially increase depending on the sex of the family members with hypertension, if any. This could be a **confounding factor**. To examine if it really is, the association between recurrence of eclampsia and family history should be examined separately in the groups with (i) no family history of hypertension, (ii) only female members with history of hypertension, (iii) only male members with history of hypertension, and (iv) both male and female members with history of hypertension. Thus, the data on recurrence of eclampsia are stratified into four groups based on family history of hypertension. We can answer the following three questions:

(i) Is there any association at all in any stratum?
(ii) If there is, is their degree the same in all the strata (if the degree of association in each of these groups is the same, it can be concluded that family history of hypertension has no role)?
(iii) If the degree is the same, what is the pooled estimate of the odds ratio or relative risk?

Stratified analyses are considered fundamental to causal thinking. When confounders exist, overall results are not valid and stratum-specific results should be reported, whereas unadjusted associations are acceptable in the absence of confounding. For adjustment, methods such as the M-H chi-square could be used to get a combined chi-square that would find if there is any association. To get the pooled estimate, the association in different strata should be homogenous, which can be tested, for example, by the **Breslow–Day test** for odds ratio. We explain the M-H procedure for 2 × 2 tables stratified into $K$ strata. Thus, this is limited to subjects cross-classified by two binary characteristics observed for $K$ groups. This incidentally is also the most common and most simple application of the M-H procedure. For further details of the M-H procedure, see Agresti [1].

### *Mantel–Haenszel (M–H) Chi-Square*

Add a subscript $k$ to the observed frequencies in a 2 × 2 table for the $k$th strata ($k = 1, 2, \ldots, K$) so that these are now denoted by $a_k$, $b_k$, $c_k$, and $d_k$, respectively, in place of $a$, $b$, $c$, and $d$. The null hypothesis is that there is no association between the two binary characteristics in any stratum. This can also be stated as OR = 1 for all $k$. The alternative is that OR ≠ 1 for at least one $k$. For cross-sectional studies, the corresponding pooled chi-square is given by

M-H chi-square:

$$\chi^2_{MH} = \frac{\left[\Sigma\left\{(a_k d_k - b_k c_k)/n_k\right\}\right]^2}{\Sigma\left[(a_k + b_k)(c_k + d_k)(a_k + c_k)(b_k + d_k)/\left\{(n_k - 1)n_k^2\right\}\right]},$$

where $a_k$, $b_k$, $c_k$, and $d_k$ are the cell frequencies in the $k$th 2 × 2 table, and $n_k$ is the total number of subjects in the $k$th stratum, that is,

$n_k = (a_k + b_k + c_k + d_k)$. This chi-square has 1 df. It can be shown with some algebra that the numerator of this expression is the square of the (observed – expected) frequencies, and the denominator is the estimated variance of these squared differences.

As for almost any chi-square, M-H also requires a large sample size for all strata together. For small samples, an exact procedure is also available in some statistical software packages. This also requires that all observations are independent, which effectively means that the different subjects do not belong to any specific cluster (such as belonging to one family). Another important prerequisite is that the two binary characteristics under study should have the same chance of being positive in each subject. The association between the two binary characteristics under study should be either positive in all strata or negative in all strata. If it is positive in some and negative in others, the M-H chi-square may not be able to detect it. Statistical significance of M-H chi-square is evidence that the association is consistently in one direction in almost all strata. The one difficulty with the M-H procedure is that only one confounder can be conveniently studied at one time, and the procedure fails if there are many confounders. Also the confounder must be categorical. If it is continuous, categorize this first into meaningful groups and then use the M-H test.

### *Pooled Relative Risk*

In case the M-H test finds significant association, the next step is to use the Breslow–Day test for checking their homogeneity across strata. If yes, a pooled estimate can be obtained. For **prospective studies**, the adjusted M-H pooled RR is given by

$$\text{pooled RR: } \mathrm{RR}_{\mathrm{MH}} = \frac{\sum_k \left[ a_k (b_k + d_k)/n_k \right]}{\sum_k \left[ b_k (a_k + c_k)/n_k \right]}.$$

In case any cell frequency is zero, 0.5 is added to all cell frequencies for computing pooled RR. The sum is over the values of $k$.

The calculations for $\mathrm{RR}_{\mathrm{MH}}$ are illustrated next with the help of an example that also shows how it can help in practical applications.

Consider two strata (males and females) and frequencies of antecedent and outcome characteristics as in Table M.2. Using the usual formulas for **relative risk**, the results for this table are as follows:

$$\mathrm{RR}_1 \text{ for males} = \frac{3/100}{13/450} = 1.04$$

from the first two columns of Table M.2

$$\mathrm{RR}_2 \text{ for females} = \frac{97/400}{12/50} = 1.01$$

from the middle two columns of Table M.2.

**TABLE M.2**
**Cell Frequencies in Two Strata and Combined**

| | Males | | Females | | Combined | |
|---|---|---|---|---|---|---|
| | Antecedent (Exposure) | | Antecedent (Exposure) | | Antecedent (Exposure) | |
| **Outcome** | **Present** | **Absent** | **Present** | **Absent** | **Present** | **Absent** |
| Present | 3 | 13 | 97 | 12 | 100 | 25 |
| Absent | 97 | 437 | 303 | 38 | 400 | 475 |
| **Total** | **100** | **450** | **400** | **50** | **500** | **500** |

These two are not much different.

$$\mathrm{RR}_c \text{ for combined} = \frac{100/500}{25/500} = 4.00$$

from the last two columns of Table M.2.

The combined RR is so different from each of the strata in this example mainly because in males, only 100 are exposed out of 550, but in females, 400 are exposed out of 450. This imbalance is a situation where the M-H procedure is very effective. In this example, by the formula given earlier,

$$\mathrm{RR}_{\mathrm{MH}} = \frac{\left(\frac{3\times 450}{550}\right) + \left(\frac{97\times 50}{450}\right)}{\left(\frac{13\times 100}{550}\right) + \left(\frac{12\times 400}{450}\right)} = \frac{13.2323}{13.0303} = 1.02.$$

The M-H procedure restores the right value, which was masked in the combined data. This is adjusted for the confounding effect of sex.

### *Pooled Odds Ratio*

For **retrospective studies**, the M-H adjusted

$$\text{Pooled OR: } \mathrm{OR}_{\mathrm{MH}} = \frac{\sum_k (a_k d_k / n_k)}{\sum_k (b_k c_k / n_k)}$$

For a simple explanation and an example of use of pooled OR, see Le [2]. As in the case of RR, this pooling also is admissible when the homogeneity of ORs in different strata is not refuted by the Breslow–Day test.

## maps (statistical), *see* choroplethic map, cartogram, spot map, thematic map

## marginal distribution, *see* bivariate distribution, multivariate distribution

## Markov process, *see* stochastic process

## masking, *see* blinding, masking and concealment of allocation

## matched pairs, *see also* matching

Matched pair is a set of two subjects whose characteristics that can influence the outcome but are not of our interest are deliberately matched. One subject of the pair goes to one group under study and the second subject to the other group, such as one gets test regimen and the other gets placebo. This helps in ruling out the effect of such extraneous factors on the results. Identical twins are a good example of matched pair. Statistically, matched observations can also arise naturally in some setups such as in before–after experiments and

crossover designs where the subjects are not matched but the values are pairs as they belong to the same subjects. Matched pairs also arise when the same specimen or its parts are sent to two different laboratories for evaluation, or the same image is examined by two radiologists.

Deliberate matching can be done in any setup but is common in the **clinical trials** that have a small number of subjects in the treatment and the control group. The method generally advocated for equivalence of the two groups in clinical trials is to **randomize** the subjects. This indeed is the gold standard but works well for large samples and is feasible when an adequate number of eligible subjects willing to be randomized are available. Randomization in case of small samples can easily fail to yield two groups with equivalent baseline. Thus, matching is preferred for small samples.

If the number of cases is not as large, examine if matched pairs are available and if the two persons forming a pair can be randomized to receive the test and the control regimen. Thus, randomization and matching can go on simultaneously—they are not mutually exclusive. Matched pair design may be suitable for acute rather than chronic conditions. If the number of eligible subjects is even less, controls may have to come from elsewhere. In this situation, matching becomes even more important. Experiments using matching instead of randomization are called **quasi-experiments**. Evidence from such experiments is not considered as strong as from randomized trials.

It is possible in some situations to simultaneously give a different treatment to known pairs such as two eyes or two limbs of the same persons. Randomization can be done within each pair to determine which one will receive the test regimen and the control regimen. If the trial is on comparison of methods such as pulse oximeter and sphygmomanometer, blood-pressure readings can be taken at the same time in the two arms, and many pairs would be easily available. If the trial is for treatment regimen, it could be extremely difficult to find suitably matched paired organs in some situations, such as of the same severity of glaucoma in the two eyes, or both limbs with same degree of paralysis.

In a **case–control study**, the control group should ideally include exactly similar subjects except for the disease and the antecedent factors under study so that it is parallel in a true sense. Ensuring exact similarity may not be feasible, but it is easy to understand that the cases and controls should be matched with respect to all those factors that do not fall into the set as hypothesized risk factors but can influence the outcome.

Consider a trial on vitamin D supplementation for severe pneumonia in under-five children. It is suspected that the effect of vitamin D could be influenced by the preexisting nutritional status of the children. One strategy to rule out this confounding effect is to choose two children with nearly identical nutritional status, and assign one to the treatment group and the other to the control group. Now move on to select another pair with the same nutritional status and assign to the two groups under study, and so on. The nutritional status of the second pair need not be the same as that of the first pair. Both the groups receive regular treatment, but one group gets vitamin D supplementation and the other gets placebo. This is an example of matched pairs, but the results would still be affected if, for example, well-nourished children are overrepresented in both the groups compared with the target population.

Matching tends to take away the independence of the values that is so commonly needed in the analysis of data, and separate methods are used in case of matched pairs. In case of quantitative data, these methods generally use the difference in the values of the pairs rather than the values themselves. If the recovery time of one subject of a pair is 5 days and that of the other is 7 days, the difference is –2 days. Such differences are obtained for each pair, and the analysis is done of these differences. Realize that these differences belong to different pairs of subjects—and thus are independent. Usual statistical methods can be used on these differences. This is the method followed, for example, in the **Student *t*-test** for paired data.

In the case of qualitative response, the magnitude of difference cannot be obtained; instead concordant and disconcordant pairs are counted. Both subjects of the pair with the same response are called concordant, and the pairs with one subject's response different from the other are called disconcordant. For **dichotomous** outcomes, we have methods such as **McNemar chi-square** for testing the statistical significance of the association, and for polytomous outcomes, methods such as **Cohen kappa** are used to assess the degree of association. See those topics for examples.

## matching, *see also* matched pairs

Choosing subjects of a study that are similar with respect to the extraneous characteristics that can affect the outcome and allocating them to different groups for some intervention, such as test regimen and placebo, is called matching. This is a popular statistical strategy for ruling out the effect of some extraneous factors that can influence the results. Matching helps in minimizing the bias in study results, but the matching criteria should be identified before conducting the study and should be stated in the protocol. Matching after seeing the data can produce biased results. Matched data can also arise naturally in some setups such as in **before–after** studies, **repeated measure** studies, and **agreement** studies.

In addition to selection, matching should also be in ascertainment. Consider whether the cases and controls in a study are likely to respond to the questionnaire in a similar manner, and no bias is likely to creep in due to the differential pattern of responses not related to the factors under study. The controls must be assessed with the same keenness and with the same methodology as for the cases. Similar proforma and procedures should be used as far as possible. If cases are being interviewed in a clinic, the controls should also be interviewed in a clinic. Controls may be healthy subjects, but interviewing them at home or by telephone can alter the response. Cases with disease may be more motivated, but try to extract the same cooperation from the controls as well. Controls should be able to provide an equally correct estimate of the rate of occurrence of antecedents in subjects without the disease.

Ideally, all relevant characteristics that might influence the outcome, except those under study, should be matched. This does not stop at age and sex as is sometimes done. Nonetheless, comprehensive matching for all prognostic factors may not be feasible in all situations, and some constraints on conclusions may become necessary. For example, in a trial of a new oral antidiabetic drug, the subjects in the test and the control group could be matched for age, sex, and perhaps obesity, but it may be difficult to match for genetic factors and stress conditions. These two factors can also influence the outcome. The other important prognostic factors in this setup are severity of the disease and any coexisting disease. All such factors may have to be adjusted at the time of analysis. Note that matching characteristics cannot be studied later on for finding their effect on the outcome—thus, the matching criteria should be carefully chosen.

The other limitation is that matching can be tried only for the known factors. There might be other factors in the **epistemic** domain about which nobody knows yet—an uncertainty that still remains. Note that randomization has the advantage of giving chance to

known as well as unknown factors to be equally distributed; matching does not have this feature.

You can see that matching may mean incurring extra cost due to baseline investigation on a large number of subjects, many of which may be discarded as unmatchable. Generalizability suffers as the control group is somewhat distorted and interactions cannot be properly assessed. Also, matched data require special methods of statistical analysis such as **repeated measures ANOVA** and **Cohen kappa**.

**Matched pairs** are discussed as a separate topic in this volume. The following are the details of other types of matching.

### *Baseline Matching*

Baseline matching applies to **prospective studies** including before–after studies. For valid comparison in these studies, the exposed and unexposed groups must be similar at baseline, particularly with regard to the factors that can influence the outcome and are not of interest. If the objective is to study the effect of recently acquired central obesity on the electrocardiogram changes over time, factors such as age, gender, personality traits, stress conditions, and smoking need to be matched between the study group (with central obesity) and the control group (without central obesity). If complete matching is not possible, as would generally happen in practice, statistical methods are used to do the required adjustment at the time of analysis. Such an adjustment can become incomprehensible if done for a large number of factors. If exposure is by choice such as smoking and taking aspirin, the unexposed group may have to be matched also for factors affecting such exposure.

### *One-to-One and One-to-Many Matching*

The results of **case–control studies** are much more valid if there is one-to-one matching between cases and controls, i.e., each case should have a corresponding one matched control. These are also called **matched pairs** and the process is called matching. The attempt should be to simulate an identical twins situation. The purpose is to be able to conclude that any difference between the cases and controls is attributable to the antecedent under study and to no other factor. Thus, the role of extraneous factors is minimized. In the case of near-perfect one-to-one matching, the statistical analysis should consider two groups as paired and not independent samples.

It may not be possible to find a control of age 62 years for matching with a case of 62 years. In most situations, matching within ±2 years for adults is considered adequate. Such relaxation can be possibly allowed for other factors as well. An alternative is to divide age into age groups and match for age group.

In most cases, one matched control is included in the study for each case, but when controls are easy to find and are less expensive, you can include two or more controls for each case. This increases the sample size and helps to increase the reliability of the conclusion. These controls can also be matched with respect to all the extraneous factors of no interest to the investigation. This gives rise to one-to-many matching. Depending upon how many controls are available, two—sometimes even three or four—controls are included for each case.

### *Frequency Matching or Group Matching*

Matching more than two or three confounders is an uphill task because of limited availability of eligible subjects. Generally, matching stops at age and sex, which are influential factors in almost every medical setup. If matching of many confounders is required, which indeed is desirable, an acceptable but less valid procedure is *group matching* (also called *frequency matching*). Under this scheme, controls are matched with the cases on average or with regard to pattern of presence of the extraneous factors. If obesity is such a factor, and if 35% of cases are obese, then nearly the same percentage of controls should also be obese for group matching. Since finding controls with many matching characteristics can be difficult, some factors may have to be adjusted at the time of analysis even when group matching is done.

### *Overmatching*

We have made out a case for matching for all the factors that can affect the outcome except the ones under study. The last qualifier is the actual operational clause. This is sometimes ignored. The real question is what to do with factors that affect the outcome as well as the risk factors under study—called **confounders**. Matching for these can sometimes result in overmatching, and biased results toward the null are obtained. For example, in a study on the effect of postmenopausal estrogens on uterine cancer, matching on uterine bleeding can present invalid findings since uterine bleeding is associated with uterine cancer also. Any matching on such outcome-related variable can distort the results. Look also at the following example.

Marsh et al. [1] describe a study of relation between radiation exposure and mortality from leukemia in workers at a nuclear reprocessing plant. The matching factors in this study were site, sex, work status, age (within 2 years), and date of entry (within 2 years). Note that risk of leukemia varies with these factors, and they looked like valid factors for matching. Date of entry was considered necessary as the risk of leukemia changes with calendar time. Examination of data since 1950 shows that the radiation dose steeply declined after 1980. Matching for date of entry unwittingly also matched for radiation exposure, which was the antecedent under study. Such overmatching obscured the relationship between radiation dose and risk of leukemia. Likewise, exposure-related variables that can make risk factor distribution similar in cases and controls should not be matched as overmatching can reduce the statistical significance of the results.

## maternal mortality ratio, *see also* mortality rates

The term *maternal mortality* applies when the cause of death in women is related to or aggravated by pregnancy or its management. For practical reasons, the World Health Organization (WHO) definition includes only maternal deaths that occur either during pregnancy or within 42 days after the termination of pregnancy. The cause may be direct such as hemorrhage, sepsis, eclampsia, and abortion, or indirect such as heart diseases in pregnancy and hepatitis. However, accidental or incidental deaths are excluded. Maternal mortality is measured as follows:

$$\text{Maternal mortality ratio: MMR} = \frac{\text{maternal deaths}}{\text{live births}} * 100{,}000.$$

The denominator in this formula is live births, but multiple births are counted as one. Realize that maternal mortality can also occur at the time of stillbirth or abortion. The data on stillbirths may be available; it is extremely difficult to get the count of abortions even

in the best of conditions. The group at risk comprises women of reproductive age, but this is not used as the denominator for the events in the numerator—thus, MMR is called a ratio and not a rate. If the denominator is replaced by the number of women of reproductive age group, this becomes a rate.

Maternal deaths in developing countries are now receiving more attention. Many of these countries do not have a sufficiently strong system to monitor every maternal death; some deaths escape attention. Thus, the reported rate is low compared with the actual rate. WHO, United Nations Population Fund, the World Bank, and United Nations Children's Emergency Fund made joint efforts to arrive at more realistic estimates of MMR in all countries. They used surrogates such as proportion of births with different types of birth attendants and general fertility rate to arrive at these estimates [1]. Data on these surrogates are more easily available and more accurate. According to these estimates, the global MMR declined by 45% between 1990 and 2013—from 380 deaths to 210 deaths per 100,000 live births. The minimum MMR in 2013 was nearly 1 in Belarus, and the maximum was 1100 in Sierra Leone per 100,000 live births [2].

## Mauchly test for sphericity

The Mauchly test assesses the validity of the sphericity assumption that underlies univariate **repeated measures analysis of variance** (ANOVA). It was developed by John Mauchly in 1940 [1]. We first explain sphericity and then describe the Mauchly test.

### *Sphericity in Repeated Measures*

In repeated measures, sphericity is the equality of variances of the differences in values observed at different points in time and covariances of these differences being zero. As usual, this refers to the population parameters rather than to the sample values. Repeated measures ANOVA uses these differences, and such homogeneity is required for valid results. Note that the concept of sphericity applies only when you have three or more repeated values. If you have just two repetitions, there is only one difference, and the question of sphericity does not arise.

Suppose the brain size of pregnant women [2] is measured by magnetic resonance imaging at 3, 6, and 9 months of pregnancy to find if pregnancy affects the brain size. Let the values obtained be as in Table M.3. The differences and their variances are also shown in the table. Sphericity is about equality of variances at the bottom of the last three columns. In this example, the variance of the difference in brain size between 3 and 9 months, and between 6 and 9 months are nearly the same, but the variance of the difference between 3 and 6 months is large. Thus, the sphericity condition is not likely to be valid for repeated measures ANOVA in these data.

The sphericity can also be studied by the correlation structure of the values obtained at different time points. This is sometimes confused with *compound symmetry* where not just the covariances between values at different time points are the same, but the variances of values at different time points are also the same. This is more than required for sphericity. Sphericity requires same variances of the differences but not the same variances of the values at different time points. In other words, compound symmetry is sufficient for sphericity but not necessary.

**TABLE M.3**
**Sample Variances of Differences in Brain Size of Pregnant Women at Different Periods of Gestation**

| | Brain Size ($cm^3$) | | | Difference | | |
|---|---|---|---|---|---|---|
| Subject No: | t1 = 3 Months | t2 = 6 Months | t3 = 9 Months | t1-t2 | t1-t3 | t2-t3 |
| 1 | 1260 | 1273 | 1232 | –13 | 28 | 41 |
| 2 | 1159 | 1143 | 1123 | 16 | 36 | 20 |
| 3 | 1232 | 1223 | 1221 | 9 | 11 | 2 |
| 4 | 1342 | 1302 | 1295 | 40 | 47 | 7 |
| 5 | 1167 | 1198 | 1163 | –31 | 4 | 35 |
| 6 | 1252 | 1241 | 1232 | 11 | 20 | 9 |
| **Mean** | **1235.33** | **1230.00** | **1211.00** | **5.33** | **24.33** | **19.00** |
| **Variance** | **4554.27** | **3159.20** | **3617.20** | **603.47** | **254.67** | **254.80** |

Let us also mention as a side note that sphericity is the requirement for repeated measures ANOVA when univariate methods are used and not for multivariate methods. A univariate method is advised when the sample size is relatively small (say, $n < K + 10$, where $K$ is the number of repeated measures), unequal from group to group, and sphericity is not violated. There is another twist to the story. When sphericity is violated, the univariate solution is to reduce the degrees of freedom (df) by what is called **Huynh–Feldt correction** or similar other corrections. This correction is a multiplier less than or equal to 1, called ε, and depends on the extent of lack of sphericity in the data—the more the departure, the more the correction. The mean squares and other calculations including the actual value of the $\boldsymbol{F}$-statistic remain the same; only the df changes. This reduction in df increases the critical value and thus adjusts the Type I error to the correct level for lack of sphericity. Since this correction to the df is available, you can directly use this correction without going through the process of checking the validity of sphericity in your data. This makes the Mauchly test redundant but is still commonly used for medical data.

Repeated measures can also be analyzed by **MANOVA** where sphericity is not a strict requirement. But MANOVA requires a large sample and still depends on the covariance structure. MANOVA is recommended when sphericity is seriously violated (say, $\varepsilon < 0.7$), but group sizes should be equal.

### *Mauchly Test*

The computational formula for the Mauchly test is a complex one that we wish to avoid. However, this is the default test of sphericity in several common statistical software programs. You should not have any difficulty in using this test when needed. This follows a chi-square distribution with $\left(\frac{K(K-1)}{2}-1\right)$ df, where $K$ is the number of repeated measures. Note that $K(K-1)/2$ is the number of pairwise differences when the measurement is repeated $K$ times.

The validity condition of the Mauchly test includes multivariate Gaussian (normal) distribution of the data, and the test is not robust to non-Gaussianity. If the data do not have a Gaussian pattern, think

of some transformation before using the Mauchly test. In that case, the repeated measures ANOVA will also be on the transformed values. The other limitation of the Mauchly test is that it fails when the sample size is too small and overdetects sphericity in very large samples. A significant Mauchly test result indicates that the assumption of sphericity is untenable, and the df in repeated measures ANOVA $F$-test needs correction as already suggested.

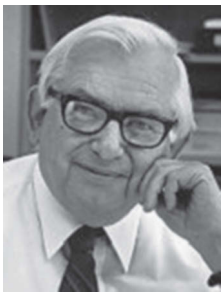
## maximum likelihood method, *see* likelihood, log-likelihood, and maximum likelihood estimates

## McNemar–Bowker test

This test is for internal symmetry in a $C \times C$ (square) **contingency table**, and checks whether the frequency in the $i$th column and the $j$th row is different or not from the frequency in the $j$th column and the $i$th row ($i = 1, 2, \ldots, C$; $j = 1, 2, \ldots, C$) in that population. This kind of problem arises in matched pairs when the assessment is in **polytomous** categories in place of the usual **dichotomous** categories. Thus, this is an extension of the **McNemar test** from 2 to many categories. If the corresponding probabilities in the population are denoted by $\pi_{ij}$, the null hypothesis for the McNemar–Bowker test is $H_0$: $\pi_{ij} = \pi_{ji}$ for all $(i, j)$, and the alternative hypothesis is $H_1$: $\pi_{ij} \neq \pi_{ji}$ for at least one pair of $(\pi_{ij}, \pi_{ji})$. Albert Bowker [1] provided this extension, and the test is also referred to simply as the **Bowker test** in the literature. This is computed as

$$\text{McNemar} - \text{Bowker test: } Q_{\text{MB}} = \sum_{i<j} \frac{(O_{ij} - O_{ji})^2}{O_{ij} + O_{ji}},$$

where $O_{ij}$ is the observed frequency in the $(i,j)$th cell and $O_{ji}$ in the $(j,i)$th cell. This has **chi-square** distribution with $C(C-1)/2$ degrees of freedom (df) for large samples. Thus, the ***P*-value** can be easily obtained.



Albert Bowker

A good example of an application of the McNemar–Bowker test is comparing a health parameter of the right side with the left side of the same person, such as cataract (nuclear, cortical, and subscapular) in the left eye and the right eye, and size (shrunk, normal, and enlarged) of the left kidney and the right kidney. There are many paired organs in our body where this kind of test would be needed when the measurement is qualitative in more than two categories.

**TABLE M.4**
**Follow-Up Clinical and MRI Results for Spinal Infections Patients**

| | Improved Clinically | No Change Clinically | Worse Clinically | Total |
|---|---|---|---|---|
| MRI improved | 33 (33.7%) | 12 (12.2%) | 0 (0.0%) | **45 (45.9%)** |
| MRI unchanged | 16 (16.3%) | 5 (5.1%) | 3 (3.1%) | **24 (24.5%)** |
| MRI worse | 20 (20.4%) | 4 (4.1%) | 5 (5.1%) | **29 (29.6%)** |
| **Total** | **69 (70.4%)** | **21 (21.4%)** | **8 (8.2%)** | **98 (100%)** |

It is not necessary that the row and column categories are same. However, the characteristic in the row should have exactly the same number of categories as the characteristic in the column, and both characteristics should be assessed for the same subjects. Baxi et al. [2] compared the follow-up clinical status and magnetic resonance imaging (MRI) of patients with spinal infections in the United States and obtained the data on 98 patients as given in Table M.4. The objective is to evaluate the concordance between clinical improvement and MRI improvement. In this table, $C = 3$ as there are three rows and three columns. Thus, the df for the McNemar–Bowker test is $3 \times 2/2 = 3$. The authors report the McNemar–Bowker test highly significant ($P < 0.001$), indicating that MRI improvement did not correspond with clinical improvement. They concluded that the use of MRI without new clinical indications in routine follow-up testing should be interpreted with caution.

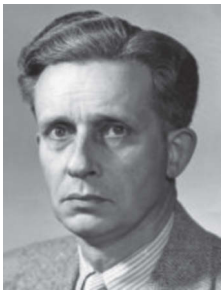
## McNemar test

Introduced by Quinn McNemar in 1947 [1], this test is used to assess statistical significance of association between two attributes when a pair of observations is taken on the same group of subjects. The usual procedure described under the topic **chi-square test for 2 × 2 tables** is valid only when the two groups of subjects are independent. Independence is lost when there is one-to-one matching or pairing, a frequently adopted mechanism in medical studies. Pairing also occurs when the same group of subjects is observed before and after therapy. A matched pair is considered one unit, and the contingency table contains the number of units or pairs with both elements positive, the first element positive and the second negative, the first negative and the second positive, and both negative. These can be denoted respectively by $a$, $b$, $c$, and $d$ as in Table M.5. This table is arranged for a prospective study with exposure–outcome format. There are $n$ matched pairs in all in this table, and the cell frequencies are the numbers of the pairs in different categories. For example, $b$ is the number of pairs in which the exposed partner develops

**TABLE M.5**
**Matched Pairs with Dichotomous Antecedent and Dichotomous Outcome: Prospective Study**

| | Partner 1 Antecedent Not Present (Not Exposed or Control) | | |
|---|---|---|---|
| **Partner 2 Antecedent Present (Exposed or Experiment)** | **Positive Outcome (Disease+)** | **Negative Outcome (Disease–)** | **Total** |
| Positive outcome (disease+) | *a* | *b* | ***a + b*** |
| Negative outcome (disease–) | *c* | *d* | ***c + d*** |
| **Total** | ***a + c*** | ***b + d*** | ***n = a + b + c + d*** |

the disease and the nonexposed partner does not develop the disease. This is the number of disconcordant pairs of one type—the other being *c*. *a* and *d* are the numbers of concordant pairs.



Quinn McNemar

A very popular criterion for testing association in case of matched pairs is as follows:

$$\text{McNemar test: } \chi^2_M = \frac{\left(|b-c|-1\right)^2}{b+c},$$

where *b* and *c* are as given in Table M.5. For large *n*, this is referred to as a chi-square distribution with 1 df for obtaining the *P*-value. The restriction of no expected cell frequency less than five applies to the cells containing *b* and *c*. The subtraction of one in the numerator of this formula represents a **continuity correction** similar to Yates correction for chi-square. Note that the concordant pairs *a* and *d* do not contribute to the decision, and it is based solely on the number of discordant pairs of the two types. Significance would mean that the disconcordance is not symmetric, and the pairs do not match with respect to the outcome. The numbers *b* and *c* can be large, but if they are equal, the test will not give significance. This is illustrated in the example below.

To evaluate the role of a therapy in relieving common cold within a week, suppose 50 cases underwent the therapy and another group of 50 cases served as controls. The experimental and control cases were matched one-to-one for age, gender, and body mass index (BMI) so that these do not act as confounders. Matching on BMI was done largely to rule out nutritional status as a confounder. The results obtained are summarized in Table M.6. There are 22 pairs in which both types of subjects—with therapy and without therapy—felt relieved in 1 week's time. In 15 pairs, the subject with therapy felt relieved, but the subject without therapy did not feel so. The

**TABLE M.6**
**Trial for Therapy for Common Cold: Matched Pairs**

| | Without Therapy (Control Group) | | |
|---|---|---|---|
| **With Therapy (Experimental Group)** | **Relieved within 1 Week** | **Not Relieved within 1 Week** | **Total** |
| Relieved within 1 week | 22 | 15 | **37** |
| Not relieved within 1 week | 5 | 8 | **13** |
| **Total** | **27** | **23** | **50** |

frequencies in the second row can be similarly explained. In this table, $b = 15$ and $c = 5$. Therefore,

$$\text{McNemar } \chi^2_M = \frac{\left(|15-5|-1\right)^2}{15+5} = 4.05.$$

A software package gives $P = 0.044$, which is less than 5% for this value of chi-square. The null hypothesis in this case is that the therapy has no effect. But the likelihood of this sample coming from this null is extremely small—less than 5%. Thus, reject $H_0$ and conclude that the therapy is helpful in relieving common cold within 1 week. Note that the number of those relieved by therapy (15 subjects) is much more than those relieved without therapy (5 subjects) among the discordant pairs.

The McNemar test is valid for large *n*. For small *n*, there is an exact test for association in matched pairs as described under the topic **binomial test**.

1. McNemar Q. Note on the sampling error of the difference between correlated proportions or percentages. *Psychometrika* 1947;12(2):153–7. http://link.springer.com/article/10.1007%2FBF02295996

## mean (arithmetic, geometric and harmonic), *see also* mean, median, and mode (calculation of)

### *Arithmetic Mean*

The usual mean, called the average in day-to-day language, is statistically called the arithmetic mean. This is calculated as $\Sigma x/n$ in the case of ungrouped data and as $(\Sigma f_k x_k)/n$ in the case of grouped data, where $f_k$ is the frequency (number of subjects) in the $k$th class interval and $x_k$ is the midpoint of the class interval. For further details, see the topic **mean, median, and mode (calculation of)**. The arithmetic mean is used where the numbers are additive. This does not apply to multiplicative values such as dilution and pH values. This is also not used for values measured in logarithmic units. For these, use the geometric mean (GM).

### *Geometric Mean*

In place of sum of the values used in arithmetic mean, the GM uses the multiplication of the values, and in place of dividing by the number of values *n*, it takes the *n*th root of the values. Thus,

$$\text{GM} = (x_1 * x_2 * \cdots * x_n)^{1/n}.$$

This shows that $\log\text{GM} = (1/n)*\Sigma \log x_i$. Thus, the GM is the antilogarithm of the arithmetic mean of logarithms. In the case of grouped data, this becomes

$$\text{GM (grouped data): } \log\text{GM} = (1/n)*\Sigma f_k \log x_k,$$

where $x_k$ is the midpoint of the $k$th ($k$ = 1, 2, …, $K$) interval that has $f_k$ frequency, and $n = \Sigma f_k$.

Since the $n$th root is involved, the GM can be calculated only when all $x$'s are positive. The GM can be very different from arithmetic mean; for example, the GM of 4, 16, and 64 is 16, whereas the arithmetic mean of these values is 84/3 = 28.

The GM is used extensively in microbiological and serological research where the observations are often expressed as titers: the dilutions of certain suspensions or reagents at which a specified phenomenon (for example, agglutination of red blood cells) first takes place. With repeated observations, the possible values of a titer will usually be multiples of the same dilution factor, for example, 2, 4, 8, 16, etc., for twofold dilutions. Denote the titer by $x$ and the log titer by $u$ (= log $x$). The arithmetic mean of $u$ is the logarithm of the GM—take the antilog to get the GM. Another common use of this measure is in tissue attenuation correction for gastric emptying time. The GM of gastric counts is considered the **gold standard** for this correction. Gastric counts generally have a multiplicative feature so that the GM is more appropriate than the arithmetic mean. The GM is also used for gamma radiation count since these also are multiplicative rather than additive.

Situations in which logarithmic transformation of values is helpful in achieving certain desirable statistical properties are discussed under the topic **logarithmic scale/transformation**. The GM can be gainfully used in those cases. A statistical property of the GM is that it can never be greater than the arithmetic mean, and the two means are equal only if all the $x$'s are the same. This property can be used to find if the values are nearly the same or not. If the GM and the arithmetic mean are given and the actual values are not known, you can roughly assess the variation in the values by the closeness of the GM to the arithmetic mean.

### *Harmonic Mean*

This type of mean transforms the data to reciprocals, calculates the arithmetic mean on the transformed scale, and then converts back to the original scale by taking the reciprocal again. The resulting quantity is known as the harmonic mean (HM). In simple terms, the HM is the reciprocal of the mean of the reciprocals. It is rare to find this being used but is useful for averaging the rates.

Sometimes rates are stated in a reciprocal manner. An example is the average population served per doctor. If this is 1000 for the rural area in a district and 500 for the urban area, what is the average for the district as a whole? Even if the populations in rural and urban areas are equal, the average is not 750. The data in Table M.7 explain this anomaly.

When rural and urban areas are combined, the average population served per doctor is 100,000/150 = 667 in area 1 and not 750, the simple average of 1000 and 500. This correct average can be computed as follows:

$$\text{Average population served per doctor} = \frac{50{,}000 + 50{,}000}{\frac{50{,}000}{1000} + \frac{50{,}000}{500}} = 667.$$

This is the HM. If the populations in rural and urban areas are unequal as in area 2 in Table M.7, the average population served per doctor is 100,000/125 = 800. This also can be obtained as the HM:

$$\text{Average population served per doctor} = \frac{75{,}000 + 25{,}000}{\frac{75{,}000}{1000} + \frac{25{,}000}{500}} = 800.$$

The general procedure for calculating the HM for grouped data is as follows:

$$\text{Harmonic mean} = \frac{\Sigma f_k}{\frac{f_1}{x_1} + \frac{f_2}{x_2} + \cdots + \frac{f_K}{x_K}},$$

where $x_k$ is the value in $f_k$ subjects. In case of categorized metric data, $x_k$ is the midpoint of the $k$th class interval ($k$ = 1, 2, …, $K$). For ungrouped data, each $f_k$ = 1 for all $k$ and $K = n$. Note the following:

- The GM gives relatively small weight to the large values, and the HM gives relatively large weight to the small values. This may become necessary in some cases as illustrated above. However, the use of these two averages is relatively rare and rightly so since they are difficult to calculate and understand, and are not desirable unless really needed.
- Just as the GM, the HM too cannot be computed if one or more values are zero or negative.

## mean deviation, *see* variation (measures of)

## mean, median, and mode (calculation of), *see also* central values (understanding and which one to use)

Mean, median, and mode are three statistical measures of central values in the data. Statistically, mean is of three different types as separately described under the topic **mean (arithmetic, geometric, and harmonic)**. When not so qualified, mean is the arithmetic mean

**TABLE M.7**
**Population Served per Doctor in Rural and Urban Areas: Equal and Unequal Rural–Urban Population**

| | | Area 1 (Equal Rural–Urban Distribution) | | Area 2 (Unequal Rural–Urban Distribution) | |
|---|---|---|---|---|---|
| Area | Population Served per Doctor | Population | Number of Doctors | Population | Number of Doctors |
| Rural | 1000 | 50,000 | 50 | 75,000 | 75 |
| Urban | 500 | 50,000 | 100 | 25,000 | 50 |
| | **Total** | **100,000** | **150** | **100,000** | **125** |

and is the usual average. Mean still is the most useful statistical tool ever invented and perhaps the most widely used.

The average is a very popular measure of central value. If $x_1$, $x_2$,..., $x_n$ are $n$ observations in our sample, the sample mean is $\bar{x} = \Sigma x_i/n$. The median is the middle value, which is obtained as the $\left(\frac{n+1}{2}\right)$th value if $n$ is odd, after arranging in ascending order, and the average of $\left(\frac{n}{2}\right)$th and $\left(\frac{n}{2}+1\right)$th if $n$ is even. The mode is the most common value. Their calculation in a simple data is illustrated next.

The following are the days of immobility in 38 women with acute polymyositis of the back:

| | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 7 | 5 | 9 | 7 | 36 | 4 | 6 | 7 | 5 | 8 | 3 | 6 | 5 |
| 7 | 8 | 10 | 7 | 14 | 10 | 9 | 4 | 6 | 11 | 9 | 6 | 5 |
| 8 | 8 | 6 | 7 | 5 | 5 | 12 | 3 | 5 | 9 | 10 | 7 | |

Mean = 7.9 days
Median = Average of the 19th and 20th values after rearranging in ascending order
= (7 + 7)/2 = 7 days
Mode = 5 days and 7 days, occurring in 7 patients each

Mean is denoted by $\bar{x}$ for sample and by μ for population. No such universally accepted notations are available for median and mode.

Mean should not be calculated for codes, but when the measurement is **dichotomous** such as code 0 for absence of a characteristic and 1 for presence of the characteristic, the average has a valid physical meaning—it is the proportion of cases with the presence of the characteristic. Mean, median, and mode can be calculated for **ordinal** data such as 0 for no disease, 1 for mild, 2 for moderate, 3 for serious, and 4 for critical disease; but these are then used as scores and not codes in the sense that the sum of one mild with score 1 and one moderate case with score 2 is equal to score 3, which is the score for serious disease. Be careful since this kind of implication is not valid for many ordinal characteristics.

### *Calculations in the Case of Grouped Data*

When the exact values are available, the calculations must invariably be based on such values. However, for reasons given for **categories of data values**, the data are sometimes available in grouped form. In that case, the calculations become approximate. In many applications, the midpoint of the class intervals containing the required central value is considered adequate. However, the best approximations are obtained as follows.

Let the class intervals in ascending order be $(a_0, a_1)$, $(a_1, a_2)$, …, $(a_{K-1}, a_K)$ and their midpoints $x_k = (a_{k-1} + a_k)/2$, $k = 1, 2, \ldots, K$. Note that these are continuous intervals, and there is no gap between $a_{k-1}$ and $a_k$. Be careful of this requirement. If age intervals are like 10–14, 15–19, etc., they have to be considered as 10–15, 15–20, etc. This actually is so since age 14 in completed years is the same as age <15 years. However, the frequency can be zero in any interval—that does not make them discontinuous. Let the number of subjects or the frequency in the first interval be $f_1$, the second interval $f_2$, and so on. Then,

$$\text{grouped data: mean} = \frac{\Sigma f_k x_k}{n}, \text{ where } n = \Sigma f_k,$$

$$\text{grouped data: median} = a_{m-1} + \frac{n/2 - C}{f_m} * h_m,$$

where
$f_m$ is the frequency in the interval containing the $(n/2)$th observation (called the median interval).
$a_{m-1}$ is the lower limit of the median interval.
$C$ is the cumulative frequency preceding the median interval.
$h_m$ is the width of the median interval.

$$\text{Grouped data: mode} = a_{M-1} + \frac{f_M - f_{M-1}}{2f_M - f_{M-1} - f_{M+1}} * h_M,$$

where
$f_M$ is the frequency in the interval with the highest frequency (modal class).
$f_{M-1}$ and $f_{M+1}$ are the frequencies in the preceding and succeeding intervals.
$a_{M-1}$ is the lower limit of the modal class.
$h_M$ is the width of the modal class.

The last considers adjacent frequencies to identify the peak that determines the mode. The following example illustrates the calculations. These are the same data as in the previous example in this section, but they are now grouped.

The continuous intervals formed in Table M.8 are a natural consequence of the observed durations. The duration of immobility would rarely be exactly 6 days or exactly 8 days. When it is noted as 6 days, it is likely to be anywhere between 5.5 and 6.5 days. If the duration is noted in terms of completed days, then 6 days is really between 6 and 7 days. In that case, the continuous intervals would be (3–6), (6–9), etc., and the mean, median, and mode would change accordingly. For the data in Table M.8,

$$\text{mean} = (11 \times 4 + 16 \times 7 + 8 \times 10 + 2 \times 13 + 1 \times 36)/38 = 7.8 \text{ days.}$$

For the median, the interval containing the 19th and 20th observations is (5.5–8.5) days. Thus, $f_m = 16$, $a_{m-1} = 5.5$, and $C = 11$. Also, $h_m = 3$. Thus,

$$\text{median} = 5.5 + \frac{19-11}{16} \times 3 = 7.0 \text{ days.}$$

**TABLE M.8**
**Grouping of Data in Duration of Immobility in Cases of Acute Polymyositis**

| Group ($a_{k-1}$, $a_k$) | 2.5–5.5 | 5.5–8.5 | 8.5–11.5 | 11.5–14.5 | 36 | Total |
|---|---|---|---|---|---|---|
| Midpoint ($x_k$) | 4 | 7 | 10 | 13 | 36 | |
| Frequency ($f_k$) | 11 | 16 | 8 | 2 | 1 | **38** |
| Cumulative frequency | 11 | 27 | 35 | 37 | 38 | |

Note that 19 is away from cumulative 11, and it is reasonable to divide this difference proportionately. For the mode, the interval containing the highest frequency is again (5.5–8.5) days. Thus, $f_M$ = 16, $a_{M-1}$ = 5.5, $f_{M-1}$ = 11, and $f_{M+1}$ = 8.

$$\text{Mode} = 5.5 + \frac{16-11}{32-11-8} \times 3 = 6.7 \text{ days.}$$

In case the graphical representation indicates that there are two or more modes, similar calculations will be required for each mode, after identifying its modal class. As explained for **bimodal distribution**, one mode may be for smaller peak and the other for the higher peak.

### *Features of Mean, Median, and Mode*

The values of mean, median, and mode sometimes change because of grouping. The values obtained on the basis of the ungrouped data in our example are exact. The approximation in grouped data occurs because all observations in an interval are assumed to be at its midpoint. The magnitude of error depends mostly on the width of the intervals. You may wish to try another grouping and see how the values of the mean, median, and mode are affected.

Mean, median, and mode are proportionately affected by change of origin and scale. For example, if you add 6 to each value of $x$, the mean will also be 6 more. If you multiply each value of $x$ by 3, the value of the mean will also be thrice as much as the original. That is,

$$\text{mean}(a + bx) = a + b^*\text{mean}(x).$$

If body temperature is measured in Fahrenheit and subsequently required to be converted to Celsius, there is no need to calculate the mean again. Since C = 5/9*F – 160/9, (mean in °C) = 5/9 × (mean in °F) – 160/9. This property is also true for median and mode.

Compared to the mean, the median has a number of disadvantages.

(i) It wastes information in the sense that it takes no account of the precise magnitude of most of the observations. This, in fact, is a strength of the median as much as a weakness. Strength arises due to its insensitivity to outliers or extreme values—thus, it could be a suitable measure when such values are present. The weakness is that if one value changes from 3 to 5 days or from 12 to 14 days in our example, the median will not change.

(ii) If two groups of observations are pooled, the median and mode of the combined group cannot be expressed in terms of the medians or modes of the two component groups. This is not so true with the mean. If the mean of one group of $n_1$ subjects is $\bar{x}_1$ and that of the second group with $n_2$ subjects is $\bar{x}_2$, the combined mean is $\frac{n_1\bar{x}_1 + n_2\bar{x}_2}{n_1 + n_2}$.

(iii) Median is not much amenable to mathematical manipulations as mean is.

Whereas mean and median are unique in the sense that you cannot have two means or two medians for the same set of data, you can have two modes. For details, see the topic **bimodal distributions**. In addition, sometimes a dataset may have two modes just by chance due to sampling, which may not really exist in the population from which this sample was drawn. Thus, extra care is needed when dealing with modes.

## mean squares due to error (MSE), *see* mean squares in ANOVA

## mean squares in ANOVA

Like **variance**, mean square is the average of sum of squares of deviations from mean. The difference is that variance is obtained for the data as a whole, whereas mean square is obtained after breaking the total sum of squares into its various components such as between groups and within groups. Consequently, the mean from which deviations are taken and the divisor also change. Mean squares are used in the **analysis of variance (ANOVA)** to find the contribution of various factors to the total variance and to assess their statistical significance. This is applicable when the outcome is quantitative and the groups in statistical terms are the categorical **independent variable**.

We explain the mean squares with the help of a simple setup of **one-way ANOVA** with three or more groups. The objective is to find whether or not the means in these groups are same in the population. We also assume that the number of subjects in each group is the same $n$ indexed by $i$ ($i$ = 1, 2, …, $n$). This can be easily extended to unequal $n$ and two-way and higher-way ANOVA, but the notations become complex.

Let the $i$th value in the $j$th ($j$ = 1, 2,…, $J$) group be denoted by $y_{ij}$, the mean in the $j$th group by $\bar{y}_{\cdot j}$, and the combined mean for all groups together by $\bar{y}_{\cdot\cdot}$. Now the total sum of squares for all groups combined is the numerator of the usual variance given by $\Sigma_i\Sigma_j(y_{ij} - \bar{y}_{\cdot\cdot})^2$. With little algebra, it can be shown that

$$\Sigma_i\Sigma_j(y_{ij} - \bar{y}_{\cdot\cdot})^2 = \Sigma_i\Sigma_j(y_{ij} - \bar{y}_{\cdot j})^2 + \Sigma_i\Sigma_j(\bar{y}_{\cdot j} - \bar{y}_{\cdot\cdot})^2.$$

Or total sum of squares = within-groups sum of squares + between-groups sum of squares.

Within-groups sum of squares is also called the **error sum of squares** or *sum of squares due to error*. The term *error* here is just for deviation from the respective mean and not for a mistake. Similarly, the total degrees of freedom (df) can also be broken as $(nJ - 1) = J(n - 1) + (J - 1)$, i.e., total df = error df + between-groups df. When divided by the respective df, we get the following.

$$\textbf{mean squares due to error (MSE)} = \frac{\Sigma_i\Sigma_j(y_{ij} - \bar{y}_{\cdot j})^2}{J(n-1)},$$

$$\text{between-groups mean squares} = \frac{\Sigma_i\Sigma_j(\bar{y}_{\cdot j} - \bar{y}_{\cdot\cdot})^2}{J-1}.$$

The MSE is also called **error variance**. This should make it clear what mean squares are. As stated earlier, these are the average sum of squares of deviations from the respective means. Similar mean squares can be obtained for several other setups such as two-way ANOVA, random effects models, and regression. These mean squares are used to test the significance of the difference between group means as well as for other such purposes depending on the setup. If between-groups mean squares is substantially greater than the within-groups mean squares (MSE), the means in the groups are considered statistically significantly different. This is checked by ***F*-test** using the ratio of these two in place of the difference as the ratio follows an $F$-distribution. For this reason, this is also called the ***F*-ratio**.

## measurement errors, *see also* errors

When the measurement of an object is not what it actually is, error is said to have occurred. Error is the difference between the obtained value and the actual value. For example, consider an ideal situation where each birth is immediately registered so that the baby's age at any time would be exactly known. If you ask the person 41 years later and he/she reports an age of 40 years, there is an error of 1 year. If a person's exact age is 41 years, 8 months, and 21 days, and the reported age at the time of an interview is 42 years, the error is 3 months and 9 days. It is a different matter whether this error is of any consequence or not. In many cases, the error can be so small that it can be safely ignored, or in some cases, our instrument may not be able to detect it.

Measurement error could be systematic or random. In case you are measuring blood pressure (BP) by mercury sphygmomanometer and there is a bubble in the mercury column, this will always give BP more than the actual value. This is a systematic error. The number of births and deaths in an area with incomplete registration system will always be underreported—it cannot be overreported. This is a systematic error although it can vary from area to area. The average underreporting could be considered as an estimate of the systematic error, although this requires that the correct value in at least some sample subjects is obtained by intensive effort. Thus, this estimate can be obtained only when a **gold standard** is available against which the error is measured. This is rarely available in health and medical setup, and the best available method tends to be recognized as gold for this purpose.

When the same object measured twice in the same state by the same method yields two different values, the difference of these values is also called the measurement error. This error occurs in nearly all situations, although there are some situations in which it is so minor that it can be ignored. This error is random in the sense that it will be negative in some subjects and positive in some, and the average tends to become zero in the long run. Random error looks unpredictable by its very nature, and it is really so in individual subjects; but the beauty is that these errors tend to follow **Gaussian distribution** when considered for a large number of subjects—thus, their long-term pattern is predictable. We know that if the errors are truly random, their mean would be zero, most errors would be clustered around zero with equal proportion of positives and negatives, and a few can be large.

How do we know whether the measurement error is systematic or random? If the mean is zero, it is random, and if the mean is significantly different from zero, at least part of it is systematic. This can be easily checked by the **Student *t*-test**, particularly for large samples. Systematic errors generally have small standard deviation (SD) because this is mostly constant from subject to subject. Random errors may have a relatively large SD. Both would generally have a Gaussian distribution. In situations where the error can become large for large values, the distribution would be positively **skewed**. An example of this is duration of disease. If a disease is present for several years, it could be reported as 10 years instead of 11 years—a difference of 365 days; but if it is present just for 11 days and reported as 10 days, the error is just 1 day. Both look the same in terms of percentage, but they are very different in absolute value. If the variable is duration of disease comprising all diseases, the distribution of errors would be skewed to the right. If the measurement errors have both systematic and random components, just subtract the mean error from each measurement and what is left is the random component.

No matter what the errors are, they always breed uncertainty. If these are more than the ignorable threshold, relationships and dependences could be misinterpreted. The confidence intervals would be inflated, and tests of statistical significance can call a significant effect as nonsignificant. This happens because the presence of errors would inflate the **standard error (SE)** of the estimate. Just becoming aware of these implications may make you more alert to adopt methods that have less measurement errors.

## measures of central tendency, *see* central values (understanding and which one to use)

## measures of dissimilarity and similarity

These measures quantify the extent of similarity or dissimilarity between two or more observations. In the case of univariate values such as a brain size of 1254 $cm^3$ in one person and 1267 $cm^3$ in another person, we immediately know that the difference is 13 $cm^3$ and this difference is just about 1% of the usual size. If a third person's brain size is 1256 $cm^3$, we know that it is "similar" to that of the first person and dissimilar to the brain size of the second person. For quantitative values, the dissimilarity could be in terms of absolute difference or relative difference. In case of qualitative data, if two persons have cancer at the same site, we know that these persons are similar with respect to the site of cancer. In case of ordinal data also, we know that mild disease is more similar to moderate disease compared with serious disease. Thus, measurement of similarity in univariate observations is pretty much straightforward.

The question of dissimilarity and similarity assumes importance in case of multivariate observations. If one person is hypertensive, is male, is 58 years old, and has body mass index [BMI] of 32 $kg/m^2$ and total cholesterol of 220 mg/dL, and the second person is diabetic, is male, is 67 years old, and has BMI of 28 $kg/m^2$ and total cholesterol of 184 mg/dL, how similar or dissimilar are these persons with respect to these five measurements? The answer is not easy for multivariate observations that comprise both qualitative and quantitative values but can be answered in a variety of ways when all measurements are either quantitative or all qualitative.

### *All Measurements Quantitative*

Consider the diastolic blood pressure level of $n$ pairs of persons where each person of a pair has been on a similar diet (such as a husband and his wife eating the same food for 10 years). This gives rise to bivariate measurements. Dissimilarity between the values in each pair can be assessed in terms of the difference in diastolic levels, and that for the group by, say, the average difference. But it might be more useful to find the correlation coefficient between these values. This can also be obtained when you measure systolic and diastolic levels of $n$ persons or even when you measure age and BMI. While this measure has considerable merits, there are a lot of demerits also as mentioned under the topic **correlation coefficient**. This is obtained as **Spearman rank correlation** for rank data. Similarity as measured by correlation coefficient is just for pattern (when one is increasing, how consistently the other is also increasing) and not for closeness of the values, and it is restricted to linear relationship. Correlation coefficient will be perfect if one value is always, say, six less than the other. For one-to-one matching, explore if you can use **agreement** methods. If several quantitative measurements are available on each person, **intraclass correlation** might be appropriate.

For absolute values (and not trend), a popular measure of dissimilarity in multivariate quantitative measurements is the **Euclidean distance** as presented under that topic. A variation of this is the **Mahalanobis distance** that adjusts the Euclidean distance by the covariance structure among them.

For measuring dissimilarity in a **clustering** setup, where the same quantitative characteristic is measured for two groups of subjects, we have indices such as nearest neighbor as used in the **single linkage method**, farthest neighbor used in **complete linkage**, distance between **centroids**, distance between **medians**, etc. All these methods of clustering are discussed under the respective topics.

### *All Measurements Qualitative*

Similarity between qualitative characteristics is generally measured in terms of degree of association. For this, a host of indices are available. For **association between dichotomous characteristics**, we have measures such as relative risk, odds ratio, Jaccard coefficient, Yule Q, etc. For measuring the degree of **association between polytomous characteristics**, choose among phi coefficient, contingency coefficient, and Cramer *V*. In case of matched data such as agreement between two raters, **Cohen kappa** measures the degree of concordance. For **association between ordinal characteristics**, we have Kendall tau, Goodman–Kruskal gamma, and Somer *d*. See these topics for details.

## median, *see* central values (understanding and which one to use); mean, median, mode (calculation of); confidence interval (CI) for median

## median effective dose, *see* $ED_{50}$

## median method of clustering

See the topic **clustering** to understand what it is. In brief, this is the process to group the observations into clusters such that they are similar to one another within the clusters but different from other groups—a property called internal homogeneity and external isolation. This requires a metric that can measure similarity (or its opposite, distance) between groups of values that can be used to assign values to the most similar cluster. This is not easy when the observations are multivariate—a situation where clustering is most commonly adopted. For **hierarchical clustering**, several metrics are available such as **single linkage**, **complete linkage**, **average linkage**, **Ward**, and **centroid**. All these are discussed in this volume under the respective topics.

The median method of clustering is intimately related to the centroid method. The centroid method considers the distance between the means of two clusters as the distance between the clusters. When a big cluster is merged with a small cluster in hierarchical clustering, the centroid method gives proportionately more weight to the mean of the larger cluster. Gower [1] developed an alternative strategy—give equal weight to the clusters being merged irrespective of their size. This is called the median method of clustering. This allows small and big groups to have an equal effect on the characterization of larger clusters into which they are merged. However, this method can result in a **dendrogram** that is hard to interpret. For this reason, this is rarely used in medical sciences.

1. Gower JC. A comparison of some methods of cluster analysis. *Biometrics* 1967;23:623–8. http://www.jstor.org/stable/2528417

## median test, *see also* sign test, Wilcoxon signed-ranks test

The median test is used for testing equality of medians in two or more populations. This is used for quantitative data only where median has a meaning. You may be aware that medians are used as a measure of central value for highly skewed values since mean is not a good representative in this situation. But the requirement of independence of values in different populations remains. The requirement of same distribution pattern in the populations under comparison is not so strict for this test. This is also called the *Mood median test*.

The median test uses **chi-square** for the data divided into two sets in each group with common median as the cutoff. Suppose you have sample values from $K$ populations, referred to as $K$ groups in the literature. The procedure is to find the combined median of all these $K$ samples. The null hypothesis is that the median in each group is the same. If this null is true, the number of observations greater than the common median would be the same in each group as the number less than the common median. (In a continuous distribution, values exactly equal to the median are not expected—if they occur in a sample, they can be ignored and $n$ correspondingly reduced.) These would be the expected frequencies ($E_{ik}$, $i = 1, 2$; $k = 1, 2, \ldots, K$) for calculating the chi-square. Find the actual frequencies greater than or equal to and less than the common median in each group. These would be the observed frequencies ($O_{ik}$, $i = 1, 2$; $k = 1, 2, \ldots, K$). Display the data with a $2 \times K$ two-way contingency table, and calculate chi-square as usual by $\chi^2 = \Sigma[(O_{ik} - E_{ik})^2/E_{ik}]$ with $(K - 1)$ df. Ignore the group if the sample size is 2 or less. A large value of $\chi^2$ would indicate that the null hypothesis is false.

Consider the ambulation time of bariatric surgery patients divided into three body mass index (BMI) (kg/m$^2$) groups: 40–49, 50–59, and 60+. The number of patients in these BMI groups is 40, 33, and 27, respectively, for a total of 100 patients. The distribution of ambulation time is highly skewed on the positive side with some patients taking a very long time to ambulate. The objective is to find whether or not the median ambulation time is the same in each of these BMI groups.

Suppose the median ambulation time of these 100 patients is 120 h. This is the combined median with 50 patients less than 120 h and 50 patients greater than or equal to 120 h. When the patients in each BMI group are divided by this combined median, the numbers observed in the samples are as shown in the left panel of Table M.9. If all groups have the same median, this would be the same as the combined median. In that case, the numbers in each group would be equally divided above and below the combined median. These expected frequencies are shown in the right panel of the table. These values give $\chi^2 = 6.87$. At 2 df, this gives $P < 0.05$. Thus, the median ambulation time in the three BMI groups cannot be considered equal.

For two groups, the Wilcoxon ranks sum test is widely believed to test the equality of medians. It ranks all of the observations from both groups and then sums the ranks from one of the groups. It is possible, although not common, for groups to have different rank sums and yet have equal or nearly equal medians. Thus, strictly speaking, the Wilcoxon ranks sum test requires that the distribution pattern of the populations under comparison is the same; otherwise, it can give statistical significance even when the medians are nearly the same. This is not so for the median test. The median test requires a large sample to be able to use chi-square, but the Wilcoxon ranks sum test is basically for small samples. The median test can be used with three or more groups, whereas the Wilcoxon test is for two groups only. The corresponding nonparametric test for

**TABLE M.9**
**Observed Frequencies Above and Below the Common Median and Expected Under the Null Hypothesis of Equal Medians**

| Ambulation Time | BMI Group (kg/m²) | | | | BMI Group (kg/m²) | | | |
|---|---|---|---|---|---|---|---|---|
| | 40–49 | 50–59 | 60+ | Total | 40–49 | 50–59 | 60+ | Total |
| ≥120 h | 14 | 18 | 18 | **50** | 20.0 | 16.5 | 13.5 | **50** |
| <120 h | 26 | 15 | 9 | **50** | 20.0 | 16.5 | 13.5 | **50** |
| **Total** | **40** | **33** | **27** | **100** | **40.0** | **33** | **27** | **100** |
| | Observed | | | | Expected under the null hypothesis | | | |

three or more groups is **Kruskal–Wallis**, but that also is basically for small samples and requires the same distribution pattern in different groups under comparison.

## mediators and moderators of outcome

In a cause–effect setup, mediators and moderators are those extraneous factors that can alter the nature and extent of relationship. Clarity regarding distinction between these two types of factors can help in substantially improving the understanding of how a particular effect has emerged. Kraemer et al. [1] have discussed such factors in detail.

Moderators are those factors that are present before the cause starts to operate such as age, sex, and nutritional status (when these are not the causes of interest such as in smoking–lung cancer relationship), and mediators are those that emerge after the cause starts to operate such as switching to filter cigarettes, treatment taken for cough, and dietary supplements for weakness in smoking–lung cancer relationship. In this example, mediators involve steps that are taken after smoking starts to affect the lungs. In an experimental setup, such as in clinical trials, preexisting factors such as age, sex, and nutritional status are moderators again since these can affect the outcome, and mediators are nursing care, compliance with the regimen, diet modifications, etc.

Moderators precede the intervention and are not correlated with the intervention. They either amplify or attenuate the effect or the outcome on their own. Randomization is supposed to equalize the moderators between different intervention groups—thus, their effect can be minimized by random allocation. Otherwise, the subjects can be stratified by the level of moderators, e.g., divide the subjects by age and sex if the outcome is anticipated to be affected by these factors, and then allocate. Comparison of like with like tends to eliminate the effect of the moderators. Such stratification will also help in identifying the subgroup that has more favorable outcome. Proper stratification of moderators before the study helps in improving the study design for controlling their effect more effectively.

Mediators emerge during the course of the intervention and affect the progress from the intervention to the outcome. Thus, these naturally depend on the intervention. Mediators also either amplify or attenuate the outcome, but they are in the causal pathway and are not the cause of the effect. Knowledge of mediators does not affect the design. Their control is only in terms of close supervision so that all the subjects follow the routine as planned, and by handling them at the time of analysis of data if they continue to have potential to alter the outcome. If a mediator is found to enhance the positive outcome, this can be a good indicator of how to modify the intervention for better outcome.

For more details of mediators and moderators, see Shephard [2].

## medical care errors (statistical control of)

Errors in the context of medical care are those that mostly occur due to carelessness and thus are avoidable. These do not include errors beyond human control as per the existing norms such as imperfect tools (lack of sensitivity and specificity of medical tests), nonavailability of the best of otherwise available tools, universal lack of knowledge (epistemic gaps), and nonavailability of human and other resources. Medical care errors include medication errors (deviation from the prescriptions), improper application of tools such as incorrect use of medical devices and disproportionate radiation or anesthetic dose, inadequate nursing care, nosocomial infections, etc. These lead to preventable adverse events. According to an estimate provided by MacDonald [1], hospital medical errors are the third leading cause of death in the United States. Theoretically, all these can be eliminated; practically, they can be minimized.

While a large number of care-providing steps can be suggested to prevent medical errors, our concern is with their statistical control. This in effect means that all the errors of each type are tracked and counted to see if they exceed a predefined acceptable level. Thus, the emphasis is on their control rather than on elimination or even minimization.

The first step in controlling errors remains acknowledging that an error has occurred wherever it does. This is easier said than done since underreporting is common. Granting that they are reported nearly as much as they occur, a control chart as presented under the topic **quality control** can be prepared. This requires setting up a tolerance limit considering the practical limitations. Statistically, the tolerance limit is +2SE beyond the average seen in an excellent hospital, where SE is the standard error. The errors occurring each day or each week are plotted on the control chart. As and when the tolerance limit is crossed, an alert is generated that triggers concerned authorities to investigate why this has occurred and to take action accordingly. This chart should be prepared separately for each kind of error—(i) for medication errors that result into adverse drug reactions; (ii) for anesthesia errors that can result in death; (iii) for sloppy surgeries that can result in resurgery; and (iv) for inadequate nursing care that can increase ambulation time, etc. **Cusum charts** can also help in detecting an unfavorable trend in errors.

## medical decisions (statistical aspects of)

It may not be apparent to many clinicians how biostatistics plays a substantive role in their day-to-day decisions regarding managing patients. Decisions regarding diagnosis, treatment, and prognosis are rarely absolute and depend on the confidence a clinician places on the accurate assessment of the status of the patient. A measure of this confidence is the probability as discussed in the topic **probabilities in clinical assessment**. This includes how statistical probabilities of misdiagnosis and missed diagnosis help in devising strategies for better outcomes.

Medical tests contribute significantly to the medical decision process. Their validity indices such as sensitivity and specificity are important parameters for factoring into this process. These indices are biostatistical in nature. The **receiver operating characteristic (ROC)** curve helps in identifying the best cutoff with highest sensitivity and specificity of quantitative tests, and in comparing overall performance of one test with the other.

Clinicians like dichotomous categories much more than measurements in continuum. For example, they like to know what levels are normal and what are not normal that require intervention. Gray areas and consequent indecision are sometimes considered sign of incompetency. For decision regarding treating or not, such cutoffs are indeed helpful, and these cutoffs almost invariably are based on statistical rather than clinical considerations (see **normal range**).

Clinicians also like to divide, for example, body mass index (BMI) into normal, overweight, obese, morbidly obese, and super obese categories (rather than the BMI itself), say for deciding the dietary and exercise regimen. Most researchers realize that convenient categorization such as considering BMI 40–49 as morbid obesity and 50+ as super obesity is arbitrary, but many clinicians prefer categories. Some objectivity in such categorization can be achieved through the statistical method of clustering, although this method is rarely used in this context.

We have described only some of the statistical aspects of medical decisions—they, in fact, pervade deeply. For some other aspects, see **decision analysis tree**, **scoring systems**, and **clinimetrics**.

## medical experiments, *see* experimental studies

## medically important difference (tests for detecting), *see also* medically important effect (the concept of)

The null hypothesis commonly used for statistical tests is of no difference. When this is rejected, the only conclusion reached is that a difference is present, without any implication on the magnitude of the difference. The difference could be very small with no clinical implication or could be large enough to be medically important. This uncertainty is tackled by setting up an $H_0$ that specifies the magnitude of the medically important difference.

In such problems, the medical profession needs to decide the minimum acceptable or tolerable difference that justifies the intervention under consideration. The specification could be either in terms of proportion or in terms of mean. The statistical methods used to detect medically important differences are discussed in this section, first for the proportions and then for the mean. Similar tests can be devised for other effects such as odds ratio and relative risk.

### *Detecting a Medically Important Difference in Proportions*

You may be aware that a small difference between groups can become statistically **significant** when the sample size is large. If the cure rate after 1 month of a particular new therapy is 40% in a sample of subjects versus 30% with the existing therapy, the difference would be statistically significant if the number of subjects in each group is 123 or more. But this small difference may not be worth the trouble of switching over to the new therapy if it is relatively more difficult to implement. A difference of even 1% can be statistically significant for a sufficiently large sample, but very few clinicians, if at all, would change their practice for 1% gain. Thus, the medical significance of the difference is always a potent consideration.

In view of the importance of **medical significance** of the result vis-à-vis statistical significance, the concern could be to fairly ensure that a medically important difference is not missed when present. It is for the medical profession to specify the minimum difference that would be considered medically important. The biostatistician has little role.

If a difference of more than 20% is considered to be of some consequence, then $H_0$: $(\pi_1 - \pi_2) = 0.20$. The conventional null is $(\pi_1 - \pi_2) = 0$ (nil), but $(\pi_1 - \pi_2) = 0.20$ is an equally valid null despite not being nil. If this is rejected, the alternative hypothesis $H_1$: $(\pi_1 - \pi_2) > 0.20$ is accepted provided that the sample difference is more than 0.20. If the difference in sample proportions is 0.20 or less, there is no scope for $H_1$ to be true. There is no way, then, that $H_0$ can be rejected in favor of the alternative that says that the difference is more, and there is no need to carry out the test of statistical significance in that case. The question of testing arises only when the sample difference is more than 0.20, and the intention is to find whether it can still be 0.20 (or less) in the target population. This type of argument applies to most **one-tailed tests**. In some situations, the argument can be reverse. The sample difference is less, and you want to know if it still can be a higher value in the population.

For two independent samples of large size, the criterion to test $H_0$: $(\pi_1 - \pi_2) = \pi_0$ is only slightly different from the usual criterion. This is

$$z = \frac{(p_1 - p_2) - \pi_0}{\sqrt{\frac{p_1 q_1}{n_1} + \frac{p_2 q_2}{n_2}}},$$

where the denominator is the estimated standard error (SE) of $(p_1 - p_2)$ when $\pi_1$ and $\pi_2$ are different. The notations $p_1$ and $p_2$ are for the sample proportion in the two groups as usual. The usual criterion is based on the null hypothesis that $\pi_1 = \pi_2$, which is no longer true in this new setup since the null is not of equality. If $p_1 = 0.40$, $p_2 = 0.30$, each based on a sample of size 50, and $\pi_0 = 0.20$, $H_0$ cannot be rejected in favor of $H_1$: $(\pi_1 - \pi_2) > 0.20$ since the sample difference is less than 0.20. Now consider $H_1$: $(\pi_1 - \pi_2) < 0.20$. Since $n_1 = n_2 = 50$, the value of the criterion is

$$z = \frac{(0.40 - 0.30) - 0.20}{\sqrt{\frac{0.40 \times 0.60}{50} + \frac{0.30 \times 0.70}{50}}} = -1.05.$$

For $H_1$: $(\pi_1 - \pi_2) < 0.20$, smaller values of $z$ would favor $H_1$, and we need to find $P(z \le -1.05)$. Note that $H_1$ and the $P$-value both have

the same direction: in this case, the less-than type. From Gaussian distribution, this is 0.1469, which is not small, i.e., $H_0$ cannot be rejected. The chance that the samples have come from the populations with difference in proportions = 0.20 is not small, and the likelihood of this cannot be denied. However, this does not mean that the difference is 0.20.

In this example, the therapy group is labeled as the first group and the control group as the second group, and $(\pi_1 - \pi_2)$ was expected to be +0.20 under $H_0$. If the labels were reversed, $H_0$ would specify this difference to be –0.20. When everything else is accordingly changed, the conclusion would remain the same.

### *Detecting Medically Important Difference in Means*

Let the minimum acceptable (or tolerable) difference be $\mu_0$. Then $H_0$: $\mu_1 - \mu_2 = \mu_0$ and $H_1$: $\mu_1 - \mu_2 > \mu_0$. The test criterion for independent samples (pooled variance setup) is

$$t_{n_1+n_2-2} = \frac{\bar{x}_1 - \bar{x}_2 - \mu_0}{s_p\sqrt{1/n_1 + 1/n_2}},$$

where $s_p$ is the pooled standard error (SE) of difference in means. This is same as the usual **Student *t*-test** for unpaired samples except for extra $\mu_0$ in the numerator. Similarly, the criterion for a paired setup would also be the same as in a paired *t*-test except for the difference $\mu_0$ in the numerator. For a right-sided $H_1$, the *P*-value would be the probability that *t* is *more* than the value obtained for the sample. Reject the null hypothesis when the *P*-value so obtained is less than the predetermined level of significance. The conditions for application of the criterion just given are the same as for the two-sample *t*-test such as Gaussian conditions, equality of variances, and independence. The following example illustrates the procedure.

It is now well known that an increased level of homocysteine is a risk factor for myocardial infarction and stroke. It has been observed in some populations that vitamin B converts homocysteine into glutathione, which is a beneficial substance, and reduces homocysteine level. To check whether this also happens in nutritionally deficient subjects, a trial was conducted in 40 adults with Hb < 10 g/dL. They were given vitamin B tablets for 3 weeks, and their homocysteine level before and after was measured. Vitamin B has almost no known side effect, but the cost of administering vitamin B to all nutritionally deficient adults in a poor country with a great deal of undernourishment can be enormous. The program managers would consider this a good program if the homocysteine level were reduced by at least 3 μmol on average. In this sample of 40 persons, the average reduction is 3.7 μmol with SD = 1.1 μmol. Can the mean reduction in the target population still be 3 μmol or less?

This is a paired setup, and the medically important difference is a minimum of 3 μmol. Thus, $H_0$: $\mu_1 - \mu_2 = 3$ μmol and $H_1$: $\mu_1 - \mu_2 >$ 3 μmol. Thus,

$$t_{39} = \frac{3.7 - 3}{1.1/\sqrt{40}}$$

$$= 4.02.$$

The table of the Student *t* gives $P(t > 4.02) < 0.01$, which is extremely small, and the null hypothesis is rejected in favor of the alternative. The conclusion reached is that the mean reduction in homocysteine level is most likely more than 3 μmol, and the evidence from this sample is sufficient to conclude that running this program will provide the minimum targeted benefit.

## medically important effect (the concept of)

This is the **effect** that has potential to change the management of a health condition. View this against the annoying feature of statistical methods to discover *significance* in the case of large samples even when the effect of an intervention or of a factor is minimal. For a debate on this aspect, see **medical significance versus statistical significance**.

The malady lies in the **null hypothesis** that is set in testing hypothesis situations and commonly set as no effect. When this null is rejected, the conclusion is that *some* effect is present. The problem starts when this *some effect* is interpreted as *significant* for managing the health condition. The fact is that the statistical significance in this setup only means that an effect is most likely present and that it is not zero. If a new convenient and inexpensive regimen changes HbA1c (glycated hemoglobin) level in diabetics from an average of 9.8% to an average of 9.6% after use for 1 year, which happened to be statistically significant because this was tried on a large number of subjects, the medical question is that whether or not you will like to prescribe this new regimen to your patients. In view of extremely minor effect, perhaps this regimen is not worth adopting despite its convenience and low cost as the current one is probably fully established and tried. That is, the effect of 0.2% in terms of average reduction in HbA1c level is not a medically important effect even if it is statistically significant.

Consider the following examples:

1. When can a new antihypertensive drug be considered clinically effective in postsurgical cases: (i) average decrease in diastolic blood pressure (BP) by at least 2, 5, 8, or 10 mmHg; or (ii) achieving a threshold diastolic BP such as 90 mmHg in a large percentage of subjects—60%, 70%, or 90% of subjects?
2. An iron supplementation program in female adolescents is organized in a developing country. This raises the mean hemoglobin (Hb) level from 13.6 to 13.8 g/dL after intake for 30 days. Is this gain of 0.2 g/dL in the average sufficient to justify the program to all the adolescents in that area? What gain can be considered enough to justify the expenditure and efforts in running the program—0.5 g/dL, 1 g/dL, or more?
3. The prognostic severity of bronchiolitis in children can be assessed either by respiration rate (RR) alone or by using a bronchiolitis score (BS) comprising RR, general appearance, grunting, wheezing, etc. Suppose the former can correctly predict severity in 65% of cases and the latter when considered together in 69% of cases. BS is obviously more complex to implement. Is it worth the trouble to use BS in place of RR for a gain of nearly 4%? What percentage gain in predictivity warrants adopting a more complex BS instead of simple RR—5%, 10%, 15%, or higher?
4. Suppose the normal intraocular pressure (IOP) is 15.8 (SD = 2.5) mmHg in healthy subjects when measured by applanation tonometry. In glaucoma, it is elevated. In a group of 60 patients with primary open-angle glaucoma, suppose the average was 22.7 (SD = 4.5) mmHg. After treatment with a new beta-adrenergic blocker, it came down to 19.5 (SD = 3.7) mmHg. This reduction is statistically significant, but the reduced level in the treatment group is still higher than 15.8 mmHg seen in the healthy subjects. Is this reduction still clinically important? What kind of difference from the normal level of 15.8 mmHg is clinically tolerable—1/2 mmHg, 2 mmHg, or higher?

Depending on the setup, the medically important effect can be the difference in means between two (or more) groups as in our example, difference in percent efficacy, odds ratio, relative risk, etc. For details, see the topic **effect size**. This does not depend on your present data but depends on previous data, experience, and clinical assessment. Thus, it can vary from physician to physician. One may consider that improvement of 1% in HbA1c is quite a gain by such a regimen, but some other may opine that at least a decline of 2% is meaningful when the baseline level is 9.8%. Consensus among medical community is difficult but can be possibly arrived at for such parameters. Specification of medically important effect is a clinical decision and not statistical. An investigation can be planned that is capable of detecting any specified effect size if present by doing the **power analysis** for determining the sample size.

When the medically important effect is known, you can test the null hypothesis that this much effect is present. The methods for doing so are given under the topic **medically important difference (test for detecting)**.

## medical records

Records in any setup are a source of authentic information. Written records of events are probably worth much more than the ones passed orally. They also tend to be permanent and a source of remembrance and reference whenever needed. With online systems in place in most health facilities across the world, medical records tend to be automatically created. These records can provide invaluable longitudinal history of patients when proper **linkages** are done. When complete for all individuals in a community, medical records provide all-important age–sex wise incidence and prevalence rate for all diseases, and trends over time. This information is extremely useful not just to track the health of the people but also to identify the conditions that need priority attention, and to devise strategies for control with a focus on the groups with special needs. Medical records can also help in monitoring the efficacy of various treatment regimens, particularly in a hospital setup, and in identifying more effective regimens for different segments of the patients. The latter comes through when the outcomes with different alternative regimens are compared with one another. Records also help in assessing the quality of medical care provided in different departments and in assessing how much and in what cases clinical findings correlate with laboratory and radiological investigations. Medical records in hospitals are also the source for calculating various administrative indices such as bed occupancy and length of stay in different departments that help to optimize the allocation of beds and services.

A problem with most routine medical records is that they are not complete, they have almost no linkages, and they are maintained without sufficient care that takes away their authenticity. Some of these deficiencies could be because the patients do not provide complete information or sometimes provide even wrong information, but much of it is because the data entry is not done with the care it deserves. Nonetheless, the records tend to be unbiased as they are for past events—thus a good source for research. When the data are freshly collected for a particular research, there is a distinct possibility of bias in collecting the data or of chances of giving more attention to the data that tend to support a particular hypothesis. This bias is not present in the records as they are generated before the study is planned. Thus, records-based studies can provide more valid results provided the records are correct. However, the bias resulting from selected patient profile from records as opposed to random patients remains a severe bottleneck. The findings may be valid for the kind of patients seen in the hospital and may not extend to other types of patients.

With modern methods of **data mining** and **data analytics**, hospital records have become a useful resource for inventing new relationships and new patterns, and for confirming or refuting the existing ones. This is now possible as large hospitals have accumulated enormous data over a decade or so when the online system was introduced in many hospitals across the world.

Public health records, such as of medical certification of cause of death, disease registries, and surveillance systems, also have similar merits and demerits. They may be unlinked anonymously yet still provide useful information on health trends in different segments of population when properly collected and maintained with quality checks.

## medical research (types of)

Before the types of research, understand the nuances of medical research as provided under the topic **research**. Functionally, medical studies can be divided into basic and applied types. Basic research, also termed as pure research, involves advancing the knowledge base without any specific focus on its application. The results of such research are utilized somewhere in the future when that new knowledge is required. Applied research, on the other hand, is oriented to an existing problem. In medicine, basic research is generally done at the cellular level for studying various biological processes. Applied medical research could be on the diagnostic and therapeutic modalities, agent–host–environment interactions, or health assessments.

We would like to classify applied medical studies into two major categories (Figure M.2). The first category can be called primary

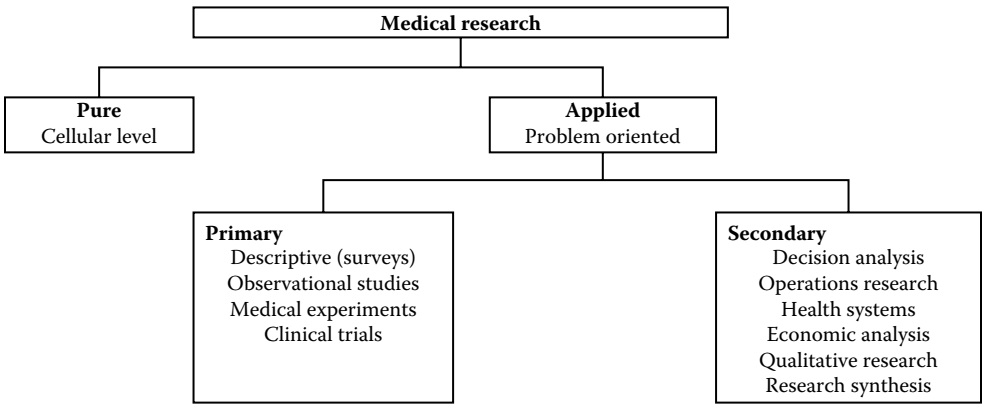

**FIGURE M.2** Types of medical studies.

research that includes **descriptive studies** (**sample surveys**), **observational studies** (**prospective**, **retrospective**, and **cross-sectional**), and **experiments** (in the laboratory on animals and biological specimens, and **clinical trials** on humans). This forms the bulk of medical research today. The second category is secondary research, quite common these days, that includes **decision analysis** (risk analysis and decision theory), **operations research** (prioritization, optimization, simulation, etc.), evaluation of health systems (assessment of achievements and shortcomings), economic analysis (cost-benefit, cost-effectiveness, etc.), **qualitative research** (focus group discussion), and research synthesis (**systematic reviews**, **meta-analysis**). Most of these are discussed in this volume under the respective topic.

## medical significance *versus* statistical significance

The term *significant* in common parlance is understood to mean noteworthy, important, or weighty as opposed to trivial or paltry. **Statistical significance** has the same connotation, but it can sometimes be at variance with medical significance. A statistically significant result may be of no consequence in the practice of medicine, and a medically significant finding may sometimes fail a test of statistical significance. In view of its importance, we explain this distinction in detail in this section.

Some medical professionals consider statistical methods notorious for discovering significance where there is none and not discovering where one really exists. The difficulty is that statistical methods give high importance to the number of subjects in the sample. If a difference exists in 12 cases of chronic cirrhosis of liver and 12 cases of hepatitis with respect to average aspartate aminotransferase (AST) levels, it can be considered a fluke because of the small size of the groups. This is like weak evidence before the court of law. But if the same difference is exhibited in a study on 170 cases of each type, it is very likely to be real. The conventional statistical methods of testing hypothesis only tell whether a difference is unlikely or not without saying how much. The difference in average AST levels between cirrhosis and hepatitis cases could be only 3 units/mL, which has no clinical relevance, but it would turn out to be statistically significant if this occurs in large groups of subjects. Medical significance of such a small difference should be separately evaluated using clinical criteria, and it should not depend exclusively on statistical significance. However, admittedly, clinical criteria could be very subjective in many situations.

Suppose it is known that 70% of cases with sore throat are automatically relieved within a week without treatment because of a self-regulating mechanism in the body. A drug was tried on 800 patients and 584 (73%) were cured in a week's time. Thus, for $H_0$: $\pi = 0.70$,

$$z = \frac{0.73 - 0.70}{\sqrt{0.70 \times 0.30 / 800}} = 1.85.$$

In this case, suppose that the drug is pretested and there is no stipulation that the drug can make the relief rate even less than 70%. Then, the alternative hypothesis is one-sided, $H_1$: $\pi > 0.70$. For this $H_1$, a one-tailed probability is required, and

$P$-value = $P(z \geq 1.85) = 0.0322$ from Gaussian distribution.

This probability is very low and certainly small in comparison with the conventional level of significance of 0.05. The sample is extremely unlikely to be in consonant with this null, and the null is rejected. Statistical significance is achieved, and the conclusion is reached that the 73% cure rate observed in the sample is really more than 70% seen otherwise. But is this difference of 3% worth pursuing the drug? Is it medically important to increase the chance of relief from 70% to 73% in case of sore throat by introducing a drug? Perhaps not. Thus, a statistically significant result can be medically not significant. A remedy is that a medically significant difference such as 10% is specified, and then a statistical test is used to check whether the difference is beyond this threshold. This aspect is discussed under the topic **medically important difference (tests for detecting)**.

The inverse possibility is not so convincing, but that can also occur. A medically important difference should be statistically significant for it to be acceptable. Consider the same setup as in our example where sore throat is assumed to be relieved in a week in 70% of cases without any intervention. Suppose now that the drug is tried in a sample of $n = 50$ patients and 40 ($p = 0.80$) respond in a week's time. Note that $np$ and $n(1 - p)$ are both at least 8, so the **Gaussian conditions** are met even with $n = 50$. Now, under $H_0$: $\pi = 0.70$,

$$z = \frac{0.80 - 0.70}{\sqrt{0.70 \times 0.30/50}} = 1.54.$$

This gives $P$-value = $P(z \geq 1.54) = 0.0618$.

If the probability of **Type I error** to be tolerated is less than 0.05, then the $H_0$ cannot be rejected. Despite 10% improvement shown by the drug in the sample, the sample still cannot be considered to provide sufficient evidence in favor of the alternative $H_1$: $\pi > 0.70$. Thus, this sample of size 50 does not favor a recommendation of use of the drug for patients with sore throat.

The gain of 10% in efficacy, from 70% to 80%, may be considered medically important, and sufficient to pursue the drug, but this rise in this sample of 50 subjects could well have arisen due to chance—due to **sampling fluctuations**. There is quite some likelihood that this rise would fail to be reproduced in another sample of 50 subjects or that it would fail to persist in the long run. Despite this negative finding, the results could be considered to justify a bigger trial because the $P$-value is only slightly more than 0.05.

### *Considerations in Proper Interpretation of Statistical Significance vis-à-vis Medical Significance*

Besides the usual considerations in statistical significance, the following considerations also help in determining medical significance of a result.

- *Whether or not a statistically significant result has any medical significance*. Perhaps it needs to be emphasized that the effect must be statistically significant for it to be medically relevant. If it is not statistically significant, nobody can be confident that the effect is actually present. Thus, the first step is to assess statistical significance. If not significant and the statistical power is adequate, there is no need to worry about its medical relevance because this effect is likely to be there by chance. If significant, further statistical testing is used to judge if it reaches a medically relevant threshold. This threshold comes from medical acumen (see **medically important effect**), and a value judgment is still required. In a randomized controlled trial, if 3 deaths occur in 100 subjects in the placebo group and none out of 100 in the treatment group, the difference is not statistically significant; but would you not try this treatment for your family if everything else has failed? Additional factors such as environment, family condition, and availability of health infrastructure are also considered while taking a final decision regarding the

management of a patient, and statistical significance alone is not enough.

- *Whether or not a plausible medical reason is available for the observed difference*. In many situations, it can be safely concluded that the increase in relief rate is due to the effect of the drug, but in some other situations, the difference is difficult to explain. Consider a random sample of 24 male and 15 female patients with leukemia, of which 4 males and 7 females survive for 5 years. The difference in their survival rate is statistically significant because $P$ would be less than 0.05 for one-sided $H_1$. No worthwhile reason may be available for this difference in their survival rate. When the level of significance is 5%, there is a 1 in 20 chance that false significance is obtained. On the other hand, there might be hitherto unknown factors that could account for such a difference between survival in the two sexes, and the difference could be real. For example, a suspected inborn resistance in females, which is surmised to partially contribute to their greater longevity, may be an explanation. Statistical significance without proper medical explanation is rarely useful with the caveat that such an explanation may not be immediately available in some situations and may emerge in the future.

It should be clear with this that a regimen can be abandoned if sufficiently **powered** study tells you that the effect is not statistically significant. At the same time, do not forget that *P*-value alone is rarely enough to draw a valid conclusion. Previous knowledge, biological plausibility, and your intuition that would also incorporate epistemic gaps must remain the guiding factors. A valid conclusion is reached when all these are considered together wherein statistical evidence plays a role though not as dominant as made out by some statisticians.

## medical uncertainties (types of), *see also* aleatory uncertainties, epistemic uncertainties

Uncertainties pervade all walks of life and medical uncertainties seem omnipresent—their unfailing presence in practically all medical situations can be easily seen. All scientific results are susceptible to error, but uncertainty is an integral part of medical framework. The realization of the enormity of uncertainty in medicine may be recent, but the fact is age-old. Also, our knowledge about biological processes still is extremely limited. These two aspects—variation and limitation of knowledge—throw an apparently indomitable challenge, sometimes becoming so profound that medicine transgresses from a science to an art.

Uncertainty is not something that doctors are used to handling; many find it hard to communicate and understand risks that pervade so much in the practice of health and medicine. Many clinicians deal with these uncertainties in their own subjective ways. Some are very successful, but most are not as skillful. To restore a semblance of science, methods are needed to measure these uncertainties, to evaluate their impact, and of course to keep their impact under control. All these aspects are primarily attributed to the domain of biostatistics. Biostatisticians make a living out of medical uncertainties.

Management of some medical uncertainties is easier when these are divided into appropriate compartments. Major categorization from the biostatistics point of view are **aleatory** and **epistemic uncertainties**. These were first highlighted by Indrayan [1] in medical context in the first edition of his book in 2001. These uncertainties are described under those topics. In addition, the following categorization may also help.

### *Diagnostic, Therapeutic, and Prognostic Uncertainties*

Diagnostic uncertainties arise because the tests or assessments used for diagnosis do not have 100% **predictivity**. An electrocardiogram can give false-positive or false-negative results. None of the procedures, e.g., fine needle aspiration cytology, ultrasonography, and mammogram, are perfect for identifying or excluding breast cancer. Cystic fibrosis is difficult to evaluate.

No therapy has ever been fully effective in all cases. Therapeutic uncertainties are particularly visible in surgical treatment of asymptomatic gland confined prostate cancer and in medical treatment of benign prostatic hyperplasia. Many such examples can be cited. In addition are substances such as combined oral pill where long-term use may increase the risk of breast, cervical, or liver cancer but reduce the risk of ovarian, endometrial, and colorectal cancer. Such anomalies also cause treatment uncertainties.

Prognostic uncertainties due to lack of knowledge exist in sudden severe illness. Such illness can occur due to a variety of conditions, and its cause and outcome are difficult to identify. Nobody can predict occurrence or nonoccurrence of irreversible brain damage after ischemic stroke. Prognosis of terminally ill patients is also uncertain. Method of care for women undergoing hysterectomy is not standardized. Degree might vary from situation to situation, but uncertainties are present everywhere in all clinical decisions including prognosis.

### *Predictive and Other Clinical Uncertainties*

Besides prediction of diagnosis, prediction of outcome of treatment, and prediction of prognosis, there are many other types of medical predictions for which knowledge barriers do not allow certainty. Look at the following examples:

- Gender of a child immediately after conception
- Survival duration after onset of a serious disease
- Number of hepatitis B cases that would come up in the next year in a country with endemic affliction
- Number of people to die of various causes in the future

These examples may be convincing to realize that uncertainties are prominent in all aspects of health and disease, and medical decisions should consider these as much as possible.

### *Uncertainties in Medical Research*

The discussion so far is restricted mostly to the uncertainties present in day-to-day clinical problems. But they are more conspicuous in a research setup than in everyday practice. The backbone of such research is **empiricism**. An essential ingredient of almost all primary medical research is observation of what goes on naturally, or how status changes after an intervention. Because of aleatory and epistemic uncertainties, such observations seldom provide infallible evidence. For example, laboratory experiments are many times replicated to gain confidence as the results of one single experiment are doubted. Results of clinical trials are almost always presented with precautions so that nothing is inferred as absolute. In epidemiological research, a strict distinction is made between an association and cause–effect. Risk factors remain probabilistic in all setups despite convincing evidence, since the results can fail in some cases.

A large number of steps are taken in a research setup to control the effect of uncertainties. Uncertainties remain, but their effect on the results is minimized by a host of biostatistics tools such as appropriate **designs**, adequate **sample size**, validated **data collection** instruments, proper data entry, scrutiny of data, expert statistical

**analysis**, and correct interpretation. Even after such extensive care, the results still are presented in terms of probability.

### *Uncertainties in Health Planning and Evaluation*

Medical care is just one component of the health care spectrum. Prevention of diseases and promotion of health are possibly more important. These can be done at the individual level but are most cost-effective when done at the population level. The first step toward this is **health situation analysis**. This contains steps such as identification of the specifics of the problem, size of the target population, magnitude of the problem, available health infrastructure, and feasibility of remedial steps. Because of interindividual, environmental, and such other variations, uncertainty remains at each step despite using the best methods. Similarly, **evaluation of health programs** also suffers from uncertainty due to better performance by some segments of population despite equal exposure and equitable allocation of resources. Also, the tools to implement the programs are never perfect. Varying motivation of the officials also contributes to the level of uncertainty.

For further details, see Indrayan [1] who has meticulously discussed medical uncertainties at length and has put up convincing arguments how biostatistics can help in managing certain aspects of medical uncertainties. Keep in mind the famous saying that if you begin with certainties, you will end in doubts, but if you begin with doubts, you can end up with almost certainties.

## medical uncertainties (sources of), *see* aleatory uncertainties, epistemic uncertainties

## mental health (indicators of)

Mental health is considered to be related to satisfaction and happiness—thus is mostly abstract. Although there is a degree of stigma attached to mental disorders that inhibit valid measurement, attempts have been made to develop indicators that can measure mental health both at individual and population levels. These indicators are used for assessing the level and trends, and to develop strategies for improvement of mental health.

Individual level positive indicators of mental health for adults comprise self-assessment of being useful to the family and the society; feeling optimistic, good, cheerful, confident, and loved; interest in new things and surroundings; creativity; successful coping with day-to-day challenges; and the like. You can ask people to rate their last week for each of such indicators on a 0 to 5 scale, where 0 is for never during the last week and 5 for always in the last week. Thus, mental health of individuals can be measured on a defined scale. However, the instrument so developed may have to be checked for its validity in local setting. The items should be chosen in a manner that the instrument reflects current concepts, yet are sustainable. When the same set of questions are asked year after year in a randomly selected group of people from the same population, the average scores can provide a good understanding of whether mental health of people is improving or declining. Note that this set of indicators does not include negative feelings such as neglect, failures, tension, stress, and anxiety. But these too can be included. Tannenbaum et al. [1] used self-reported subthreshold mental health symptoms, self-reported full diagnostic disorders such as depression and anxiety disorders, physicians' billings for outpatient mental health visits, and psychotropic medications for measuring mental health of Canadians. Their emphasis was on using the existing databases. They found that a maximum of 20% of women and 14% of men in Canada had mental health problems.

Beside percentage of population with mental disorders, epidemiological negative indicators of mental health can be aberrations such as crime rate, suicide rate, homicide rate, accidents, and divorces. You may like to include smoking and alcohol and drug addictions also. Perhaps a combination of these can be devised that can provide a single index. These data are easily available in most countries at national and subnational levels. On the positive side are availability and utilization of sports and entertainment facilities; education levels; availability and utilization of telephone, banks, and post offices; per capita income; etc.

## meta-analysis, *see also* funnel plot, $I^2$ (index of homogeneity)

Popularly known as doing statistics on statistics, meta-analysis is a synthesis technique of pooling varying results of various studies on the same parameter after a **systematic review**. For this, studies meeting prespecified quality criteria are selected after a comprehensive search of literature. A particular relevant parameter that measures effect size such as odds ratio (OR), relative risk, or mean difference is chosen, and its value with confidence interval (CI) is extracted from each selected study. Sometimes you may have to calculate CI yourself, and sometimes median/IQR type of CI may have to be converted to mean ± 2SE when that information is not directly available. The values and their CIs are examined to come up with a pooled estimate as per the procedure described later in this section. According to O'Rourke [1], the term *meta-analysis* was introduced in 1976 by Glass [2].

Now that so much research is going on each topic around the world, it is difficult to decipher a common message. Meta-analysis helps in combining the diverse results. Pooling of samples in different studies also increases the reliability of the result. Once the pooled result is available, there is rarely any need to study so many different articles on the same topic, thus saving a lot of time. Most prominent among meta-analyses are **Cochrane reviews**, whose findings are many times considered gold standard for actual implementation in health care.

Care required in selecting the articles for meta-analysis can hardly be overemphasized. Generally, databases such as PubMed, EMBase, and Google Scholar are searched for relevant terms. Some articles that do not use those terms may still escape—thus, selection of terms is crucial to spread the net without losing the focus. Secondly, it is customary to use the PECOS system, which stands for **Population, Exposure, Control, Outcome, and Study design**, to filter the relevant articles. There is a practice to pick up only the credible and relevant articles and exclude those that follow different methodology or different definitions not fitting into the preset criteria. Thus, the findings are generally unbiased for published results with a caution as described next.

There is a big drawback of meta-analysis results, however. The studies included tend to self-select because of **publication bias**. There is a **file-drawer effect**, which says that much of research with statistically nonsignificant results remains in a drawer, and studies with

negative results and neutral outcomes often go unpublished. Thus, the published articles provide a biased picture. When the results from the published articles are pooled, the bias inadvertently increases instead of being reduced. We tend to ignore such bias because perhaps nothing can be done to alleviate this problem. One way out is to give extra weight, say double, to negative results assuming that only one of the two negative findings finds its way into the literature [3].

There are statistical precautions also. Results based on a small sample size or with high standard error (SE) in different studies will obviously spread across a broad range of values compared with the results based on large samples. If you plot ORs in three studies each with a small sample size, they are likely to be far apart from one another compared with ORs in another set of three studies each with a large sample size. If you are reviewing a large number of studies—some of small size and some of large size—and plot the OR on the horizontal axis and the sample size on the vertical axis, you will get what is called a **funnel plot** because of its resemblance with an inverted funnel. If your values follow this pattern, you can feel more confident that the results included in meta-analysis conform to this requirement. An asymmetric shape of the funnel plot raises suspicion over the results since the selected studies may suffer from publication bias, favoring either higher or lower effect size. It also suggests the possibility of a systematic bias in smaller studies. If most of smaller studies tend to give larger (or smaller) effect size compared to larger studies, the bias is evident and the results of meta-analysis would not be valid. When biased studies are not included, heterogeneity among results of various studies does not cause much of a problem, and the final CI would reflect this. If needed, heterogeneity can be assessed by an index as explained under the topic ***I*² (index of homogeneity) in meta-analysis**. This measures the percentage variance attributed to between-study variation and replaces analysis of variance because the original data are not available in this case. $I^2 = 0.25$ is low, 0.50 is middling, and 0.75 is high. If this is high, identify studies causing this high value and exclude them from the meta-analysis. Both funnel plot and index of homogeneity are obtained before meta-analysis is done to get convinced that the values being used are consistent across different studies.

A meta-analysis conventionally comprises a plot of the effect size and their CI that provides graphical summary view of the varying results obtained in different studies, called a **forest plot**. For an example, see Figure M.3 for ln(ORs) for patients free of diarrhea in probiotic groups compared with the control groups. This plot provides a great deal of information about the studies included and the results obtained along with the sample size of each. Horizontal lines in Figure M.3 are the 95% CI, and the numerical values are stated in a column on the right side. For pooling the results, the average is calculated, but all studies are not given equal weight in this average. Generally, studies with a larger sample size or with a smaller SE get more weight. The area of the black square represents this weight, and this is also mentioned in another column on the right side in this figure. You may use any other weight that is uniformly available or can be obtained for all the studies. The pooled result is shown by a diamond touching the *x*-axis. The width of this diamond is the width of the pooled CI. If this touches or crosses the line of no effect (OR = 1 in this example), the pooled conclusion is that the effect is not statistically significant. In Figure M.3, the diamond is on the left side of OR = 1; thus, the protective effect of probiotics for diarrhea is statistically significant.

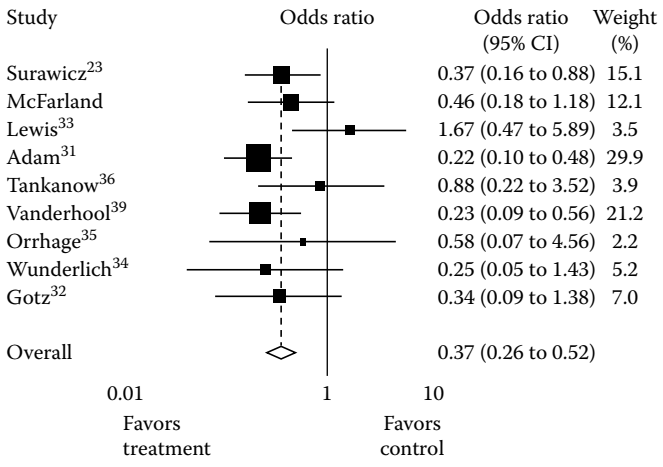

**FIGURE M.3** Plot of the log of odds ratios for the proportion of patients free of diarrhea in probiotic groups compared with control groups. (From D'Souza AL et al., *BMJ* 2002(8 June);324:1361. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC115209/.)

In place of aggregate results of studies, the emphasis now is on individual participant data. Since almost all studies around the world have data on individual subjects in electronic form, they can be easily pooled in a collaborative effort that would provide a direct estimate based on a large number of subjects. Thompson et al. [5] have provided this kind of analysis based on 154,211 participants in 31 studies on hazard ratio for coronary heart disease per 1 g/L raised baseline fibrinogen. Care is needed while pooling in this case also because the participants within each study form a cluster with shared similarities, and the effect of clustering is factored into pooling.

The type of meta-analysis we have described typically considers one particular outcome measure. Studies that do not report this outcome cannot be included, and this can introduce bias. An extension is available, called *network meta-analysis*, which can include two or more end points. Woods et al. [6] have described a meta-analysis that combines count and hazard ratio of survival in **multiarm trials** into single analysis.

Although meta-analysis seems to obviate the need to do large-scale multicentric studies, there are legitimate questions regarding meta-analysis being a proper replacement. Probably this is just a makeshift strategy to arrive at a more reliable conclusion to meet the pressure of quick yet informed decisions.

## meta-analysis of observational studies in epidemiology (MOOSE) guidelines

**Meta-analysis** is increasingly used to arrive at an evidence-based reliable result after pooling the information available in publications on different segments of population. Many of these publications are based on **observational studies** since deliberate intervention is not feasible for harmful risk factors such as for smoking. Such studies are especially susceptible to inherent bias and varying designs. MOOSE is a set of guidelines for reporting of meta-analysis of results from observational studies so that the reporting is done with care and nothing is left out. This set was initially developed in a workshop held in Atlanta, Georgia, in 1997 under the aegis of Center for Disease Control and Prevention of the United States [1].

These guidelines are in the form of a checklist as given in Table M.10. If you want to follow these guidelines, see that your manuscript has all these components. If any is missing, either include that or justify why this cannot be included in the manuscript. Readers, authors, reviewers, and editors can use this checklist to confirm the quality and completeness of the meta-analysis. For further details, see Stroup et al. [1].

## meta-regression, *see also* meta-analysis

Similar to **meta-analysis**, meta-regression is a method used to combine results from several studies, but here **regression analysis** is used to come to a unified result. The **regressors** are study characteristics such as year of study, type of participants (e.g., mean age, percentage of males, and ethnicity), method of data collection (cross-sectional, longitudinal, length of follow-up, etc.), and assessment of the quality of the study. These regressors can be quantitative or qualitative, fixed or random. Studies can be weighted to reflect the sample size or the precision in terms of the inverse of variance. The dependent could be the effect size as in meta-analysis, and the unit of analysis is a study instead of an individual. Meta-regression is one of the methods of **systematic reviews** that provides an insight of how study characteristics are affecting the effect size. When studies are done at different points in time, say in the years 1980, 1995, 2003, and 2010, their combination after accounting for other factors can provide a legitimate trend of change in the effect size over time.

As in the case of meta-analysis, the studies for meta-regression too are identified after intensive search of the literature for a set of predefined inclusion criteria. These are appraised to check that they indeed deserve to be included or not. Because of **publication bias** and **file-drawer effect**, the results of meta-regression can also suffer from bias just as the results of meta-analysis do.

The analysis is done by following the **generalized linear regression** approach depending on the type of regressors (quantitative, qualitative, or mixed; **fixed or random effects, or mixed effects**) and the **scale** of the dependent (quantitative, ordinal, or nominal) variable. All these terms are explained in this book in easy language for medical professionals who are not familiar. For quantitative dependent and fixed effect regressors, it can be analysis of covariance; for nominal or ordinal dependent, it will be logistic regression; and for counts, it will be Poisson regression. One big problem with meta-regressions is that the number of eligible studies may be small, whereas the number of regressors is large that can overfit the model. Make sure that an enough

**TABLE M.10**
**Reporting Checklist for Meta-Analyses of Observational Studies (MOOSE)**

| MOOSE Checklist |
|---|
| Reporting of background should include |
| Problem definition |
| Hypothesis statement |
| Description of study outcome(s) |
| Type of exposure or intervention used |
| Type of study designs used |
| Study population |
| Reporting of search strategy should include |
| Qualifications of searchers (e.g., librarians and investigators) |
| Search strategy, including time period included in the synthesis and keywords |
| Effort to include all available studies, including contact with authors |
| Databases and registries searched |
| Search software used, name and version, including special features used (e.g., explosion) |
| Use of hand searching (e.g., reference lists of obtained articles) |
| List of citations located and those excluded, including justification |
| Method of addressing articles published in languages other than English |
| Method of handling abstracts and unpublished studies |
| Description of any contact with authors |
| Reporting of methods should include |
| Description of relevance or appropriateness of studies assembled for assessing the hypothesis to be tested |
| Rationale for the selection and coding of data (e.g., sound clinical principles or convenience) |
| Documentation of how data were classified and coded (e.g., multiple raters, blinding, and interrater reliability) |
| Assessment of confounding (e.g., comparability of cases and controls in studies where appropriate) |
| Assessment of study quality, including blinding of quality assessors; stratification or regression on possible predictors of study results |
| Assessment of heterogeneity |
| Description of statistical methods (e.g., complete description of fixed or random effects models, justification of whether the chosen models account for predictors of study results, dose–response models, or cumulative meta-analysis) in sufficient detail to be replicated |
| Provision of appropriate tables and graphics |
| Reporting of results should include |
| Graphic summarizing individual study estimates and overall estimate |
| Table giving descriptive information for each study included |
| Results of sensitivity testing (e.g., subgroup analysis) |
| Indication of statistical uncertainty of findings |
| Reporting of discussion should include |
| Quantitative assessment of bias (e.g., publication bias) |
| Justification of exclusion (e.g., exclusion of non-English language citations) |
| Assessment of quality of included studies |
| Reporting of conclusions should include |
| Consideration of alternative explanations for observed results |
| Generalization of the conclusions (i.e., appropriate for the data presented and within the domain of the literature review) |
| Guidelines for future research |
| Disclosure of funding source |

number of eligible studies are available so that the results are reliable. For further details of this method, see Thompson and Higgins [1].

A typical example of use of meta-regression is in obtaining the estimates of prevalence rates of various diseases in different countries by combining similar studies in nearby areas. These estimates are used, for example, in burden of disease studies. For an example, see Kassebaum et al. [2] in which this method, along with others, has been used to estimate the prevalence, incidence, and trend over the years 1990–2010 of untreated caries in all countries of the world on the basis of 192 studies comprising 1,502,260 children aged 1–14 years in 74 countries, and 186 studies on a total of 3,265,546 individuals aged 5 year or older in 67 countries for untreated caries in deciduous and permanent teeth, respectively. Tsivgoulis et al. [3] used meta-regression for studying the effect of disease-modifying therapies on brain atrophy in patients with relapsing–remitting multiple sclerosis based on just four studies.

The effect of disease modifying therapies on brain atrophy in patients with relapsing–remitting multiple sclerosis: A systematic review and meta-analysis. *PLoS One* 2015 Mar 10;10(3):e0116511. http://journals.plos.org/plosone/article?id=10.1371/journal.pone.0116511

## metric categories, *see* categories

## metric scale, *see* scales of measurement (statistical)

## misclassification

Misclassification occurs when an object is assigned to a category to which it does not belong. This includes misdiagnosis and missed diagnosis in a clinical setup, but the term is mostly used when a predictive **statistical model** wrongly tells you that the subject is in particular category A while it actually is non-A. You will know about misclassification only if you know the correct class; otherwise, it can go unnoticed.

Misclassification in our context primarily happens with two statistical methods, namely, the **logistic regression** and **discriminant analysis** as per the details provided for those topics. Briefly, in logistic regression, the category of a dependent binary variable, such as presence or absence of memory complaints in geriatric subjects, is sought to be predicted or identified on the basis of a set of regressor **variables**. These variables may be able to correctly identify presence of memory complaints in, say, 80% of the subjects with such complaints and correctly identify absence of complaints in 95% of subjects without these complaints. If so, the total misclassifications are not 25% but would depend on how many subjects were in each group. If the number of subjects in the two categories are the same, the total misclassification would be (20 + 5)/2 = 12.5%. See Table M.11 for unequal numbers where the category misclassifications are again 20% and 5% but the total misclassification is (40 + 3)/260 = 16.5%.

As evident from Table M.11, there are two types of misclassifications: one when absence is misclassified as presence and the other when presence is misclassified as absence. A model may be extremely good in correctly excluding the disease but poor in confirming its presence, and another model may be extremely good in confirming the presence but poor in correctly excluding it. Thus, these two types of misclassifications should be separately interpreted. In our example in the preceding paragraph, the model is good in correctly identifying absence of complaints but not so good in correctly identifying presence of complaints.

**TABLE M.11**
**Classification Table in Logistic Regression—Misclassifieds Are in Bold Italics**

| | Predicted | | |
|---|---|---|---|
| **Observed↓** | **Presence** | **Absence** | **Total** |
| Presence | 160 | ***40*** | **200** |
| Absence | ***3*** | 57 | **60** |

The setting is the same in discriminant analysis, but the exercise is for predicting the category of future observations on the basis of the known categories of the available observations. The classification table remains the same as in Table M.11 for two categories. Discriminant analysis can handle many categories simultaneously and would mostly require that the regressors are quantitative, while logistic does this by handling binary outcome at a time, though without restriction on the scale of the regressors.

## missing data, *see also* imputation for missing values and nonresponse

Missing data is a frequent problem in medical and health setup. In a clinical setup, decisions regarding diagnosis, treatment, and prognosis are taken despite incomplete history of the patients and incomplete reporting of complaints by the patients. Sometimes the required investigation cannot be done because of the absence of facility for that investigation, or because there is no time to wait. Sometimes the patient is in a coma or in aberrant condition, and cannot adequately describe his or her sufferings, while secondary reporting by the attendants may be incomplete, even misleading. Missing data in this setup compromise the quality of decisions. Except exercising care, probing, and reprobing, possibly nothing better can be done in this setup.

Our concern in statistics is primarily with missing values that occur due to nonavailability of information after a subject is included in a study. Suppose in a sample of 150 subjects from the population of eligible subjects with consent, some are not available at the appointed time and place, or fail to report at the clinic due to sudden illness or any other exigency in the family. Some may fail to recall the event of your interest. This problem is particularly acute in clinical trials where follow-up is required. The difficulty is that the nonrespondents are rarely random—thus, their exclusion can introduce bias. Some patients may withdraw after consent as they no longer wish to continue. This can happen when they find that it is too much of a hassle for them to be under trial or that the treatment to which they are allocated is not to their liking. Such missing data should be counted among the failures of the treatment and should not be neglected. Ignoring missing data may introduce bias in the results and may lead to invalid conclusions. Statistical methods such as **imputations** have limitations—they cannot compensate for missing data—only that they intend to provide best approximations. Careful planning and meticulous execution of the study are the only answer

to ensure that the missing values do not occur or occur with ignorable frequency. For more details, including aspects of trial design that limit the chance of missing data, see Singhal and Rana [1].

1. Singhal R, Rana R. Intricacy of missing data in clinical trials: Deterrence and management. *Int J Appl Basic Res* 2014;4(3):2–5. http://www.ijabmr.org/article.asp?issn=2229-516X;year=2014;volume=4;issue=3;spage=2;epage=5;aulast=Singhal, last accessed March 11, 2015.

## misuse of statistical tools, *see also* fallacies (statistical)

If a child cuts his/her finger with a sharp knife, should you blame the child or the knife? If a person takes an excessive dose of sleeping pills and dies, the pills cannot be blamed. Abuse or misuse of statistics has precisely the same consequence. An *abuse* occurs when the data or the results are presented in a distorted form with the intention to mislead. Sometimes part of the information is deliberately suppressed to support a particular hypothesis. A *misuse* occurs when the data or the results of analysis are unintentionally misinterpreted because of lack of comprehension. The fault in either case cannot be ascribed to statistics; it lies with the user. Correct statistics tell nothing but the truth. The difficulty, however, is that the adverse effects of wrong statistical methods are slow to surface, and this makes these methods even more vulnerable to wrong use. The other difficulty is that the learning curve of medical professionals for statistical methods, particularly for intricate methods, is shallow and daunting—thus, errors become inevitable. Few researchers, if any, are able to engage a qualified statistician from beginning to end. They tend to depend on their colleagues, their own experience, and software *Help* files. This support is incomplete, to say the least. At the same time, many biostatisticians also are not above the board. Besides biostatistical competence, their appreciation of medical implications is a severe constraint. The following are some instances of misuse of statistical tools. These include abuses also, although we call them misuses in the hope that these are not intentional.

### *Misuse of Percentages and Means*

Percentages can mislead if calculations are (i) based on small $n$ or (ii) based on an inappropriate total. If two patients out of five respond to a therapy, is it correct to say that the response rate is 40%? In another group of five patients, if three respond, the rate jumps to 60%. A difference of 20% looks like a substantial gain, but in fact, the difference is just one patient. This can always occur due to sampling fluctuation, and the percentage based on small $n$ can easily mislead. It is preferable to have $n \geq 100$ for valid percentages, but the following is our subjective guideline in this regard.

1. State only the number of subjects without percentages if $n < 30$.
2. For $n \geq 30$, percentages can be given, but $n$ should always be stated.

The second misuse of percentages occurs when they are calculated on the basis of an inappropriate group. The following example illustrates this kind of misuse.

Consider a group of 134 cases of heart bypass surgery who are followed for postsurgical complications. The data obtained are presented in Table M.12.

**TABLE M.12**
**Complications in Cases of Heart Bypass**

| Complication | Number of Cases | Wrong Percentage (Out of 44) | Correct Percentage (Out of 127) | |
|---|---|---|---|---|
| Excessive bleeding | 9 | 20.5 | 7.09 | |
| Chest wound infection | 15 | 34.1 | 11.81 | |
| Other infections | 8 | 18.2 | 6.30 | |
| Breathing problems | 10 | 22.7 | 7.87 | |
| Blood clot in the legs | 13 | 29.5 | 10.24 | |
| Others | 11 | 25.0 | 8.66 | |
| Any complication | 44 | 100.00 | 34.65 | |
| No significant complication | 83 | | 65.35 | |
| Total (data available) | 127 | | 100.00 | (94.78) |
| Data not available | 7 | | | (5.22) |
| **Grand total** | **134** | | | **(100.00)** |

Information was not available for seven patients. Since 83 did not experience any significant complication, it would be wrong to calculate the complication rate on the basis of the 44 patients who experienced complications. It unnecessarily magnifies the problem. The correct base for the complication rate is 127. The fact is not that 20.5% had excessive bleeding but that 7.09% of the patients had this problem. It would also be wrong to include seven patients in this calculation for whom the data are not available. For a nonresponse rate, however, the correct base is 134. This can be separately stated as shown in parentheses in the table. This example also illustrates the calculation of percentages in the case of multiple responses where a patient can have two or more complications. Thus, the percentages are not additive in this case.

For misuse of means, consider the popular saying by detractors of statistics: Head in an oven, feet in a freezer, and the person is comfortable, on average! There is no doubt that an inference on mean alone can sometimes be very misleading. It must always be accompanied by the standard deviation (SD) so that an indication is available about the dispersion of the values on which the mean is based. Sometimes the standard error (SE) is stated in place of the SD. This also may mislead unless its implications in the context are fully explained. If smoking prevalence in percent with the SE in male students of fifth grade is stated as $0.93 \pm 0.47$ [1], what kind of message do you get? Also, $n$ must always be stated when reporting a mean. These two, $n$ and the SD, should be considered together when drawing any conclusion based on mean. Statistical procedures such as confidence intervals and test of significance have a built-in provision to take care of both of them. A mean based on large $n$ naturally commands more confidence than the one based on small $n$. Similarly, a smaller SD makes the mean more meaningful.

You should also evaluate whether the mean is an appropriate indicator for a particular data set. Averages are not always what they seem. If in a group of 10 persons, 9 do not fall sick and 1 is sick for 40 days, how correct is it to say that the average duration of sickness in this group is 4 days per person? If extreme values or outliers are present, mean is not a proper measure—either use the median or recalculate the mean after excluding the outliers. If exclusion is done, this must be clearly stated. Else, consider if proportions are more adequate than mean as in our example of duration of sickness.

### *Misuse of Graphs*

As mentioned for **graphs and diagrams**, some misuse of graphs can occur by choosing an inappropriate scale. A steep slope can be

represented as mild and vice versa. Similarly, a wide scatter may be shown as compact. In addition, variation is sometimes shown as ±1 SD in graphs, whereas actually it is much more. Also, means in different groups or means over time can be shown without corresponding SDs. They can be shown to indicate a trend that really does not exist or is not statistically significant.

One of the main sources of misuse of graphs is their insensitivity to the size of $n$. A mean or a percentage based on $n = 2$ is represented the same way as the one based on $n = 100$. The perception, and possibly cognition, received from a graph is not much affected even when $n$ is explicitly stated. One such example is box-and-whiskers plots drawn by Koblin et al. [2] for the time elapsed between cancer and AIDS diagnoses among homosexual men with cancer diagnosed before or concurrently with AIDS in San Francisco during 1978–1990. Five lines (minimum, $Q_1$, median, $Q_3$, and maximum) are shown on the basis of only four cases of anal cancer. It was concluded on the basis of the figure that "Hodgkin's disease cases occurred relatively close to AIDS diagnoses." This may have merit but is stated without checking statistical significance and in disregard of the small number of available cases.

### *Misuse of* P-*Values*

Statistical ***P*-values** seem to be gaining acceptance as a gold standard for data-based conclusions. However, biological plausibility should not be abandoned in favor of *P*-values. Inferences based on *P*-values can also produce a biased or incorrect result.

A threshold of 0.05 (called the **level of significance**) for a Type I error is customary in health and medicine. Except for convention, there is no specific sanctity of this threshold. There is certainly no cause for obsession with this cutoff point. A result with $P = 0.051$ is statistically almost as significant as one with $P = 0.049$, yet the conclusion reached would be very different if $P = 0.05$ is strictly used as the threshold. Borderline values always need additional precaution.

A value close to the threshold such as $P = 0.06$ can be interpreted both ways. If the investigator is interested in showing the presence of difference, (s)he might argue that this $P$ approaches significance. If the investigator is not interested, this can be easily brushed aside as not indicating significance at $\alpha = 0.05$. It is for the reader to be on guard to check that the interpretation of such borderline *P*-values is based on objective consideration and not driven by bias. We generally interpret $P = 0.06$ or 0.07 as encouraging though not quite good enough to conclude a difference. They can be called marginally significant. If feasible, wait for some more data to come and retest the null in this situation.

The second problem with a threshold of 0.05 is that it is sometimes used without flexibility in the context of its usage. In some instances, as in the case of a potentially hazardous regimen, a more stringent control of Type I error may be needed. Then $\alpha = 0.02$, 0.01, or 0.001 may be more appropriate. It is not necessary to use $\alpha = 0.01$ if a value less than 0.05 is required, and the value $\alpha = 0.02$ can also be used. In some other instances, as in concluding the presence of differences in social characteristics of the subjects, a relaxed threshold $\alpha = 0.10$ may be appropriate. For most physiological and pathological conditions, however, the conventional $\alpha = 0.05$ works fine—that is why it has stayed as a standard for so long.

There are situations where a one-tailed test is appropriate, but a two-tailed test is unnecessarily used that makes the test conservative. In case of iron supplementation for increasing hemoglobin (Hb) level, biological knowledge and experience confirm that iron supplementation cannot reduce the Hb level. Use of the two-tailed test in this case makes it unnecessarily restrictive and makes rejection of $H_0$ more difficult. Most statistical packages provide two-tailed *P*-values as a default, and many workers would not worry too much about this aspect. Scientifically, a conservative test does not do much harm, although some real differences may not be detected when a two-tailed test is used instead of a one-tailed test. Our advice is to use a one-tailed test only where a clear indication is available for one-sided gain or loss, but not otherwise. In most medical situations, assertion of one-sided alternative is difficult and a two-sided test is needed.

See the topic **multiple comparisons** for adjustment of *P*-values while comparing several groups. In practice, you may have tried many statistical tests before reaching to the final ones you decide to report. Hardly anybody makes adjustment for such "behind-the-scene" statistical tests, although they also affect the final *P*-value. See the topic ***P*-values** for examples on how this is dramatized by some authors and how this is calculated for nonrandom samples where this is not applicable.

### *Misuse of Statistical Packages*

Computers have revolutionized the use of statistical methods for empirical inferences. Methods requiring complex calculations are now done in seconds. This is a definite boon when appropriately used but is a bane in the hands of nonexperts. Understanding of the statistical techniques has not kept pace with the spread of their use. This is particularly true for medical and health professionals. The danger arises from misuse of sophisticated statistical packages for intricate analysis without fully appreciating the underlying principles. The following are some of the common misuses of statistical packages.

Popularly termed as torturing until it confesses, data are sometimes overanalyzed, particularly in the form of post-hoc analysis. A study may be designed to investigate the relationship between two specific measurements, but correlations between pairs of a large number of other variables, which happen to be available, are calculated and examined. This is easy these days because of the availability of computers. If each correlation is tested for statistical significance at $\alpha = 0.05$, the total error rate increases enormously. Also, $\alpha = 0.05$ implies that 1 in 20 correlations can be concluded to be significant when actually it is not. If measurements on 16 variables are available, the total number of pairwise correlations is $16 \times 15/2 = 120$. At the error rate of 5%, 6 of these 120 can turn out to be falsely significant. Hofacker [3] has illustrated this problem with the help of randomly generated data. This underscores the need to consider any result from post-hoc analysis as indicative and not conclusive. Further study should be planned to confirm such results. This also applies to post-hoc analysis of various subgroups that were not part of the original plan, such as trying to find the age–sex or severity groups that benefited more from the treatment than the others. Numerous such analyses are sometimes done using a drop-down menu in the hope of finding some statistical significance somewhere. Again, such detailed analysis is fine for searching a ground to plan a further study but not for drawing a definitive conclusion. However, this is not to deny existence of Americas because it was not in Columbus' plan: evidence as hard as this must be given credence. In most empirical cases though, it may be sufficient to specifically acknowledge that the results are based on post-hoc analysis and possibly need to be confirmed.

## mixed diagram, *see also* graphs and diagrams

A diagram is called mixed when two or more diagrams are shown together as one diagram. This is used when it is advisable to simultaneously show the variation in two or more characteristics, each measured on the same *x*-axis. This definitely saves space and helps to provide a more comprehensive view. Figure M.4 shows the age-wise prevalence of cataract blindness in a community and the percentage operated (surgical coverage). The former is shown by bars and the latter by a line. Thus, this is an example of a mixed diagram.

Although both measurements on *y*-axis in Figure M.4 are percentages, they are on a different scale. This itself makes reading difficult. Moreover, if the units are different, then different measurements on the *y*-axis can create more confusion. Prepare a mixed diagram with abundant precautions and interpret it with greater care.

## mixed effects models

This is an extension of the **analysis of variance (ANOVA)** method that includes random effects in addition to fixed effects. In case you are not familiar with **fixed and random effects**, see that topic. The conventional ANOVA considers that all the factors have fixed effect; that is, if you have studied three hospitals in ANOVA, the results would be valid for these three hospitals only and cannot be extended to any other hospital. When the studied hospitals are random samples from all the hospitals, they will be studied as factors with random effect, and then the results can be extended to other hospitals not in your sample. For mixed effects, there must be at least one factor with fixed effect and at least one factor with random effect. The random effects factor can be for **longitudinal data**, where some specified points in time are included in the analysis, but the results are sought for other time points as well. ANOVA would generally include only the factors with **nominal** categories, but mixed models can include continuous **covariates** (just as we do in **analysis of covariance**) also. The mixed models can accommodate both time-dependent covariates (e.g., dose levels that can vary from week to week) and static covariates (e.g., sex and age that would not change if the follow-up is a few weeks). The dependent in all of this is a quantitative variable. In short, the term *mixed models* is a synonym for **general linear models** where there is no restriction on the regressors.

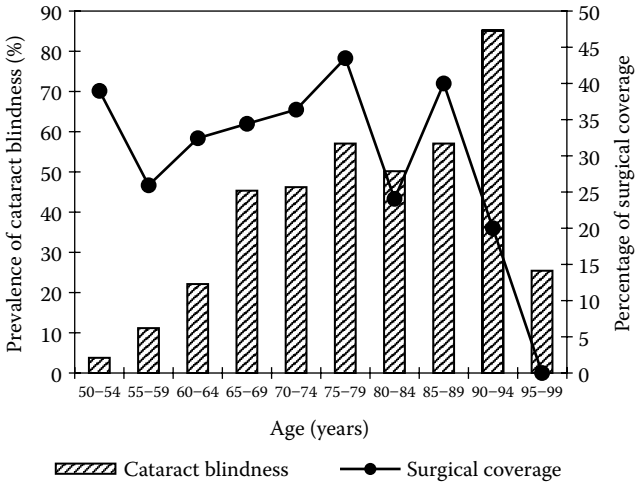

**FIGURE M.4** Mixed diagram: age-wise prevalence of cataract blindness (one or both <6/60) and the percentage of surgical coverage.

Consider a simple study on the effect of lifelong fully vegetarian and partially vegetarian diet on body mass index (BMI) of eighth grade students in a city. Suppose that, out of 42 such schools in the city, 4 are randomly selected for the study. Thus, there are two factors in this study—the type of diet (factor A) is fixed with two levels and school (factor B) is random with four levels. BMI is the dependent variable. The sum of squares and **mean squares** would be obtained as in the usual ANOVA, but the ***F*-test** changes for diet because of random effect of schools. If diet is indexed by $j$ ($j = 1, 2$), school by $k$ ($k = 1, 2, 3, 4$), and subject by $i$ ($i = 1, 2, \ldots, n$), the usual two-factor ANOVA model is

$$\text{fixed effects model: } y_{ijk} = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk} + \varepsilon_{ijk},$$

where $\mu$ is the overall mean, $\alpha_j$ is the main effect of the $j$th level of factor A, $\beta_k$ is the main effect of the $k$th level of factor B, $(\alpha\beta)_{jk}$ is the interaction term, and $\varepsilon_{ijk}$ is the error, which is the only random component in this model. The last is generally considered to follow a **Gaussian distribution** with mean zero and variance $\sigma^2$, written as $\varepsilon_{ijk} \sim N(0, \sigma^2)$. In a mixed effects model, if factor B is random, as are schools in our example, $\beta_k$ will be replaced by $b_k$ and this will also be random following, say, $N(0, \sigma_B^2)$ distribution. Thus,

$$\text{mixed effects model (factor A fixed, factor B random): } y_{ijk} = \mu + \alpha_j + b_k + (\alpha b)_{jk} + \varepsilon_{ijk}.$$

Because of this new formulation, the test of significance for fixed effect factor A would be $F = \text{MSA/MSAB}$, where MSA is the **mean square** due to factor A and MSAB is the mean square due to the interaction. This is different from what we do in the usual fixed effects ANOVA where each mean square is divided by mean square due to error (MSE). Tests for the random factor B and for interaction AB remain the same, $F = \text{MSB/MSE}$ and $F = \text{MSAB/MSE}$, respectively, as in the fixed effects ANOVA.

We have explained just about the simplest situation with a mixed effects model. But that should be adequate to clarify how mixed effects models are different from the usual fixed effects models and how they affect the statistical tests of significance in ANOVA. As mentioned earlier, this model is applicable to a variety of situations. For an application to longitudinal data analysis, see Kim et al. [1]. While working with statistical software, caution is required in specifying the model so that you get correct results. Our advice is that this should be done by only those who have sufficient expertise. Presence of random effects in a mixed effects model also involves issues such as **intraclass correlation** and **components of variance**. These are as explained separately. For further details of mixed effects models, see West et al. [2].

## models (statistical)

A model, by definition, is a simple version of a complex process. By its very nature, it is imperfect, but the attempt is to be able to capture the essentials of the process so that it can be understood, explained, or predicted with reasonable accuracy. Statistical models aim to do the same by means of equations with a dependent or the response **variable** on one side and the independents or the explanatory variables on the other side. The objective is again to explain or predict the response or outcome on the basis of some ancillary information. The explanation or prediction is never perfect but can have high degree of **validity** and **reliability**. Popular examples of statistical models are ordinary **regression models**, **logistic models**, and **Cox models**, but there are other models such as **infectious disease models**, **pharmacokinetic** models, **time-series** models, and **stochastic** models. All these models are also referred to as mathematical models in the literature, though hardly any model in medicine would be strictly mathematical with no probability component.

You may have guessed from the preceding paragraph that statistical models are etiologically of two types (we will come to the third type a little later): the predictive and the explanatory. The distinction is thin but it is there, at least in concept. There is a considerable overlap in the usage of these terms in the medical literature. The nature of both the models is the same, but the objective is different. Statistical methods for arriving at and evaluating the utility of both are the same.

In a **predictive model**, the focus is on correctly reaching at the outcome irrespective of the predictor set. Two different sets of predictors can be equally good in predicting the outcome. You may have a model to predict hospital survival of a critical patient on the basis of APACHE score at the time of admission, and another model to predict survival on the basis of age, hemoglobin level, and the care he/she gets. The choice of the predictor set is not important, and the model is considered good as long as it is able to predict the correct outcome in a large percentage of cases. There is no issue of how the predictor set and the outcome are biologically related, or not related.

In the **explanatory model**, on the other hand, the choice of regressors is important as the objective is to understand the mechanism of how these regressors are leading to the outcome. All those variables that can biologically affect the outcome are considered, and the significant ones are retained. van Oostveen et al. [1] investigated cost of care in hospitalized surgical patients in a Dutch university hospital and found through linear regression analysis that medication during hospitalization, complications, comorbidity, medical specialty, age, undergoing surgery, and length of stay are the significant factors that explain the cost of care. If the outcome is the incidence of swine flu, the explanatory variables would be different for bed planning than for stopping the epidemic, despite the fact that the outcome in both the models would be incidence of swine flu.

Both predictive and explanatory models are associational in nature and cannot be interpreted to describe the **cause–effect relationship**. As explained in that topic, cause–effect relationship is much more serious and requires special investigations. In the context of models, as for clinical trials, a **control group** is of tremendous help to infer cause–effect relationship. Models based on case–control studies where controls are matched with the cases except for the purported cause can provide a convincing evidence of a factor being the cause and not merely a correlate. This is the third etiological type of the statistical models referred to earlier.

There is always a question about evaluating the performance of a model. Most researchers would check it on the same dataset that is used to develop the model. Remember that the performance on the same dataset (called internal validity) could be extremely good since the model is based on that dataset. At best, this provides evidence that the model is not wrong. If it is not good on this dataset, the model should be immediately discarded after learning the lessons for such exercise. But if it is good on that dataset, the question still remains if the model is good for other subjects. Thus, external validation is required. Statistically, it is advised to test the model on another sample. Steps such as splitting the available sample into two parts—use one for developing the model and the other to test it—are suggested. Sometimes **simulations** are advised, but they rarely serve as a good approximation of reality. In any case, the work is not fully done unless the model has been put to real-life test.

## monotonic relationship

A monotonic relationship is said to exist between two variables when the value of one variable increases (decreases) or remains the same as the value of the other increases (decreases). Thus, values of both the variables change in the same direction, but the relationship continues to be called monotonic even if one remains stationary. The probability of death after the age of 5 years is monotonic despite being nearly constant between the ages 5 and 40 years. However, if the age less than 5 years is also included, the relationship in many populations is not monotonic between the age 0 and 100 years since the probability of death is generally high in infant period, declines till the age 5 years, remains constant for some time, and rises thereafter. The shape of this relationship is as shown in the figure in the topic **bathtub curve**. However, you can say that this relationship is monotonically decreasing from the age 0 to 5 years and monotonically increasing from the age 5 to 100 years. Figure M.5 illustrates another kind of monotonic relationship where the value of one variable increases with the other, remains the same for some time, and then rises again.

The knowledge of whether a relationship is monotonic or not can be helpful for modeling. For example, a **linear** relationship with nonzero slope is always monotonic. In fact, it is what is called strictly monotonic since there are no constant or stationary values in linear relationship when the slope is not zero. The relationship of the type

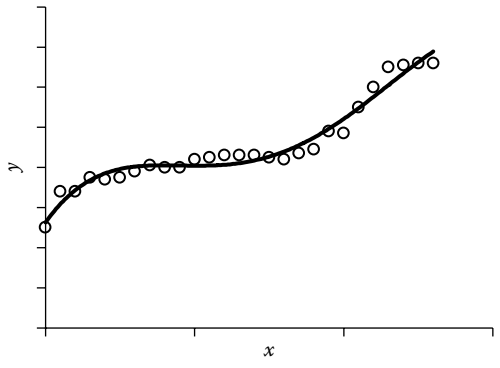

**FIGURE M.5** Monotonic relationship.

shown in Figure M.5 may require a fourth degree polynomial—it is **curvilinear**. Secondly, monotonic relationship also helps in investigating the biological reasons for stationarity if that happens. If the relationship is of the type shown in Figure M.5, it would be helpful to know why for some middling values of $x$, the variable $y$ does not show an increase, while it shows so for small and large values of $x$.

For examples of the use of monotonic relationships in medicine, see Ruckart et al. [1] who observed a monotonic relationship between benzene exposure during the entire pregnancy and term low birth weight in North Carolina. Kirli et al. [2] found a monotonic relationship between N-methyl-D-aspartate (NMDA) conductance onto the pyramidal cells with network gamma in schizophrenia, whereas this relationship was inverted U (not monotonic) with conductance onto fast-spiking interneurons.

## Monte Carlo methods

Monte Carlo methods are algorithms that use deliberately generated random observations to derive conclusions. Originally, the method was developed and used for those data that are difficult to study through mathematical formulations, but now it is used in a variety of setups such as for assessing the effect of violation of the requirements of a statistical model. Eckhardt [1] explains that the method was secretly developed by von Neumann and Ulam in 1947 and codenamed Monte Carlo.

Suppose you suspect that a coin is biased and has a tendency to show tails more often than heads. If you toss it 1000 times and note how many times it shows tails for assessing bias, this would be a form of a Monte Carlo experiment. If you are able to analyze the same blood sample 1000 times for, say, blood sugar level using a machine, you will have a good idea of the reliability of the machine. You can find how many times the value found by the machine is within 1% of the mean. Without this, it is difficult to assess the reliability of a machine. Such opportunity to generate a large number of observations is rare in practice, particularly in statistical modeling, and computer **simulations** are done to circumvent the problem. This requires generating a large number of observations by a repetitive process through computer algorithm. Simulation is now the most common tool used in Monte Carlo methods. This can be used, for example, to generate 10,000 random observations from any model, examine the pattern, and draw conclusions.

For an illustration of Monte Carlo simulations in biostatistical applications, consider a group of stroke patients who either survived with full health, survived with disabilities, or died. Suppose the interest is in finding whether the type of outcome has anything to do or not with blood groups O, A, B, and AB. The data will give **cell frequencies** in a $3 \times 4$ table for which an established test for association is **chi-square**. But if the total sample is small, say, just 40 subjects, many cell frequencies would be less than 5, and chi-square cannot be used. One way out is to use the Monte Carlo method and generate thousands of $3 \times 4$ tables with same row and column totals, and find the percentage of tables that give cell frequencies equal to the observed or more tilted toward the **association**. This will give the ***P*-value** required to decide statistical significance of the association between the type of outcome and the blood group pattern in stroke patients.

Pérez-Pitarch et al. [2] have described a study based on a Monte Carlo–generated sample of 2000 treatment-naive patients of ulcerative colitis based on a validated population pharmacokinetic model. Six dosing strategies for maintenance therapy were simulated on this population. Strategy of fixed dose of 5 mg/kg and individualized interdose intervals proved most effective. Zhang et al. [3] evaluated the efficiency of skull optical clearing solution-induced method with Monte Carlo simulations based on the measurements of divergence of beam spot and collimated transmittance of skull. Thus, the method has wide applicability in medical setups.

## MOOSE guidelines, *see* meta-analysis of observational studies in epidemiology (MOOSE) guidelines

## morbidity indicators, *see also* incidence, prevalence, and prevalence rates

These are those indicators that assess the extent and magnitude of morbidity. Morbidity indicators are separate for individuals compared to those for community. Individual level indicators are duration of disease and severity (see **disability weight**), whereas community level indicators are **incidence**, **prevalence**, average duration of disease, and severity distribution. Severity distribution tells us what percentage of affected subjects have mild, moderate, serious, or critical condition.

Incidence and prevalence are generally computed separately for each disease and health condition, and for each age group and sex, using tools such as the International Classification of Diseases. Duration of disease can be combined for all conditions together and can be calculated as disability days per year of life at different ages separately for each sex, or as total disability days during the life so far. When worked out for the entire life for all persons in a population, and adjusted by disability weight, this can give the **disability-adjusted life-years** lost per 1000 population during the year under study.

Morbidity rates across populations are seldom comparable because of several variations. First, the definition of sickness can vary from population to population and from age to age. For working population and school students, absenteeism due to sickness can be a useful indicator. But many people work or go to school even when mild sickness is present. This raises the question of whether or not conditions such as cold and cough should be counted. Similarly, mild muscle spasm or cramp and mild injury can be classified either way. Second, no globally acceptable scale is available to categorize disease as mild, moderate, serious, or critical. This varies from one condition to another and from population to population. It may also

depend on what part is affected and also the mood of the person at the time this assessment is being made. In addition, what is mild for one may be serious for someone else.

Individual level morbidity can come from clinics presuming that nobody is taking home remedy. That is a big if, though. Surveys are done to assess morbidity, but they too can mislead since the reporting is based on perception of the affected person rather than the actual physical examination. Then there are issues with failure to recall since mild conditions tend to be ignored. Old-age persons may not report vision and breathing problems considering that these are normal at their age. On the other hand, some old-age persons can feel harassed by a small problem and magnify its reporting. Such aberrations should be kept in mind when interpreting morbidity survey data.

Morbidity data are rarely complete for the entire population of any country and have to be estimated. The estimation method can become complex because of poorly understood geographic and socioeconomic differentials that can be substantial in addition to the known age–sex differentials. For the purpose of planning, projections can be done by synthesizing data for different individual years. For one such exercise for coronary diseases and diabetes in India, see Indrayan [1]. For global and regional estimates of morbidities with uniform methodology, see WHO [2].

## mortality rates, *see also* death rates

For overall deaths, see the topic **death rates**. The present section is devoted to the mortality indicators for specific age groups. Among these, fetal deaths are discussed separately as a part of **abortion rate/ratio** and **still birth rate/ratio**. We begin this section with perinatal deaths that include late fetal and early neonatal period (Figure M.6) and move up to the adults. **Maternal mortality ratio** in adult women is also discussed separately.

### *Perinatal and Neonatal Mortality*

Late fetal deaths are those that occur after 28 weeks of gestation. Early neonatal deaths are those occurring during the first week of life (<7 days). With these, the following can be defined:

$$\text{perinatal mortality rate (PMR)} = \frac{\text{late fetal deaths} + \text{early neonatal deaths}}{\text{late fetal deaths} + \text{live births}} * 1000$$

$$\text{perinatal mortality ratio (PM ratio)} = \frac{\text{late fetal deaths} + \text{early neonatal deaths}}{\text{live births}} * 1000.$$

A more precise definition considers births weighing at least 1000 g because those weighing less have poor prognosis anyway. This gives

$$\text{PM ratio} = \frac{\text{late fetal deaths} + \text{early neonatal deaths weighing} \geq 1000\ \text{g}}{\text{live births weighing} \geq 1000\ \text{g}} * 1000.$$

Even though the frequency of occurrence is the essential feature of a rate, note that the preceding formulas use the term **rate** when the numerator is part of the denominator; otherwise, it is considered a **ratio**. This distinction is not universal though. These are generally calculated on annual basis for each calendar year.

The measures of mortality after a live birth has taken place are the following:

$$\text{neonatal mortality rate (NMR)} = \frac{\text{neonatal deaths}}{\text{live births}} * 1000$$

$$\text{postneonatal mortality rate} = \frac{\text{postneonatal deaths}}{\text{live births}} * 1000.$$

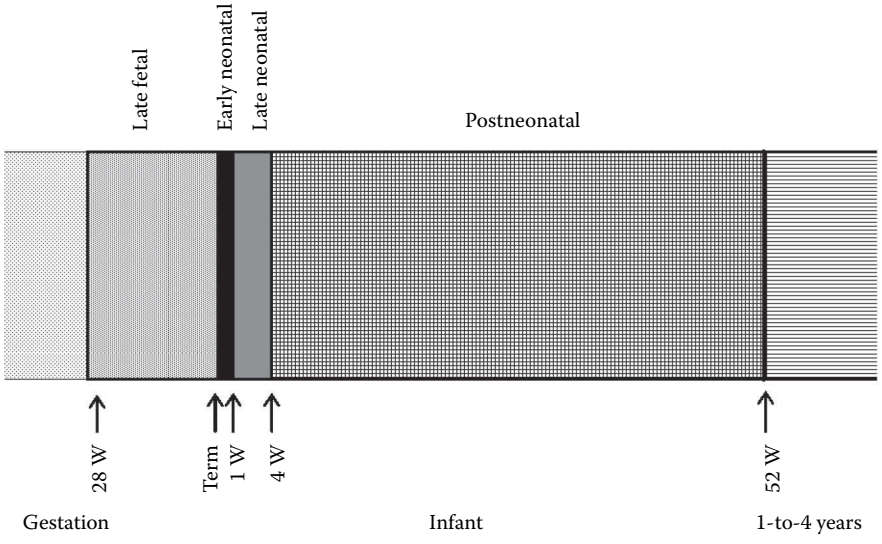

**FIGURE M.6** Childhood age groups important for study of mortality in a community.

The neonatal period is the first 27 days of life, and the postneonatal period is 28–364 days. In the case of rate in the formula just given, the postneonatal deaths can be calculated out of those who survive the neonatal period. This could be substantially different in areas where neonatal deaths are high.

Neonatal mortality is generally determined by the health of the mother and the adequacy of services available at the time of birth. The main causes of neonatal mortality are prematurity and birth asphyxia. Postneonatal mortality is mostly due to infections and undernourishment since birth. International efforts have succeeded in controlling much of the postneonatal mortality, but the neonatal mortality is slow to respond to these efforts. Emphasis is now given to maternal nutrition and skilled attendance at birth in developing countries to control neonatal mortality, and that is paying dividends.

### *Child Mortality*

Neonatal and postneonatal periods together form the infantile period. Note that an infant is a child *less* than 1 year of age, and a neonate is *less* than 4 weeks of age, which is the same in completed days as just stated. The sum of the neonatal and postneonatal mortality is the infant mortality when their denominator is the same live births:

$$\text{infant mortality rate (IMR)} = \frac{\text{deaths of infants}}{\text{live births}} * 1000.$$

A popular mortality rate for children is the under-5 mortality rate (U5MR). It is calculated as

$$\text{under-5 mortality rate (U5MR)} = \frac{\text{deaths of children} < 5 \text{ years}}{\text{live births}} * 1000.$$

The U5MR is also called the child mortality rate, although this term is sometimes used for mortality in the 1–4 years age group. These rates are different from the respective **age-specific death rates** because the denominator in these mortality rates is the number of live births and not the population of that age group. It is customary to use the term *mortality rate* when the denominator is live births and the term *death rate* when the denominator is population.

The mortality count used in the numerator in these formulas is not necessarily out of the live births in that year. A child born in the month of October may die in the month of January in the next calendar year. The birth and the death of the same child, thus, would be counted in different years. Despite this anomaly, these are called rates and the terms are retained as such because of simplicity in counting. The births are not required to be followed up to count the deaths for these rates. The effect of this anomaly on the rate is minimal because of the averaging-out phenomenon.

Some professionals modify the denominators for calculating some of these rates. For example, for calculating postneonatal mortality rate, they use (live births – neonatal deaths) as the denominator. Although this can be justified, such a modification introduces complexity and interferes with the feature of additivity of some of these rates. For this reason, we advocate simple denominators as stated.

All these childhood mortality rates are considered very sensitive indicators of population health in the global context. Attention is particularly paid to IMR because this is relatively easily understood and is now almost universally available. A large number of background and proximate factors such as education, affluence, nutrition, availability and utilization of health care facilities, and cultural practices affect IMR. This rate is affected rather quickly by health programs in developing countries and so is also used to measure the effectiveness of such programs.

### *Adult Mortality*

Child mortality is a huge concern in some populations, but those populations who have low child mortality shift their focus to adult mortality. Since geriatric mortality does not contribute much to the study of adverse health, adult mortality is concerned with deaths between the age of 15 and 59 years and ignores deaths at age 60 years and beyond. Thus,

$$\text{adult mortality rate} = \text{probability of death between 15 and 59 years per 1000 population of this age,}$$

and can be obtained through a **life table**. Adult mortality rate arouses passion as it concerns the most productive segment of the population and is supposed to be the healthiest period of life. Adult mortality is generally higher in males than females. This differential is attributed to greater exposure of males to hazards at work, stress, and strain, and also to their biological vulnerability.

See the topic **maternal mortality ratio** also for another aspect of adult mortality.

## moving averages

Moving averages is a smoothing mechanism for fluctuating serial data—mostly **time series** data. This is done to extract trend in the series. If there is a series of, say, 50 years from 1965 to 2015 of incidence rate of cataract for a population of age 60 years and above, which hardly fluctuates somewhat from year to year, moving averages, say for each consecutive 5 years, can give a somewhat smooth trend. These would be the average of incidence rates in the years 1965–1969, 1966–1970, 1967–1971, and so on, up to 2011–2015. These moving averages would take away much of the fluctuations but would still preserve the trend, including any persistent slowdown or reversals. Such averages are then assumed to be for the midpoint of the periods successively averaged. In our example, the first moving average will be considered to be for the year 1967, the second for the year 1968, and the last for the year 2013. Thus, initial and last few time points will not have any moving average. This loss is not much if you have a long series.

The method of moving averages is evidently applicable to only large series, and it requires a fair assessment of the period for averaging every time. The two, in fact, are related since the period cannot be large for relatively small series. For example, for only 50 data points as in our cataract example, the period cannot be 20 years, but for 200 data points, a 20-point moving average can be tried. This periodicity also depends on whether the objective is to find a short-term trend or to assess a long-term trend. Depending on how many time points are available, a 5-time point moving average will give a short-term trend, whereas a 50-time point moving average will give a long-term trend. A 10- or 20-time point moving average may provide a medium-term trend.

In a medical setup, suppose you are monitoring every 5 min the systolic blood pressure (BP) level of a patient in critical care. A short-term moving average may be good to assess the effect of each dose of drug, whereas a long-term trend would assess the improvement of the patient. Figure M.7 illustrates 30-min (6 time points at 5-min interval) and 120-min (24 time points at 5-min interval) moving averages. A short-term trend based on 6-point moving averages

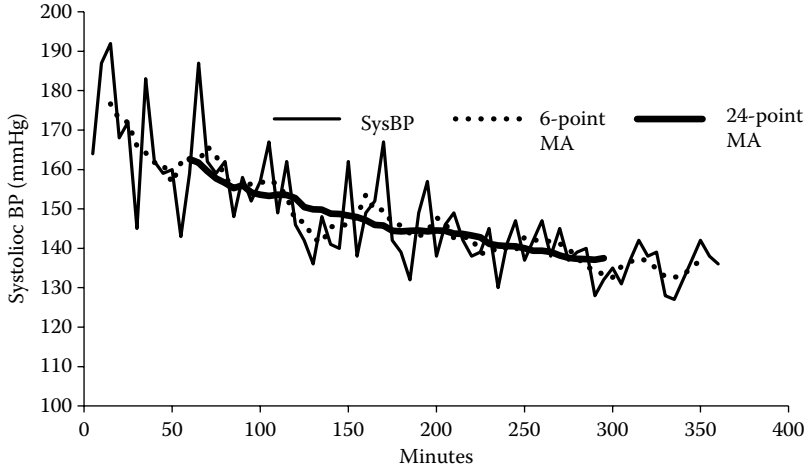

**FIGURE M.7** Systolic BP in a critical patient at 5-min intervals and moving averages (MAs).

is still wavering, but a 24-point trend is solid evidence of declining systolic BP. The last of course is not available for the first and last 12 time points (first and last 1 h). This may not be important too for the patient management.

If the periodicity is known, such as seasonal disease each year, you will be better off using the 12-month moving averages on monthly data. If a high afternoon temperature is expected each day for some patient, a 24-h moving average of hourly (or 6-point four-hourly) temperature could provide the trend of clinical importance. Bedside monitors can be programmed to provide trends based on such moving averages. If two or more series are available such as systolic and diastolic BP that move in the same direction, but are observed to move in reverse directions, such as one moving downward and the other moving upward after reaching a particular threshold, one can provide useful clues of what possibly is going on, say, by way of body reactions, and set alarm for doing something to arrest this conflicting trend.

Having provided clinical examples, let us say that such applications of moving averages in hospitals are not widespread yet. The method is mostly used for time series data on incidence and prevalence rates. In this case, it might be worthwhile also to plot the **confidence intervals** for each moving average. This plot will give you a confidence band.

## MSE, *see* mean squares in ANOVA

## multiarm trials

This is a trial that seeks to compare several regimens in one go. Conventional trials have one group that receives the test regimen and one more group that receives the control. Multiarm trials will have two or more regimens besides the control. These regimens could be different doses of the drug, different modes of administration of the same drug, or different regimens altogether such as comparing laparoscopic and open tension-free inguinal hernia repair with Shouldice operation [1].

Because of the high pace of development in medicine, sometimes many promising competing regimens are simultaneously ready for testing. Multiarm trials provide the opportunity to test all of them together. Otherwise also, multiarm trials are always cheaper than the conventional case–control trials because now at least the control group is shared. Administrative logistics are also shared, and the requirements of the subjects are also fewer. The latter happens because the same subjects on, say, regimen 1 are used to compare with regimen 2 and the control. You can see how the same trial is used for multiple comparisons, obviating the need to conduct several independent trials. Subjects may be relatively easy to recruit as a wide spectrum of treatment choices is available in this format. Thus, multiarm trials are efficient and cheaper, save time and resources, and are recommended for setups where several regimens are to be tested.

There is a flip side too. Multiarm trials are difficult to plan and execute as many regimens are involved, and there is a risk of overlapping of concepts. These are relatively bigger than the conventional two-arm trials, and it may not be easy to find so many subjects at the same time. They also involve issues of **multiple comparisons** and statistical control of **Type I error**. Real problem arises when the main outcome of interest varies from one regimen to another. For example, it could be recovery for one regimen and arrest of the disease for the other. Even if it is the same as recovery for all the regimens, the ancillaries such as speed of relief, cost of treatment, and adverse side effects may differ, and the comparison becomes complicated. The researcher must anticipate these variations and decide beforehand on how these would be reconciled to come to a unified conclusion.

There are not many examples of multiarm trials, although their design has been discussed. Royston et al. [2] described designs for comparing four new chemotherapy regimens for advanced ovarian cancer. Magirr et al. [3] presented flexible **sequential designs** for multiarm trials, and Wason et al. [4] discussed Type I error correction for multiple testing in such trials.

## multicentric trials

As the name implies, these are **clinical trials** that are simultaneously conducted at several centers following a common **protocol**. The goals of these trials are (i) to get more cases as one center may not have sufficient cases, (ii) to have a better cross-section of cases as different centers can have different patient profiles, (iii) to study the impact on efficacy and side effects of the varying environments prevailing in different centers, and (iv) to have a more realistic assessment of the reliability of results not just because of more accrual of cases but also by checking that different centers provide consistent results despite each being based on a relatively small sample. All of these can help to be more confident of the results and can also help in the better generalizability of these results.

Multicentric trials pose tough challenges. The most prominent among them is to devise a common protocol—different centers may have different opinions and different problems. Protocol development for a multicentric trial is a long and arduous task, and requires extensive consultation with investigators at different centers. The collaborators must have a flexible attitude and should come to a consensus to realize a common goal. The second challenge is in executing the protocol uniformly. Some centers may experience unforeseen problems that require deviation from the agreed protocol, and the investigators at some centers may want deviation after initially agreeing to participate. Interest of the patients is commonly cited to justify such deviations. Some of these deviations can be serious so as to contaminate the results. Another challenge is in arranging huge funds that a multicentric trial needs. The fourth challenge is in the analysis of data. The data from different centers are sent to one place where they are scrutinized again for inconsistent entries even if they have already been checked at each center. Pooling can be done only after ensuring that the data from different centers are not heterogeneous. This means that center-wise data are analyzed separately and checked for consistency in results for all the centers. The method of stratified analysis such as the Mantel–Haenszel chi-square may be used for analyzing data from multicentric trials. If the results differ despite sticking to the uniform protocol, perhaps a new hypothesis can be forwarded to explain the differences.

Although varying conditions are an essential ingredient of multicentric trials, they tend to exacerbate due to varying interpretations of the protocol requirements. The difficulty arises when such variations are not acknowledged and go on inadvertently, finally damaging the comparability. Thus, these trials need periodic review—much more than single-center trials do. Reviews such as those by the **Data Safety and Monitoring Board** help in quality assurance and uniformity across sites. Complex regimens that require intensive training may not be appropriate for multicentric trials.

Despite all the problems just stated, multicentric trials are commonly conducted in view of their positive features. Chen et al. [1] have reported a multicentric trial conducted in the United States on inactivated monovalent influenza virus vaccine. Du Toit et al. [2] have described a multicentric trial in the United Kingdom on different strategies of peanut consumption and avoidance to determine which strategy is most effective in preventing the development of peanut allergy in infants at high risk for the allergy.

## multicollinearity

Multicollinearity among a set of variables is said to exist when some of them are highly correlated with each other. Some statistical methods such as ordinary and logistic **regressions** can give weird results when such collinearity is present among the **regressors**. The estimates of the **regression coefficients** are still valid, but they are not reliable. The **standard errors** of the estimates will be unduly large in case of multicollinearity, indicating that the estimates are unstable. Consequently, the **confidence intervals** and the **tests of significance** will not be valid. But multicollinearity can be ignored in some situations. We will come to the solution, but first, one needs to know how to assess whether multicollinearity really exists. The common methods used for detecting multicollinearity are as follows:

- Examine the biological relationship among the regressors. For example, it is well known that systolic and diastolic blood pressures have strong **correlation**. Similarly, hemoglobin level and mean corpuscular hemoglobin concentration are highly correlated, so are skinfold thickness and waist–hip ratio.
- Obtain the correlation coefficient among all pairs of the regressors and check if one or more correlations are high, say >0.7. Whereas high correlation is a good indication of presence of multicollinearity, small correlations are no guarantee that multicollinearity does not exist.
- Examine the **variance inflation factor** (VIF) of each suspected variable. This may be calculated for any regressor by doing a linear regression of that variable on all the other regressors, and then obtaining the **multiple correlation** coefficient $R^2$ from that regression. The VIF = $1/(1 - R^2)$. High VIF (say, more than 2.5) indicates presence of multicollinearity since a variable then can be reasonably predicted by others.
- Statistical significance of the overall ***F*-test** but no significance of any of the individual **regression coefficients** also indicates multicollinearity.
- Nonsignificance of a regression coefficient of a variable that you know on theoretical grounds should contribute significantly is also an indication that multicollinearity exists.
- Drop the variable that is suspected to be collinear with one or more of the others from the regression model and see if the regression coefficients change drastically. If this happens, there is evidence in favor of the suspicion.
- A regression coefficient is found negative when theoretically the dependent should increase with increasing values of that regressor or vice versa. That is, if a variable is known to have positive contribution to the response yet the regression gives negative contribution, suspect multicollinearity.
- If there are many similar datasets or splits of the same dataset, and if the estimates of the regression coefficients substantially vary in models obtained by different datasets, suspect multicollinearity.

Multicollinearity among covariates that are there in the regression just for control and not of direct interest to the research objective does

not matter much. Similarly, high correlation due to one variable being the power or the product of the others (such as $x_3$ as $x_1^2$, and $x_4$ and $x_{1*}x_2$) should also not cause worry. Multicollinearity among indicator variables for categories that add up to 100% also is natural since the increase in the percentage of one category will automatically decrease the percentage in the other categories. However, if it is there among variables of primary interest, a solution must be found and implemented.

The easiest solution is to drop one variable in a pair of variables that are highly correlated; you should use your judgment to decide which one should be dropped. Do not drop the variable that you know has biological justification to be considered for inclusion in the regression. The second solution is to increase the sample size. As mentioned earlier, multicollinearity affects reliability and not validity, and reliability can be taken care of by increasing the sample size. The third solution is to try to combine correlated variables into an **index** when this index can be given a biological meaning. The fourth solution is what is called centering by subtracting the mean. Centering of the offending variables may reduce multicollinearity, but the interpretation of the corresponding regression coefficients changes. When centering is done for all the variables, the intercept becomes zero. There are other complex methods based on interactions and variances, but we leave them out from our purview. If you are interested, consult the book by Mendenhall and Sincich [1].

M

## multinomial distribution/test

Multinomial distribution is an extended version of the binomial distribution that is used for multiple categories instead of two categories. The topic **binomial distribution** gives details of the situation where the variable is observed in just two categories such as death/survival, pain/no pain, male/female, agree/disagree, and test positive/negative. Now suppose it is not just death/survival but also survival with disability, making three categories, namely, death, survival with disability, and survival without disability. A disease severity can be divided into categories none, mild, moderate, serious, and critical, and a person can belong to any one of these categories and nothing else. These categories are **polytomous** and **mutually exclusive and exhaustive**. Multinomial distribution is built up precisely for this setup. This distribution gives the probability of $O_k$ subjects falling into the $k$th ($k = 1, 2, \ldots, K$) category whose probability is $\pi_k$. The probability in this distribution can be calculated as

$$\text{Multinomial distribution: } P = \frac{n!}{O_1!O_2!\cdots O_K!} * \pi_1^{O_1}\pi_2^{O_2}\cdots\pi_K^{O_K};$$

$$\Sigma O_k = n \quad \text{and} \quad \Sigma\pi_k = 1.$$

If the probability of survival without disability after stroke is $\pi_1 = 0.50$, that of survival with disability is $\pi_2 = 0.30$, and that of death is $\pi_3 = 0.20$, the probability that out of 8 such patients, 6 will survive, 1 will die, and 1 will survive with disability with this formula is $P = 8!/(6!\times1!\times1!)\times(0.5)^6\times(0.3)^1\times(0.2)^1 = 0.0525$. Thus, there is nearly a 5% chance that the outcome of 8 stroke patients will be in this pattern. Such probabilities can be used to build a statistical test of significance for polytomous data.

### *Multinomial Test*

The major application of multinomial distribution is in testing of the hypothesis for multiple categories. This is approximated by chi-square for large $n$, but for small $n$, exact probability based on multinomial distribution as just mentioned should be obtained. For this, a null hypothesis $H_0$ is set for the category probabilities, and the plausible alternative hypothesis $H_1$ comprises all the probabilities other than the ones specified under the null but favoring the alternative. The $P$-value is obtained after summation of $P$ just mentioned over the configurations of the frequencies that are as observed in the sample or more extreme favoring $H_1$. Manual computation can become too complex even for moderate $n$. It is advisable to use a software package for calculating this probability. The following example illustrates the calculations that may help in understanding how these probabilities are obtained.

Suppose a regimen for control of angina pectoris is considered effective if at least 60% of patients on this regimen do not have any attack in 1 year of follow-up and not more than 10% have two or more attacks. Thus, the desired ratio is as follows:

| Number of angina attacks | 0 | 1 | 2+ |
|---|---|---|---|
| Desired percentage of patients | 60 | 30 | 10 |

These define the null hypothesis—$H_0$: $\pi_1 = 0.60$, $\pi_2 = 0.30$, $\pi_3 = 0.10$.

A higher percentage of patients with a lower number of attacks is even better. A lower percentage in these categories is $H_1$. The null hypothesis in this case is for the effectiveness of the regimen, whereas generally it is stated for ineffectiveness. The regimen under trial is lifestyle changes such as yoga, dietary changes, and physical exercise. After excluding other causes, only six eligible volunteers could be followed up for 1 year. The data obtained are as follows:

| Number of angina attacks | 0 | 1 | 2+ |
|---|---|---|---|
| Observed number of patients | 2 | 3 | 1 |

The observed ratio is loaded more toward a higher number of attacks than postulated under $H_0$. Is the regimen ineffective according to the criterion?

In this case, $O_1 = 2$, $O_2 = 3$, and $O_3 = 1$. The configurations adverse to $H_0$ and favoring $H_1$, beginning from the observed, are shown in Table M.13. This includes all configurations adverse to $H_0$ that have two or fewer patients with no attack. (It can be debated whether configuration (2, 2, 2) is adverse to (2, 3, 1). In the first case, two patients have one attack and another two have two or more attacks. In the second case, three patients have one attack and one patient has two or more attacks.) There are 18 such configurations. From the equation given earlier, the probability of observing the first configuration under $H_0$ is

$$P_1(O_1 = 2,\ O_2 = 3,\ O_3 = 1) = \frac{6!}{2!3!1!}(0.60)^2\,(0.30)^3\,(0.10)^1 = 0.058.$$

Similar probabilities can be calculated for the other configurations. But there is no need to do so here because $P_1$ itself is more than 0.05. The sum of the probabilities for these 18 configurations is going to be higher in any case. Since this $P$-value is not sufficiently small ($P_1$ itself is more than 0.05), the null hypothesis cannot be rejected. The evidence is not sufficient to call the regimen

**TABLE M.13**
**Configurations Adverse to $H_0$ and Favoring $H_1$ in Our Example**

| No. of Angina Attacks | Notation | Configurations Favoring $H_1$ (as Extreme as or More Extreme than the Observed) | | | | | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | **1** | **2** | **3** | **4** | **5** | **6** | **7** | **8** | **9** | **10** | **11** | **12** | **13** | **14** | **15** | **16** | **17** | **18** |
| 0 | $O_1$ | 2 | 2 | 2 | 2 | 2 | 1 | 1 | 1 | 1 | 1 | 1 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| 1 | $O_2$ | 3 | 0 | 1 | 2 | 4 | 0 | 1 | 2 | 3 | 4 | 5 | 0 | 1 | 2 | 3 | 4 | 5 | 6 |
| 2+ | $O_3$ | 1 | 4 | 3 | 2 | 0 | 5 | 4 | 3 | 2 | 1 | 0 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |

ineffective in controlling angina attacks. Note again the reverse nature of the null we have considered in this example.

You may have noticed that with only $n = 6$ subjects and just $K = 3$ categories in our example, the number of configurations is already large. If, for example, $n = 12$ and $K = 4$, the number of configurations, even those adverse to $H_0$, may become enormous. This is the reason for the advice to use a software package to calculate this probability. The calculations in this example are given only to enhance your understanding of the underlying procedure.

The categories in this example are metric. But the method of computing probabilities considers them **nominal**. The only use made of the metric scale of categories is in identifying the configurations adverse to $H_0$.

## multiple comparisons, *see also* Bonferroni procedure (test), Dunnett test, least significant difference, Tukey test for multiple comparisons

These are comparisons of statistical summaries (such as means and proportions) in different groups, particularly where a group is used more than once. For example, comparisons of the mean in group 1 with the mean in group 2 and the mean in group 1 with the mean in group 3 are multiple comparisons since the mean in group 1 has been used twice. This affects the statistical results even when the groups are independent. Repeated use of the same data for statistical significance inflates the probability of **Type I error**, more so if it involves the same group—thus, special methods are needed that can keep this error within control.

Multiple comparisons most frequently arise in **analysis of variance (ANOVA)**. Overall significance of difference among group means is indicated by the ***F*-test** in ANOVA, significance of which tells that there is some difference somewhere. Once this significance is obtained, the next step is to identify the groups that are different from one or more of the others. For this reason, this is also called **post-hoc comparisons**. This requires several comparisons. In case of pairwise comparisons, for example, if there are 4 groups, the comparisons are group 1 with group 2, 1 with 3, 1 with 4, 2 with 3, 2 with 4, and 3 with 4. There are a total of 6 comparisons, and these are called multiple comparisons. Means of two groups are generally compared by the Student *t*-test, but repeated application of this test at, say, 5% level of significance on the same data blows up the total probability of Type I error to an unacceptable level. If there are 15 tests on the same data, each done at the 5% level, then the overall (*experiment-wise*) Type I error could be as high as $1 - (1 - 0.05)^{15} = 0.54$. Compare this with the desired threshold of 0.05.

The Type I error allowed for each individual comparison is called the *comparison-wise error rate*, whereas the total error for all the comparisons together is called the *experiment-wise error rate*. To keep the probability of a Type I error within a specified limit such as 0.05 for an experiment, many procedures for multiple comparisons are available. Each of these is generally known by the name of the scientist who first proposed it. Among them are Bonferroni, Tukey, Scheffe, Fisher's LSD, Newman–Keul, Duncan, and Dunnett. These methods differ in how they take care of inflated Type I error and are suitable in different setups. The **Bonferroni** can be used in a variety of setups, and the **Tukey** procedure is for pairwise comparisons. These two are commonly used in medical and health literature and are also the most suitable ones. The **Dunett test** is used specifically when each group is to be compared with the control only. These are described under these topics in this volume. For other procedures, see Klockars and Sax [1]. Note that all these methods are for quantitative data, particularly the mean. Bonferroni can be used for qualitative data as well where chi-square or any other test has been used.

The issue of multiple comparisons also arises in interpreting the results reported in publications. Many *P*-values may have been considered to arrive at a conclusion. Researchers may have tried many statistical tests before reaching to the final ones that they decide to report. Hardly anybody will make adjustment for such *behind-the-scene* statistical tests, although they also affect the final *P*-value. Also, several tests of statistical significance, each at $\alpha = 0.05$, in the same article for various comparisons would make the total error much higher than acceptable. A wiser approach is to limit the calculation of *P*-values to the original question and not give too many *P*-values that can raise a question mark on the overall result.

There might be two or more publications on the same set of data with different focus or with different outcome variables. Each publication may be complete within itself for multiple comparisons but would be oblivious to the comparisons made for the other papers. The argument can be extended to Type I errors committed by other workers in similar studies and possibly in lifetime. For some researches, ignoring accumulation of Type I errors is one of the reasons that the statistically significant results fail to reproduce. Just be on guard for such fallacies.

## multiple correlation

This is the correlation between one variable $y$ and a linear combination of several other variables $(x_1, x_2, \ldots, x_K)$. Multiple correlation is easily computed when all these variables are quantitative but can be extended to include categories of **nominal** variables also when recoded by **indicator variables**. When nonlinear

combinations of $x$'s are considered, this becomes the **coefficient of determination**.

While considering multiple correlation coefficient as the Pearsonian **correlation coefficient** between one variable $y$ and the *best* linear combination of the variables ($x_1$, $x_2$,…, $x_K$), two words are important: best and linear combination. The linear combination of these variables is $b_1x_1 + b_2x_2 + \ldots + b_Kx_K$, but for multiple correlation coefficient, $b$'s are chosen in such a manner that the correlation between this combination and $y$ is maximum. This is what we mean by *best* linear combination. These $b$'s happen to be the same as the **regression coefficients** obtained by the **least squares method**. Thus, the best linear combination of the $x$'s is the same as the predicted value of $y$ by linear regression. This gives another definition of multiple correlation coefficient—this is the Pearsonian correlation coefficient between $y$ and its value **predicted** by the linear regression model. This coefficient is denoted by $R$, but for ease of interpretation, $R^2$ is used instead. The value of $R^2$ is the proportion of the total variance of $y$ explained by the linear regression. If $R^2 = 0.73$, this means that 73% of the variation in the values of $y$ can be explained by the differences in the values of the $x$'s from subject to subject. This, in a way, measures the utility of the regression in predicting the value of $y$. The other 27% is unexplained or is due to the factors not considered in this regression equation including the random fluctuations. In case of simple linear regression with one independent variable, $R^2 = r^2$, where $r$ is the notation for the usual correlation coefficient. The following example may help in fixing the ideas.

Consider the prediction of glomerular filtration rate (GFR) in kidney recipients 12 months after transplantation by graft kidney volume/recipient BSA ratio, donor age, and recipient gender [1]. A group of, say, 160 such patients were followed up for 12 months, and these measurements were recorded. A linear regression equation was obtained to predict the GFR at 12 months with the ratio, age, and gender as regressors. Now, plug in these values of the ratio, age, and gender in the regression equation and obtain the predicted GFR for these 160 patients. The Pearsonian correlation between these predicted values and the actual observed values will be the multiple correlation coefficient. If the square of this correlation coefficient $R^2 = 0.22$, you know that the three regressors (ratio, age, and gender) together, when their best linear combination is considered, are able to account for just 22% variation in the GFR at 12 months.

$R^2$ is also used to compare one model with another. If $R^2$ for one model is 0.63 and for the other model it is 0.76, then the model with the higher $R^2$ is considered a better fit. Increasingly better fit can be obtained by progressively adding new regressors, but a large number of regressors make the model difficult to interpret. Thus, a model is considered good when it contains a small number of regressors but gives a sufficiently large value of $R^2$. A value more than 0.70 is generally considered desirable, between 0.80 and 0.89 good, and 0.90 or more excellent. These are relative and not absolute since $R^2 < 0.50$ can also be useful in rare cases where almost nothing is known. The success in achieving large $R^2$ depends on the proper choice of the regressors and on the right specification of the model. In health and medicine, it is many times difficult to obtain a high value of $R^2$ because the appropriate regressors are not known for some situations, and they have to be assumed on the present knowledge or on available data. Both these sources may be inadequate.

Since $R^2$ continues to improve as more regressors are added, a realistic assessment is made when adjusted for the number of regressors. The details are given under the topic **adjusted $R^2$**.

A statistical procedure similar to the $F$-test for ANOVA is available to test the statistical significance of $R^2$ as well as of addition to $R^2$ made by any additional variable. Most statistical software packages do this easily. It is thus possible to specify a large number of regressors and ask the computer program to include only those that contribute significantly. Methods such as forward selection, backward elimination, or **stepwise** are used for this purpose. These methods tend to automatically exclude variables that have high **multicollinearity** with other regressors.

High $R^2$ for small $n$ is not much helpful because standard errors are still high and the reliability of the estimates is low. High $R^2$ can occur in a structurally inappropriate model. This can also occur in case of multicollinearity where many individual regression coefficients are not statistically significant.

### Coefficient of Determination

Overall statistical significance of a regression model is checked by an $F$-test similar to the one we use for ANOVA. This significance indicates only that the model is not useless, but it may or may not be a sufficiently good fit. A regression model (whether linear or nonlinear) is considered a good fit if all the **residuals** $e = (y - \hat{y})$ are small. Since residuals fluctuate around zero in any case, small residuals would necessarily yield a small **sum of squares** $\Sigma e^2$. This is the residual sum of squares, popularly called the sum of squares due to error (SSE). Its magnitude, when compared with the total sum of squares, $SST = \Sigma(y - \bar{y})^2$, provides a measure of "lack of fit" of the regression. The difference (SST – SSE) is called *regression sum of squares* (RegSS). Each of these sums of squares has associated degrees of freedom (df's) as in the case of ANOVA. RegSS measures how much of the total sum of squares the regression has been able to account for. This is the "goodness of fit" and its proportion of the SST is denoted by $\eta^2$, i.e.,

$$\eta^2 = \frac{\text{RegSS}}{\text{SST}} = 1 - \frac{\text{SSE}}{\text{SST}}.$$

The quantity $\eta^2$ is interpreted as the proportion sum of squares of $y$ explained by the regression and called the **coefficient of determination**. The larger the $\eta^2$, the better the fit. If the residual sum of squares is as small as, say, 10% of the total sum of squares, then $\eta^2 = 0.90$. The fit, then, is said to account for 90% variation in $y$. A fit with such high $\eta^2$ should be adequate in most cases, especially if $n$ is large.

Note that we have not restricted to linear regression in this case, and it can be nonlinear. When the regression is linear, $\eta^2$ is the same as $R^2$. To reiterate, coefficient of determination is the square of the multiple correlation coefficient when linear combinations are considered. The term *coefficient of determination* can be used for any regression but is more appropriate for nonlinear regressions.

Most researchers present results in term of $R^2$ and not $\eta^2$ because they generally consider only the linear regression. The notation $\eta^2$ for coefficient of determination is general and applies to all regression setups. However, in case of multiple or simple linear regression, this is denoted by $R^2$.

## multiple imputations, *see* imputation for missing values

## multiple linear regression, *see also* linear regression, simple linear regression

A **linear regression** with more than one regressor is called multiple linear regression. When the regressor is just one, the term used is **simple linear regression**. If you are not familiar with this, review that topic first to understand what multiple linear regression is. A multiple linear regression is of the form

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_K x_K + \varepsilon,$$

where the variable $y$ is called the dependent, whereas $x_1, x_2, \ldots x_K$ are the $K$ independent variables, and $\varepsilon$ is called the error term that is left over part of the variable $y$ not accounted by the $x$'s. The $x$'s can be nonlinear such as $x_3 = x_2^2$, but the $\beta$'s have to be linear for the regression to be called linear. If the $\beta$'s are nonlinear, this becomes a **nonlinear regression** and much more complex to obtain. The dependent is also called the response variable or the outcome variable depending on the context and the independents have names such as predictors, explanatory variables, and regressors. For details of these variables, see the topic **dependent and independent variables**. The values of the independent variables in this regression are considered fixed and not stochastic.

The $\beta$'s in the multiple linear regression equation are called the regression coefficients. See the topic **regression coefficients** to understand their interpretation, and for confidence intervals and tests of hypotheses on these coefficients. The notation $\beta$ is for the regression coefficients in the population from which the subjects have been selected and measured for running the regression. The corresponding sample estimates of $\beta$'s are denoted by $b$'s. When the values of $b$'s are substituted in the regression equation and the value of $y$ is computed for any set of values of $x$'s, this is called the predicted value of $y$ and denoted by $\hat{y}$. This predicted value, in fact, is the average of predicted $y$ for the fixed set of values of $x$'s. This implies that if several values of $y$ are obtained for the same fixed values of the $x$'s, $\hat{y}$ would be the average of the predicted values. This is explained a little later in this section by an example.

Two basic methods are used to estimate $\beta$'s. The first is to find those $b$'s that make the regression closest to the observed values in the sample in the sense that the sum of squares of the difference between the observed and predicted values of $y$ is minimum. In notations, this sum of squares is $\Sigma(y - \hat{y})^2$ and is called the residual sum of squares. The method that minimizes this sum of squares is called the method of **least squares**. The second method is to find those values of $b$'s that make the observed sample values most likely to occur. This is called the method of **maximum likelihood**. Quite commonly, particularly when the errors have Gaussian distribution, the two methods give the same estimates of the regression coefficients. For more details, see the topic **regression fitting (general method of)**. Statistical software packages give these estimates easily once you specify the regression and the dependent and independent variables.

Consider regression of birth weight of full-term healthy babies on the weight of the father and mother. Suppose the regression equation obtained on the basis of a random sample is

$$\text{BW} = 2.65 + 0.008 \times (\text{MW}) + 0.004 \times (\text{FW});$$
$$55 \le \text{MW} < 80;\ 60 \le \text{FW} < 90;$$

where BW is birth weight, MW is mother's weight, and FW is father's weight. All weights are in kilograms. Note that the regression is based on the mothers whose weight ranges from 55 to 80 kg and the fathers whose weight ranges from 60 to 90 kg. Thus, this regression is valid for these weight ranges only. Slight extrapolation on either side may be admissible.

Since there are two regressors, graphically a surface is obtained in place of a line. The response surface of this equation is shown in Figure M.8. If there are any square or any such term for weight of mother or father or both, the shape of the surface will not be a plane but curved. If there is a third regressor, the shape will be three-dimensional such as a pyramid or cuboid for linear regression and difficult to be represented graphically. Four or more regressors are even more difficult to visualize. Higher dimensions can only be conceptualized and not depicted.

The values of the regression coefficients show that for every kilogram weight of the mother, the birth weight increases on average by 8 g, and for every kilogram weight of the father, the birth weight increases by 4 g. The influence of the father's weight on birth weight is one-half of that of the mother in this example. When the mother's weight is 60 kg and the father's weight is 70 kg, the predicted birth weight is $2.65 + 0.008 \times 60 + 0.004 \times 70 = 3.41$ kg. This, in fact, is the predicted average birth weight of children of all those parents whose weights are 60 kg (mothers) and 70 kg (fathers). Note that this regression is for full-term healthy babies. Even in this group, it is known that the birth weight actually does not depend exclusively on the parental weight. Inclusion of other influential factors in the regression may improve the prediction.

As noted earlier, the prediction in this example is for the *average* weight of babies with specific weights of parents. The actual weight in individual births could be different. This difference would be due partly to deviation from the average and partly to the influence of factors other than parental weight.

In a classical multiple linear regression, all the $x$'s are quantitative and so, of course, is $y$. However, if some of the $x$'s are nominal, indicator variables can be created for each category of each nominal variable that would effectively give separate regression equations for each category of the nominal variables. For example, we can insert a variable gender of the child in our example with value gender = 1

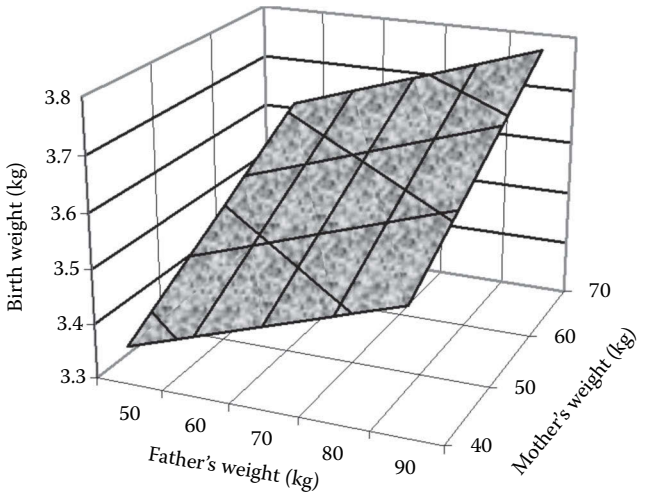

**FIGURE M.8** Response surface for a child's birth weight for different weights of the mother and father.

M

for male child and gender = 0 for female child. This is the indicator variable for gender. Insertion of this variable would most likely change all the regression coefficients. Suppose the new regression equation is

$$BW = 2.63 + 0.007 \times (MW) + 0.005 \times (FW) + 0.4 \times (\text{gender});$$
$$55 \le MW < 80;\ 60 \le FW < 90.$$

For gender = 1 (male child), this equation is BW(male child) = 2.63 + 0.007 × (MW) + 0.005 × (FW) + 0.4 × 1, or BW(male child) = 2.67 + 0.007 × (MW) + 0.005 × (FW). For gender = 0 (female child), this equation is BW(female child) = 2.63 + 0.007 × (MW) + 0.005 × (FW) + 0.4 × 0, or BW(female child) = 2.63 + 0.007 × (MW) + 0.005 × (FW). Because of the indicator variable, the same regression equation produces two equations—one for male children and the other for female children. The only difference we have represented in this example is only in the **intercept**, but regressions can be devised so that the regression coefficients for MW and FW are different for male children than for female children. This could be obtained by including **interaction** terms between the indicator variable and MW or FW or both.

As explained under the topic **models**, a multiple linear regression could be explanatory, predictive, or causal. **Adequacy of regression fit** is a separate topic but mostly, in case of multiple linear regression, is assessed by the value of the square of the **multiple correlation** coefficient $R^2$. If there are a large number of candidate variables for consideration in multiple linear regression, **variable selection** may become necessary. This also helps in obtaining a more parsimonious model. All regressions, including multiple linear regression, are valid under certain conditions as explained in the topic **regression requirements (validation of)**.

## multiple responses

You know that one person can have just one age and one hemoglobin level at a point in time but can have multiple symptoms or multiple diseases. The person may report that he/she is suffering from diabetes, hypertension, and vision loss at the same time. Such responses are called multiple responses. Data on these responses require special care in analysis and presentation.

Consider the data in Table M.14 on the number of cases of abdominal tuberculosis with major symptoms. This is a classification of the cases, but the symptoms are neither exclusive nor exhaustive. They are not exclusive because one patient can have two or more complaints: a patient may have vomiting as well as constipation. This is what we call multiple responses. The categories are not exhaustive because only major symptoms are listed: patients with other symptoms may be present but are not included in this table. When the categories are exhaustive and multiple responses are present, the sum total of frequencies would necessarily exceed the total number of subjects. In Table M.14, the sum is more even when the categories are not exhaustive. To avoid confusion, the total number of subjects in the case of multiple responses is called a base in place of total. Percentages are generally calculated using this base and not the total.

**TABLE M.14**
**Cases of Abdominal Tuberculosis with Major Symptoms**

| Symptom | Number of Cases | Percent |
|---|---|---|
| Pain in abdomen | 126 | 89.4 |
| Vomiting for a long time | 85 | 60.3 |
| Constipation for a long time | 57 | 40.4 |
| **Total cases (Base)** | **141** | **100.0** |

*Source:* Adapted from Das P et al., *Am J Proctol* 1975; 6:75–86. http://www.ncbi.nlm.nih.gov/pubmed/1119554#

**TABLE M.15**
**Conversion of Cases of Abdominal Tuberculosis with Major Symptoms into a Contingency Table**

| Group of Major Complaints | Number of Cases | Percent |
|---|---|---|
| Pain, vomiting, and constipation | 44 | 31.2 |
| Pain and vomiting, no constipation | 37 | 26.2 |
| Pain and constipation, no vomiting | 10 | 7.1 |
| Vomiting and constipation, no pain | 2 | 1.4 |
| Pain, no vomiting, no constipation | 35 | 24.8 |
| Vomiting, no pain, no constipation | 2 | 1.4 |
| Constipation, no pain, no vomiting | 1 | 0.7 |
| Other symptoms | 10 | 7.1 |
| **Total** | **141** | **100.0** |

Because of the multiple responses, Table M.14 is not a **contingency table** and cannot be analyzed by **chi-square**. Graphs that require a meaningful total such as **pie diagram** cannot be made on data with multiple responses. But the data can be converted to a contingency table when additional information is available. One way to do it is suggested in Table M.15. Note that the categories are now **mutually exclusive and exhaustive**. Perhaps this table provides more useful clinical information.

## multistage random sampling

In studies that involve a population of large size, it is sometimes helpful to draw samples in stages. If the subjects spread all over a state are the target, you may select a small number of districts or counties in the first stage (first stage units are called **primary sampling units**); then some blocks, colonies, or hospitals in the second stage from the selected districts or counties; and finally the subjects from the selected colonies/hospitals. Thus, there are sampling units of various sizes. When sampling is done in stages from bigger to smaller units within the units selected at the previous stage, it is called multistage sampling. When selection in each stage is random, this becomes multistage random sampling (MRS).

In a study to find the prevalence of smoking in females of age 20 years and above in a particular state with, say, a million families, you may, for example, first select 4 counties by the random method, then 12 census blocks within each selected county, and 50 families within each selected block. All females of age 20+ years in the selected families could be the unit of inquiry, although the sampling units successively are counties, blocks, and families. Some families may have two or more units of inquiry and some none at all but most may have just one. If there are many families with two or more eligible females, this can produce a **clustering effect**.

In the preceding example, a total of 4 × 12 × 50 = 2400 families could be in the sample. This looks like an extremely small number

compared with a total of a million families in the state. Yet this could provide a fairly precise estimate of the prevalence of smoking among females of age 20+ years in the state.

If a **simple random sampling** (SRS) of 2400 families out of a million is chosen instead of an MRS, the selected families may be scattered all over the state, say in 200 census blocks. A block may have to be visited for just one family in the sample. This could mean a substantially higher cost of travel by the survey team and loss of time. In the case of MRS in this example, only 4 counties need to be visited, and the survey work will concentrate in 12 blocks within each county. Thus, the major advantages of MRS are reduced costs and saving of time because of less travel. Another advantage is that a full **sampling frame** of the smaller units is not required. In this example, the frame required is the list of all counties in the state, the list of blocks in the *selected* counties, and the list of families in the *selected* blocks only. In the case of SRS, on the other hand, the frame will be the list of all families in the entire state. Preparation of this frame in itself could be a major exercise in some situations. Another advantage of MRS is that, in most practical situations, the smaller sample chosen by MRS may be sufficient to achieve good precision relative to SRS.

An example of MRS is provided by Milias et al. [1] who studied prevalence of self-reported hypercholesterolemia in Greek adults. In this nationwide survey, 5003 adults of age 18–74 years were enrolled by multistage sampling. Full details are not given, but they state that the multistage sampling was based on age–sex distribution of the Greek population according to the 2000 census. However, the stages are not identified. The accompanying table in their article on the age–sex distribution of the sample and population indicates that the age representation in the sample was nearly the same as in the population. The reporting made in this article has provided a few lessons. First, the sampling is stated as multistage, but stages are not identified. They may have selected a few districts in the first stage, a few counties in the second stage, and a few families in the third stage, but not stated. Second, the authors use the term "study population" instead of study sample for the selected 5003 adults. Such misuse of the term **population** is quite common in medical literature. Third, the proportionate representation of age indicates that possibly age stratification has been used but not explicitly stated.

## multivariate analysis of variance (MANOVA)

Analysis of variance (ANOVA) is used where a quantitative variable is dependent on qualitative characteristics such as case and control group, or different types of treatment. This is called univariate setup since the dependent is just one variable. Now consider a setup where the dependent is not one variable but a set of quantitative variables, and the objective continues to be to study the difference in means in different groups.

### *Regular MANOVA*

Multivariate ANOVA (MANOVA) is used when a set of correlated quantitative variables is considered dependent on a set of qualitative variables. For example, the dependent could be kidney functions (creatinine clearance, urea clearance, and diotrast or *p*-aminohippurate clearance) in persons of age 50–59 years. These persons may be grouped into those taking different diets (vegetarian, meat based, fish based, etc.) and grades of physical activity (sedentary, mild, moderate, and heavy). They may also be categorized into male and female. The dependent variables in this case are various kidney functions. These are **multivariate data** and quantitative. The independents are gender and the category of diet and physical activity, which are qualitative. Just as in ANOVA, the primary purpose of MANOVA in this case would be to test the null hypothesis of equality of means of kidney function parameters in people in different categories of independent factors. Interaction among these independent factors can also be investigated. We illustrate this with the help of an example.

To evaluate the effectiveness of an exercise intervention for people with early and midstage Parkinson's disease, 51 men and women with the disease were randomly allocated to two groups [1]. One group received individual instructions for exercise three times a week for 10 weeks, and the other group remained in the usual care (control). In this study, 46 completed the trial. The outcome measures are functional axial rotation for spinal flexibility, functional reach, and the supine-to-standing time for measuring physical performance. Thus, there were three dependent variables. MANOVA performed for these three variables demonstrated a significant difference ($P < 0.05$) between the two groups. It was concluded that better improvement could be achieved by a 10-week exercise program for people in early and midstage Parkinson's disease.

Note that the conclusion in this example is based on simultaneous consideration of the three outcome variables. When each of them is considered individually in a univariate setup, functional axial rotation and functional reach showed a significant difference but not the supine-to-sitting time. It can be argued that univariate analyses allow a more focused conclusion because they tell which particular outcome is affected and which is not. However, combining the univariate conclusions on correlated variables can sometimes be erroneous because the joint conclusion is subject to a relatively high **Type I error** than is otherwise apparent. Also, in general, a combined conclusion cannot be drawn by univariate analyses when some outcomes show change and others do not. Multivariate analysis helps to draw a clear conclusion for all the variables together.

In the case of a univariate setup, the Student *t*-test is a special case of the ANOVA *F*-test when the number of groups is two. The corresponding analog of MANOVA for two groups is **Hotelling $T^2$**. In other words, MANOVA for two groups gives the same result as Hotelling $T^2$.

The following remarks about MANOVA may be helpful in clarifying certain issues:

- The underlying requirement for a MANOVA test is a **multivariate Gaussian** (normal) pattern of the observations. This is not easy to verify. However, each variable separately can be checked for a Gaussian pattern using the methods described in the topic **Gaussianity (how to check)**. When each is not far from Gaussian, there is a great likelihood that they are jointly multivariate Gaussian.
- The other requirement for a valid MANOVA test is homogeneity of the **dispersion matrices** of $y$'s in different groups. This matrix is the multivariate analog of the variance. Methods such as the **Box *M* test** are used for testing their homogeneity, keeping in mind that this heavily depends on multivariate Gaussianity of data. You can depend on a statistical software package for performing this test. When the same set of variables is measured in

two or more groups, the dispersion matrices should be comparable, and there would be rarely any need to worry on this account.
- The test criterion used for the MANOVA test is generally either Pillai trace or **Wilks Λ**. Their distribution in most cases can be transformed, at least approximately, to the usual *F* as applicable to ANOVA. Statistical software would do this and provide the ***P*-value**.
- Empty cells due to missing observations or otherwise are a more serious handicap in a multivariate setup than in a univariate setup. If information on just one variable is missing, the entire record is generally deleted. This may reduce the available sample size considerably when values for different variables are missing for different subjects.
- This method assumes that all dependent variables have equal importance. If homocysteine and insulin levels both appear as dependents in the data for coronary artery disease (CAD) cases, both are given the same importance unless a weighting system is applied in the analysis. For example, it is possible in the analysis of data of a study on CAD to incorporate six times more importance to homocysteine level compared with insulin level. This will modify the method to some extent, but the major problem for a clinician would be to determine these weights objectively.

### *MANOVA for Repeated Measures*

Another example where the dependent is a correlated quantitative response is drug concentration in the blood at different points of time (repeated measures) after its administration to two or more groups of patients (e.g., experimental/control or control/drug 1/drug 2). The qualitative independent in this case is the group. The objective is to find whether or not the mean response at different points of time is different in various groups, and not to explore the time trend of the response. The mean response in this case refers to the mean over the patients and not the mean over time. MANOVA would simultaneously compare several means, one at each time point, in one group with those in the other groups. Such simultaneous consideration obviates the need to examine univariate parameters such as time to reach the peak concentration ($T_{max}$) and the peak concentration ($C_{max}$) reached unless they are otherwise needed for evaluating pharmacological properties of the regimen. MANOVA in this case could be an alternative to the area under the (concentration) curve (AUC) used by many workers for this setup. As explained under the topic **area under the curve (AUC)**, this can lead to erroneous conclusions in some cases.

Repeated measures are naturally correlated and provide an apt situation for use of MANOVA whenever dependent is quantitative. Univariate **repeated measures ANOVA** is discussed separately, but MANOVA is considered better when the group sizes are equal (balanced design) because, then, MANOVA is quite robust to violation of **sphericity**. Sphericity is contrasts (differences at various time points with the previous value) being independent (covariance = 0) and having the same variance (homogeneity). This is tested by the **Mauchly test**. These are rather strong requirements for univariate repeated measures ANOVA but not as much for MANOVA. Univariate analysis is recommended for unbalanced design (unequal group sizes) where df's are corrected by **Huynt–Feldt** epsilon for *F*-test when sphericity is violated.

If you are using MANOVA because of balanced design in repeated measures, care is needed in specifying the design regarding what factors are between subjects and what are within subjects. In repeated measures, time will always be within subjects, but there might be other factors as well. Also, for MANOVA for repeated measures, prefer **Pillai trace** as the criterion instead of Wilks Λ for testing differences between groups, because Pillai trace is generally more robust to assumption violation. The interaction between groups and time will indicate whether different groups have the same time trend or not. Do not forget to test homogeneity of dispersion matrices between groups by the Box *M* test. Gaussian distribution of the errors is required for all these tests.

For further details of MANOVA, see Morrison [2].

## multivariate data/methods

Simultaneous consideration of several measurements gives rise to multivariate data. The only condition is that they should be all **stochastic**—depend on chance and cannot be predicted with certainty, or are not fixed by design. In this setup, each individual measurement gives partial picture, and the complete picture is available when all these are considered together. For example, a child's weight does not tell you much about his or her growth unless you consider age, sex, and height also. Systolic level itself is not good enough for clinical evaluation, and diastolic level also should be simultaneously considered. For BP also, age and other comorbidities help in obtaining a complete picture. In fact, all health and disease conditions require that more than one measurement be considered in juxtaposition with one another to arrive at any unified conclusion. In this sense, all medical evaluations are intrinsically multivariate.

In view of what we have stated in the preceding paragraph, isn't it strange that most statistical analyses of data are done as though each variable is stand-alone? The Student *t*-test, *z*-test for proportions, binomial test, analysis of variance, and corresponding confidence intervals (CIs) are all univariate methods. Even ordinary regression and logistic regression are effectively univariate as only the dependent is considered stochastic—the independents in both these regressions are considered fixed. Whereas methods such as survival analysis are adequate as univariate methods because it can be considered by itself, most other analyses are oblivious of the correlations a variable has with other variables. For example, if there is any conclusion for HDL-cholesterol (HDL-C), it will not consider LDL-cholesterol (LDL-C) or triglyceride; if the study is on diabetic neuropathy alone, it will not consider age or body mass index. Such conclusions have risk of being compromised, even wrong, because other factors affecting it are not simultaneously considered. Even if you consider HDL-C and LDL-C both but independently and separately, the effect of their correlation is still ignored. A joint conclusion can be rarely drawn when correlated variables are separately studied. This underscores the need to be careful about conclusions regarding one variable at a time.

**Correlations** and **chi-square for *R* × *C*** contingency tables are examples of methods that consider two variables together—correlation where both the variables are quantitative and chi-square where both are qualitative. Both these are bivariate methods and good enough to assess the presence and degree of dependence. If one is quantitative and the other qualitative, **point-biserial correlation** can be used. But this kind of bivariate analysis does not

go beyond since, for example, the **simple regression** that finds the nature of relationship considers the independent variable on the right side of the equation as fixed and not stochastic. Thus, this is not a bivariate method.

As mentioned, the primary reason that several variables are considered together is that they depend on one another—they are correlated. Thus, the correlation structure among the variables is an important consideration in the multivariate setup. This structure can also be considered in the form of **dispersion matrix**. Even if the variables are not correlated, the results arrived at by individual variables could provide a different result than when considered simultaneously. Statistically, this happens because combination of individual ***P*-values** or the CIs is not the same as the *P*-value or the CI in the multivariate setup.

We have already given examples of multivariate data: child growth parameters where age, sex, height, weight, etc., are considered together; and lipid profile where total cholesterol and its components are considered together. Similarly, liver functions comprising albumin, bilirubin, AST, and ALP can be considered together; and kidney functions comprising creatinine, urea, uric acid, etc., can also be considered together. One example of actual multivariate data on lung functions in 70 adult males is in Table M.16, where multivariate lung functions comprising FVC, $FEV_1$, PEFR, and TLC can be investigated for dependence on age, height, and weight. We use these data to illustrate some multivariate methods in other sections, but the dataset here illustrates what multivariate means. There are a large number of such examples in health and medicine, but most publications consider the variables one at a time for ease of analysis interpretation and avoid the complexity of joint inference on a set of measurement. Wide availability of statistical software packages has made it easy to analyze multivariate data, but their joint interpretation still remains a concern for many of us. Thus, univariate methods still persist for good reason.

Among common multivariate statistical methods are **multivariate analysis of variance (MANOVA)** and **multivariate regression**. In both of these, the dependent is a set of quantitative variables and independents are qualitative in MANOVA and can be almost any in multivariate regression. Two-population analog of this is **Hotelling $T^2$**. If the dependent set is qualitative, multivariate logistic regression can be used. This is too complex for the level of this book, and we have not included this here. In all of these, the independents are considered fixed. If the dependent is one qualitative variable that depends on several stochastic variables, **discriminant functions** can be the right method where the independents are not considered fixed. Similarly in **factor analysis**, qualitative constructs are sought to be extracted on the basis of multivariate data. **Cluster analysis** is used to discover affinity structure among multivariate observations. Beyond these, not many multivariate methods are used in health and medicine.

One big difficulty with multivariate methods is that they ignore the entire set of values for one subject if just one measurement is missing. In the data in Table M.16, multivariate analysis will not consider the values for subject numbers 30 and 35 because of missing values and would be based on 68 subjects in place of 70 subjects in the sample.

## multivariate distributions

A multivariate distribution is the joint distribution of several variables. To get a flavor of multivariate distributions, see **bivariate distribution**, where only two variables are considered together. That also may tell you how difficult it does become to present a distribution of three or more variables. One example is in Table M.17 where **joint distribution** of 1544 adults is shown by sex, age group, and **smoking index**. Smoking index is zero for never smokers.

In the data in Table M.17, sex is qualitative and age and smoking index are quantitative. Actually these are exact values for each of the 1544 persons in the sample but are categorized for easy presentation in the table. This representation is still adequate to explain certain features of multivariate distributions. The top panel of the table is the age group–smoking index bivariate distribution of males, and the middle panel is for females. Thus, there are two bivariate distributions—one for males and the other for females. Their combination in the bottom panel of the table is a bivariate distribution of age group and smoking index. This is called the **marginal distribution** after collapsing sex into one group. Similarly, there are three bivariate distributions of age group and sex for each of the three categories of smoking index, and four bivariate distributions of sex and smoking index for each of the four categories of age. The marginal distributions are represented by the corresponding totals. Further collapsing also provides another level of marginal distributions. For example, the last row of the table is the marginal distribution of smoking index in these 1544 persons.

Imagine now that you have actual values of age and smoking index. The marginal distributions of these will be continuous. For example, the marginal distribution of smoking index (after excluding zero) would be like that shown in Figure M.9. The peak (mode) is around smoking index = 8 or 9 when the actual values are considered. Zero value of smoking index is not shown as the frequency 1223 for this value is too large to accommodate in this graph. If you look at the total frequencies in different age groups, it seems that the mode in marginal distributions of age would be around 40 years, i.e., the commonest age in people surveyed is around 40 years.

The shape of the joint and marginal distributions helps in deciding which statistical method would be appropriate for analyzing our data. For example, the distribution of smoking index in our example is far from **Gaussian**, particularly when zero value is also considered. Thus, conventional methods such as confidence intervals and tests of hypotheses for **regression coefficients** are not applicable if smoking index is to be considered as dependent on age and sex. The other important issue in multivariate distributions is the **dispersion matrix**. Whereas variances can be calculated of one variable at a time, covariances require that all pairs of the variables be considered. There will be one covariance between age and sex, another one between age and smoking index, and a third covariance between sex and smoking index. These covariances decide the correlations.

For simplicity, we have discussed multivariate distributions with the help of an example of a trivariate distribution. This could be of any dimension. We hope that our description will help you to conceptualize a *K*-dimensional distribution. A popular example of a discrete multivariate distribution is **multinomial distribution**.

## multivariate Gaussian distribution, *see also* bivariate Gaussian distribution

See the topic **multivariate distributions** to understand their essentials. A distribution is called multivariate Gaussian (Normal) when their joint distribution of many variables has a Gaussian pattern. For a bell-shaped picture of bivariate Gaussian distribution, see the figure in the topic **bivariate Gaussian distribution**. A distribution in more than two dimensions is difficult to depict on a paper, but that picture can give you an idea of what a multivariate Gaussian distribution would look like.

**TABLE M.16**
**Lung Functions in a Sample of 70 Adult Males of Age 20–49 Years**

| Subject Number | Age (Years) | Height (cm) | Weight (kg) | FVC (L) | FEV1 (L) | PEFR (L/s) | TLC (L) |
|---|---|---|---|---|---|---|---|
| 1 | 27 | 156 | 61 | 4.46 | 3.17 | 5.66 | 6.93 |
| 2 | 26 | 163 | 60 | 4.02 | 3.19 | 5.70 | 5.67 |
| 3 | 32 | 153 | 54 | 3.35 | 2.74 | 3.68 | 4.60 |
| 4 | 35 | 155 | 45 | 3.50 | 3.93 | 2.88 | 6.61 |
| 5 | 35 | 148 | 53 | 2.58 | 2.29 | 5.46 | 3.28 |
| 6 | 38 | 163 | 50 | 3.26 | 3.05 | 6.95 | 3.94 |
| 7 | 26 | 161 | 54 | 3.97 | 3.44 | 8.87 | 5.17 |
| 8 | 32 | 155 | 43 | 2.49 | 2.56 | 5.57 | 2.73 |
| 9 | 26 | 155 | 43 | 4.35 | 4.34 | 8.71 | 4.91 |
| 10 | 28 | 147 | 49 | 2.85 | 2.63 | 7.32 | 3.48 |
| 11 | 28 | 164 | 63 | 3.23 | 2.81 | 6.66 | 4.19 |
| 12 | 29 | 167 | 57 | 3.88 | 2.74 | 4.92 | 6.09 |
| 13 | 19 | 161 | 54 | 4.00 | 3.43 | 4.56 | 5.24 |
| 14 | 27 | 161 | 52 | 4.48 | 3.73 | 5.93 | 6.04 |
| 15 | 30 | 162 | 60 | 3.41 | 3.51 | 7.79 | 3.72 |
| 16 | 20 | 162 | 45 | 3.06 | 2.66 | 5.39 | 3.98 |
| 17 | 20 | 160 | 45 | 2.77 | 2.97 | 4.44 | 2.99 |
| 18 | 30 | 161 | 46 | 3.77 | 2.87 | 5.76 | 5.51 |
| 19 | 23 | 160 | 47 | 4.20 | 3.38 | 4.55 | 5.86 |
| 20 | 20 | 159 | 47 | 3.42 | 2.96 | 4.63 | 4.45 |
| 21 | 28 | 163 | 49 | 3.36 | 3.16 | 6.01 | 4.03 |
| 22 | 24 | 162 | 45 | 3.89 | 3.02 | 8.65 | 3.12 |
| 23 | 35 | 165 | 45 | 3.94 | 3.12 | 5.63 | 5.59 |
| 24 | 24 | 167 | 56 | 5.27 | 4.05 | 5.95 | 7.66 |

| 68 | 25 | 163 | 47 | 3.20 | 2.61 | 3.82 | 4.41 |
| 69 | 34 | 162 | 50 | 3.85 | 3.31 | 8.32 | 6.12 |
| 70 | 28 | 159 | 55 | 4.84 | 3.51 | 6.78 | 3.81 |

*Note:* FEV1: forced expiratory volume in 1 s; FVC: forced vital capacity; PEFR: peak expiratory flow rate; TLC: total lung capacity.

**TABLE M.17**
**Trivariate Distribution of a Sample of 1544 Adults by Age Group, Sex, and Smoking Index in a Community Survey**

**Number of Subjects**

| Sex | Age Group (Years) | Smoking Index 0 | 0.1–9.9 | 10.0+ | Total |
|---|---|---|---|---|---|
| Male | 15–24 | 135 | 21 | 7 | **163** |
| | 25–44 | 202 | 51 | 33 | **286** |
| | 45–59 | 154 | 52 | 28 | **234** |
| | 60+ | 69 | 13 | 9 | **91** |
| | **Total** | **560** | **137** | **77** | **774** |
| Female | 15–24 | 176 | 13 | 2 | **191** |
| | 25–44 | 224 | 23 | 14 | **261** |
| | 45–59 | 187 | 35 | 13 | **235** |
| | 60+ | 76 | 5 | 2 | **83** |
| | **Total** | **663** | **76** | **31** | **770** |
| M + F | 15–24 | 311 | 34 | 9 | **354** |
| | 25–44 | 426 | 74 | 47 | **547** |
| | 45–59 | 341 | 87 | 41 | **469** |
| | 60+ | 145 | 18 | 11 | **174** |
| | **Total** | **1223** | **213** | **108** | **1544** |

*Note:* Smoking index = 0 for never smokers.

In a multivariate Gaussian distribution, marginal distribution of each variable is Gaussian. This, however, does not mean that Gaussian marginal distribution of each variable implies joint Gaussian. Examples can be constructed when this is not so, but that would be rare and hardly ever in practice. Thus, Gaussian pattern of marginal distribution of each variable is considered sufficient to assume that their joint distribution is also Gaussian.

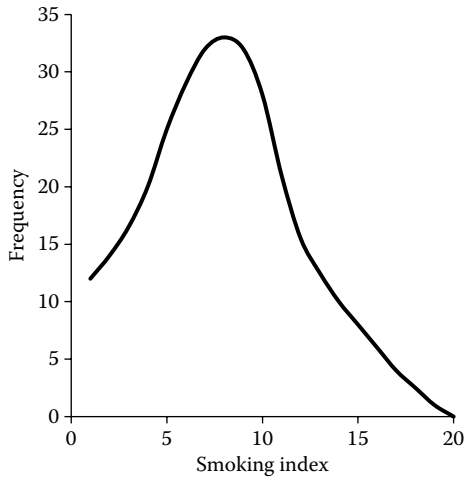

**FIGURE M.9** Marginal distribution of smoking index (excluding zero) based on exact values.

When the distribution of $K$ variables is jointly Gaussian, each variable can be expressed as a linear combination of the other $(K - 1)$ variables. This linearity is a big convenience, particularly in using Pearsonian correlation coefficient as a measure of the degree of dependence among variables. This correlation is able to capture only the linear dependence and not the nonlinear dependence as explained under the topic **correlation coefficient**, and that is all you need for multivariate Gaussian distribution. Such linear dependence also helps in using linear regression in this setup. The mean of the variables and the **dispersion matrix** completely specify a multivariate Gaussian distribution. The dispersion matrix when its elements are expressed as correlations tells us which pairs of variables have high dependence on each other and which have low dependence. They are all independent when the correlations for each pair are

zero. In samples, they may still exhibit correlations despite independence because of sampling fluctuations, but these should be low.

A multivariate Gaussian distribution is a requirement for many multivariate methods. For example, this is needed for testing the hypothesis of equality of group means by **Wilks Λ** in **MANOVA** and for repeated measures. For **multivariate regression** also, this is needed for obtaining confidence bands and tests of hypotheses, although not for obtaining the regression equation. For discriminant functions also, multivariate Gaussianity is helpful. However, this is not a requirement for multivariate methods of **cluster analysis** and **factor analysis**.

## multivariate logistic regression, *see also* logistic models/regression (multinomial, ordinal, and conditional)

This expresses a set of binary variables as a function of one or more regressors. Just as in the case of (univariate) logistic regression, the regressors can be qualitative or quantitative. Many times in the literature, univariate logistic regression when the regressors are more than one has been called multivariate logistic regression. This is a wrong usage as the right term for this setup is *multivariable* logistic regression and not *multivariate*.

Consider a set of data on patients where presence or absence of diabetes, hypertension, and arthritis are to be studied together and not one at a time. These are anticipated to be dependent on age, sex, body mass index, family history of diabetes, family history of hypertension, physical activity score, etc. The relationship of three binary variables together in this example with the regressors can be studied by multivariate logistic regression. Studying them together is all the more important in this case since diabetes, hypertension, and arthritis are interdependent conditions.

Although mathematically quite complex and not easy to implement by the existing software packages, the right approach in this situation is to consider all the binary variables in a multivariate setup and run the regression similar to what we do for univariate logistic regression. This would require complete specification of the joint distribution as discussed by Liang and Zeger [1]. An alternative approach generally advocated for this setup is **generalized estimating equations**. As discussed under that topic, this incorporates working correlations. Another approach is to run separate logistic for each dependent and make adjustment in the standard errors of the logistic coefficients for the possible correlation among the dependents. The third approach is to pool multiple binary outcomes into a single categorical outcome or some sort of score, and regress this on the regressors. For further details, see Lu and Yang [2]. The method of multivariate logistic regression is yet to evolve as a standard statistical tool and is rarely used.

## multivariate regression

In contrast to the ordinary (univariate) **regression**, multivariate regression has a set of quantitative dependent variables in place of just one variable and another set of regressors. Take the example of height, weight, head circumference, and chest circumference of a child dependent on parity, years of education of the mother, and per capita income of the family. Thus, there are four dependent and three independent variables in this case. All are quantitative. As an extension, now consider a general situation where there are $J$ independent variables denoted by $x_1, x_2, \ldots, x_J$ and $K$ dependent variables denoted by $y_1, y_2, \ldots, y_K$. In other words, the dependent vector has $K$ components. Let the $y$'s be correlated with one another so that they need to be considered simultaneously. The independent variables $x$'s may or may not be related to one another. In fact, it is desirable that the $x$'s are not highly correlated so that **multicollinearity** is not present. In any case, $y$'s are related to $x$'s; otherwise, there is no point in studying their relationship. The dependent set should preferably be the outcome or response of the independent set so that the relationship is plausible and interpretable. As before, the regression becomes multiple when the independent set contains more than one variable. Thus, a multivariate regression can be simple with one regressor or multiple with many regressors. This gives rise to the term *multivariate multiple regression*. This can be linear when all the **regression coefficients** are linear or could be nonlinear when these parameters are not linear. For simplicity, we restrict ourselves to multivariate multiple linear regression only in this section.

Multivariate multiple linear regression gives the same regression coefficients as the corresponding univariate regressions, and the regression equation does not change. Thus, there is no need for the multivariate method if the objective is to obtain regression equations only. However, if the objective is to check statistical significance of the regressions, then multivariate methods give the right answers for correlated dependents. This is explained next with the help of an example.

Consider the dependence of lung functions (forced vital capacity [FVC], forced expiratory volume in one second [$FEV_1$], peak expiratory flow rate [PEFR], and total lung capacity [TLC]) on age, height (Ht), and weight (Wt) in apparently healthy males of age 20–49 years. The data for a random sample of 70 subjects are given in the table in the topic **multivariate data/methods**. Part of the information is not available for two subjects. These two have been deleted casewise. The univariate and multivariate results for the remaining 68 subjects are as follows.

Regressions (univariate and multivariate are the same):

$$FVC = 0.67 - 0.0016(age) + 0.0182(Ht) + 0.0011(Wt)$$
$$FVV_1 = 3.07 - 0.0220(age) - 0.0073(Ht) + 0.0332(Wt)$$
$$PEFR = 5.04 + 0.0022(age) - 0.0173(Ht) + 0.0661(Wt)$$
$$TLC = -5.21 + 0.0122(age) + 0.0596(Ht) - 0.0006(Wt)$$

*Univariate tests of significance*: Univariate $P$-values (each lung function investigated separately to depend on three regressors, i.e., one dependent and three independent variables in the regression) are given in Table M.18.

**TABLE M.18**
***P*-Values for Univariate Regression in Our Example—Lung Functions Dependent on Age, Height, and Weight**

| Lung Function | *P*-Values | | | |
|---|---|---|---|---|
| | Age | Height | Weight | All Three Together |
| FVC | 0.899 | 0.250 | 0.924 | 0.580 |
| $FEV_1$ | 0.090 | 0.661 | 0.007 | 0.023 |
| PEFR | 0.939 | 0.632 | 0.014 | 0.071 |
| TLC | 0.576 | 0.037 | 0.975 | 0.128 |

The *scatter plot matrix*, which plots each dependent vs. each independent, is in Figure M.10. No trend is immediately discernible, although some *P*-values in Table M.18 are less than 0.05. The plot also indicates that the independents chosen in this study do not have much predictive power. A discerning eye can pick up subject number 65 with age 52 years in the data table, which should be between 20 and 49 years as stated for this example. This looks like a data entry error about which a caution should have been exercised.

First consider the univariate simple regression results when Ht, Wt, and age are the individual regressors on individual lung functions. At $\alpha = 0.05$, Ht has a statistically significant effect on TLC ($P = 0.037$) but not on any other lung function (Table M.18). On the other hand, Wt has a significant effect on $FEV_1$ ($P = 0.007$) and PEFR ($P = 0.014$), but not on FVC ($P = 0.924$) and TLC ($P = 0.975$). When Ht, Wt, and age are considered together, they have significant effect on $FEV_1$ ($P = 0.023$) and marginally on PEFR ($P = 0.071$), but not on FVC ($P = 0.580$) and TLC ($P = 0.128$). In view of these conflicting results, what sort of conclusion can be drawn about the effect of Ht, Wt, and age on lung functions as a whole? The answer is given by the multivariate results.

*P*-values under multivariate setup (four lung functions together investigated to depend on three regressors, i.e., four dependent and three independent variables in the regression) based on **Wilks Λ** are given in Table M.19.

Ht does not have a statistically significant ($P = 0.304$) influence on the "vector" of lung functions when assessed by these four measurements together, but Wt has a significant ($P = 0.024$) influence. Such a conclusion has less than 5% overall chance of being wrong. The multivariate method allows one to draw a conclusion on the basis of a joint Type I error for all four measurements of lung functions together. Multivariate multiple regression results for all the three independents together show that their joint effect on lung functions is not statistically significant ($P = 0.056$) if the maximum tolerable error of Type I is 0.05. If the level of significance is relaxed to 0.06, the conclusion in the multivariate setup is that the lung functions are

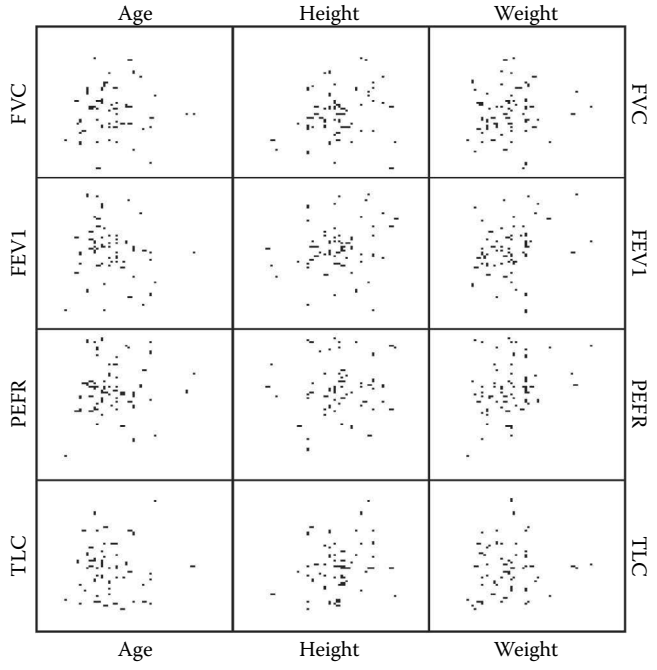

**FIGURE M.10** Scatter plot matrix of four dependent and three independent variables.

**TABLE M.19**
***P*-Values in Multivariate Setup for Our Example**

| | *P*-Values | | | |
|---|---|---|---|---|
| | **Age** | **Ht** | **Wt** | **All Three Together** |
| Lung functions (all four together) | 0.463 | 0.304 | 0.024 | 0.056 |

significantly affected. Therefore, it can be concluded with relaxed level of significance that age, Ht, and Wt together do influence the lung functions on the whole in the population from which this sample was drawn. If a threshold of 0.05 for Type I error is used strictly, the conclusion is that of nonsignificance. The cautious conclusion is that the effect of age, Ht, and Wt on lung functions is *marginally significant*. In any case, the conclusion is different from the one obtained by univariate regressions.

The requirement of external validation as for univariate methods applies to the multivariate methods as well. In the case of multivariate multiple regression, for example, the model may be an excellent fit to the data on which it is based, but the evidence of its utility on new subjects comes when the model is tested on a new set of data.

## mutually exclusive and exhaustive categories, *see also* multiple responses

Categories arise naturally for **nominal** and **ordinal** data but are many times also created for **continuous** data for convenience as explained under the topic **categories of data values**. Categories are called mutually exclusive when only one of them is applicable to one subject. While measuring body mass index (BMI), categories such as –l4, 15–24, 25–34, and 35+ $kg/m^2$ are mutually exclusive because a person's BMI can be in only one of these categories. These are exhaustive too because no BMI can be beyond these categories. In contrast to this, complaints in a patient are not mutually exclusive, nor are diseases. One person can have multiple diseases at the same point in time. Even if you list more than 100 diseases, they may still not be exhaustive as someone may have a disease not listed. A remainder category such as "others" can take care of this problem.

An important implication of mutually exclusive and exhaustive categories is that the probability of each category can be easily obtained and the sum of these probabilities is 1. This is the setup where multinomial distribution can be rightly used. Addition **law of probability** is applicable to mutually exclusive categories, although it does not require exhaustive categories. That is, in this case, the probability can be added.

Mutually exclusive and exhaustive categories have a special place in surveys. If the question is on use of tobacco, the person may say that he/she smokes a cigarette as well as chews a tobacco. These are not mutually exclusive and are not exhaustive either as the person smoking a cigar may also be using snuff, etc. Thus, the questionnaire should be structured to include all possible responses. It is customary in survey questionnaires to have the last category as "any other" so that nothing is left out.

Mutually exclusive and exhaustive categories are easy to analyze because the probabilities sum to 1. For regression analysis, such categories can be easily identified by indicator variables. This cannot be done for multiple response variables, and they need separate methods. Contingency tables and, consequently, chi-square are applicable to mutually exclusive and exhaustive categories, and not for multiple responses.

# N

## national well-being

National well-being is the average personal well-being of the population of a country. Well-being is a concept closely linked to health but goes beyond physical health and economic indicators. It considers health in its holistic form, which includes physical, mental, and social health. The mental health component dominates in this concept and includes aspects such as people's cognitive and affective evaluations of their lives. These valuations are mostly self-rated instead of being objectively measured and depend on how worthwhile or satisfied we rate our lives and our happiness, feelings of anxiety, and mental well-being [1]. The aim of this assessment is to provide a fuller picture of how society is doing by supplementing existing economic, social, and environmental measures [1]. A national index may help inform the society about balancing work with recreation and about nurturing relationships.

In its most simplistic form, one question, "How do you feel about your life as a whole?," with a rating on a 7-point response scale ranging from delighted to terrible can give you an answer about the self-rated feeling of well-being of the person [2]. Generally, though, a validated questionnaire consisting of several questions on physical, social, and mental aspects is administered to a random sample of adults. They can be asked to provide a rating of how yesterday was for them. The total response is scored on, say, a 0 to 100 scale, and the average provides an idea of the national well-being.

There are risks associated with the results of this kind of exercise. Too much satisfaction that will give a high score on well-being may leave people unmotivated, but the greater risk comes from its volatility as the score can quickly change with the mood of the person at the time of the interview. In addition, the score given by the young can be very different from the response given by the elderly because of their widely divergent experience. These problems occur with almost any subjective scoring system, but it still provides a baseline to work on and to compare different segments of the society and different time points.

The Office of National Statistics, United Kingdom, is trying to develop a measure of national well-being [1]. Efforts are made periodically to combine various indicators and come up with a comprehensive measure of well-being in its holistic sense. For example, there may be indexes that measure how people feel in control of themselves, make choices, and have a sense of purpose and belonging. However, an index that measures well-being in its entirety is not yet available. There is ongoing debate regarding what such an index should contain.

The **human development index** and the **quality of life index** are two of some of the currently more popular indexes of well-being. The former is computed each year for almost all nations of the world by the United Nations Development Programme after combining expectation of life, education, and income indicators. The quality of life index is popular for individual assessment, particularly for patients suffering from chronic ailments. In the United States, there is the Community Need Index that looks at economic and educational needs and identifies communities with barriers to access of resources [3]. A national well-being index is a work in progress and may produce worthwhile results shortly in the future.

## natural clusters, *see* cluster analysis

## natural experiments

When a rare or unique opportunity is available to observe or to study the effects of specific events as a result of naturally occurring changes, it is called a natural experiment. A natural experiment is a kind of **medical experiment** that occurs in nature without being planned for. To be called an experiment, you need a hypothesized cause that can be manipulated and an anticipated effect. The experiment is, by necessity, speculative (otherwise, there would be no need for an experiment in the first place) and you must be able to anticipate the outcomes that can be subsequently observed. All these conditions are fulfilled by a natural experiment although in a restricted sense. For example, the cause is not manipulated by humans but by nature. Statistically, these causes or precipitation factors are the independent variables and the outcome is the dependent variable. The group assignments in natural experiments are not strictly random but mimic random assignments in the sense that those receiving the intervention are not generally chosen on the basis of the population characteristics.

The tsunami of 2005 provided a rare opportunity to study the health consequences of such a disaster. The population affected was not much different from those unaffected in other coastal areas. The similar baseline in such comparisons helps in attributing the change to the intervening factor—in this case, the tsunami. Mining accidents, avalanche, and extreme weather conditions are also natural experiments. These help in studying the effect of such disasters. The effect of spraying insecticides on crops on human health or of genetically modified crops can be studied through natural experiments. The study of the effect of radiation therapy on the quality of life of cancer patients is also a natural experiment. To extend this further, the study of twins brought up in different environments can be a natural experiment. Whether or not there are different maternal complications in anemic or nonanemic women can be assessed by an experiment performed by nature since anemic and nonanemic women are already present and maternal complications among them can be observed. Similarly, the occurrence of goiter of various grades in areas with iodine deficiency in water where some are severely affected, some are mildly affected, and some not affected, is also a result of a natural experiment. John Snow's classical discovery that cholera is a waterborne disease was also the outcome of a natural experiment. None of these "interventions" is intentionally made by man.

Natural experiments have strength since they occur in natural settings, which makes the results more realistic. Participants do not know that they are being studied; thus, there is no **Hawthorne effect**. Such experiments provide an opportunity to study those interventions that are harmful and ethically not acceptable in human experiments. However, because of no control over extraneous factors, natural experiments may provide contaminated results. They may not provide a cause–effect relationship that a planned experiment would do. Nevertheless, they remain a useful tool to answer a research question that cannot be answered in any other way because of ethical problems in hazardous interventions.

Epidemiologically, natural experiments generally come under the domain of **observational studies**. Experimental evidence, even if from natural experiments, is generally more compelling than that available from the usual observational studies.

## negative binomial distribution

This is the statistical **distribution** of the number of independent "trials" needed to get $K$ "successes" and relates to **inverse sampling**. Suppose a hospital wants to set up an operation theater that can handle two open heart surgeries in a day. How many heart patients are needed on average per day to get two patients requiring open heart surgery? If this number is denoted by $x$, this would follow a negative binomial distribution. In this example, getting a patient requiring open heart surgery is "success" and the number of heart patients required to get two such patients is the number of "trials." Contrast this with **binomial distribution** where the number of trials $n$ is fixed and the interest is in the number of successes in those $n$ trials. In the negative binomial distribution, the number of trials is a variable and denoted by $x$ and the number of successes is fixed in advance. The distribution of $x$ obviously depends on the probability of success in any trial. If this probability is denoted by $\pi$, the probability that you need $x$ independent trials to get $K$ successes is given by

$$\text{Negative binomial distribution } (x) = \frac{(x-1)!}{(K-1)!(x-K)!}\pi^K(1-\pi)^{x-K},$$

$$x = K, K+1, \ldots,$$

where $x$ has no limit—it can theoretically reach infinity, which in our example means that you have to wait eternally to get two patients requiring heart surgery. However, the chance of this happening is almost zero. The factorial sign (such as $a!$) in this expression means the product of integers up to and including $a$, and $0! = 1$. The negative binomial distribution is sometimes expressed for the number of failures before $K$ successes, in which case $x$ is replaced with $y = x - K$, and now $y$ can be 0 as well.

In our example, if the probability of heart patients coming to that hospital requiring open heart surgery is $\pi = 0.06$ (i.e., on average, 6% of such patients require open heart surgery), the probability that you may have to wait for $x = 10$ patients to get $K = 2$ patients requiring open heart surgery is (using negative binomial distribution)

$$P(x = 10 \text{ for } K = 2) = \frac{(10-1)!}{(2-1)!(10-2)!})0.06^2(1-0.06)^{10-2};$$

$$= 0.02.$$

This shows that there is only 2% chance that you will have to wait for exactly 10 patients. This is nearly one-fifth of the binomial probability of getting 2 such patients out of a fixed 10, since this is $\frac{10!}{(10-2)!2!}\,0.06^2\,(1-0.06)^{(10-2)} = 0.099$. The difference is in the constant upfront in the two equations. The utility of a negative binomial is mostly in the cumulative probability; for example, the probability that you will have to wait for a maximum of 10 patients to get 2 successes is $P(x \le 10) = 0.12$. This chance is not high and says that most likely you may have to wait for more than 10 patients.

An estimate of the population proportion $\pi$ is $p = \frac{K-1}{n-1}$, where $K$ is the number of subjects with the characteristic you wish to have in the sample and $n$ is the size of the sample that had to be scanned to get $K$ subjects of the desired type. This is valid when the chance of getting a "success" remains the same with each subject and the sample subjects are independent of one another. The standard error (SE) of this estimate is given by

$$\text{SE } (p\text{: negative binomial distribution}) = \frac{\pi(1-\pi)}{n-2},$$

which can be estimated by replacing $\pi$ with its estimate.

A negative binomial distribution is sometimes used for regression models where the outcome is the count such as the relation between the number of teeth lost and the smoking intensity studied by Similä and Virtanen [1] for a Finnish birth cohort. Asiki et al. [2] explored the factors associated with the number of adverse pregnancy outcomes using negative binomial distribution.

When $K = 1$, this becomes, what is called, a *geometric distribution*. This gives the probability of waiting for $x$ trials to get one success. For its application to ocular chlamydial infection, see Lietman et al. [3].

## negative trials

These are trials that do not substantiate the presence of an anticipated effect. This can happen for a variety of reasons: (i) the **effect size** is smaller than the study was planned for, or the effect is not present at all; (ii) the study is not sufficiently powered to detect the stipulated effect (the sample size is smaller than required for statistical significance); (iii) the study is not properly focused—there are too many variables in that study so that the combined conclusion is negative; (iv) the study is not properly planned and **bias** has occurred either at the planning, execution, analysis, or interpretation stage (which generally works in favor of a positive result but can inadvertently work against it).

**TABLE N.1**
**Duration of Taking Tranquilizer in the Support Group and the Conventional Group**

| | Tranquilizer Support Group | Conventional Management Group | Total |
|---|---|---|---|
| Still taking tranquilizer after 16 weeks | 5 | 10 | **15** |
| Stopped taking tranquilizer by 16 weeks | 10 | 5 | **15** |
| **Total** | **15** | **15** | **30** |

Freiman et al. [1] reexamined reports of 71 negative trials to determine whether a sufficiently large sample was studied. They concluded that 50 of these trials had a greater than 10% risk (**Type II error**) of missing a true 50% therapeutic improvement. This happened because the size of the sample was not sufficiently large. Dimmick et al. [2] reported similar findings for surgical trials. The sample size must be adequate to inspire confidence that a medically relevant difference would not go unnoticed. The following example explains this problem, although this is for the proportions and not for the means.

Table N.1 contains results of a trial in which patients receiving a regular tranquilizer were randomly assigned to continued conventional management and a tranquilizer support group. The null hypothesis is that the two groups are similar. Under this $H_0$, the expected frequency in each cell is $15 \times 15/30 = 7.5$. Since no expected frequency is less than 5, a chi-square analysis can be safely applied. When the **Yates correction for continuity** is applied, $\chi^2 = 2.13$ and $P > 0.05$ at 1 df. Note that the number of patients who stopped taking the tranquilizer in the support group is twice of that in the conventional group, yet the difference is not statistically significant. There is a clear case of a trial on a larger $n$. If the same type of result was obtained with $n = 30$ in each group, then the difference would be statistically significant. However, in many situations, the kind of effect needed to change our practice is just not present and, in this case, an increase in sample size will not help.

Many journal editors are much too keen to publish reports that give a positive result regarding the efficacy of a new regimen compared with the negative trials that did not find any difference. This is called the **publication bias**. In a straw poll of the published reports, those with positive results would hugely outscore those with negative results. Yet, the fact of the matter might be just the reverse. On the other hand, too many negative trials because of the reasons enumerated earlier can provide misleading results. Kurt et al. [3] have discussed how negative trials on lipoprotein(a) may have severely underestimated its potential role in atherosclerosis. Similar observations can be made for some other results.

BioMed Central publishes a large number of open-access journals. Among these is the *Journal of Negative Results in BioMedicine*. This is in realization of the need of professionals to know about negative trials as much as about positive trials.

## *n*-of-1 trials

An *n*-of-1 is a clinical trial with just one participant. The disease under investigation may be rare or unusual such as orthostatic hypotension or narcolepsy, for which enough cases are not available for conducting a full-blown **randomized controlled trial** (**RCT**). The treatment under investigation might work only in a very specific type of cases precluding its use in RCT groups. In such situations, a trial on a single patient can be considered for evaluating individual efficacy though not for generalized conclusion. Such trials can be conducted only for chronic stable conditions with reversible symptoms and quantifiable outcome.

An *n*-of-1 trial is a variation of a **crossover** strategy where several pairs of treatment periods are used. The test regimen is given in one period and the control treatment is given in the other period in a crossover trial so that the patient serves its own control. The order of these two treatments is randomized within each pair of periods separately in a crossover trial. *n*-of-1 is an extension of this methodology where there is just one patient but repeatedly administered a treatment, and is possible only when the patient is hugely willing to cooperate.

Obviously, a trial is done when efficacy is in doubt. This is always the case for a new regimen. If a patient is reluctant to comply with the existing regimen because it is not effective in his or her case or because of side effects, he/she might agree to participate in an *n*-of-1 trial. This trial provides a unique opportunity to test a new regimen for a particular patient.

As in the case of crossover trials, a suitable regimen for an *n*-of-1 trial is the one that can be rapidly started and stopped. There should not be any carryover effect, and the disease must come back to its original severity after the washout period. A minimum of three crossover pairs are advised. Blinding helps minimize patient and observer bias and should be used wherever feasible.

Nixdorf et al. [1] have used this kind of trial for stellate ganglion blocks on a patient with orofacial pain who was not responding to conventional treatment. Yuhong et al. [2] have described an *n*-of-1 trial of a Chinese medicine Liuwei Dihuang decoction versus placebo on 47 patients, each completing three pairs of periods. Since this is not restricted to one patient, the target is not one patient but to come up with a more general conclusion.

## nominal categories, *see* categories of data values

## nominal scale, *see* scales of measurement (statistical)

## nomogram

A nomogram consists of a set of lines each representing a continuous variable plotted in such a way that the value of one variable can be read in relation to the values of two or more other variables (like a slide rule). The lines are rescaled so that corresponding values of the variables lie on a straight line and the values can be read using a simple ruler, thus obviating the need to do calculations.

For example, Figure N.1 shows a nomogram designed to find the number of clusters (C-lines) required in a **cluster sampling** for a survey to estimate the prevalence of a disease with specified precision ($L$ as percentage of $P$, where $P$ is the prevalence) and specified confidence level ($1 - \alpha$) when a guesstimate of prevalence ($P$-line) is used and the cluster size or the **design effect** is known [1]. The design effect ($D$) and the cluster size ($B$) is measured in terms of the ratio $D/B$. This nomogram was used for rapid surveys to assess the prevalence of senile cataract blindness in a community. As an illustration, a cross-sectional line is drawn in the figure, which shows that when the guesstimate of the prevalence of blindness attributed to senile cataract is $P = 0.04$, the ratio of design effect to cluster size ($D/B$) = 0.05, and then the number of clusters required is nearly 460 for 95% confidence for estimating prevalence within one-tenth of its value ($L = 10\%$ of $P$). The notation ($1 - \alpha$) is for the level of confidence.

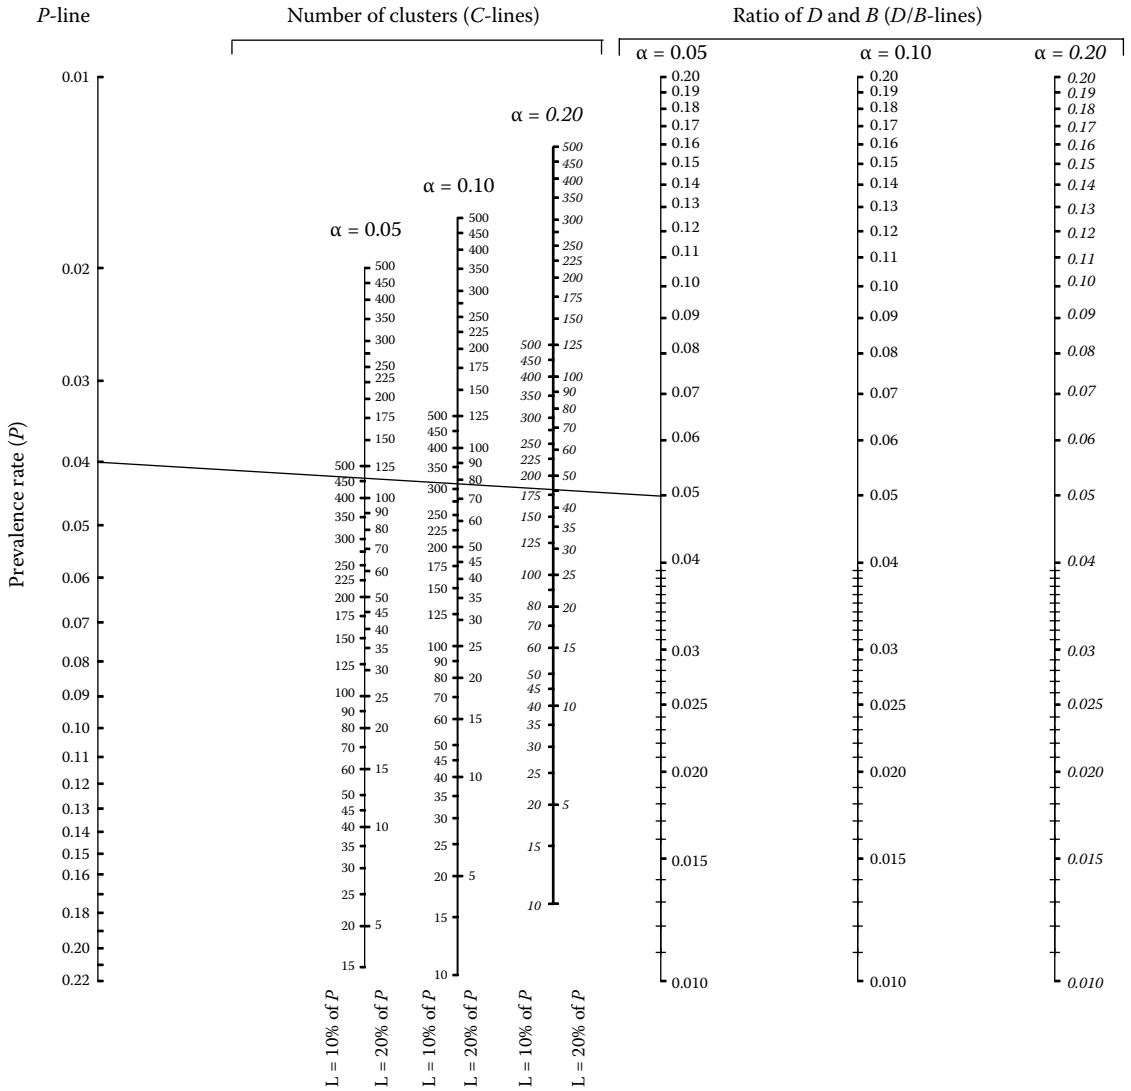

**FIGURE N.1** Nomogram: number of clusters required for rapid assessment of prevalence of a disease for different cluster sizes. (From Kumar A, Indrayan A. *Int J Epidemiol* 2002;31:463–7. http://ije.oxfordjournals.org/content/31/2/463.abstract.)

Such nomograms are used in several different applications. Lawoyin and Onadeko [2] developed a nomogram to predict the birth weight category of babies born at term on the basis of the maternal weight changes at different periods of gestation. Malhotra and Indrayan [3] constructed a nomogram for sample size for estimating sensitivity and specificity of medical tests with specified precision. Partin et al. [4] developed a nomogram based on clinical stage, Gleason score of the prostate needle biopsy, and serum prostate-specific antigen. This was designed to improve the ability to predict the pathologic stage of a prostate tumor.

## non-Gaussian distributions, *see* distributions (statistical)

## noninferiority test, *see* equivalence, superiority, and noninferiority tests

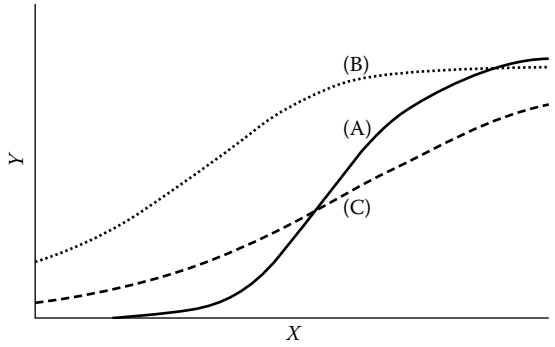
## noninferiority trials, *see* equivalence and noninferiority trials

## nonlinear regression, *see also* linear regression, curvilinear regression

To understand nonlinear regression, first refer to **linear regression** if you are not familiar with the basics. This is given by

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_K x_K + \varepsilon,$$

where $x_1$, $x_2$, …, $x_K$ are the regressors and β's are the **regression coefficients**. These are the unknown parameters of the regression model that we wish to estimate by the regression analysis. The term ε is the difference between the observed value of $y$ and its regression-predicted value. All the regression coefficients are linear—they would not be linear when, say, $\beta_2 = \beta_1^2$ or $\beta_2 = \log(\beta_1)$, or any other nonlinear function. Statistically, when any regression coefficient is nonlinear and cannot be converted to linear by any transformation, it is called nonlinear regression. We later give examples of regression that look nonlinear (graphically, they yield a curve instead of a line) but are intrinsically linear in the statistical sense. For some examples of nonlinear regression, see Figure N.2 in this section and the figures in the topic **regressions (types of)**.



(A) $\beta_1 = 1$, $\beta_2 = -3.22$, $\beta_3 = 8$, $\beta_4 = 3.33$
(B) $\beta_1 = 0.95$, $\beta_2 = -4.61$, $\beta_3 = 10$, $\beta_4 = 0.33$
(C) $\beta_1 = 1$, $\beta_2 = -2.3$, $\beta_3 = 4$, $\beta_4 = 1.25$

**FIGURE N.2** Concentration of drug at time $x$ after injection with different choices of the values of the parameters in nonlinear regression represented by Equation A. (From Gravbill FA, Iyer HK. Nonlinear regression, Chapter 9, in: *Regression Analysis: Concepts and Applications.* Colorado State University. http://www.stat.colostate.edu/regression_book/chapter9.pdf. With permission.)

Nonlinear models are difficult to fit—they are not fitted by the method of **least squares** that we commonly use for linear regressions but require an *iterative procedure*. The software asks you to specify the model and sometimes to supply your initial set of guess estimates of the parameters. It does calculations by a mathematical algorithm using guess estimates, calculates residual sum of squares, and presents adjusted estimates that are better fit. This is one iteration. Now, these adjusted estimates are inserted and another set of values that are better fit to the observed values is obtained. This completes the second iteration. These iterations go on till such time that the estimates obtained at any iteration and subsequent iteration are almost the same. This is called *convergence*. These are the best estimates from the available data though not necessarily good enough to provide a good fit to the data. It is a good idea to start with another set of initial guesses and see whether or not the same final estimates are obtained.

In some cases, convergence does not occur and the software stops after making reasonable attempts. In this case, the software will give you the message that the there is no convergence. This can happen either because of insufficient data or because of improper specification of the model.

Nonlinear models are complex and should be used only when linear models fail to provide a good explanation or a good fit to the data, particularly when stakes are high and it is necessary to get a more accurate model. Suppose the interest is in the 24-h pattern of concentration of a drug in blood after it is injected. This is expected to depend on a host of parameters such as the liver functions of the patient, kidney functions, age, and sex. One such model can be

$$\text{(A)} \quad \text{Concentration: } y = \frac{\beta_1}{1 + e^{-(\beta_2 + \beta_3 x)^{\beta_4}}} + \varepsilon,$$

where β's are the parameters such as various liver and kidney functions that determine the concentration of the drug in blood at time $x$ after injection. Note that the Equation A cannot be modeled as linear by any transformation and is a genuinely nonlinear regression. Depending on the values of these parameters, the drug concentration can follow one of many possible patterns; three of these for some specific values of β's are shown in Figure N.2. If the drug

is such that it starts at zero concentration, rapidly rises, and then stabilizes, curve (a) as per the values of the parameters shown at the bottom of the figure may be a good representation. If the drug is expected to have some low level immediately after injection and rising gradually, curve (c) can be chosen. If the drug is expected to have substantial level immediately on injection and rising gradually and then leveling off, curve (b) may be adequate. Other values of parameters will give other shapes, and the software packages can be asked to find estimates of the parameters that best fit the data.

The adequacy of a nonlinear fit can be assessed in some situations by the **coefficient of determination** ($\eta^2$), which is obtained as the regression sum of squares as a proportion of the total sum of squares. Square of the multiple correlation coefficient ($R^2$) is for linear regression and should not be used for nonlinear regression. A good statistical software package will give the value of $\eta^2$ and will also give the results of test of hypothesis regarding the parameters and the confidence intervals. In other setups, residual plots give a good idea of the adequacy of the regression. This plot should be random with small variance. For details, see Gravbill and Iyer [1].

Chen et al. [2] have discussed nonlinear growth trajectory of brain, and Chin et al. [3] have studied the relationship between aortic valve area and mean pressure gradient measurements with nonlinear regression with implications for patients with small-area low-gradient aortic stenosis.

Examples of the so-called nonlinear regressions that give a curved shape but are intrinsically linear are mostly curvilinear, as described under the topic **curvilinear regression**. All polynomial regressions are curvilinear. The exponential growth curve $y = ae^{bx}$, seen in the multiplication of organisms when not interrupted as in a laboratory, is apparently nonlinear but is also intrinsically linear since, in this case, $\ln(y) = \ln(a) + bx$, which takes the form $z = b_0 + bx$ with $z = \ln(y)$ and $b_0 = \ln(a)$. This is then a straight line but is between $\ln(y)$ and $x$. There are several other "nonlinear" forms of the equation that are intrinsically linear. They are not termed as nonlinear for statistical regression.

## nonparametric methods/tests (overview)

These methods are not concerned with **parameters** of the statistical **distributions** such as mean and variance but are concerned with other aspects such as shifts in the location of the distribution or association among the variables. The most commonly used nonparametric methods are the **chi-square test** and the **Wilcoxon tests**.

The term *nonparametric method* implies a method that is not for any specific **parameter**. The Student *t*-test, for example, is a parametric method because it is concerned with a parameter, namely, the mean. In the case of nonparametric methods, the hypothesis is concerned with the pattern of the distribution as in a **goodness-of-fit test** or with some characteristic of the distribution of the variable such as randomness and trend. More commonly, though, the interest would be in the location of the **distribution** without specifying the parameter. This is illustrated in Figure N.3, where the distributions are identical except for location. Location shift of the entire distribution is clear and it is not necessary to talk of mean or median or any such parameter in this case.

Nonparametric methods are sometimes also called **distribution-free methods**. These are methods that are based on functions of sample observations whose distribution does not depend on the form of the underlying distribution in the population from which the sample was drawn. The chi-square test is distribution free as it remains valid for any categorical data whether the underlying distribution of the variable is Gaussian (normal) or not. Although nonparametric methods and distribution-free methods are not synonymous, most nonparametric tests are also distribution free. Both categories of methods are generally considered as nonparametric methods. These methods derive their strength from transforming the values to ranks. Thus, they are applicable to ordinal data as well.

Nonparametric tests are preferred when the underlying distribution is far from Gaussian and, at the same time, $n$ is small. A small $n$ precludes the use of the **central limit theorem**, which allows the use of Gaussian distribution for many estimates. Nonparametric methods are especially suitable when outliers are present, which are genuine in the data set (not artifacts) and cannot be ignored. Outliers do not affect these methods because these methods mostly work with ranks. When Gaussian conditions are present, the performance of nonparametric methods is not as good as those of parametric methods such as the **Student *t*-test** and the **ANOVA *F*-test**, but they work well with non-Gaussian data.

Nonparametric methods are not as developed as parametric methods. If you have data more suitable for a nonparametric method for which such a method is not readily available, the recommended procedure is to use the parametric method on the actual data as well as on the rank-transformed data, which makes it nonparametric [1]. If the two methods give nearly identical results, you are done. If not, take a closer look at the data for outliers or for highly skewed distribution and use rank-transformed data for inference when such features are present.

Many researchers take Gaussianity for granted and use Gaussian-based parametric methods even for small samples. The tests for checking Gaussianity such as **Kolmogorov–Smirnov**, **Anderson–Darling**, and **Shapiro–Wilk** generally work well with large samples and not so much with small samples. Thus, small samples would not be able to provide evidence against Gaussianity because of lack of power. For small samples, try to have some extraneous evidence (from experience or literature) that the distribution is Gaussian or of any other form. Sometimes, plots give a good idea of the distribution pattern. If the plot suggests a non-Gaussian pattern, it might be safe to use nonparametric methods for small samples. On the other hand, some researchers are nonparametric enthusiasts and use these methods even when the sample size is large. This is not advisable as this could result in loss of power. Thus far, fortunately, the number of such enthusiasts is not high.

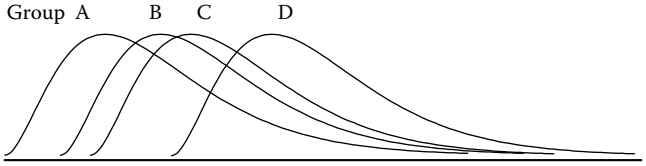

**FIGURE N.3** Distribution in four groups differing only in mean.

Besides the ones mentioned in this section so far, the other nonparametric methods discussed in this book are as follows:

- The **Sign test** for paired data to check if the two groups have the same location
- The **Wilcoxon signed-ranks test** for paired data when the magnitude and the direction of the differences are important
- The Mann–Whitney–Wilcoxon test for two independent samples (algebraically identical to the **Wilcoxon rank-sum test**)
- The **Kruskal-Wallis test** for the comparison of location of three or more groups
- The **Friedman test** for a two-way layout with one observation per cell

For further details of nonparametric methods, see Conover [1].

## nonrandom sampling, *see* sampling techniques

## nonresponse

The inability to elicit full or partial information from the subject after inclusion in a study is termed nonresponse. This can happen as a result of the subject's noncooperation, relocation, injury, death, or any such reason. The opportunity for nonresponse is particularly present in follow-up studies, but even in the case of one-time evaluation, the subject may refuse to answer certain questions or may not agree to submit to a particular investigation or examination even when prior consent has been obtained. The problem of nonresponse can be particularly severe in mailed questionnaires and **telephone surveys**, primarily because of disinterest of the respondents.

Nonresponse has two types of adverse impacts on the results. The first is that the ultimate sample size available to draw conclusions reduces, and this affects the **reliability** of the estimates and the **power** to detect an effect. This deficiency can be remedied by increasing the sample size corresponding to the anticipated nonresponse. The second is more serious. If only 2200 respond in a sample of 3000 out of 1 million, the results could be severely biased. These responders could be conformers or those with strong views. If not biased, a sample of 2200 is not too bad to provide a reliable estimate or to test a hypothesis in most situations. Mostly, the nonresponding subjects are not random segments but are of specific type. For example, they may be seriously ill who do not want to continue in the study or very mild cases who opt out after feeling better, or some such peculiar cases. Their exclusion can severely bias the results. A way out is to take a subsample of the nonrespondents, undertake intensive efforts for their full participation, assess how these subjects in the subsample are different from the regular respondents, and adjust the results accordingly. A provision for such extra efforts to elicit responses from some nonrespondents should be made at the time of planning the study.

Experience suggests that some researchers fail to distinguish between nonresponse and zero value or the absence of a characteristic. Take care that this does not happen in the data you are examining as evidence for practice or in the data you are recording for research.

Elsewhere in this book, we have described methods such as **imputation for missing values** and **intention-to-treat analysis** that can partially address the problem arising from nonresponse, but no analysis, howsoever immaculate, can replace the actual observation. Thus, all efforts should be made to ensure that nonresponse is minimal if not altogether absent. Strategies for this should be devised at the time of planning the study, and all necessary steps should be taken to minimize nonresponse. A proper groundwork with the sample subjects such as explaining the benefits of the study may help in getting their cooperation. The investigations should be such that these cause least inconvenience or distress to the respondents and should have no adverse financial implications for them. In fact, it may be necessary in some cases to provide some sort of compensation to the subjects for their time and inconvenience so that they extend full cooperation.

## nonsampling errors

Nonsampling errors in the results are not due to not using sampling but are human errors that occur due to various types of biases in concepts, sample selection, data collection, analysis, and interpretation. These are the genuine methodological errors opposed to the **sampling errors** that in fact are not errors and occur due to variation among the subjects from sample to sample. Nonmethodological errors such as in diagnosis and medication are not included among nonsampling errors. Sampling errors are natural and random, whereas nonsampling errors are systematic and tend to destroy the study findings. Sampling errors reflect the **reliability** of the results, whereas nonsampling errors hit the **validity**—the study may not be answering the question you started with when substantial nonsampling errors are present.

Besides bias, which we will mention in the next paragraph, some prominent nonsampling errors are as follows:

- Unclear questions and not being able to communicate properly
- **Nonresponse**, **recall lapse**, and wrong response
- Wrong coding and wrong entry of data
- Inadequate analysis that does not consider all **confounders** and inappropriate use of statistical methods such as the **black-box approach**
- Interpretation based on partial analysis, or wrong interpretation of the computer output

Biases that result in nonsampling errors are a burning problem in most medical studies. For this reason, we have discussed these under several different topics in this book:

1. The topic **bias (overview)** enumerates and briefly describes more than 30 types of biases that can occur at different stages of study from the planning to arriving at the conclusion. Some of these such as **Berkson bias** and **Hawthorne effect** are discussed in detail as separate topics.
2. **Biased sample**.
3. Bias in **case–control studies, cross-sectional studies, and prospective studies**—discussed under these respective topics.
4. **Bias in literature review**.
5. **Bias in medical studies and their minimization**.
6. **Publication bias**.

Nonsampling errors are controlled by better thinking, better design, better methods, better training, and so on. It may be necessary to work intensively with the respondents to elicit correct answers. On the other hand, sampling errors are controlled mostly by increasing the size of the sample. A large sample with nonsampling errors tends

to aggravate bias instead of controlling, and a large sample in this case provides a false sense of security. Sampling errors in most cases are overt and can be easily handled with statistical methods but nonsampling errors can easily slip your attention. Often, they remain obscure for long till such time a new finding emerges that exposes previous wrong findings due to nonsampling errors.

For further details, see McNabb [1]. You may also like to explore the error matrix approach suggested by Keus et al. [2] for examining the validity of the available evidence including the nonsampling errors.

## nonsense correlation, *see* correlation (the concept of)

## normal distribution, *see* Gaussian distribution

## normality (test of), *see* Gaussianity (how to check)

## normalization

The term *normalization* in statistics is used in two senses. First is normalization of values and the second is normalization of a database.

### *Normalization of Values*

Normalization of values is rescaling them on (0, 1) from minimum to maximum. All the values are rescaled accordingly. If you want to normalize values of a variable that ranges from $a$ to $b$, the value $a$ will be linearly rescaled to 0 and the value $b$ will be linearly rescaled to 1. Any value in between, say, $x$, will be rescaled as

$$\text{Normalized value of } x = \frac{x-a}{b-a}.$$

This will always be between 0 and 1. If you are measuring the serum urea of 230 persons and find that the minimum is 17 mg/dL and the maximum is 43 mg/dL, the normalized value of a person with a urea level of 24 mg/dL is $(24 - 17)/(43 - 17) = 0.27$. This gives an idea how far the value is from the minimum relative to the range. Normalized values are sometimes confused with **standardized values** that have a mean of 0 and a standard deviation (SD) of 1, and sometimes they are confused with normal values found in healthy subjects. Those are erroneous usages.

The purpose of normalization is to make values on different scales comparable. If the normalized value of the urea level of a person is 0.27 and the normalized value of the creatinine level of the same person is 0.65, you know that creatinine is higher relative to the urea level in this person. Both creatinine and urea are measured in milligrams per deciliter, but consider lymphocytes, which are measured in terms of percentage. If the normalized value of lymphocytes is 0.90, you know that it is relatively very high compared to the urea level. Normalized values do not have units, and that makes them comparable.

The second big advantage of normalized values, arising from the first, is that the values on different scales can be averaged. For some reason, if you are interested in finding the average level of serum urea, serum creatinine, and lymphocytes in the example just mentioned, the average normalized value is $(0.27 + 0.65 + 0.90)/3 = 0.61$. This may be absolutely meaningless for many health parameters but may be useful in isolated situations.

Kramer et al. [1] used normalized permutation entropy (PeEn) values to compare them in the sternal, mid-costal, and crural areas 1–81 days after phrenicotomy and concluded that electromyographic PeEn represents a new and distinctive assessment for characterizing intramuscular function after denervation and reinnervation. The United Nations Development Programme uses normalized values for indexes of education, life expectancy, and income and averages them to come up with the **human development index** for each country.

A big problem with normalization is its oversimplicity. A normalized value of 0.90 may look 20 points away from 0.70 but may not be so far away when mean, SD, or percentiles are considered. For this reason, they are seldom used for statistical conclusions.

### *Normalization of Database*

In the context of database, normalization is the process of efficiently organizing data in a database. It is a method to remove all the anomalies and bring database to a consistent state. This includes eliminating redundant data but preserving dependencies. When this is done, it can drastically enhance the capability to exploit the data without spending too much time and effort, besides saving the storage space.

Normalization of a database requires creating lots of tables and examining them for duplication and clarity. It involves hard work and some consider it a luxury. Perhaps the best strategy is to be careful at the designing stage itself so that no anomalies occur. Sometimes, they still occur as all of them can rarely be anticipated at the designing stage. Once the database starts to build up, some of these anomalies become apparent or can be perceived. It is a good idea to take preemptive action so that such instances do not recur. The design could be modified accordingly for future records and to change the existing records.

For details such as data normalization rules, see Ambler [2].

## normal probability plot, *see also* quantile-by-quantile (Q–Q) plot

Let us first explain the probability plot without involving the term *normal*. A probability plot is the graph of cumulative probabilities at different values of the variable. In the case of samples, the cumulative probabilities are replaced by cumulative relative frequencies. For example, if the variable is the body temperature of healthy subjects, the proportion of subjects with temperature less than 97.5°F, less than 98.0°F, less than 98.5°F, less than 99.0°F, and so on are plotted versus 97.5°F, 98.0°F, 98.5°F, and 99.0°F. Since these proportions are cumulative, subjects with a body temperature less than 98.5°F would contain those with temperature less than 98.0°F and that in turn would contain subjects with temperature less than 97.5°F and so on (Table N.2). The probability plot of the data in Table N.2 is in Figure N.4a although the data are based on cumulative relative

**TABLE N.2**
**Distribution of Body Temperature in 468 Healthy Subjects and the Cumulative Relative Frequencies**

| Body Temperature (°F) | Frequency | Cumulative Frequency | Cumulative Relative Frequency |
|---|---|---|---|
| <97.0 | 2 | 2 | 0.0043 |
| 97.0–97.4 | 17 | 19 | 0.0406 |
| 97.5–97.9 | 86 | 105 | 0.2244 |
| 98.0–98.4 | 152 | 257 | 0.5491 |
| 98.5–98.9 | 133 | 390 | 0.8333 |
| 99.0–99.4 | 65 | 455 | 0.9722 |
| 99.5–99.9 | 12 | 467 | 0.9979 |
| 100+ | 1 | 468 | 1.0000 |

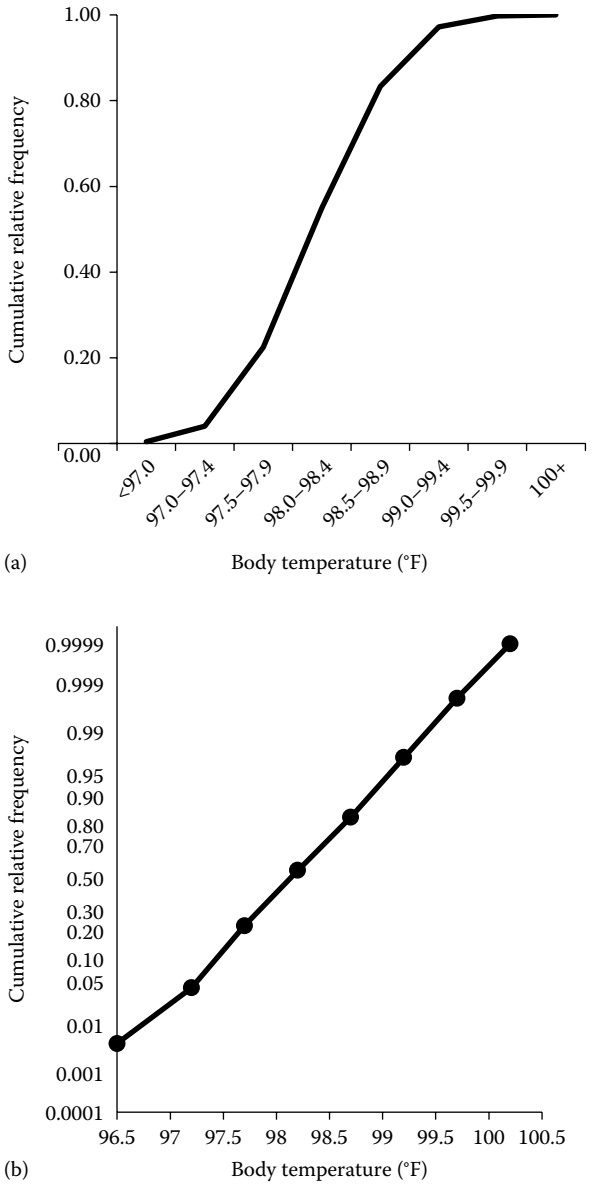

**FIGURE N.4** (a) Probability plot for the data in Table N.2. (b) Normal probability plot.

frequencies in place of the cumulative probabilities. In most cases, this will yield an S-shaped curve as shown in this figure.

Now, for a normal (Gaussian) probability plot, the *y* axis is compressed in the middle and stretched at both ends as per the probabilities in a Gaussian distribution (Figure N.4b). If the data follow a Gaussian distribution, the points will fall in a straight line when the scale on the *y* axis is the Gaussian probability. Sample values can show minor random variations. If the points do not fall in a straight line and follow some other systematic pattern, you have evidence that the distribution of values is not Gaussian. For example, you can have points at both ends away from the straight line. Thus, the normal probability plot is a graphical technique for assessing whether or not a data set has approximate Gaussian distribution, but this assessment could be very subjective in the absence of a test of significance. Tests such as **Kolmogorov–Smirnov** and **Anderson–Darling** are numerical but require a relatively larger sample.

We have illustrated the method by classifying the data into class intervals (Table N.2). The method can be used directly on the values without categorizing them into intervals. For this, the values are first rearranged in ascending order and **quantile** values are obtained using a normal inverse function that gives the Gaussian probability. See the topic **Q–Q plot** for details.

## normal range of medical parameters

The term *normal* is used in medicine with several different meanings. It is normal for a 70-year-old person to have myopia, and it is normal for women undergoing chemotherapy for breast cancer to lose hair. Murphy [1] has given a very interesting discussion of the different uses of this term in medical literature. A moot question is whether normal is the same as ideal or optimal. If yes, how does one define optimal? It is possible that a person with a 37.5°C body temperature and a 149/92 mmHg blood pressure (BP) does exceedingly well when accompanied by other corresponding physiologic changes. Who knows!

The normal level of a quantitative measurement in health can be defined in many ways. Most will agree that normal values are those that are generally seen in healthy subjects. However, each individual has his own normal (call it self-normal) in a healthy condition and, whenever possible, the evaluation of the current condition should be made against the value normally present in that person in a healthy state. If a person is known to have a BP of 110/70 mmHg when healthy, then a level of 130/80 mmHg would be considered a definite rise, sufficient to put the attending clinician on alert for contemplating some action despite the raised level being in the healthy range. For example, this can happen in pregnancy-induced hypertension.

The range of plasma levels of most hormones in healthy subjects is wide. As a consequence, the level of a hormone in an individual may be halved or doubled (and thus be grossly abnormal for that person) but still be within the so-called normal range. However, the healthy level of a patient coming to a clinic for the first time is seldom known. In such cases, the patient's level is evaluated against the levels generally seen in healthy subjects in that population. Call these population-normals that serve the purpose of reference values. Thus, **reference values** are the levels generally seen in healthy subjects in a population. Such references can also be used to delineate the maximum allowable variation in a subject even when his/her own healthy levels are known. In the example just cited, because a raised BP of 130/80 mmHg is still well within the normal limits for the other healthy subjects, therapy may not start unless the complaints are severe. Most likely, there would be no such complaints. Yet a big rise is surely enough to put you on alert.

### How to Establish Normal Range

Normal values or reference values are based on measurements of healthy subjects, preferably the healthiest segment of the population. The following are the criteria for normals to be reliable:

- They should be based on a sample that includes at least 200 individuals in each group (say, 200 males and 200 females) if the group-wise reference values are required. A smaller sample would be adequate only when the inter-individual variability is really small.
- There should not be any outliers in the data.
- The sampling procedure must be scientific so that the sample indeed represents the entire spectrum of values present in the group.
- Measurements should be carefully made by trained workers using adequately tested standardized instruments and methods. The data should be available to anyone for review.

When the inter-individual variation among healthy subjects is small, as in the case of body temperature, the normal level could actually be a single value (e.g., 98.6°F) instead of a range. This single value is a representative **central value** and would be a mean, median, or mode. When the distribution is **Gaussian** (normal), all three are the same and any one is nearly as good as another. However, the mean is preferred because of its good statistical properties, particularly its relative consistency from sample to sample. For distributions other than Gaussian, the choice again would mostly be the mean because of its easy understandability and better reliability. The median is used when the distribution is highly **skewed** or when extreme values or **outliers** are present in the data that cannot be excluded. When interest is specifically in the most common value for some reason, the choice naturally is the mode.

When the inter-individual variation in healthy subjects is large, a single normal value is not sufficient and we need a range of normal values. This is not as easy as it seems since there always are persons with very high or very low values who are still absolutely healthy. Thus, there could be considerable overlap between normal and abnormal values. Determining a threshold that works in all situations has remained an elusive objective. The following approaches are available.

*Disease Threshold:* The best method to delineate normal levels is to observe people with different levels for a sustained period and then to identify a threshold beyond which most people start feeling the burden in some sense—being unable to do work to one's full capacity or entailing a risk for an adverse condition later in life. This is an extremely complex procedure and requires consultation from experts, who in turn should have full evidence for the threshold they propose. The cutoff 140/90 mmHg for BP is such a threshold as experts have observed that a higher BP considerably increases the risk of coronary artery disease. Not many examples of this type of cutpoint are available, but there would be a caveat in this too as there would be people with level 145/92 who would be healthy and there would be people with level 136/88 and not healthy (with complaints such as headache and irritability). Thus, even this threshold does not rule out errors. This type of threshold is known as the disease threshold of normal level.

*Clinical Threshold:* The second alternative is to compare levels of those who are in perfect health with those who are not. Since each of these groups will have a distribution of its own, the situation typically will be as in Figure N.5. This figure has the following features:

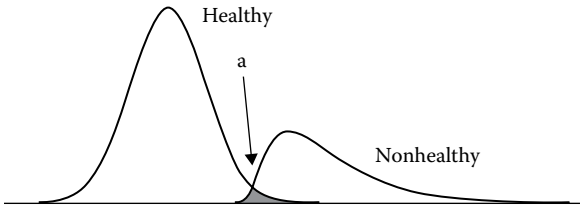

**FIGURE N.5** The pattern and overlap of measurement in healthy and nonhealthy subjects.

The number of healthy persons far exceeds the number of nonhealthy persons.

- The distribution among healthy subjects is Gaussian, whereas it is skewed in nonhealthy persons.
- The variation in the levels is smaller for healthy than for nonhealthy persons. Note how scatteredness in the levels of nonhealthy is relatively large.
- In this figure, nonhealthy subjects have higher levels. This is true for many measurements such as $T_3$, $T_4$, BP, blood glucose, and so on, but not for all. Higher levels of hemoglobin, peak expiratory flow rate, HDL cholesterol, and so on indicate good health. For such measurements, the curve for nonhealthy will be on the left side.
- There is some overlap between the levels seen in healthy subjects and the levels seen in nonhealthy subjects. This is shown as the shaded area in Figure N.5. If there is no overlap, the healthy levels and nonhealthy levels can be immediately defined. In practice, this overlap is substantial and causes problems in defining healthy levels. Whatever level is defined as the cutoff for healthy people, there would always be an error.

Statisticians have shown that the point where the two curves intersect provides the cutoff with the least number of misclassifications. This level is indicated as "a" in Figure N.5. This is the clinical threshold that could be used to define normal levels. Indeed, this is a very convincing approach but can be adopted only when the distribution in the healthy and nonhealthy groups is known and the overlap is minimal. The biggest problem in this approach is the choice of criterion to categorize a person as healthy or nonhealthy for drawing these curves. The threshold will not be known without the curves and the curves cannot be drawn without categorizing subjects as healthy and nonhealthy. Obviously, external criteria are needed, and those may or may not work. Nonetheless, such clinical threshold has inbuilt provision for tolerating error of misclassification as indicated by the shaded area. Errors are not ruled out by this method. The bigger the overlap, the larger the shaded area and the higher the chances of error.

### Statistical Threshold of Normal Values

When the distribution is Gaussian (mean − 2SD, mean + 2SD) are considered the normal limits, where SD is for the standard deviation. They exclude nearly 2.5% of healthy subjects with extreme measurements on either side. This is arbitrary but is now accepted around the world. The mean and SD are computed from measurements obtained on a large number of healthy subjects. These are statistical

thresholds and popularly known as ±2SD limits. Most of the normal ranges used in medical practice are obtained in this manner.

When the distributional shape is far from Gaussian, the range from 2.5th to 97.5th **percentile** points is considered normal instead of ±2SD limits. Note that the ±2SD limits for the Gaussian distribution are also from the 2.5th to 97.5th percentile. One can therefore forget about ±2SD limits and use the percentile-based range for all measurements irrespective of the shape of the distribution, but ±2SD limits are ingrained in the minds of many clinicians and statisticians alike. One reason for this is that the ±2SD limits fit well into the confidence interval and testing hypothesis strategy that are so common in statistical parlance. Note the following for such statistical thresholds:

- No matter how healthy the subjects are, there are always 2.5% healthy subjects at the lower end and another 2.5% at the upper end who will have levels outside such a normal range. This is an error but is tolerated because an error of this magnitude may always occur irrespective of the method used to establish normal limits. This error is at least quantitatively known for statistical thresholds but would not be easily known in other approaches.
- The ±2SD limits are purely statistical. A level beyond these limits is abnormal only in the sense that such an extreme level is rare in healthy subjects. Whether this translates to medical problems is not known. However, these limits seem to be working well as an aid in most situations encountered in medical practice.
- A measurement such as 106 mg/dL for fasting blood glucose level is not abnormal when the normal range is from 75 to 105; just that the chance of this value occurring in a healthy person is small—less than 2.5%. Gaussian theory stipulates that this chance reduces steeply as the measurement becomes farther and farther away from mean. A value of 104 mg/dL has nearly the same prognosis as the value 106 mg/dL. No miracle happens at the cutoff, such as 105, that would suddenly make a measurement abnormal. Nonetheless, such cutoff is needed somewhere as a guideline to start suspicion that the condition needs some kind of intervention and mean ±2SD provides such a cutoff, but it is applicable to one type of measurement at a time.
- If there are five different types of measurements such as different components of lipid profile, the chance of a healthy person labeled as healthy by such statistical criteria for all measurements together is not large because of accumulation of error of 2.5% multiple times.
- Some disease entities are based almost exclusively on a single parameter. Diagnosis of anemia caused by iron deficiency is based on hemoglobin level, that of hypertension is based on BP levels, diagnosis of diabetes mellitus is based on serum glucose level, and that of glaucoma is based on intraocular pressure. Other indications such as signs–symptoms play a minor role for classifying such diseases. There is evidence that persons with statistically abnormal levels do have an increased risk of the concerned morbidity and mortality. An intervention, such as therapy, to bring the level back to the normal range helps reduce this risk.
- The normal levels, whether statistical ±2SD limits or based on the healthy–sick dichotomy, should be determined by measuring a large number of subjects according to the guidelines given earlier. Only then do they command confidence. Normative data based on small samples can at best be indicative that they need confirmation in subsequent testing. Small-sample–based normals can seldom be used for diagnostic or prognostic purposes.

Reference values could be different for different segments of the population. A vital capacity normal for females would not be normal for males. A level of BP seen normally in adults would not be normal for children. The normal weight of 2-year-olds in Sudan may not be the same as the normal weight of 2-year-olds in Sweden. Normals may also change from time to time; for example, height seems to have increased all over the world during the past 50 years and lung functions also seem to be improving.

## notations (statistical)

Notations help make generalized statements. The following description of statistical notations may help you better understand the topics in this book, as well as to understand other statistical literature.

In statistics, a language that involves a number of conventions regarding notation with a mix of English (e.g., *P*-value) and Greek alphabets (e.g., alpha) has evolved. English (Roman) notations are used in italics (note *P* in *P*-value) whereas Greek notations are generally used straight. The convention in statistics is to use Roman notation for sample values and Greek for population **parameters**. Thus, $s$ is the notation for sample standard deviation (SD) and $\sigma$ is the notation for population SD; $\bar{x}$ for sample mean and $\mu$ for population mean; $r$ for sample correlation coefficient and $\rho$ for population correlation coefficient; $b$ for sample regression coefficient and $\beta$ for population regression coefficient, and so on.

It is customary in statistics to denote the variables by $x$ or $y$. Strictly speaking, capital letters such as $X$ and $Y$ are used for the name of the variables and small $x$ and $y$ are used for their realized values. For example, we may denote systolic blood pressure (BP) by $X$, and its value in a person such as 136 mmHg is denoted by $x$. We may have $x_1 = 136$ for the first person, $x_2 = 143$ for the second person, $x_3 = 125$ for the third person, and so on. These are all values of the variable $X$—in this example, the systolic BP. Such distinction between uppercase $X$ and lowercase $x$ is important for theoretical statistics but could be difficult for medical professionals. In this book, we have always used small $x$.

Universal notation for the sample size is $n$, which is generally indexed by $i$ and written as $i = 1, 2, \ldots, n$ to identify each of the $n$ subjects. Thus, in our BP example, we may have $x_n = 128$ that would tell that the last person in the sample has sysBP = 128 mmHg. Note that the subscripts 1, 2, and 3 of $x$ in the preceding paragraph are not in italics since they are not notation, but $n$ in the subscript is italic as this is a notation. The sample size $n$ could be 23 in one study and 386 in another study, or any number for that matter. For other numbers, such as the number of independent variables in a regression equation and the number of groups in a study, the notation we have used is $J$ or $K$. This is not standard but we find that convenient for nearly all setups. The indexing subscript for these are lowercase $j$ and $k$, respectively, written as $j = 1, 2, \ldots, J$, and $k = 1, 2, \ldots, K$.

You may find most books using lowercase $p$ for *P*-value. However, we have kept small $p$ to denote sample proportion. The notation for

corresponding population proportion, which generally is the same as the probability, is Greek π. The notation capital *P* is for probability as in *P*-value. This adaptation has allowed us to keep the distinction between a proportion and the probability.

Alpha (α) and beta (β) are the standard notations, respectively, for the probability of **Type I** and **Type II errors**. There are other standard notations such as chi-square ($\chi^2$), which is for a special statistic based on sample values, and similarly there are *F*, *t*, and *z* for statistical criteria used for testing of different hypotheses.

## nuisance parameters

A nuisance **parameter** is the one that we have to consider while drawing conclusions on the parameter of real interest. For example, while finding the confidence interval for the mean or for testing the hypothesis on the mean, we also need to consider the variance. Thus, variance is the nuisance parameter in this situation since the interest is only in mean. In a **multicentric trial**, the focus may be on estimating the effect size of the intervention but within- and between-centers variations are also considered in order to reach a valid conclusion. In clustered observations such as in longitudinal studies, within-subjects correlation is a nuisance parameter that cannot be ignored. The need to consider nuisance parameters makes the inference about the important parameters complicated: it will be good if a test statistic independent of the nuisance parameters can be devised, but that is not practically possible in many situations at the present state of our knowledge.

Cohen et al. [1] have discussed how age is a nuisance parameter for estimation of disease burden and its effect is sought to be neutralized by age-adjustment, **age-standardization**, and so on. Rubin and van der Laan [2] have discussed a situation of **structural estimating equations** that gives rise to a nuisance parameter while making adjustment for covariates.

## null and alternative hypotheses

A **hypothesis** is a supposition about the state of any phenomenon for starting an investigation about its truth or falsification. Depending on the quality of investigation, we may not be able to establish or deny a hypothesis, and may find that the evidence is not sufficient to reach any decision. Thus, there are three possibilities: convincing evidence that the hypothesis is true, clear evidence of it being false, and no sufficient evidence either way. Statistical testing of hypothesis also starts from setting up one, but this one is called null hypothesis as explained next, as well as a counter hypothesis, called the alternative. The evidence to confirm or refute them is in terms of the data obtained in the investigation, generally termed as a study.

### *Null Hypothesis*

In the case of statistical decisions, the supposition initially made generally is that there is no effect, called null hypothesis, which actually implies that the status of our knowledge about this phenomenon is the same as before the study. A clear understanding of this nature of the null is necessary to proceed further with the statistical aspects of a study. Data are collected with the aim of gathering evidence against the null and of rejecting the null if sufficient evidence against it is available. The study is done in the hope of overturning the null. Thus, a null hypothesis is equivalent to the presumption of innocence in the court setting where also evidence is presented against this presumption. The notation used for this is $H_0$. This is the hypothesis under scrutiny and is sought to be refuted by conducting a study on a sample of subjects just as criminal investigations are done to find evidence against a suspect. Thus, null is something you suspect or do not believe to be true.

Depending on the evidence available from the collected data, $H_0$ is either rejected or not rejected but is never accepted in empirical setup of the type we encounter in statistics. Not rejecting a null may mean two things: (i) carry out further investigations and collect more evidence so that a decision one way or the other can be taken, and (ii) continue to accept the present knowledge as though this investigation was never done. The "truth" remains unchanged in this case. This can be easily explained with the help of a telling example described in the next paragraph.

Ptolemy, in the second century AD, propounded that the sun revolves around the earth. It remained the "truth" for 14 centuries until Galileo came up with evidence against it in the 16th century and established a new truth that says that the earth revolves around the sun. Newton's laws of mechanics were accepted until Einstein discussed circumstances in which some of them did not hold. Peptic ulcer was believed to be caused by acidity until sometime ago when *Helicobacter pylori* was found to be a culprit in some cases. As of today, coronary heart disease is not considered to be caused by any infection, but who knows that a rebuttal will come soon.

Empirical strategy is to find evidence against a hypothesis that is stated in null form. Similar to a court judgment, if this evidence is sufficient, the null hypothesis is rejected; otherwise, it continues to be considered "truth" by default. Transplanted to the development of a new therapeutic regimen, it seems reasonable to demand evidence against the hypothesis that there is no effect at all. This process is difficult to implement without setting up a null hypothesis.

Since samples by their very nature are uncertain, the conclusion depends on what sort of data are obtained from the subjects. Statistical tests are precisely meant to deal with uncertainties arising from sampling fluctuations. They provide the answer to the question: What is the likelihood of sample values given that the null hypothesis is true? If this likelihood is exceedingly small, say, less than 5%, the null is considered implausible and rejected. At the same time, it would be ridiculous to accept a hypothesis whose likelihood of giving the obtained sample is only 15%. Thus, the only conclusion drawn in this case is that the sample fails to provide sufficient evidence to reject the null hypothesis. It is not accepted and the situation reverses back to what it was before that study. Many would consider it idiosyncratic that the sample values are searched for evidence against a null without recourse to finding what they are for—what they support. The alternative hypothesis explained next should clarify this dilemma, but the process of finding evidence against it is widely followed in empirical setup.

As another example, consider the claim of a manufacturer that his drug is superior to the existing angiotensin-converting enzyme inhibitors in improving insulin sensitivity in diabetic hypertensives. Suppose in a trial of matched cases, improvement was seen in 7 out of 10 patients who were given the new drug compared with 6 out of 10 who were given the existing drug. The methodology for testing the statistical **significance** of this difference is described separately, but you can see that the sample size $n = 10$ in each group is small

and the difference is too small to provide confidence to pronounce that the new drug is better. The difference could have arisen because of sampling fluctuation. If so, the claim of superiority is not tenable. The manufacturer needs to withdraw the claim forever or until such time that more evidence is available for scrutiny. The medical fraternity is expected to continue with their existing practice and not take cognizance of the claim until the claim is adequately substantiated.

The concept of null hypothesis is not restricted to the difference between two groups. It could concern difference between many groups, association or relationship between two or more characteristics or variables, or any other aspect of the problem under investigation.

### *Alternative Hypothesis*

If a null hypothesis is false, what alternative is true? The alternative hypothesis, denoted by $H_1$, is the opposite of $H_0$ that must be true when $H_0$ is rejected. If the null is that a drug is not effective, then the alternative has to be that it is effective. In the preceding example, the claim is that of superiority of the new drug, and this is the alternative hypothesis in this case. This is a **one-sided alternative** if inferiority is ruled out. Most often, it is not possible to claim that one group is better than the other, and the only claim is that they are different. In the case of peak expiratory flow rate (PEFR) in factory workers exposed to different pollutants, there may not be any a priori reason to assert that it would be affected more by one pollutant than another. Then, the alternative is that the mean PEFRs in workers exposed to different pollutants are unequal. This is called a two-sided alternative. The null is that they are equal in various groups. One-sided and two-sided $H_1$ are also sometimes called one-tailed and two-tailed $H_1$, although these terms should be used for the corresponding probabilities of **Type I error**.

Consider qualitative data where the interest is in proportion. Suppose that a pharmaceutical company claims that its particular drug has at least 72% efficacy in the long run. Thus, the null is $H_0$: $\pi = 0.72$. To test this claim, a researcher tries the drug on a random sample of $n = 40$ patients and 28 respond positively. Thus, the efficacy is 70%. Now, the question is: can population proportion still be at least 72%? If not, the inference would be that it is 72% or less. The null would be rejected in favor of this alternative. Thus, the alternative hypothesis is $H_1$: $\pi < 0.72$. Now, let us give it a slight twist. Suppose 32 out of 40 patients in the sample respond. Thus, $p = 0.80$. The question can now be whether the long run efficacy can still be less than the claimed 72%. The alternative hypothesis in this setup is $H_1$: $\pi > 0.72$. Thus, the alternative hypothesis can take either direction depending on what question is to be answered.

In a mathematical formulation of the null hypothesis, there will typically be an equality sign as illustrated in our example. The alternative hypothesis typically has inequality. This could have either a "less than" sign, a "more than" sign, or just a "not equal to sign."

## number needed to treat (NNT)

NNT measures the average number of patients that would need to be treated to prevent one additional adverse outcome or for one additional success compared with the standard or any other treatment (or even placebo). Statisticians have found that NNT = 1/ARR where ARR is **absolute risk reduction**; NNT converts the more difficult concept of ARR into a useful and readily understood quantity.

The concept of NNT has gained popularity because of its simplicity. It is especially useful in comparing the efficacy of two treatment regimens with binary outcome. For example, the NNT to cure one patient of atherosclerosis using a diet–exercise regimen may be 7 and the NNT using drug-X may be 5. Then, drug-X therapy would be considered more effective. This number also measures absolute efficacy in the sense that 5 patients on average are required to be treated by drug-X in this example to cure 1 patient, and thus this drug may not be considered a sufficiently effective strategy because the number 5 seems large for one positive response. Thus, NNT is a useful aid to the clinical decision process. Clinicians understand and appreciate NNT much better than probabilities underpinning the ARR. However, NNT does not work for one patient.

Also, if 32 patients of atherosclerosis are needed to be treated to prevent one death and 18 cases of diabetes are needed to prevent one death, you have some idea of where to put the better part of the resources, particularly if the financial and social cost of treatment of these types of cases is known. Also, due consideration should be given to the factors such as age, severity of disease, and duration of sickness while interpreting NNT.

Further caution is required when a regimen is to be used for mass adoption on the basis of NNT. Heller [1] gives an example of thrombolysis with NNT = 7 for prevention of one adverse outcome in secondary prevention after nonhemorrhagic stroke, and aspirin with NNT = 33. However, only 4% of the stroke patients are eligible for thrombolysis due to the time window and other factors, whereas 70% are eligible for aspirin. Despite better response, there may not be sufficient opportunity to use the regimen in practice.

The distributional properties of NNT are not fully known and a makeshift procedure is adopted to get its confidence interval (CI). This is easily implemented when the difference in efficacy of two treatments under comparison is statistically significant. In this case, the first step is to calculate CI for ARR. Call this ($ARR_L$ to $ARR_U$). Then, CI for NNT is $\left(\frac{1}{ARR_U} \text{ to } \frac{1}{ARR_L}\right)$. Note that L and U have switched their position (mathematically because we are now dealing with reciprocals). If the CI for ARR is from 0.04 (i.e., $ARR_L$) to 0.15 (i.e., $ARR_U$), the CI for ARR is from $\frac{1}{0.15} = 6.67$ to $\frac{1}{0.04} = 25$. For nonsignificant ARR, the situation is complex as explained next.

Generally, ARR would be small in a trial. If the efficacy of drug A is 70% and that of drug B is 75%, $(\pi_1 - \pi_2) = 0.05$. This has the same interpretation as ARR. Since $\frac{1}{\pi_1 - \pi_2} = 20$, NNT = 20 in this case. That is, 20 subjects are needed to be treated by drug B to get one extra success. The CI for $(\pi_1 - \pi_2)$ in this case can include negative values also such as −0.02 to +0.12. This interval includes zero where NNT is infinity. This causes problems. Zero within this CI indicates that ARR is not statistically significant. If nonsignificance is disregarded, the reciprocals give −50 to +18 as CI for NNT. This interval does not even include the original point estimate NNT = 20. Thus, this method of obtaining CI for NNT fails in this case. NNT is one example where sensible CI is obtained only when ARR is statistically significant.

For independent samples, NNT can also be obtained in terms of **relative risk** (RR) instead of attributable risk (AR):

$$\text{NNT} = \frac{1}{\text{AR}} = \frac{1}{R_2 - R_1} = \frac{1}{R_1(\text{RR} - 1)} = \frac{1}{p(\text{RR} - 1)},$$

where $p$ is the proportion affected in the control group. Note that $p$ and $R_1$ are the two notations for the same quantity. Just as RR can be approximated by **odds ratio** (OR) in special cases, so can NNT, and thus it is possible to calculate NNT through **case–control studies**

also in these conditions. In most situations, however, an immaculately carried out **randomized controlled trial (RCT)** is needed to correctly calculate NNT.

Beware of the anomalies that can occur in interpreting NNT. In a paper published in a reputed journal [2], the numbers show that NNT = 83 patients to be treated with statins to prevent one event of myocardial infarction (MI) and NNT = 142 patients to be treated with statins to prevent one event of stroke. These were for a mean follow-up of 3½ years. The authors wrongly interpreted and claimed that 24 patients needed to be treated for 1 year to prevent one MI and that 42 patients needed to be treated for 1 year to prevent one stroke, forgetting that NNT would be much higher for 1 year than for 3½ years.

## numerical analysis/method

This is a strategy that tries to solve mathematical problems through various combinations of numbers in place of looking for solutions through notations. For example, those familiar with quadratic equations know that the solution to the equation $ax^2 + bx + c = 0$ is $x = [-b \pm (b^2 - 4ac)]/(2a)$. This is the algebraic solution and called the closed-form solution. Many mathematical problems can be directly solved in closed form with the help of other methods such as differentiation and integration. Do not worry if you are not aware of these mathematical terms. Important is that some problems cannot be explicitly solved and some may be intractable. For such problems, the numerical methods are many times used to arrive at a solution. The solution may be approximate but reasonable enough to go ahead.

Consider the **area under the concentration curve**. This plots the availability of the drug in an organ after it is ingested. Theoretically, this would be a curve as shown in Figure N.6. Without knowing the mathematical equation of this curve, it is not possible to correctly obtain the area under this curve. However, an approximate area can be obtained by the numerical method. For this, the area is divided into small segments and each segment is approximated by a trapezoid. We know how to calculate the area of a trapezoid, and their sum can be obtained to get the area under the curve as illustrated next.

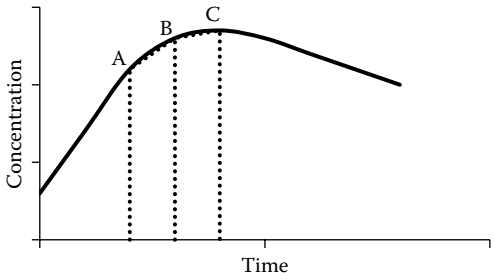

**FIGURE N.6** Numerical method for obtaining area under the concentration curve.

In Figure N.6, we show two trapezoids. Note that points A and B are connected in the trapezoid by a straight (dotted) line while they are actually connected by the (solid) curve. The curve is so close to the top of the trapezoid that the area under the curve between points A and B is nearly the same as the area of the trapezoid. Our trapezoids have big widths so as to illustrate the distinction between the curve and the top line but they can be made as small as we like. Then, the curve and the top line will be almost indistinguishable for small trapezoids. The area of each trapezoid can be calculated by using a computer algorithm. When these areas are added, we get the area under the curve. This is the numerical method of obtaining the area under the concentration curve and is followed by all statistical packages for this purpose.

For solving some mathematical problems, some guess values are tried in the first step and the error in the solution revealed by them is fed back to revise the solution. Sometimes, many iterations are needed. Quite often these days, a computer algorithm that does the iterations and finally comes up with a solution is used. A solution is considered to have been reached when the values with two successive iterations are sufficiently close—called *convergence* in mathematical terms. Such difficult and intractable problems are common in the engineering sciences but are now seen in medical sciences as well. This makes numerical analysis a broad discipline with close connections with computer science, mathematics, engineering, and the sciences.

Numerical analysis concerns all aspects of the numerical solution of a problem: from the understanding of numerical methods to their practical implementation in a reliable computer program. Most numerical analysts share some common concerns such as the size and the form of error. They try to develop algorithms that are efficient and give precise results. The algorithm must be sensitive to the changes in the data.

Medical applications of numerical analysis are wide and varied. Sometimes, the term has been used in a nontechnical sense for any method where numbers are used, such as for separating categories of patients. Anitha et al. [1] used the term *numerical analysis* to validate the findings regarding identifying the respective regions in the femoral neck and to prove that drug treatment elicits local changes in the mean outer radius and mean cortical thickness of femoral necks in postmenopausal women. Yu et al. [2] obtained the approximate function describing the relationship between the geometric parameters of the nasal airway and the nasal functions by what they called numerical methods.

## obesity (measures of), *see also* body mass index

Obesity is excess fat in the body than normally expected in healthy subjects. For assessing obesity by this definition, we need to measure body fat in a person and compare this with what is normally expected in healthy subjects. This requires that healthy subjects are defined and how much fat is expected in them is somehow obtained. This obviously would be different for different age and sex, and possibly also in different races and ethnicities.

Obesity has been found to be associated with risk of diseases such as hypertension, atherosclerosis, gallbladder disease, and diabetes. It is now standard practice in clinics to assess obesity and give advice accordingly. Since the amount of fat in the body is difficult to assess, a large number of surrogates are used. Many of them are variants of the **ponderal index**. A general form of this index is

$$\text{Ponderal index: weight/(height)}^b,$$

where $b$ is estimated from the **regression** of log(weight) on log(height) separately for each age, and weight is generally measured in kilograms and height is in meters. The coefficient $b$ varies from population to population. Freeman et al. [1], for example, found that $b = 2.08$ for boys of 7 years, $b = 2.20$ for girls of 7 years, $b = 2.44$ for boys of 16 years, and $b = 1.75$ for girls of this age in the United Kingdom. For neonates, $b = 3$ is considered more appropriate. The value of $b$ is large in children and progressively declines with age and settles to 2.0 in adults. Note that $b = 2$ makes it the popular **body mass index** (BMI).

A simple index of obesity is the **Broca index**, which compares weight (in kilograms) with (height in centimeters − 100). Among other measures of obesity are **waist–hip ratio** and waist–height ratio. They measure central or truncal obesity instead of the overall obesity. The latter is in consideration that waist measurement depends on height and cannot be considered as a stand-alone indicator. Whereas others are discussed as separate topics, we give details of two not described by us elsewhere in this book. Both focus on waist circumference (WC), which has been found to be a risk factor for early mortality in adults independent of BMI [2].

$$\text{Waist-height ratio} = \frac{\text{waist circumference}}{\text{height}}.$$

A value of more than 0.6 of this ratio is considered a health risk. This also has similar association with ischemic stroke as most other measures of obesity [3].

$$\text{Body shape index} = \frac{\text{waist circumference}}{\text{BMI}^{2/3} * \text{height}^{1/2}}.$$

This was obtained by regressing log of WC on log of height and log of weight. It has been found to have little correlation with weight, height, and BMI. Healthy body shape index is around 0.0800.

## O'Brien–Fleming procedure, *see also* Lan–deMets procedure

A medical experiment, particularly a clinical trial, is sometimes appraised one or more times while it is ongoing. The purpose of such interim reviews is to examine if the study has already provided believable evidence of the desired efficacy so that further investigations can be stopped, and cost and efforts are saved. This can also save exposure of the patients to inferior treatment. If no firm evidence is available, the trial runs its full course. The trial can also be stopped for futility if it turns out that there is practically little chance of reaching the minimum target effect.

When such multiple testing of hypothesis is done, the probability of **Type I error** is adjusted for each appraisal so that the total Type I error does not exceed the prefixed **significance level** and the statistical **power** of detecting a prespecified effect remains intact. This adjustment can be made in several ways, one of which is the O'Brien–Fleming procedure. The other popular method for this is the **Lan–deMets procedure**.

O'Brien and Fleming developed this procedure in 1979 [1]. This is restricted to comparing two treatments with **dichotomous** data. Under the usual setup, the result of such a trial would be in terms of a 2 × 2 table. The statistical test of significance for this is **chi-square** with 1 df. Multiarm trials and the trials with quantitative outcomes such as those aiming reduction in total cholesterol level are not covered by this procedure. The stages of appraisals and the number of appraisals are fixed in advance and would be part of the protocol. For example, the trialist may decide to do two interim appraisals—first after completing trial on one-third of the subjects and second after completing trial on two-thirds of the subjects. The last, of course, if needed, will be after completing trial on 100% of the subjects. When this scheme is followed, there are a total of $K = 3$ appraisals. They need to be equally spaced—a limitation later removed by the Lan–deMets procedure.

Suppose successive reviews are planned after every $n_1$ subjects in the treatment group and another $n_2$ in the control group. Let the number of planned appraisals be $K$—thus, the total subjects if the trial runs its full course is $K*n_1$ in the treatment group and $K*n_2$ in the control group. As mentioned earlier, all these are fixed in

**TABLE O.1**
**Value of O'Brien–Fleming $P(K,\alpha)$ for Selected $K$ and α**

| | Number of Stages ($K$) | | | | |
|---|---|---|---|---|---|
| α | 1 | 2 | 3 | 4 | 5 |
| 0.05 | 3.84 | 3.92 | 4.02 | 4.10 | 4.16 |
| 0.01 | 6.64 | 6.66 | 6.74 | 6.80 | 6.88 |

advance. For the hypothesis of no difference between the efficacy of the test and the control regimen at the $k$th appraisal,

O'Brien-Fleming procedure: Reject $H_0$ if $(k/K)\chi_k^2 \geq P(K,\alpha)$,

where $\chi_k^2$ is the usual chi-square calculated for all the samples till the $k$th stage and $P(K,\alpha)$ is the value derived by the O'Brien–Fleming procedure corresponding to the significance level α and the value of $K$. These values are derived in a manner that keeps the probability of Type I error under control. Some of these values are given in Table O.1. For $K = 1$, these values are the same as for the usual chi-square. If $\chi_K^2$ does not exceed $P(K,\alpha)$ after completing all $K$ tests, the conclusion is that the equality of the two regimens cannot be denied at the α level of significance.

For example, consider a trial to be appraised a total of $K = 3$ times, with $n_1 = 30$ and $n_2 = 30$. Thus, the total trial is planned to have 90 subjects in each group. After the results are available for the first 30 subjects in each group, suppose the data give $\chi_1^2 = 6.93$. This gives $(k/K)\ \chi_k^2 = (1/3) \times 6.93 = 2.31$. Since this is less than $P(3,0.05) = 4.02$, you are not able to reject the null. Had it been planned as a single stage trial with 30 subjects in each group with no appraisal, $\chi_1^2 = 6.93$ was enough to reject the null. In view of the nonsignificance, the trial adds another 30 subjects in each group and repeats this test at stage 2. For these 60 subjects in each group, let $\chi_2^2 = 10.87$. Now, $(k/K)\ \chi_k^2 = (2/3) \times 10.87 = 7.25$. Since this is more than 4.02, reject the null and conclude that the regimens are different in efficacy at the 5% level of significance. There is no need to go to stage 3—thus, the last 30 subjects are saved.

The O'Brien–Fleming procedure is applied to a **group sequential design**. In this design, the subjects are sequentially added if needed after testing at each stage. However, there are flaws in the O'Brien–Fleming procedure. For example, even a small **intraclass correlation coefficient** among responses of the subjects can substantially inflate the Type I error. Also, if the sample size is curtailed because of statistical significance at interim stages, consider whether the sample subjects covered so far are really representative or nonrepresentative of the population under target. A full sample is likely to be representative as usual, but a curtailed sample will not be if the first few subjects in sequence happen to be different, say, more severe than others. For details of such difficulties in this procedure, see Lui [3].

## observational studies, *see also* natural experiments

Observational studies are those that depend on just observations of what is naturally happening, in contrast to experimental studies and trials where a deliberate intervention is introduced to study its effect. However, observational studies also are **analytical studies** where the objective is to study the antecedent–outcome relationship such as between exposure and disease.

Observational studies exploit the premise that nature is a great experimenter. Many changes occur naturally, requiring no human intervention. Some people are exposed to iodine-deficient water because of environmental conditions, and some women have low hemoglobin levels because of their nutritional status. The study of such naturally occurring events can be invaluable in studying cause–effect relationship with conviction. Such a study can be based on records or on actual observations, or a combination of both. This type of study is also sometimes referred to as an **epidemiological study**. Since there is no deliberate human intervention (such as a drug) in this setup, such studies carry little risk of harm to the subjects or the society, although they are invasive with regard to time and privacy of the respondents. An observational study is generally conducted for specific groups such as those with high disease prevalence or those with high prevalence of a risk factor—thus, extrapolation to the general population is not immediate. Many observational studies are done in a hospital setup rather than in communities. For example, change in Oswestry disability index score 1 year after microdecompression and laminectomy in patients with central lumbar spinal stenosis, when based on records of previously treated patients, is an observational study [1]. This study had two types of surgery as interventions, but these were going on naturally without a design. As pointed later in this section, this can be a great limitation of observational studies in giving a valid conclusion.

An observational study can be done in one of many formats (Figure O.1): (i) **prospective studies** such as cohort, longitudinal, and repeated measures; (ii) **retrospective studies** such as case–control, nested case–control, and uncontrolled; and (iii) **cross-sectional studies**. For merits and demerits of each and their comparative performance, see the topic **retrospective studies**. **Ecological studies** and many **case studies/case series** are also observational.

Observational studies might look simple to carry out but they provide valid results only when carried out with full precaution. The antecedent under study and the outcome of interest must be sharply defined and all **confounders** must be under control. Such studies require representative and random samples so that there is no bias in the results, but this could be an uphill task in observational studies. In contrast to this, note that a random sample is not a strict requirement for clinical trials. Because of lack of randomization, the results of observational studies are seldom conclusive. Matching is adopted in some observational studies to address this limitation, but this also requires careful consideration of what should be matched and to what extent, and there is no **overmatching**. Some confounders may still escape attention and can contaminate the results. Thus, there is widespread perception that the results of observational studies are only indicative and not conclusive. On the contrary, in **randomized controlled trials (RCTs)**, the results are far more robust for the effect of intervention because of strict control of the conditions in which these are done. RCTs are insulated from extraneous factors that observational studies are not. Smith and Ebrahim [2] have cited an instance of the cardioprotective effect of hormone replacement therapy found in several observational studies overturned by subsequent RCTs. There are many such instances. For communication of the results of an observational study, the

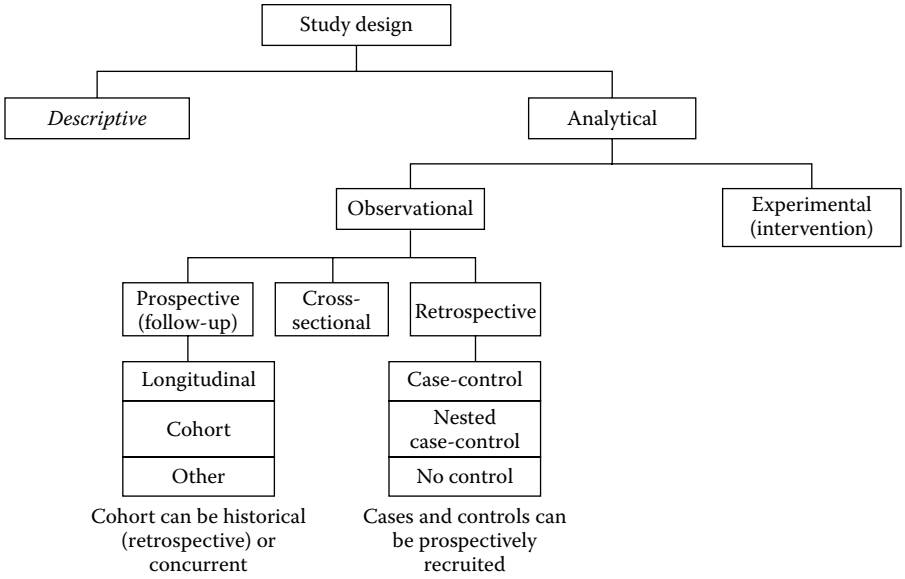

**FIGURE O.1** Types of observational studies.

**STROBE** format is recommended, which tends to take care of some of these discrepancies.

## observations (statistical)

*Statistical observations* is the term used for realized values of a variable. The variable is the characteristic and the observations are the measurements of that characteristic in a set of subjects. For example, bone mineral density *T*-score is a variable, but its actual values in persons such as −1.52, −0.87, +1.20, and so on are the observations. This term is quite often used in statistical parlance, and generally these observations are denoted by $x_1$, $x_2$, $x_3$, and so on. The subscript identifies the subject number.

When we say mean = $(x_1 + x_2 + \ldots + x_n)/n$, $x$'s are the notations for the observations on $n$ subjects. In the regression equation $y_i = b_1x_{1i} + b_2x_{2i} + \ldots + b_Kx_{Ki} + e_i$, the observations are $(y_i, x_{1i}, x_{2i}, \ldots x_{Ki}, e_i)$ for the $i$th subject. Note that in this equation, there are $K$ independent and one dependent variable.

Statistical observations depend on their unit. We are not pointing to unit of measurement but to unit of observation. You can have family as a unit of observation for a variable such as family size or number of family members with similar history; you can have country as a unit for expectation of life or physician–population ratio; you can have a mouse as a unit in an experiment for measuring the duration of survival; and, of course, you can have individual human being as a unit for observations on pain score or creatinine level.

There are terms such as independent observations and dependent observations. The example of regression just mentioned is for independent and dependent variables and not for observations. The variable could be birth weight, but the observations are dependent when birth weight is measured for twins, or even when measured for siblings. Description of statistical methods tends to become confusing when the same variable measured in two groups of subjects is considered as two distinct variables. In our example, the birth weight of one sibling can be one variable and the birth weight of a second sibling can be another variable. Then, they become dependent variables instead of dependent observations. Many times, this kind of distinction is lost in statistical literature, and this does not seem to hurt either.

## observed zeroes, *see* contingency tables

## observer bias/errors/variation

Observer bias occurs when there is a systematic error in the values obtained by an observer and when the variation and errors occur because of lack of care. Bias is generally one sided (either positive or negative), whereas variation and error will be positive in some subjects and negative in others.

### *Observer Bias*

Observer bias occurs when wrong methods are used or inadequate assessments are done. It can arise if the subjects with disease are evaluated more intensively and more carefully than those without disease. **Blinding** is used as a means of safeguarding against this bias, but such blinding is rarely feasible in many clinical setups and in studies requiring long follow-up. Then, this bias can go on unnoticed.

There are many other examples. Some agencies deliberately underreport starvation deaths in their area as a face-saving device and overreport deaths caused by calamities such as flood, cyclone, and earthquake to attract funds and sympathy. Improvement in the condition of a patient for reasons other than therapy can be wrongly ascribed to the therapy. Tighe et al. [1] studied observer bias in the interpretation of dobutamine stress echocardiography. They concluded that the potential for observer bias exists because

of the influence of ancillary testing data such as angina pectoris and ST-segment changes. Lewis [2] found that psychiatric assessments of anxiety and depression requiring clinical judgment on the part of the interviewer are likely to suffer from observer bias. These examples illustrate some situations in which observer bias can occur.

Biases attributed to intentional abuses of methods and instruments, however, are nearly impossible to handle and can remain unknown until they expose themselves. One approach is to be vigilant regarding the possibility of such biases and deal sternly with them when they come to notice. Scientific journals can play a responsible role in this respect. If these biases are noticed before reaching the publication stage, steps can be sometimes taken to correct the data. If correction is not possible, the biased data may have to be excluded altogether from analysis and conclusion.

It is sometimes believed that bad data are better than none at all. This can be true if sufficient care is exercised in ensuring that the effect on the conclusion of bias in bad data has been minimized, if not eliminated. This is rarely possible if the sources of bias are too many. Also, care can be exercised only when the sources of bias are known or can be reasonably conjectured. Even the most meticulous statistical treatment of inherently bad data cannot lead to correct conclusions.

### *Observer Errors*

There are unintentional errors, and they will be positive in some cases and negative in others. Sometimes the exposure or the accompanying baseline information and sometimes the outcome are not correctly recorded. This can occur as a result of carelessness of the observer or of the recording clerk who may unwittingly classify a subject into a particular category. Incorrect information can also arise for the following reasons. These can occur in any setup but are typically more common in a prospective study setup.

- Human error in correctly assessing the condition of the patient. This can be attributed to either carelessness or lack of expertise of the observer. The physician may lack competence and the recording clerk may lack training or motivation. Assessment during the latter part of a longitudinal study may be less accurate as fatigue sets in or more accurate because of the learning effect.
- Inaccurate reports from the laboratory arising from use of nonstandardized techniques or chemicals, or from use of faulty instruments.
- Doubtful validity of the diagnostic or screening test.

There can be a lack of care in obtaining or recording information when, for example, sufficient attention is not paid to the appearance of Korotkoff sounds while measuring blood pressure by a sphygmomanometer or to the waves appearing on a monitor for a patient in critical condition. This can also happen when responses from patients are accepted without probing and some of them may not be consistent with the response obtained on other items. If reported gravidity in a woman does not equal the sum of parity, abortions, and stillbirths, then obviously some information is wrong. A person may say that he does not know anything about AIDS in the early part of an interview but states sexual intercourse as the mode of transmission in the latter part of the interview. The observer or the interviewer has to exercise sufficient care so that such inconsistencies do not arise.

All such errors in assessment can be reduced simply by being more careful and by using precise instruments, measurements, and classification criteria that have been pretested for their validity. Many inadvertent errors can be avoided by imparting adequate training to the observers in the standard methodology proposed to be followed for collection of data, and by adhering to the protocol as outlined in the instruction sheet. Many investigations do not even prepare an instruction sheet, let alone address adherence.

### *Observer Variation*

Barring some clear-cut cases, clinicians tend to differ in their assessment of the same subject. Interpretation of x-ray films is particularly notorious in this respect. Disagreement exists concerning simple tools such as a chart for assessing growth of children. Physicians tend to differ in grading a spleen enlargement. One physician may consider a fasting blood glucose level of 136 mg/dL in a male of age 60 years sufficient to warrant active intervention, but another might opt just to monitor. Variation in blood pressure readings due to differences in hearing acuity or in interpretation of Korotkoff sounds is on record. Some clinicians are more skillful than others in collating pieces of information into solid diagnostic evidence. Such variability on the part of the observer, researcher, or investigator is a fact of life and cannot be wished away. It is inherent in humans and represents a healthy feature rather than anything to be decried. Efforts are made from time to time to reconcile and come to a consensus, and indeed such a consensus is reached on many occasions. Yet, many issues remain unresolved and new ones keep cropping up, and they continue to contribute to the spectrum of uncertainty.

Quite often, an investigation is a collaborative effort involving several observers. Not all observers have the same competence or the same skill. Assuming that each observer works to his fullest capability, faithfully following the definitions and protocol, variation can still occur in measurement and in assessment of diagnosis and prognosis. This can happen because one observer may have a different acumen in collating the spectrum of available evidence than others.

### *Inability of the Observer to Get Confidence of the Respondent*

Patient–doctor equation plays an important role in extracting correct and full information. This inability can be attributed to language or intellectual barriers if the subject and observer come from widely different backgrounds. They may then not understand each other and generate wrong data. In addition, in some cases such as in sexually transmitted diseases (STDs), part of the information may be intentionally distorted because of the stigma or the inhibition attached to such diseases. An injury in a physical fight may be ascribed to something else to avoid legal wrangles. Some women hesitate to divulge their correct age. Some may refuse physical examination, forcing one to depend on less valid information. Correct information can be obtained only when the observer enjoys full confidence of the respondent.

**TABLE O.2**
**Odds for Some Probabilities**

| Probability ($\pi$) | 0.02 | 0.10 | 0.33 | 0.50 | 0.80 |
|---|---|---|---|---|---|
| Odds | 2:98 = 1/49 | 10:90 = 1/9 | 33:67 = 1/2 | 50:50 = 1/1 | 80:20 = 4/1 |

## odds, *see also* odds ratio

Odds of an event are defined as the ratio of the probability of its occurrence to the probability of nonoccurrence. If the probability of occurrence is $\pi$, the odds are $\pi/(1-\pi)$. Table O.2 gives the odds ratio for some values of $\pi$. For probability 0.02, the chance of nonoccurrence is 49 times of the chance of occurrence. For probability 0.5, the odds are even. For probability 0.80, the chance of nonoccurrence is one-fourth of the chance of occurrence.

Odds are commonly used in betting. For example, the odds of winning 1:3 imply that a loss is three times as likely as a win. In health and medicine, odds are used instead of probability for expressing the chances of presence of an antecedent. The chance of an outcome is expressed in terms of risk, whereas the chance of an antecedent is expressed as odds. This is because the probability is perceived for an event yet to occur, whereas the antecedent has already occurred. Odds are conventionally used in **case–control studies** that investigate the antecedents in the known cases and controls. If 67% of all cases of hypertension are obese in a particular segment of population, the odds of obesity are 67:33, or 2 to 1 in these subjects. That is, a subject with hypertension is twice as likely to be obese as being nonobese. This is a quirky measure but has been found extremely useful in medical research as explained next.

The most prominent statistical use of odds is in **logistic regression** where the dependent is **logit** of the probability of the event when observed as yes/no, present/absent, and so on. This is defined as log of odds: $\text{logit} = \ln[\pi/(1-\pi)]$. The main advantage of this transformation is that the probability with range (0, 1) is mapped onto $(-\infty, +\infty)$. This helps in mathematical manipulations and more useful interpretation. Note that for probability 0.5, the odds are 1 and its logit is 0. Odds are important measures by themselves, but their importance increases manifold when they are expressed as a ratio in one group relative to another. See the topic **odds ratio** for details.

## odds ratio (OR), *see also* odds

An odds ratio (OR) is the ratio of **odds** of an event in one group to that in another group, which itself is a ratio. The groups generally are cases with disease and controls without disease. Thus, OR is a ratio of ratios. This is commonly used in **case–control studies**. The OR represents the odds that an antecedent has a role in a given disease, compared to the odds of the antecedent's role in the absence of disease. This is treated differently in two independent samples compared to matched pairs.

### *OR in Independent Samples*

The data take the form as given in Table O.3 in an independent-samples setup. In this case, $\pi_{12} = 1 - \pi_{11}$ and $\pi_{22} = 1 - \pi_{21}$.

The odds of the presence of an antecedent among cases are $\pi_{11}/(1-\pi_{11})$ and those among controls are $\pi_{21}/(1-\pi_{21})$. Thus, the OR is

$$\text{OR} = \frac{\pi_{11}/(1-\pi_{11})}{\pi_{21}/(1-\pi_{21})} = \frac{\pi_{11}\pi_{22}}{\pi_{12}\pi_{21}}.$$

**TABLE O.3**
**Structure of Study for OR: Independent Samples**

| | Antecedent | | |
|---|---|---|---|
| **Outcome** | **Present** | **Absent** | **Total** |
| Present (cases) | $a$ ($\pi_{11}$) | $b$ ($\pi_{12}$) | $\boldsymbol{n_1}$ **(1)** |
| Absent | $c$ ($\pi_{21}$) | $d$ ($\pi_{22}$) | $\boldsymbol{n_2}$ **(1)** |
| **Total** | $\boldsymbol{O_{\cdot 1}}$ **(**$\boldsymbol{\pi_{\cdot 1}}$**)** | $\boldsymbol{O_{\cdot 2}}$ **(**$\boldsymbol{\pi_{\cdot 2}}$**)** | $\boldsymbol{n}$ |

If the sample estimate of $\pi_{11}$ is $p_1$ and that of $\pi_{21}$ is $p_2$, OR is estimated as

$$\text{OR} = \frac{p_1/(1-p_1)}{p_2/(1-p_2)} = \frac{ad}{bc},$$

where $a$, $b$, $c$, and $d$ are as in Table O.3. Since the numerator is the product of the elements in the leading diagonal of this table and the denominator is that of the elements in the other diagonal, OR is also sometimes called the **cross-product ratio**. OR loses definition when any cell frequency is zero and becomes inflated if any observed frequency is exceedingly small. In that case,

$$\text{Modified estimate of OR: } \text{OR}_{\text{mod}} = \frac{(a+0.5)(d+0.5)}{(b+0.5)(c+0.5)}.$$

The interpretation of OR is similar to that of **relative risk (RR)**, although now for the antecedent rather than for the outcome. An OR = 2 means that the presence of the antecedent is twice as common among the cases with disease as in the controls. OR = 1/3 means that the presence of antecedent is one-third as common among the cases as in the controls. This could mean that the antecedent has a protective effect. Thus, OR is also a measure of the degree of **association** between two dichotomous outcomes, and OR = 1 implies that there is no association between the exposure and the outcome.

Cornfield [1] showed that the OR approximates the RR fairly well when the outcome of interest is rare, say, less than 5%, in the target population. Most outcomes of medical interest are rare. If the outcome is not rare, an OR of more than one leads to an overestimate of RR and an OR of less than one leads to an underestimate. This can be serious if the risk or the probability of outcome is more than 20%.

Consider the data in Table O.4 on the parity status of 210 anemic and 140 nonanemic women. Anemic and nonanemic women were assessed for parity so that the design is retrospective.

$$\text{OR} = \frac{98 \times 48}{92 \times 112} = 0.46$$

Thus, the likelihood of parity ≤ 2 among anemics is less than one-half of that among nonanemics. Since anemia in women is not rare, particularly in developing countries, this OR may fail to

**TABLE O.4**
**Parity Status in Anemic and Nonanemic Women**

| **Anemia** | **Parity ≤ 2** | **Parity ≥ 3** | **Total** |
|---|---|---|---|
| Present | 98 | 112 | **210** |
| Absent | 92 | 48 | **140** |

approximate RR. If it is really rare, then the conclusion could be that parity ≤ 2 has less than one-half the risk of anemia compared to the risk in parity ≥ 3, or the risk of anemia in women with parity ≥ 3 is more than twice that for women with parity ≤ 2.

Some features of OR are as follows:

- Interestingly, OR for the antecedent is the same as OR for the disease. For both, it is $(ad)/(bc)$. Thus, these terms can be interchangeably used.
- The sample OR is always a good estimate of the population OR irrespective of the disease being rare or common in the population.
- Besides, when the disease is rare, OR is a good estimate of the RR when the cases and controls are representative of the people with disease and without disease, respectively, in the population with respect to the history of exposure.
- In case–control studies, the response refers to the presence or absence of an antecedent characteristic. For this, it could be inappropriate to use the term *incidence*. Nor does the term *risk* seem appropriate to indicate the presence of an antecedent characteristic. The term *odds* is used, which appropriately describes the situation.
- Although OR = 0.5 and OR = 2 are half and double of OR = 1, respectively, their average is not 1. OR is a ratio and logarithm removes this discrepancy—ln(OR)s can be averaged as usual, but if you need to average ORs, use the **geometric mean**.
- RR can lead to a very different conclusion depending on whether a positive outcome or a negative outcome is being measured. OR is not affected by such a consideration. For instance, consider the data in Table O.5 from a cross-sectional study of breast and lung cancer cases.

  The estimated RR of death within 1 year among breast cancer versus lung cancer cases in these data is (2/50)/(1/100) = 4. The same data also lead to the OR (2/48)/(1/99) ≈ 4. Thus, both measures indicate nearly four times the risk of dying among breast cancer patients compared with lung cancer patients. Now, use the same data, this time with respect to survival instead of death. The RR of survival is (48/50)/(99/100) = 0.97, while the OR of survival is (48/2)/(99/1) = 0.24. The RR results are different depending on whether the study is summarized with respect to death or with respect to survival. For the OR, it really does not matter. Breast cancer has approximately four times the odds of death within 1 year compared with lung cancer or approximately one-fourth the odds of survival compared with lung cancer. Both convey the same result in case of OR.
- The OR from a **cross-sectional study** is computed the same way as that from a retrospective study. However, it is necessary that the sample is a true reflection of the proportion of subjects with and without outcome as well as of the proportion with and without antecedent. Thus, for valid results, a cross-sectional sample must be a truly random sample from the target population.
- Logistic regression can be used to adjust the OR to measure the association between an antecedent and an outcome after removing the effect of intervening factors and confounders. See the topic **adjusted odds ratio (OR)** for details.
- See the topic **pooled odds ratio (OR)** for calculating combined OR when the data are available for different strata.

Since OR is a ratio, it is best dealt with after taking logarithm. Note for estimated OR that $\ln(\text{OR}) = \ln a + \ln d - \ln b - \ln c$. This is linear and makes it eligible for **central limit theorem**. Thus, ln(OR) has an approximate **Gaussian distribution** for large $n$. With this, the **confidence interval (CI) for odds ratio** can be easily worked out as described under that topic. For test of hypothesis, note that OR = 1 is the null in this case as that says that there is no association. This can again be tested by the Gaussian ***z*-test** by using its standard error (SE) as mentioned for its CI, but it is more convenient to use **chi-square test for odds ratio**.

### OR in Matched Pairs

Consider Table O.6 on matched pairs. This is similar to Table O.3 but now uses $A$, $B$, $C$, and $D$ as notation for cell frequencies in place of $a$, $b$, $c$, and $d$ to distinguish the matched-pairs setup with the independent-samples setup. Note also that the labeling of the cells has now changed.

The total number of pairs is $A + B + C + D$. In this table, $A$ is the number of pairs with both case and control subjects found exposed and $D$ is the number of pairs with both found nonexposed. These two together are the concordant pairs. The OR is computed on the basis of the discordant pairs: $B$ is the number of pairs in which the case partner is exposed but the control partner is nonexposed, and $C$ is the number of pairs in which the case partner is nonexposed but the control partner is exposed. In case of a positive association between exposure and disease, clearly $B$ should be more than $C$.

$$\text{Odds ratio (matched pairs): } \text{OR}_\text{M} = \frac{B}{C}$$

The distribution of $\ln\text{OR}_\text{M}$ is nearly Gaussian for large $n$. Large $n$ also implies that no $B$ or $C$ is small, say, less than 5. For large $B$ and $C$,

$$\text{SE}(\ln\text{OR}_\text{M}) = \sqrt{\frac{1}{B} + \frac{1}{C}}.$$

**TABLE O.5**
**Deaths in Breast Cancer and Lung Cancer Cases**

| | Deaths within 1 Year | Survival after 1 Year | Total |
|---|---|---|---|
| Breast cancer | 2 | 48 | **50** |
| Lung cancer | 1 | 99 | **100** |

**TABLE O.6**
**Matched Pairs in a Case–Control Study with Dichotomous Antecedent**

| | Controls (Partner 1) | |
|---|---|---|
| **Cases (Partner 2)** | **Antecedent Present (Exposed)** | **Antecedent Not Present (Nonexposed)** |
| Antecedent present (exposed) | *A* | *B* |
| Antecedent not present (nonexposed) | *C* | *D* |

The 95% CI for log of OR, as usual, is $\ln OR_M \pm 1.96 * SE(\ln OR_M)$. In this case, this becomes

$$\ln \frac{B}{C} \pm 1.96 * \sqrt{\frac{1}{B} + \frac{1}{C}}.$$

Take the exponential of the limits and get

$$95\%\ \text{CI for OR in matched pairs: } \frac{B}{C} e^{\pm 1.96\sqrt{\frac{1}{B}+\frac{1}{C}}}.$$

While the CI for $\ln OR_M$ in symmetric, it is not symmetric for $OR_M$ itself.

The relevant null hypothesis in this case again is $H_0$: $OR_M = 1$. To test this against a one-sided alternative $H_1$: $OR_M > 1$ or $OR_M < 1$, calculate

$$z = \frac{B - C}{\sqrt{B + C}}.$$

For large $n$, refer it to the usual Gaussian distribution to find out whether the $P$-value is sufficiently small. For a two-tailed test, it may be easier to calculate

$$\text{McNemar } \chi^2_M = \frac{\left(|B - C| - 1\right)^2}{B + C}$$

and refer it to chi-square with 1 df. This incorporates the correction for continuity.

We illustrate the calculations with the help of an example. Consider a case–control study of births with multiple malformations. The malformations considered are cleft lip, cleft palate, anal atresia, heart defects, hypospadias, and so on. They are considered multiple when at least two are present. The controls were one-to-one matched for birth order, maternal age, socioeconomic status, and the place of delivery. The objective is to find any excess of one gender over the other in such births. Suppose the data obtained are as shown in Table O.7.

In these data, $B = 60$ and $C = 50$. Thus, the odds are 1.2 times in these subjects that the malformed child is male and not female. Now,

$$SE(\ln OR_M) = \sqrt{\frac{1}{60} + \frac{1}{50}} = 0.1915.$$

Thus, the 95% CI for the OR is

$$(1.2 \times e^{-1.96 \times 0.1915},\ 1.2 \times e^{1.96 \times 0.1915}),\ \text{or } (0.82,\ 1.75).$$

**TABLE O.7**
**Sex of Children with and without Multiple Malformations**

| | Matched Control | | |
|---|---|---|---|
| **Cases** | **Male** | **Female** | **Total** |
| Male | 70 | 60 | **130** |
| Female | 50 | 40 | **90** |
| **Total** | **120** | **100** | **220** |

Note that this interval contains $OR_M = 1$, which shows that this null hypothesis cannot be rejected. Otherwise, if the null hypothesis of $OR_M = 1$ is to be tested by the criterion just mentioned, then

$$z = \frac{60 - 50}{\sqrt{60 + 50}} = 0.95.$$

This gives $P = 0.3422$ for a two-sided alternative. Also, the McNemar chi-square in this case is

$$\chi^2_M = \frac{\left(|60 - 50| - 1\right)^2}{60 + 50} = 0.74.$$

This again gives $P > 0.05$.

None of the three procedures is able to reject $H_0$: $OR_M = 1$. Thus, these data do not allow the conclusion that either gender is more prone to multiple malformations at birth.

There are several points that you can note in this example: (i) The CI is not symmetric to $OR_M = 1.2$. It is skewed to the right in this case because $1.75 - 1.20 = 0.55$ is more than $1.20 - 0.82 = 0.38$. (ii) The antecedent characteristic is not conventional exposure but is the sex in this example. (iii) Multiple malformations are rare and thus case–control is a suitable design. Several confounders that could have influenced the outcome, namely, birth order, maternal age, socioeconomic status, and place of delivery, are controlled by matching. Perhaps there are no more confounders except those in the epistemic domain. Thus, any difference between male and female children can be ascribed to their gender and, of course, sampling fluctuations.

The results obtained by three methods for $H_0$: $OR_M = 1$ are consistent in our example as all three fail to reject this null, but you might see some variation in other situations. This variation tends to vanish as $B$ and $C$ increase. Use the McNemar test if the alternative is two sided and do not use the CI because the CI uses a greater degree of approximation.

## ogive

Ogive is a **line diagram** that plots cumulative **frequency** (or cumulative percentage) at upper end points of the **class-intervals** of a quantitative data. This is the number of subjects with values less than or equal to the upper end of each interval. Thus, this is applicable where the data are quantitative and frequencies in different class-intervals are given or can be computed. This will not apply to contingency tables based on nominal data. For the age distribution of subjects in Table O.8, this plot is shown in Figure O.2. Note that the cumulative percentages for age 49, 59, 69, 79, and beyond 79 are 11, 32, 78, 95, and 100, respectively.

In the case of Gaussian distribution of values, the ogive takes a smooth **sigmoid** shape (S shape). It is this shape that has given rise to the term *ogive*. The shape tells us where the frequencies are steeply increasing and where they are gradually increasing. Whatever the distribution, ogive can be used for obtaining approximate **quantiles** in case of grouped data. To obtain a $p$th $s$-tile, draw a horizontal line at $100p/s\%$ and read the value on the $x$ axis where this horizontal

## one-sided bound, *see* confidence bounds

## one- and two-tailed alternatives/tests

You may be aware that statistical tests of hypothesis begin with setting up a null hypothesis and an alternative hypothesis. If not, see the topic **null and alternative hypotheses**. The nature of the alternative hypothesis determines that the statistical test is going to be one tailed or two tailed.

The alternative hypothesis, denoted by $H_1$, is the opposite of the null, denoted by $H_0$. The alternative must be true when $H_0$ is found false. If the null is that a drug is not effective, then the alternative has to be that it is effective. If the claim is that of superiority of the new drug over the existing one, this is the alternative hypothesis. This is a one-sided alternative if inferiority is ruled out. Mostly, it is not possible to claim that one group is better than the other, and the only claim is that they are different. In the case of peak expiratory flow rate (PEFR) in factory workers exposed to different pollutants, there may not be any a priori reason to assert that they would be affected more by one pollutant than another. Then, the alternative is that the mean PEFRs in workers exposed to different pollutants are unequal. It could be higher or lower. This is called a two-sided alternative. The null is that they are equal in various groups. One-sided and two-sided $H_1$ are also sometimes called one-tailed and two-tailed $H_1$.

It is sometimes asserted that there is no scientific reason to have a one-sided alternative—that the negative effect of a regimen can never be ruled out. This is too strong a statement, which may be mostly true but not always. Other things being equal, an exercise regimen among obese can only reduce or not reduce weight on average—it can never be suspected to increase the weight on average. Increase in weight can happen in isolated cases, but it does not seem possible when the average over the subjects is considered. Statistical tests are for groups and not for individuals. Thus, it would not be wise to set up a two-sided alternative in this case. If a regimen has passed previous two **phases of a clinical trial**, the effect can rarely be suspected to be even lower than that of placebo. Thus, in a phase III trial, if the comparison is with placebo, the alternative would be that its efficacy is better than that of placebo and the null hypothesis is that it is as good as placebo (no clinical effect). If this assertion is doubted, and lower than placebo efficacy cannot be ruled out, there must be something drastically wrong with the phase II of the trial that has established its minimum efficacy for proceeding to a phase III trial. If you want to see the effect of a hematinic, it would be absurd to suspect that it could even decrease the average hemoglobin level in a group of subjects. The only possible doubt is that it helps in specified cases or not. Note, again, that a statistical hypothesis concerns the average and not the individual subjects. Individuals can show decline, but that is not an issue in a statistical test of hypothesis setup.

One-sided alternative hypotheses could be that the parameter value is either more than a specified value or less than the specified value—one of the two. In our exercise–weight example, the hypothesis would be in terms of mean and would be $H_1$: $\mu_1 - \mu_0 < 0$, where $\mu_1$ is the mean weight after the exercise regimen and $\mu_0$ is the mean weight before the regimen. This is a left-sided alternative hypothesis. If you are testing a regimen that is expected to increase HDL cholesterol level, the alternative could be right sided, which says $\mu_1 - \mu_0 > 0$. If you are not fairly assured about the one-sided alternative, set up the two-sided alternative hypothesis. This would be $H_1$: $\mu_1 - \mu_0 \neq 0$. Often, this would be the case.

One-sided alternatives require a one-tailed test and two-sided alternatives require a two-tailed test. A one-tailed test could be right tailed or left tailed depending on the side of the alternative. A right-tailed test means that the null hypothesis is rejected when the value of the test criterion is *more* than the critical value at the specified level of significance. A left-tailed test means that the null hypothesis is rejected when the value of the test criterion is *less* than the critical value. For a Gaussian ***z*-test**, at 10% level of significance, the critical value is –1.28 for a left-tailed test. Recollect that level of significance is the threshold of the probability of a Type I error. If the sample values give a value of $z$ less than this value, the null is rejected in favor of the left-sided alternative. This is shown in Figure O.3b. For a two-sided alternative, the critical region would be both tails, mostly equally divided in the two tails. For a Gaussian $z$-test, this critical value at the 10% level of significance is either less than –1.645 or more than +1.645—each tail containing 5% probability (Figure O.3a).

You can see that it is easier to reject the null in favor of the one-sided alternative compared with the two-sided alternative. In our illustration, a left-sided alternative would be rejected at a 10% level of significance when the $z$-value from the sample is <–1.28 but if it is a two-sided alternative, you would reject if $z < -1.645$. The former is easier to achieve than the latter. The objective of most studies is to collect evidence to reject the null. Thus, it is preferable to set up a one-sided alternative rather than a two-sided alternative. However, caution remains that this should be done only if you are fairly assured that the other side of the alternative is not plausible for your study.

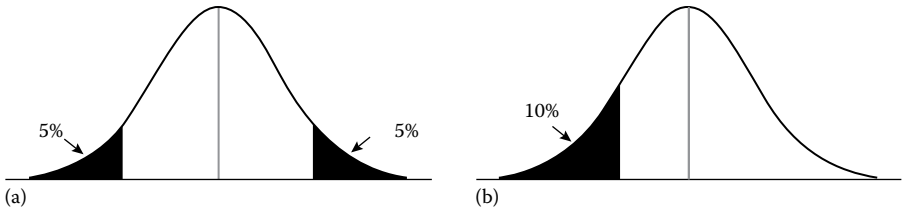

**FIGURE O.3** Two-tailed and one-tailed rejection regions for Gaussian distribution. (a) Two-tailed test. (b) One-tailed test (left tail).

Certain statistical tests are naturally two tailed, whereas some others can easily test one-sided alternatives. The chi-square test for association in a contingency table is the most prominent two-tailed test—first, because it is based on square of values (this also converts negative values to a positive number), and second, because it ordinarily considers categories as nominal. It can be devised as a one-tailed test but is seldom done. Tests for multiple groups such as analysis of variance *F*-test are also naturally two tailed—the alternative being unequal means across groups. On the other hand, Gaussian *z*-test for proportions and Student *t*-test for means in one or two groups can easily test one-sided as well as two-sided alternatives.

For another discussion on one- and two-tailed tests, see Peace [1].

## one-way ANOVA, *see also* analysis of variance (ANOVA)

One-way analysis of variance (ANOVA) is a method to find whether the mean in any of three or more groups is significantly different. The corresponding procedure for one and two groups is the **Student *t*-test**.

Consider a study in which the plasma amino acid (PAA) ratio for lysine is calculated in healthy children and in children with undernourishment of grades I, II, and III. This ratio is the difference in PAA concentration in blood before and after a meal, expressed as a percentage of the amino acid requirement. There are four groups in this study. The setup is called one way because no further classification of subjects, say, by age or gender, is sought in this case. Groups define the factor: in this case, grade of undernourishment. The response is a quantitative variable. When other factors are properly controlled, the difference in PAA ratio among subjects would be attributed to either the degree of undernourishment or the intrinsic interindividual variation in the subjects in different groups. The former is the between-groups variation and the latter is the within-groups variation. These variations are illustrated in Figure O.4 for a variable observed for four different groups. Group means are denoted by $\bar{y}_{\bullet j}$ ($j$ = 1, 2, 3, 4) and are represented by a circle. Within-groups variation is the difference between individual values and their respective group mean. This is summed over the groups. The overall mean is denoted by $\bar{y}_{\bullet\bullet}$ and is represented by a line in this figure. Between-groups variation is the difference between group means and the overall mean.

Note that part of the within-groups variation in the preceding example can be attributed to factors such as heredity, age, gender, height, and weight of the children. However, these are assumed under control and disregarded in this setup. All within-groups variation is considered intrinsic and random. In an ANOVA setup, this is generally called residual or error variance. This is measured by **mean square due to error**, popularly written as MSE. The term

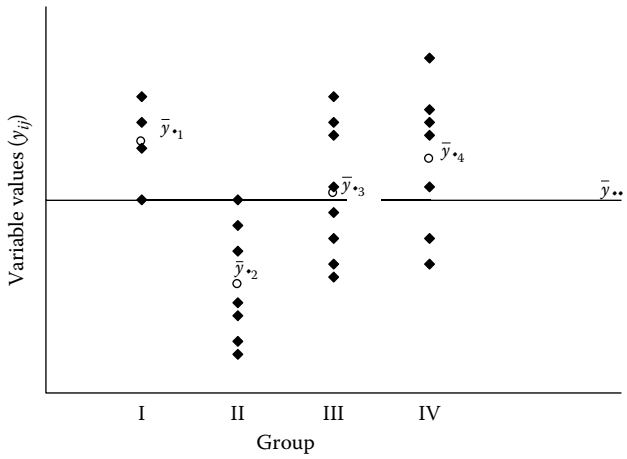

**FIGURE O.4** Graphical display of within-groups and between-groups variance.

*error* does not connote any mistake but stands only for random component, as for sampling error.

If the group differences were not really present, both the between-groups variance (call it mean square between groups and write it as MSB) and the within-groups variance would arise from intrinsic variation alone and will be nearly equal. The ratio of these two, with between-groups variance in the numerator, is the criterion *F* (for this reason, this is also called **variance ratio**). With MSB in the numerator, a value of *F* of substantially more than one implies that between-groups variation is large relative to within-groups variation. This is an indication that the groups are indeed different with respect to the mean of the variable under study relative to the intrinsic variation.

### *The Procedure to Test $H_0$*

The null hypothesis in this setup is that means in all groups are the same. A prerequisite for validity of the ANOVA procedure is that all groups have the same variance—called **homoscedasticity**. It is also stipulated in ANOVA that the pattern of distribution of the response variable is the same. This could be of almost any form if the number of subjects in each group is large. One possibility is shown in Figure O.5. The distribution in all four groups in this figure

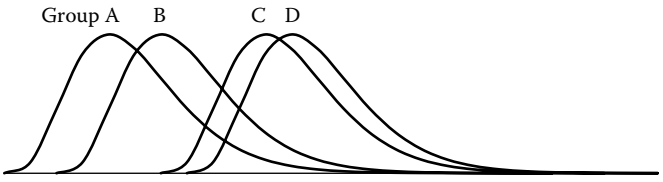

**FIGURE O.5** Distribution in four groups differing only in mean.

is identical except for a shift in location. Groups B and C are far apart from one another, but C and D are close. Only the means differ and other features of the distribution are exactly the same. If $n$ is small, the ANOVA procedure is valid only when this distribution is Gaussian. Thus, skewed distributions of the type shown in Figure O.5 are admissible for ANOVA only when $n$ is large.

In terms of notations, the null hypothesis in the case of one-way ANOVA is

$$H_0: \mu_1 = \mu_2 = \ldots = \mu_J.$$

This says that there are $J$ groups and the means in all groups are the same. This hypothesis, in conjunction with the conditions mentioned in the preceding paragraph, implies that the response variable has the same distribution in different groups. The alternative hypothesis is that at least one mean is different.

When $H_0$ as just stated is true, mean square between groups (MSB) is also an estimate of the population variance $\sigma^2$. Mean square error (MSE) is an estimate of $\sigma^2$ whether or not $H_0$ is true. The ratio

$$\text{(A)} \quad F = \frac{\text{MSB}}{\text{MSE}}$$

is expected to be one under $H_0$. When $F \le 1$, it is surely an indication that group means can be equal. If group means are different, MSB would be large and $F \gg 1$ (substantially more than 1). Just like $\chi^2$ and $t$, the distribution of $F$ under $H_0$ is known. In place of a single df, the exact shape of $F$ depends on a pair of df, namely, $(J - 1)$, $J(n - 1)$ in case of one-way ANOVA. The first corresponds to the numerator of the criterion given in Equation A and the second corresponds to the denominator. In general, these df's are denoted by $(v_1, v_2)$, respectively. The probability $P$ of wrongly rejecting $H_0$ can be obtained corresponding to the value of $F$ calculated from the data. If $P < 0.05$, the evidence can be considered sufficient to reject $H_0$ at a 5% level of significance. Standard statistical packages provide the $P$-value so that a decision can be made immediately.

The following comments provide further information on one-way ANOVA:

- The primary purpose of ANOVA is to test the null hypothesis of equality of means. However, an estimate of the effect size of the groups can also be obtained as a by-product of this procedure. For this, see the topic **main effects and interaction in ANOVA**.
- ANOVA was basically developed for evaluating data arising from experiments. This requires **random allocation** of the subjects to different groups and then exposing these groups to various interventions. In the PAA example, the groups are preexisting and there is no intervention. The design is prospective because the undernourishment groups define the antecedent and the PAA ratio is investigated as an outcome. The subjects are not randomly allocated to the different undernourishment groups. However, it is important to ensure that the subjects in each group adequately represent their group and that there is no other factor, except the undernourishment grade, that separates the groups. Such precautions in selection of subjects are necessary for a valid conclusion from ANOVA.
- Although the ANOVA method has been described here for comparing means in three or more groups, the method is equally valid for $J = 2$ groups. In fact, there is a mathematical relationship that says that two-tailed $t^2$ for two independent samples of size $n$ is the same as $F$ with $(1, 2n - 2)$ df. Note that the df of Student $t$ for two independent samples, each of size $n$, is $(2n - 2)$. Both methods lead to the same conclusion, but $F$ is a two-tailed procedure, whereas $t$ can also be used for a one-sided alternative. This flexibility is not available with the $F$-test.

For illustration, consider the following example. Tokunaga et al. [1] conducted a study for effects of some $H_1$-antagonists on the sleep–wake cycle in sleep-disturbed rats. Among the response variables was rapid eye movement (REM) sleep time. Take a similar example of a sample of 20 rats, homogeneous for genetic stock, age, gender, and so on, which are randomly divided into $J = 4$ groups of $n = 5$ rats each. Let one group be the control and the others receive drug A (diphenhydramine), drug B (chlorpheniramine), and drug C (cyproheptadine). The REM sleep time was recorded for each rat from 10:00 to 16:00 h. Suppose the data shown in Table O.9 are obtained.

These data show a large difference in the mean sleep time in various groups. Another experiment on a new sample of rats may or may not give similar results. The likelihood of getting nearly equal means in the long run is extremely remote, as will be clear shortly.

To avoid the burden of calculations, given below are the values obtained from a statistical package for these data.

$$\text{SST} = 7369.8, \text{SSB} = 5882.4, \text{ and SSE} = 1487.4,$$

where SST is the total **sum of squares**, SSB is the between-groups sum of squares, and SSE is the error (within-groups) sum of squares. Mathematical expressions of these are being avoided because of complexity. However, note that SST = SSB + SSE in a one-way setup.

The degrees of freedom for SSB are $(4 - 1) = 3$ and those for SSE are $4(5 - 1) = 16$. Mean squares are obtained by dividing these sums of squares by the corresponding df's. These values, as well as the value of $F$, are conventionally shown in the form of a table, popularly called an *ANOVA table*. This is given in Table O.10 for this example. For these data,

$$F = \frac{5882.3/3}{1487.4/16} = 21.09.$$

**TABLE O.9**
**REM Sleep Time in Sleep-Disturbed Rats with Different Drugs**

| Drug | REM Sleep Time (min) | | | | | Mean (min) |
|---|---|---|---|---|---|---|
| 0 (control) | 88.6 | 73.2 | 91.4 | 68.0 | 75.2 | 79.28 |
| A | 63.0 | 53.9 | 69.2 | 50.1 | 71.5 | 61.54 |
| B | 44.9 | 59.5 | 40.2 | 56.3 | 38.7 | 47.92 |
| C | 31.0 | 39.6 | 45.3 | 25.2 | 22.7 | 32.76 |

**TABLE O.10**
**ANOVA Table for the Data in Table O.9**

| Source of Variation | df | Sum of Squares | Mean Squares | F |
|---|---|---|---|---|
| Drug | 3 | 5882.4 | 1960.8 | 21.09 |
| Error | 16 | 1487.4 | 93.0 | |
| **Total** | **19** | **7369.8** | | |

The null hypothesis is that there is no effect of dose on REM sleep time. This is the same as saying that means in all the four groups are equal.

A statistical package gives $P < 0.001$ under $H_0$ for $F = 21.09$ or higher. That is, there is less than one in a thousand chance that equal means in groups will give a value of $F$ this large. Therefore, these data must have come from populations with unequal means. In other words, another experiment on the same kind of animals is extremely unlikely to give equal means. The evidence is overwhelming against the null and it is rejected. The conclusion is that different drugs do affect the REM sleep time differentials.

In this example, mean REM sleep time in different drugs not only differs but also follows a trend. Had the groups represented increasing dose levels, it would have implied decline in sleep time as the dose level is increased. The conventional ANOVA just illustrated allows conclusion of different means in different groups but not of any trend. Evaluation of trend in means is discussed under the topic **regression**.

In our example, there are only five rats in each group. Statistically, this is an extremely small sample. The reason that such a small sample can still provide a reliable result is that the laboratory conditions can be standardized and most factors contributing to uncertainty can be controlled. The rats can be chosen to be homogeneous, as in this experiment, so that intrinsic factors such as genetic makeup, age, and gender do not influence the outcome. Random allocation tends to average out any effect of other factors that are not considered in choosing the animals. The influence of body weight, if any, is taken care of by adjusting dose for body weight. Thus, interindividual variation within groups is minimal. On the other hand, the variation between groups is very large in this case, as is evident from the large difference between the means. This provided clinching evidence in favor of the alternative hypothesis.

### *Cautions in Using ANOVA*

The following are cautions in using ANOVA:

1. The ANOVA is based on means. Any means-based procedure is severely disturbed when outliers are present. Thus, ensure before using ANOVA that there are no outliers in your data. If there are, examine whether they can be excluded without affecting the conclusion.
2. A problem in comparison of three or more groups by criterion $F$ is that its significance indicates only that a difference exists. It does not tell exactly which group or groups are different. Further analysis, called **multiple comparisons**, is required to identify the groups that have different means.
3. When no significant difference is found across groups, there is a tendency to locate a group or even a subgroup that exhibits benefit. This post hoc analysis is alright as long as it is exploratory in nature. In conclusion, a new study should be conducted on that group or subgroup.
4. The following are requirements for validity of the ANOVA $F$-test: (i) independence of the observations, (ii) homoscedasticity across groups, and (iii) Gaussian distribution of means in different groups. The last is generally fulfilled by the **central limit theorem** when the sample size in each group is large. The small numbers of subjects in different groups in our rat example should put you on alert regarding the pattern of distribution of the measurements and of their means. It should be Gaussian. See the topics **Guassianity (how to check)** for details. When the pattern is far from Gaussian, consider a **transformation** or nonparametric **Kruskal–Wallis test** for one-way ANOVA. For checking **homoscedasticity**, see that topic. If the variances are really unequal and the number of subjects in the groups is also widely different but large, the **Welch test** is used for testing the hypothesis of quality of means. For small samples and unequal variances, consider the **Brown–Forsythe test**. Independence is the most important requirement. This is checked by the **Durbin–Watson test** for autocorrelation and by **intraclass correlation** for clusters. If you are measuring electronic waves at six different sites of the brain in each subject, and consider each site as a group, the independence is lost since these measurements belong to the same person. Serial observations, such as in a time series or repeated measures, also violate the independence requirement. See **repeated measures ANOVA** for the analysis in this setup.
5. The procedure we have mentioned is for fixed effects. See the topic **fixed and random effects** for the distinction between the two. See the topic **random effects ANOVA** for analysis in case of random effects.

## one-way designs, *see also* two-way designs

Many times, the subjects of a study are classified into groups either to attain homogeneity within groups or to study the effect of the grouping factor. If the objective is to see how blood group affects a particular outcome such as blood glucose level, the subjects will be divided by blood groups. This is the grouping factor in this case. This is called one-way design when the division of subjects is by just one factor. Blood group is the factor and the actual values of the factor such as A, B, AB, and O are called the *levels of the factor*. Statistically, the factor is the independent variable in this setup and the blood glucose level is the dependent variable. Contrast it with **two-way** or multi-way designs where the subjects are divided according to the levels of two or more factors. In addition to the blood group, you can also divide the subjects by sex and by obesity. Then, it will be a three-way design. This will have three independent variables. In this setup, the independent variables are always **categorical** and cannot be continuous. Thus, these are better understood as factors and not as variables.

A one-way design can arise in three different ways. One is that you have a sample of subjects and you divide them into groups as per your choice. This happens when you have a group of tobacco users and you divide them by the age-groups you choose. You can have age-groups <15 years, 15–34 years, 35–54 years, and 55+ years, or if you want, you can divide groups into 10-year intervals. The choice is yours, although it may be guided by which groups you consider homogeneous with respect to tobacco use. Different groupings can give different results, and this should be considered when interpreting the results. However, a person of age 23 years has to be in his/her age-group. Second is that the groups are already there and you just classify them such as males and females. Nature forms these groups and not human beings. In both these setups, you cannot decide as to which subject will go to which group. Their age or sex will decide the group. Third is that you have one group that will receive treatment A, a second group receiving treatment B, and a third group receiving treatment C, and you can randomly allocate the subjects to these treatments after they are found eligible with inclusion and

exclusion criteria. This is done in most clinical trials, or you can decide on the basis of their clinical condition as to who will receive which treatment. In this situation, the choice is yours.

Consider the data in the table under the topic **one-way ANOVA**, where the rats are divided into four groups of five rats each and their REM sleep time is recorded. In this example, the data are quantitative and the number of subjects in each group is five. They may or may not be equal groups. If the data are the number of subjects (frequencies) in place of the quantitative values, this is called a one-way **contingency table**. If there is a sample of 100 subjects from a hypertension clinic and the number of subjects with normal blood pressure (BP), with mild hypertension, and with severe hypertension is observed, this would be a one-way classification. The focus is on the number of subjects in different groups, and the role of actual levels of BP is only in categorization. The data are not the quantitative values but are the number of subjects in different groups in this case.

The quantitative data in a one-way design is analyzed by one-way ANOVA where means are compared, and the data in a one-way classification is analyzed by chi-square **goodness-of-fit** where frequencies are compared. The null hypothesis in the former case is that the means of the quantitative values in different groups is the same, whereas in the second case, the hypothesis would be that the frequencies follow a particular pattern.

## open trial

In contrast to a **blinded trial**, an open trial (fully, an open-label trial) is one in which the subjects know which treatment he/she is receiving and the researcher also knows which treatment is being given to whom. This "openness" in such trials raises the specter of bias because of the distinct likelihood of prejudiced responses from the subjects on one hand and unfair assessment by the assessor on the other. Thus, open trials are not advised. They may still have to be used in situations where blinding is extremely difficult. For example, a trial on comparison of medical treatment with surgical treatment cannot be blinded.

Subjects in an open trial can still be randomized. In this case, the subjects are told after randomization which treatment they are receiving. Randomization helps in increasing the chances of baseline equivalence of the subjects in the different groups, particularly when the groups are large. One arm can be control, which can be either placebo or the existing regimen. Thus, a **randomized control trial (RCT)** can be an open trial or a blinded trial, and a double-blind RCT is considered the gold standard.

As mentioned, there are situations where blinding is not feasible. Gupta and Gupta [1] conducted an open trial on patients with plantar warts treated with adapalene gel 0.1% under occlusion in one group and with cryotherapy in the second group. Bhatia et al. [2] describe the protocol of an open trial to evaluate the impact of yoga on cognitive functions in schizophrenia. There are many situations where there is no choice. In all these trials, special care should be taken so that the responses are not biased and the observers carry out and report unbiased readings.

## operations research

Research focused in operations, in contrast to theories and statistical methodologies, is called operations research (OR) (or operational research). For example, observational studies or clinical trials are not OR but optimization of resources for controlling a swine flu epidemic is. OR has an overbearing approach to solve existing or upcoming problems instead of generalized approaches. What steps can help minimize the waiting time in the emergency department of hospitals and what can improve the turnaround time of patients admitted in wards are examples of OR. It examines trade-offs among various options and help us take a decision that meets a specific objective.

OR is a methodological driven discipline with focus on specific applications. It requires a variety of analytical methods, including statistical methods, to reach a conclusion. OR-based modeling can help in providing a structured framework that uses the best available evidence to capture relevant uncertainties, complexities, and interactions. It recognizes that most problems are multifaceted and draws its strength from an interdisciplinary approach to arrive at an ideal sort of solution within the specified constraints. However, mathematics plays a key role.

Two basic tools that OR uses are optimization and **simulation**. The first is generally calculation intensive and the second in any case requires a computer. Zai et al. [1] have used simulations for optimizing a population management system for cancer screening. Mistry et al. [2] proposed an optimization approach for controlling drug-resistant tuberculosis in Mumbai, India, that could include effects of newer technologies, changing the balance of ambulatory and inpatient care, the effects of initiatives to improve infection control, and so on. Bartsch et al. [3] used a simulation model to study the spread and control of norovirus outbreaks among hospitals in the United States.

## optimistic index

This measures the extent of overfit (optimistic fit) of a **model** to a data set because it is based on the same data. A model based on any data set is likely to be a good fit because the calculations are based on the same data. This model may not apply with the same predictivity to a new data set. The optimistic index tries to correct the predictivity so that a realistic assessment is available regarding the practical utility of the model.

Among several methods, the most common one for finding the optimistic index for a model involves repeated fitting the model to a bootstrap subsample from the original sample and calculating the predictivity each time. This would invariably be lower than the predictivity you originally obtained based on the entire sample, since now only subsamples are being used. Average predictivity over, say,

100 bootstrap samples would be considered the actual predictivity. Difference between the original predictivity and the average predictivity based on bootstrap samples would be the optimistic index. This measures how much the model is overpredicting.

Suppose you fit a logistic model to predict mortality in acute necrotizing pancreatitis cases with a database of 400 cases. Let the classification accuracy of the model for these data be 86%. That is, the model is able to correctly predict survival or death in 86% of the cases but was wrong in the other 14% of the cases in the data set used for developing the model. In these 14%, the patient died when the model predicted survival or the patient survived when the model predicted death. Now, fit the same model to a random subsample of, say, 300 subjects from the available 400 and suppose it is found that the predictivity is 82%. Take another random subsample of 300 cases and find that the predictivity is, say, 75%. Do this 100 times. Suppose the average predictivity in these 100 random subsamples of 300 patients is 79%. Since the original predictivity is 86%, the optimistic index is 86% − 79% = 7%. The model seems to be overpredicting to an extent of 7%. You can see that the index may depend on the size of bootstrap samples. A smaller sample may have a lower predictivity not because of the small sample but because the smaller sample may not represent the full spectrum of subjects.

## ordered alternatives, *see also* one- and two-tailed alternatives/tests

These are extension of **one-tailed alternatives** hypotheses to more than two groups. In case of two groups with metric data, the one-tailed alternative takes the form $H_1$: $\mu_1 < \mu_2$ or $H_1$: $\mu_1 > \mu_2$. When the number of groups is more than two, the ordered alternative is $H_1$: $\mu_1 \le \mu_2 \le \mu_3 \le \ldots \le \mu_K$, or $H_1$: $\mu_1 \ge \mu_2 \ge \mu_3 \ge \ldots \ge \mu_K$, with at least one strict inequality, where $K$ is the number of groups. These are also called *directional alternatives*. The null is the same, that is, that means in all the groups are equal $H_0$: $\mu_1 = \mu_2 = \mu_3 = \ldots = \mu_K$. These kinds of alternatives are possible only for ordered groups (such as none, mild, moderate, serious, and critical). For nominal groups, such as subjects belonging to blood groups, O, A, B, and AB, such ordered alternatives would not be applicable. For some other apparently nominal groups, such as cancer of blood cells (leukemia), lungs, prostate, and mouth, you may still be able to set up an ordered alternative for, say, average duration of survival if you believe that the cancers of different sites can be arranged by duration of survival.

Statistical methods for comparing more than two groups are in any case complex but they become even more intricate when the alternative hypothesis is ordered. Globally acceptable methods are yet to be developed for this setup. Among parametric tests for Gaussian distributed variables are the Bartholomew test and the Williams test as discussed by Alainentalo [1]. Among nonparametric tests based on ranks, the Jonckheere test (also called the Jonckheere–Terpstra test) for trend is meant for an ordered alternative [2]. Shan et al. [3] have proposed a new test, claimed to be more powerful, based on rank difference. Rice and Gaines [4] have proposed an ordered heterogeneity test for ordered variances. These are rarely used in health and medicine and we have not included these tests in this book.

## OR, *see* odds ratio (OR)

## order of a table, *see* contingency tables

## order statistics

When quantitative **observations** of a variable are ascendingly ordered, these are called order statistics. If total bilirubin level in milligrams per deciliter in six subjects is $x_1 = 1.14$, $x_2 = 0.97$, $x_3 = 1.20$, $x_4 = 1.28$, $x_5 = 0.93$, and $x_6 = 1.15$, the order statistics are $x_{[1]} = 0.93$, $x_{[2]} = 0.97$, $x_{[3]} = 1.14$, $x_{[4]} = 1.15$, $x_{[5]} = 1.20$, and $x_{[6]} = 1.28$ from minimum to maximum. The $i$th order statistics is denoted by $x_{[i]}$. It is customary to use square brackets as subscript for order statistics, and the value in these brackets is the rank of the value. Thus, the value 1.14 has rank 3 and the value 1.28 has rank 6. In general, for observations $(x_1, x_2, \ldots, x_n)$, the order statistics are $x_{[1]} \le x_{[2]} \le \ldots \le x_{[n]}$.

Some sample summaries are easily expressed in terms of order statistics. For example, the sample range is $x_{[n]} - x_{[1]}$ and the sample median is $x_{[(n+1)/2]}$ if $n$ is odd, and the average of $x_{[n/2]}$ and $x_{[n/2+1]}$ if $n$ is even. Similarly, all **quantiles** can be easily expressed in terms of order statistics, including the 2.5th and 97.5th percentiles we use to find the **nonparametric** 95% confidence interval for the median in case of highly **skewed** data. Order statistics are commonly used to devise nonparametric tests since these tests are based on ranks instead of the actual values.

**Sampling distribution** of all order statistics can be obtained. This can be used to find, for example, the distribution of the minimum value, which, in turn, can help in estimating the minimum possible value in the population of a variable with reasonable confidence. For example, if you have total bilirubin level in a sample of six subjects as in our example, the distribution of the minimum can tell you what minimum threshold becomes unlikely in the population from which this sample has been taken, provided the subjects are randomly chosen. The minimum in our sample is 0.93 mg/dL, but the statistical distribution of the minimum may tell you that the lower limit is 0.75 and the chance of anything lower than this in the population is extremely small, say, less than 5%. Similarly, if the minimum efficacy of a regimen in a series of trials is 56%, you can find how low it can go and decide if the regimen is worth pursuing. Similarly, the upper limit of the maximum can also be obtained with a reasonable confidence. This can also be used to detect **outliers** with unlikely high values. If the maximum value happens to be 2.38 in your sample and the next is 1.83, the question is that 2.38 is or is not likely to have come up from the population from which other values have come. We can find the probability that the largest value can be 2.38. If this probability is extremely small, this can be discarded as being wrongly reported or wrongly measured.

The order does not change under linear transformation of the type $y = a + bx$ when done for all the values of $x$. However, one big problem with order statistics is a tie between two or more values. If the fourth and fifth values in increasing order are both 1.23 mg/dL, what order do they belong? The answer is 4.5. Both are given the same rank. The next rank will be 6 as 4.5 takes away both ranks 4

and 5. Such ties are known to create problems in nonparametric tests and they require modification.

For further details of order statistics, see Arnold et al. [1].

## ordinal association, *see* association between ordinal characteristics (degree of)

## outcome variables

The term *outcome* is used in several different contexts in medical research, and it is difficult to list all of them. The outcome of all medical research should be improved health care, but our concern here is with the outcome variables. The term is better contextualized in an antecedent–outcome setup where there are some inputs, some processes, and then some outputs. Antecedents could be an intervention, risk factors, or exposures, and outcome could be positive such as improvement in health or could be adverse such as side effects. In a clinical trial setup, the antecedents could be the regimen itself, its compliance, the preexisting disease severity, the quality of care, and so on, and the outcomes could be in terms of survival, duration of hospitalization, extent of relief, and so on.

Other terms for outcome are effect, response, and result. This always is a consequence and occurs after the antecedents. However, there are setups where the distinction between antecedent and outcome is blurred. Gender and blood group are determined simultaneously and none is the outcome of the other. They are not antecedent–outcome, but the association between them can still be investigated. Anxiety can cause disease and disease can cause anxiety. Cholesterol level is an antecedent for coronary outcomes but is an outcome for cholesterol-level–reducing agents. So long as you are clear in your mind and able to state it explicitly, such anomalies will not create problems.

In an **analytical study**—observational or experimental—where an antecedent–outcome framework is an essential ingredient, proper specification of the outcome variables is of paramount importance. Outcome variables depend on the main and secondary objectives of the study. For example, in patients undergoing mitral valve surgery, the outcome of interest could be sinus bradycardia, sinus arrest, atrial fibrillation, and prolonged asystolic period. It is important for research that each of them is precisely stated: when a sinus bradycardia would be called inappropriate, what would be considered prolonged asystolic period after tachycardia or otherwise, when will they be assessed—if repeatedly assessed, what time point will be considered most important for conclusion or whether trend would be considered, and so on. All these should be fully specified in the **protocol** itself so that there is no arbitrariness later on. Also, they must be carefully chosen so that they correspond with the objectives. They must be measurable and, as far as possible, should be on the metric scale because this is far more objective than ordinal and nominal scales.

In the statistical independent and dependent variable dichotomy, outcomes are dependents and the antecedents are independents. When the outcome is binary and the objective is to investigate the extent and form of relationship between the antecedents and outcome, **logistic regression** is the statistical method of choice. If the outcome is metric, ordinary least squares **regression** is used. In both these setups, the statistical requirements such as independence, homoscedasticity, and Gaussian distribution apply to the outcome variable and not to the antecedent variables. It is the nature of the outcome variable that primarily decides which statistical method is appropriate for a set of data. Thus, the outcome must be carefully chosen. Also, consider whether the outcome variable is the actual or a **surrogate**. Surrogate can be used when the actual is not measurable or extremely expensive to measure. If surrogate is used, be cautious in drawing conclusions. In this context, the article by Senn and Julious [1] may be of interest.

## outliers

Outliers are those obstinate values that are located in isolation in the graph—not fitting with the others. Many of these can be attributed to errors such as misplaced decimal, wrong method of measurement, wrong reporting, misuse of instrument, and wrong record. Sometimes, rarely though, the outlier may be right and other values may be wrong, such as when the first few values are model-based estimates that are way off the actually observed most values. At other times, an outlier may be a genuine out-of-the-box value for a very unusual person or patient.

In Figure O.6a, the percentage of cholesterol esters is shown as dependent on total bilirubin in cases of cirrhosis, hepatitis, and common bile duct obstruction. In the presence of regurgitation jaundice, the flow of bile into the duodenum may decrease, causing a reduction in the esterified form of cholesterol. Note an outlier in this figure. Scatter diagrams easily provide the opportunity to spot such outliers.

Outliers are obviously defined in terms of data spread. Beside the scatter diagram as just mentioned, outliers can be spotted by a **box-and-whiskers plot**. In this plot, values more than 1.5*IQR (IQR is the

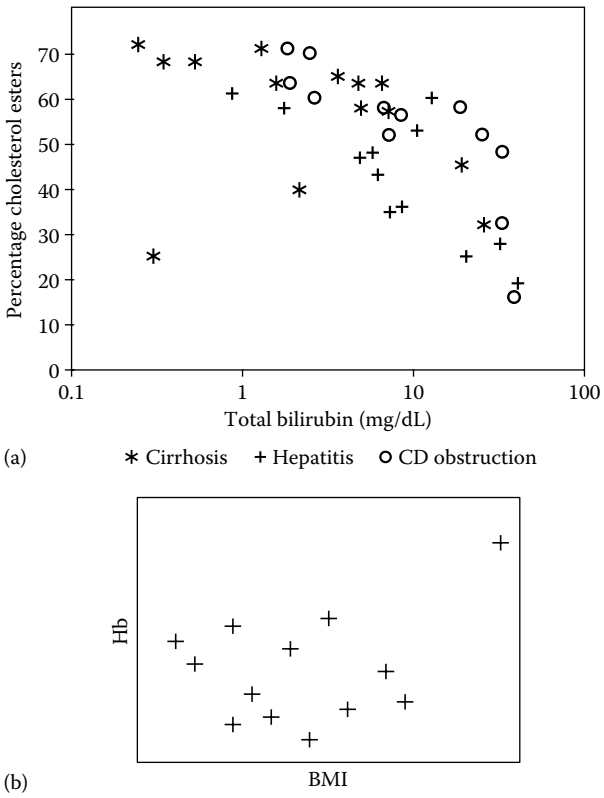

**FIGURE O.6** (a) Scatter diagram showing an outlier. (b) One outlier gives an impression of a trend.

**interquartile range**) away from the median are marked as marginal outliers and those more than 3*IQR away are marked as clear outliers. **Order statistics** can also be used to detect outliers with unlikely high values. If the maximum value happens to be 1.83 in your sample and the next is 2.38, the question is that 2.38 is or is not likely to have come up from the population from which other values have come. We can find the probability that the largest value can be 2.38 by using the distribution of order statistics. If this probability is extremely small, this can be discarded as being wrongly reported. A similar procedure can be used for unusually low values. A large absolute value of a **residual** for any particular $y$ in a **regression** is a definite indication that an outlier is present in the data, but that cannot be relied upon as a sole indicator. An outlier would most likely affect the entire regression, and thus many residuals could be moderately large and escape attention. Careful examination of residuals is required to find whether one or more outliers are present. Some software packages have an option to flag the outliers, which makes their spotting easier.

One or more outliers have the potential to distort the results—they have a disproportionate effect. The mean is the first one to be affected (the median is not affected). The mean of 5 values ranging from 7 to 20 is very different if one high value such as 36 is added. Because of this, results of all mean-based statistical tests such as Student *t*-test and ANOVA are vulnerable when one or more outliers are present. A large sample tends to moderate such distortion. Range is surely affected as everyone realizes but many do not realize that an outlier can substantially vitiate the standard deviation (SD) as well. This occurs because of the distorted value of the mean that is so intimately used in calculating the SD. Also, one outlier can present an artificial trend in regression analysis as in Figure O.6b where all other values are randomly located with no trend.

When one or more outliers are noticed in a data set, the first step is to examine whether they are genuine values or are due to assessment or data entry errors. If they are due to errors, they can be safely excluded provided they do not follow any pattern and are not too many. If there is a pattern or are too many, think of what may have gone wrong in terms of assessment or data entries. Genuine outliers are difficult to manage as their exclusion can distort the results. They can also arise as a result of missing important factors in the study that determine these values. If that is not the case, the best course would be to present results with and without these outliers and explain the difference. The other option is to use **nonparametric methods** since they are not much affected by outliers. They are based on ranks and the rank of the highest value is the same whether the highest value is 36 or 76.

On the positive side, genuine outliers can help you develop new **hypotheses**. Your subjects may suggest what possibly could have caused these values and one or more of these causes may not have been stipulated. In case the hypothesis looks plausible, you can plan a systematic study to examine this hypothesis, and present your results.

## overanalysis, *see also* data-dredging

Popularly termed as torturing the data until it confesses, data are sometimes overanalyzed, particularly in the form of post hoc analysis. A study may be designed to investigate the relationship between two specific measurements, but correlations between pairs of a large number of other variables, which happen to be available, are calculated and examined. This is easy these days because of the availability of computers.

When many correlations are examined and each is tested for statistical significance at a level of $\alpha = 0.05$, the total probability of **Type I error** increases enormously. Also, $\alpha = 0.05$ implies that 1 in 20 correlations can be concluded to be significant when actually it is not. If measurements on 16 variables are available, the total number of pairwise correlations is $16 \times 15/2 = 120$. At the error rate of 5%, 6 of these 120 can turn out to be falsely significant. Thus, there is clear risk of interpreting noise as signal. Hofacker [1] illustrated this problem with the help of randomly generated data. Any result from post hoc analysis should be considered indicative and not conclusive. Further study should be planned to confirm such results. This also applies to post hoc analysis of various subgroups that were not part of the original plan. There is always a tendency to try to find the age–sex or severity groups that benefited more from the treatment under review than the others. Numerous such analyses are sometimes done using a drop-down menu in the hope of finding some statistical significance somewhere. Again, such detailed analysis is fine for searching a ground to plan a further study but not for drawing a definitive conclusion. However, this is not to deny the existence of Americas because it was not in Columbus' plan. This is not empirical anyway. In most empirical cases though, it may be sufficient to acknowledge that the results are based on post hoc analysis and possibly need to be reconfirmed.

Another dimension of overanalysis is what has now come to be known as ***P*-hacking** as proposed by Simmons et al. [2]. This is chasing a small effect in the hope that it is hidden in the data. The data are reanalyzed in several different ways to find statistical significance somewhere. Head et al. [3] have also discussed this phenomenon, which they consider is widespread throughout science, but opine that this has not caused much damage to the science so far.

## overfit (of regression)

A regression model is said to be overfit when even the random fluctuations in the data are considered as trend. As an extreme example, if you have six data points and fit a regression with six parameters (regression coefficients), the regression will exactly go through all the points, ignoring that these data points have a random error component beside the trend. This can look like the curve in Figure O.7 between shock index and risk score for thrombolysis (thrombolysis in myocardial infarction [TIMI] score) in ST-segment elevated myocardial infarction cases. In this figure, the data are available for only five subjects, and the polynomial of degree 4 (this makes a total of five parameters when the intercept is also counted) is a perfect fit, passing through all the points. A linear fit is also shown for illustration.

As mentioned, this is an extreme example to illustrate the point, but an overfit can occur when the number of data points is not as many as needed for an adequate regression. If you have 10 data points, even a fourth-degree polynomial can be an overfit. It depends on what kind of trend you are expecting considering the biological process under study.

Note also that the regression analysis actually presumes that you have a series of values of $y$ for each value of $x$. In our example, regression would be far more satisfactory when you have a TIMI risk score for, say, 4 patients with shock index 0.5, 3 patients with shock index 0.6, 7 patients with shock index 0.7, and so on. Such

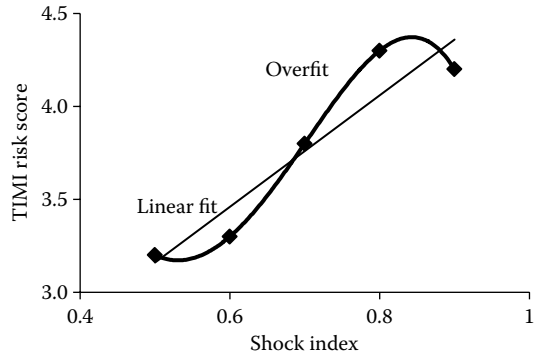

**FIGURE O.7** An overfit (thick curve) of regression passing through all the points and the linear fit (thin line).

multiple subjects for each value of $x$ help consider the average—thus ruling out, to some extent, the effect of random fluctuations. Remember that regression is for the *average* of $y$-values for each value of $x$. Many researchers tend to forget this aspect. The chance of an overfit is much more when you have one subject for each value of $x$. This is not a strict requirement for the set of $(x_1, x_2, \ldots, x_K)$ values in case of **multiple regression**. It could be an uphill task to include many subjects for each specific set of values of the $x$'s when $K$ is large. However, caution is also required in this case, particularly if you are fitting a complex regression. If you get an extremely high **coefficient of determination** (or $R^2$ in case of multiple linear regression), say, exceeding 0.90, suspect an overfit. Examine it carefully in the context of the sample size, the complexity of the model, and biological plausibility. If this coefficient is so high for a model that is not an overfit, you are in a win–win situation.

The best insulation against overfitting is a large sample. Another is to keep the model simple by judicious choice of the predictors. You should be able to justify why each of the regressors you have chosen needs to be in the regression. Also, it has now become a standard practice to **validate** the regression model. This can be external by using it on some other data set or internal by splitting the sample into training and validation data sets, or by **resampling methods**.

If you want to see overfit in action, Ryali et al. [1] have discussed the problem in the analysis of functional magnetic resonance imaging (fMRI) data because the number of regions considered is large compared to the number of participants.

1. Ryali S, Supekar K, Abrams DA, Menon V. Sparse logistic regression for whole-brain classification of fMRI data. *Neuroimage* 2010 Jun;51(2): 752–64. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC2856747/

## overmatching, *see also* matching

**Matching** of subjects in the two groups under comparison is considered a good strategy in situations where randomization is not feasible or the sample size is small such as in some case–control studies. It helps rule out the effect of matched factors on the results. Proper matching enables one to validly estimate the effect without bias caused by the presence of extraneous factors. Although matching for all the factors that can affect the outcome except the ones under study is advocated, this operational clause is sometimes ignored. The real question is what to do with factors that affect the outcome as well as the risk factors under study—called **confounders**. Matching for these can sometimes result in overmatching, and biased results are obtained. Overmatching can also reduce statistical efficiency as well as cost efficiency. For example, in a study on the effect of postmenopausal estrogens on uterine cancer, matching on uterine bleeding can present invalid findings since uterine bleeding is also associated with uterine cancer. Any matching on such outcome-related variable can distort the results. The following example illustrates this further.

Marsh et al. [1] describe a study of relation between radiation exposure and mortality from leukemia in workers at a nuclear reprocessing plant. The matching factors in this study were site, sex, work status, age (within 2 years), and date of entry (within 2 years). Note that risk of leukemia varies with these factors and they looked like valid factors for matching. Date of entry was considered necessary as the risk of leukemia changes with calendar time. Examination of data since 1950 shows that the radiation dose steeply declined after 1980. Matching for date of entry unwittingly also matched for radiation exposure, which was the antecedent under study. Such overmatching obscured the relationship between radiation dose and risk of leukemia. Overmatching reduced the statistical significance of the effect.

Likewise, exposure-related variables that can make risk factor distribution similar in cases and controls should not be matched. Remember that the effect of matched factors cannot be studied as these have the same distribution in the two groups after matching. In most situations, matching on age and sex and possibly one or two more antecedents not under investigation would suffice. In any case, finding subjects that are matched with respect to several factors is difficult and can enormously increase the cost as many unmatched subjects have to be discarded. This is what we meant when we mentioned cost efficiency of matching.

1. Marsh JL, Hutton JL, Binks K. Removal of radiation dose response effects: An example of over-matching. *BMJ* 2002;325:327–30, http://www.bmj.com/content/325/7359/327

# P

## pack-years of smoking

Tobacco use in different forms is known to be a major killer in many countries and is gradually taking center stage in the rest of the world. Pack-years is a way of measuring the extent of a person's cigarette smoking. This is measured as

$$\text{pack-years} = m_1y_1 + m_2y_2 + \ldots + m_Ty_T,$$

where $m_t$ packs of cigarettes are smoked for $y_t$ years ($t = 1, 2, \ldots, T$). If 2 packs a day are smoked for 4 years and 3 packs for 10 years, the pack-years are $2 \times 4 + 3 \times 10 = 38$. As per this definition, one pack-year is smoking one pack a day for 1 year that actually means 365 packs a year.

An index such as pack-years suffers from at least one serious deficiency. According to this index, smoking 3 packs a day for 10 years is the same as smoking 1 pack a day for 30 years, although they may have very different implications. For lung cancer, duration may be more important, whereas for coronary artery disease, the intensity of smoking may be more important. Despite this deficiency, pack-years continues to be the most commonly used measure of extent of smoking.

Doctors studying the effect of smoking on patients use the concept of pack-years to determine who should be screened for lung and other cancers. Studies suggest that people who have a 30 pack-year history of smoking might be candidates for lung cancer screening. Factoring in additional criteria (age is old or young, continue to smoke or have quit in the past 15 years), studies have found that the mortality rate from lung cancer could be cut by 20% if people meeting these criteria underwent screening.

In general, the more pack-years one has smoked, the greater the chance of getting cancer. It is a dose–response and cause–effect type of relationship established after a large number of observational studies. That said, lung cancer can occur in people who have never smoked, and many people smoke heavily for decades without getting cancer. Statistically, according to Peto [1], pack-years is unhelpful as a correlate of lung cancer.

More precision can be obtained by considering the number of cigarettes rather than packs per day. To account for duration, a measure could be the total number of cigarettes smoked so far in life. This number is given by

$$S_1 = n_1x_1 + n_2x_2 + \cdots + n_Kx_K,$$

where $n_k$ ($k = 1, 2, \ldots, K$) cigarettes per day (intensity) are smoked for $x_k$ years (duration). This is more exact than the pack-years generally used for smoking. This is the beginning point of the **Indrayan smoking index**, which considers age at start of smoking, type of smoking, years since cessation by former smokers, etc., in addition to cigarette-years.

1. Peto J. That the effects of smoking should be measured in pack-years: Misconceptions 4. *Br J Cancer* 2012;107:406–7. http://www.nature.com/bjc/journal/v107/n3/full/bjc201297a.html

## paired samples, *see also* matched pairs

Paired samples in medical research arise primarily in three situations: (i) naturally matched such as in **before–after study** with no parallel controls: the same subjects are measured twice—first before the stimulus, and then after the intervention; (ii) in crossover trials where each subject receives two or more treatments on different occasions after a washout period; and (iii) in a deliberate and strict one-to-one matching where a parallel control group of different subjects is present, but each control subject is matched to a corresponding subject for nearly all the characteristics that can affect the outcome, except of course the regimen itself. Consideration of **matching** is important for statistical analysis since matched-pair analysis is different from independent groups analysis. Matching by one or two characteristics such as age and sex generally is not considered adequate for paired analysis—instead such partially matched control group is considered independent.

An advantage of using the paired samples approach is that the sample size can be smaller first because there is no separate control group and second since within-subjects (i.e., within pairs) variability is likely to be smaller than between-subjects variability. Also, since the sampled subjects are the same for intervention, there is less chance that some external factor (**confounding variable**) will influence the result. However, there is also a downside of paired samples. In the case of a before–after study, the **Hawthorne effect** and the placebo effect are confounded with the regimen effect—you would not know how much of the difference was because of the regimen and how much due to the hidden effect of these two factors. In the case of one-to-one matching, even when all known factors are matched, there might be unknown factors that can cause the difference, and this can give false assurance. Also, you would not be able to find the effect of matching characteristics—if the subjects are matched for age, you would not know the effect of age on the outcome. Moreover, there is always a risk of **overmatching** that could provide distorted results.

For statistical analysis, when the data are quantitative, the difference between each pair of values is obtained and the situation becomes of a one-sample scenario. Confidence intervals can be calculated, and hypothesis can be tested for this difference just as for one sample. Proportions in the case of paired samples are not straightforward: they may require the **McNemar** test.

## Palma measure of inequality, *see also* Gini coefficient, health inequality

This measures how unequal the distribution of a characteristic is across the population. Although primarily devised for assessing

income inequalities, it can also be used to measure inequalities in health parameters. The Palma measure tells us whether health is nearly the same for everyone or whether a few have excellent health and many have desperately poor health.

Jose Palma

The usual measure of health inequality is the **Gini coefficient**. However, it is nonspecific, does not reveal where the inequality exists, and has no physical interpretation. It is also oversensitive to the changes in the middle values and less sensitive to the changes at the top and bottom [1]. Jose Palma in 2011 [2] suggested his measure to remedy these deficiencies of the Gini coefficient. The Palma measure compares the highest 10% values with the lowest 40% in place of each with every other done by Gini. Among several conclusions, Palma observed that people in the 5th to 9th **deciles** of income acquire their rightful 50%, and this remains stable across populations; the other 50% income is mostly grabbed by the top decile leaving little for the bottom 4 deciles. Sharing between the top decile and the bottom 4 deciles varies widely from population to population, and this mostly defines the income inequalities. Thus,

$$\text{Palma measure of inequality: } P = \frac{\Sigma_{i=1}^{n/5} x_{[i]}}{\Sigma_{i=3n/5}^{n} x_{[i]}},$$

where $x[i]$ is the $i$th value after ordering from the lowest to the highest.

The Gini coefficient is mostly affected by the middle values, whereas the Palma measure ignores these middle values. A fair criticism of the Palma measure is that this is not based on all the values. Those interested in middle values as much as the tail values will continue to use the Gini coefficient.

In a medical context, the Palma measure of inequality is the ratio of aggregation of health (in whatever metric) of the top 10% and the aggregation of bottom 40% of values. No adequate metric is available for measuring comprehensive health, but consider for illustration purposes that we are able to measure it on a 0–100 scale for 200 persons. The top decile is the top 20 people, and let their health metric have an average of 97. Thus, the aggregation is 97 × 20 = 1940. If the health metric of the bottom 80 persons has an average of 14, their aggregate is 14 × 80 = 1120. This gives a Palma measure of 1940/1120 = 1.73. Palma stops here, saying that the health of the top 10% is 1.73 times the health of the bottom 40%. However, the interpretation is clearer if you realize that this would be ¼ = 0.25 if everybody has the same health. Thus, the inequality actually is 1.73/0.25 = 6.92. This is the same as the ratio of their averages (97/14 = 6.92). Now you can say that the health inequality between the top 10% persons and the bottom 40% is nearly 7 times. This value alone may not make much sense but would be extremely useful if you find varying values in different segments of population such as 5.81 for males and 6.56 for females, which reveals that females are more unequal with respect to health compared with males in this population.

## parallel controls, *see* controls

## parallel-line assays

These are situations in **bioassays** where the ratio of the response of the test preparation to the standard preparation is the same at each dose. For this purpose, response and/or dose may be in logarithmic term or any such transformation, called *metameters*, so that the **dose–response relationship** is linear. Parallel-line assays are most commonly found in the form of indirect analytical assays where the potency of the substance under test is observed in relation to the potency of a standard. Both test and standard preparations are used at several dose levels. If the number of dose levels of test preparation is $K_1$ and that of standard preparation is $K_2$, this is called $(K_1 + K_2)$-point assay and is symmetric if $K_1 = K_2$. The number of subjects for each dose can be any and can vary, but equal numbers help in easy interpretation. The underlying requirement is that the given doses of the test preparation will yield expected responses such as would be obtained from administering the standard preparations at doses that are ρ times the given test preparation's dose: ρ is known as the **relative potency**. When the expected response is assumed to be linearly related to the dose (or its transform), the graphs of expected response (or its transform) against dose metameter for the test and standard preparations will give parallel lines. In Figure P.1a, the relationship between response and dose is curvilinear but becomes linear (Figure P.1b) when dose is transformed to ln(dose).

With the help of the parallel-line model, the statistical validity of the following hypotheses can be tested:

- The dose–response (with or without transformations) relationship is linear for the standard and the test preparation.
- The dose–response line has a significant slope and not a flat line.
- The dose–response lines of the standard and test preparations are parallel. This means that the slopes of the dose–response relationship of both the preparations are the same.

For testing these hypotheses, the analysis of variance method is used to break between-doses **sum of squares** into components due to preparations, due to regression (slope), due to parallelism, and due to linearity. Each of these is compared with the within-doses sum of squares after dividing by the respective df's, and $F$-test is used for finding the statistical significance. For a proper parallel-line assay, the hypotheses of linearity and of parallelism must hold (not rejected), and the hypotheses of no slope and no difference in preparations must be rejected. When this happens, the relative potency

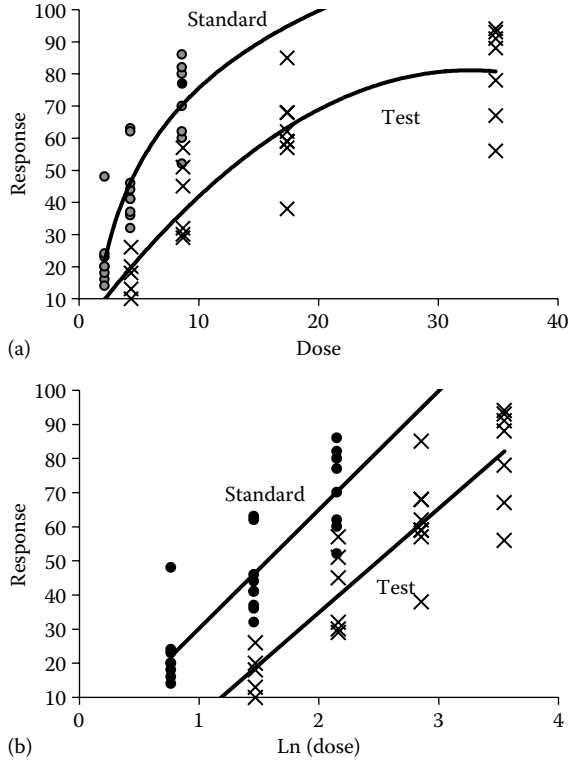

**FIGURE P.1** Graphical depiction of dose–response relationship: (a) curvilinear relationship becomes (b) parallel lines after logarithm of dose.

can be estimated as $\log\hat{\rho} = \left(\bar{x}_s - \bar{x}_t\right) - \left[\frac{\bar{y}_s - \bar{y}_t}{b}\right]$, where $\bar{x}_s$ and $\bar{x}_t$ are the average dose metameters of the standard and test preparations, respectively, $\bar{y}_s$ and $\bar{y}_t$ are the average response metameters in the standard and test groups, respectively, and $b$ is the common estimate of the slope of the dose–response relationship. The confidence interval for the **relative potency** ρ, which is a ratio, can be obtained by the **Fieller theorem**.

Deficiencies have been pointed out in the method we just outlined for detecting parallelism. Gottschalk and Dunn [1] have proposed a method based on chi-square, which is claimed to be more reliable and more appropriate. Parallelism required for the method just outlined may not hold in many situations because of effects such as partial agonism, differences in binding affinities, in vitro toxicokinetics, solubility, and sensitivity to environmental conditions as they can produce nonparallel dose–response curves [2]. To overcome such problems, Villeneuve et al. [2] proposed estimation of relative potency by multiple-point estimates over a range of responses in place of the single-point estimates.

Vieira et al. [3] report a (3 + 3) parallel-line assay for determining the potency of cefuroxime sodium in powder for dissolution for injection. See Collazo et al. [4] for an example of determination of potency of factor VIII in commercial concentrates.

## parametric models

A parametric model in statistics is the one based on a family of statistical **distributions** that can be described using a small number of **parameters**. For example, an ordinary **regression** model requires that the errors follow a Gaussian (Normal) distribution with mean zero and some variance $\sigma^2$. The mean and variance are the parameters that describe the Gaussian distribution—thus, the errors in ordinary regression follow a parametric model. Gaussian distribution not only requires parameter values but is also bound by a specific shape, generally recognized as a bell shape.

Contrast parametric models with nonparametric models, which are based on distributions that are flexible and not based on specific parameters. They may or may not have a general requirement such as symmetric or asymmetric pattern, monotonic or cyclic, and smooth or curvy. For example, a spline regression is nonparametric as there are no fixed parameters, and no specific shape of the distribution of values is required. A **logistic regression** model is semiparametric as it requires parameters but does not require any specific shape of the distribution. Nonparametric models tend to be computationally intensive and not as powerful in detecting a trend as parametric models could when their conditions are satisfied.

No **model**, whether parametric or nonparametric, is perfect. It is important to realize though that parametric models (i) are critically dependent on the "size" parameter, which can be very difficult to determine accurately in the early stages of a project; and (ii) can be highly sensitive in that small changes to certain key parameters can result in substantial changes in output estimates (see **butterfly effect**). Regardless of which model is used in a research, understand that all models are based on conventional wisdom, but parametric models are especially susceptible to the input parameters that can substantially change the resulting estimates; this is affected by the range of uncertainty encompassed by model parameters, called the **parameter uncertainty**.

Parametric models work well when the parametric assumptions are adequately satisfied; otherwise, they may be misleading, and these assumptions could be fairly strong. Thus, use parametric models only after thorough checking of the distributions and after being satisfied with the validity and reliability of the estimates of the parameters proposed to be used. For example, if a Weibull distribution is proposed to be used for the survival pattern of a set of patients, make sure that the Weibull rightly depicts the pattern and the parameter estimates you will obtain will adequately fit to the data you have. When this framework is deficient for the data in hand, parametric models have the likelihood to give fallacious results. On the other hand, if this framework is right for the data, parametric models may give much more valid results than the corresponding nonparametric models. The greatest rescuer of parametric models is the **central limit theorem** that says that the distribution of a linear combination of a large number of values tends to become Gaussian (parametric) as $n$ increases.

## parameters

In medical terminology, a parameter sometimes refers to a measurement or characteristic of a person or patient such as his/her glucose level. For example, some disease entities are based almost exclusively on a single *parameter*: diagnosis of anemia caused by iron deficiency is based on hemoglobin level; hypertension on blood pressure levels; diabetes mellitus on serum glucose level; and glaucoma on intraocular pressure. Other indications such as signs–symptoms play almost no role in the diagnosis of such diseases. Evidence exists that persons with statistically abnormal levels of these *parameters* do have an increased risk of the concerned morbidity and the associated mortality. An intervention, such as therapy, to bring the level back to the reference range helps to reduce this risk. Thus, medical parameters have extensive role in health assessments.

In statistical parlance, a parameter can be defined as a constant in a **model**, or a constant that wholly or partially characterizes a function or a probability **distribution**. The behavior of a model is governed by its structure or functional form and unknown quantities or constants of nature called *parameters*. A statistical goal of running the model might be to estimate the unknown parameters so that the model can be fully specified. If the model has been constructed in such a way that the parameters correspond to clinically interpretable effects, the model can then be a way of estimating the influence of such factors on the outcome. In practice, statistical models usually provide a concise way of estimating parameters, obtaining confidence intervals (CI) on parameter values, and testing hypothesis on them.

The parameters in a Gaussian (normal) distribution are the mean and the standard deviation, denoted respectively by $\mu$ and $\sigma$. These are the only two parameters that completely specify a Gaussian distribution. Without the values of these parameters, you will not be able to use this distribution for any worthwhile inference. Many statistical methods are devoted to finding the best estimates of such parameters because they are mostly not known. The binomial distribution has just one parameter, namely, the probability of success $\pi$, although it needs the number of trials $n$ also for full specification. The Poisson distribution also has just one parameter, namely, the mean $\mu$. On the other side, ordinary multiple linear regression equation $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 \ldots + \beta_K x_K + \varepsilon$, where $\varepsilon \sim N(0, \sigma^2)$, has $(K + 2)$ parameters of which $(K + 1)$ are the regression coefficients $\beta$'s (including $\beta_0$) and one $\sigma$. The last ($\sigma$) is the **nuisance parameter**—of no intrinsic interest for any research, although this is needed to assess the goodness of the model. Statistical methods are used to estimate these parameters, to find the CI on them, and to test the hypothesis about them. The same can be stated for logistic regression. Depending on the situation, the parameter of interest may be the correlation coefficient, odds ratio, relative or attributable risk, etc. Sample values are used to make an inference on these parameters.

## parameter uncertainty, *see* sensitivity analysis, parametric models

## parsimonious models

A parsimonious model can be said to be the simplest model that adequately describes the observed data. A model invariably is a simple representation of a complex process so that some information is necessarily and knowingly ignored. It is thus right to suspect all the models and investigate their parsimony. The concept of parsimonious models derives from the parsimony principle: among competing models, all of which provide an adequate fit for a given set of data, the one with the fewest parameters (the simplest) is preferred. In statistical models, parameters are usually unknown and have to be estimated—thus, it is preferable to work with as few unknowns as possible without losing the vital information. This approach is pragmatic and the objective is simplicity.

Also recognized as *Occam's razor*: "entia non sunt multiplicanda praeter necessitate," i.e., "One should not increase, beyond what is necessary, the number of entities required to explain anything." Occam's razor is a logical principle attributed to the fourteenth century philosopher William of Occam [1]. The principle states that one should not make more requirements than the minimum needed, and underlies all scientific modeling and theory building.

In any given statistical model, we try to rid ourselves of those concepts, variables, or constructs that are not much helpful in developing the model of interest (see the topic **variable selection**). For example, one can always draw a straight line through two data points that can tempt us to conclude that all further observations would lie on that line. However, one could also draw an infinite variety of the most complicated curves passing through the same two points, and these curves would also fit the empirical data just as well if there are only two observations. Occam's razor would, in this case, guide us in choosing the *straight* (i.e., linear) relation as the best candidate model. A similar reasoning can be made for any kind of model. But such simplification can be far from reality, and thus, the concept of parsimony requires that not losing vital information is also an important consideration.

More specifically, in regression, when the number of possible explanatory variables is large, a computer program can be used to identify and include only the statistically significant variables in the regression model. This is one of those situations where the testing of the hypothesis strategy as opposed to confidence intervals is preferred. Many algorithms can do this, but the following are commonly used: **stepwise** that includes forward selection and backward elimination, and the **best subset**. These methods can be used to get a feeling of what predictors may be empirically important, but a more realistic solution is based on their real biological worth, if extraneously available, instead of purely numerical optimization procedures such as these. You must ensure that clinically important variables are not excluded in the final model. None of these algorithms may yield the *best* model, and different algorithms may lead to different models, yet it is a good idea to examine several possible models. The final choice is based on interpretability, parsimony, and convenience in obtaining the data.

## partial correlation

In a multivariate setup, partial correlation is the measure of association between two quantitative variables, while controlling or adjusting for the effect of one or more of the other variables. When adjusted for just one variable, the partial correlation of $x$ and $y$ adjusting for $z$ can be calculated as follows:

$$r_{xyz} = \frac{r_{xy} - r_{xz} r_{yz}}{\sqrt{\left(1 - r_{xz}^2\right)\left(1 - r_{yz}^2\right)}},$$

where $r_{xy}$, $r_{xz}$, and $r_{yz}$ are the usual (Pearsonian) correlation coefficients between ($x$, $y$), ($x$, $z$), and ($y$, $z$), respectively; now better understood as *total correlations*, some call them simple correlations. For adjusting more than one variable, the formula is more complex. The variables used for adjustment are generally called covariates as these are not of primary interest. A partial correlation is also described as the correlation "after controlling for 'such and such' covariates." The controlled variables are stated after the dot in the subscript of the notation; for example, $r_{pq.rst}$ is the notation for the correlation between $x_p$ and $x_q$ after controlling $x_r$, $x_s$, and $x_t$. As for all Pearsonian correlations, partial correlation is valid for measuring the strength of only the linear relationship. Adjustment also is restricted to the linear effect. A partial correlation is generally contrasted with **multiple correlation**, which is the correlation between $y$ and its predicted value based on multiple linear regression on several regressors.

As with any correlation, there are hazards in interpreting partial correlations, especially when searching for causation. If changes in $x$ are associated with changes in a dependent variable, $y$, it is not necessarily clear why the changes in $y$ occur. Changes in $x$ may be a cause of changes in $y$, changes in $y$ may be a cause of changes in $x$, a third variable $z$ may be producing changes in both $x$ and $y$, or any combination of these possibilities may be true. One reason for this difficulty is the likely presence of **mediator** or **confounding** variables. A variable is confounding if it is related to both $x$ and $y$, making causal interpretations difficult. Mediating variables tend to enhance or reduce the correlation.

Consider the relation between body mass index (BMI) and ambulation time after a bariatric surgery. This may be affected by age, sex, duration of surgery, type of surgery, comorbidities, etc. Thus, the *net* correlation between BMI and ambulation time is obtained by removing the effect of these covariates. This is done by partial correlation. The total correlation (without any consideration of the covariates) may be 0.56 but could become 0.71 when the effect of the covariates is removed. The partial correlation can be more or can be less than the total correlation. However, as already cautioned, this adjustment is only for the linear effect. Let us also sound a cautionary note on the term *net* sometimes used for partial correlation: it is net only with respect to the covariates adjusted. Even when adjusted for all the covariates under study, it would still not be net in true sense since the adjustment can be made only for known covariates. Unknown covariates in epistemic domain continue to haunt the actual relationship.

Since the partial correlation $r_{xy.z}$ is a measure of the relationship between $x$ and $y$ keeping $z$ constant, if $r_{xy.z}$ is much smaller relative to $r_{xy}$, we can conclude that $z$ is a mediating variable. That is, $z$ may explain, at least in part, the observed relationship between $x$ and $y$. Although we talk about "explaining" the relationship based on correlations, we will not know what "causes" the relationship. Causal inference has much stringent requirements as discussed (see **cause–effect relationship**).

Partial correlation is encountered while using the statistical method of **factor analysis**. This analysis provides satisfactory results when multiple correlations of most variables are high, but partial correlations for most pairs of variables are low. This can be tested by using the **Kaiser–Meyer–Olkin measure**.

## partial least squares

The usual **least squares method** for estimating the coefficients in a **regression model** requires that none of the regressors has high correlation with any of the other regressors. When high correlations are present, called **multicollinearity**, this compromises the estimates of the regression coefficients in the sense that they tend to become less reliable. That is, the standard error of at least some of them would be unusually high. Partial least squares (PLS) method circumvents this problem and helps to obtain reliable estimates when multicollinearity exists. This also helps in a situation where the number of regressors is large relative to the sample size and the problem of overfitting occurs. The method has been seen to do well in **predictive models** but not necessarily in **explanatory models**. According to Tobias [1], the PLS method was developed by Herman Wold in the 1960s.

Consider an example of trying to predict the level of thyroid stimulating hormone (TSH) on the basis of signs and symptoms that are elicited anyway while examining a patient suspected to have hyperthyroidism or hypothyroidism. These signs and symptoms run into hundreds ranging from skin condition to trembling, brittle nails, and what not, and are the regressors. These also are highly collinear with each other. This exercise may be useful in a setup where laboratory facility for TSH is not available or is beyond reach. If there are only 80 cases, the usual multiple regression will not work since the number of regressors exceed 100 and they are collinear; the method of PLS may be helpful in this situation.

Similar to what is done in the principal components method of **factor analysis**, the PLS method tries to extract latent factors that account for the highest variation among the responses. These latent factors would be few but need to account for a large part of the variation for PLS to be successful. The extracted factors are used to predict factor scores, and these are, in turn, used to predict the response of our interest. The difference between the PLS and the principal components is that PLS uses the covariance structure between the response and the regressors, whereas the principal components method uses the covariance between the regressors alone. The PLS method is applied only after the regressors are standardized by subtracting the mean and dividing by the standard deviation (SD) that makes all the regressors on the same scale. Besides multiple linear regression, the method can also be used for **discriminant analysis** if similar constraints exist. An introduction to PLS is given by Tobias [1], and Naes and Martens [2] have provided further details.

Jiang et al. [3] used the PLS method for **age–period–cohort** analysis of body mass index in Ireland. You might be aware that there is redundancy in this analysis as two of age, period, and cohort determine the third. Thus, this is an appropriate setup for using the PLS method, although the number of regressors is not large in this case. Sousa et al. [4] used PLS-based discriminant analysis to demonstrate unsuitability of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry for bacterial typing for *Acinetobacter baumannii* clonal discrimination.

## partial likelihood

Cox [1] introduced the concept of partial likelihood in 1975 to obtain estimates of parameters of interest in survival analysis where an appropriate parametric form of the **hazard function** is often unknown and, in any case, is not of interest. The method of partial likelihood divides the **likelihood** into two parts—conditional and marginal. Only that part of the likelihood that contains the parameters of interest is maximized, and the part that contains the nuisance parameters is ignored. This does mean loss of information but becomes simple as the nuisance parameters are excluded. This also makes the method robust as the part of the likelihood does not have to be specified. Because of loss of information, the method does not provide as good results as the usual likelihood does, yet serves well in some specific situations.

A likelihood function usually depends on many parameters. Let the parameters of interest be denoted by θ and the parameters not of interest (nuisance parameter) by δ. For example, in a linear regression, interest typically lies in the regression coefficients and not in the error variance. The standard way to approach the estimation is to look for those values of both δ and θ that maximize the likelihood function. Since the primary interest lies in θ, the method of partial likelihood can be used to estimate θ without worrying about δ. A more technical explanation can be found in Armitage and Berry [2].

In survival analysis, the time to an event or failure (such as death) is recorded for each subject. If these are ordered as $t_1 \le t_2 \le \ldots \le t_n$ for $n$ subjects, then the partial likelihood function is derived by taking the product of the conditional probability of a failure at time $t_i$, given the number of cases that are at risk of failing at this time. In Cox regression, for example, where partial likelihood has the most pronounced application, the interest may be in this order, and the actual distribution of the survival times or of hazard can be ignored under some conditions. Since the hazard ratio is used in this regression, specification of the actual baseline hazard also is not needed.

## partitioning of chi-square and of table,
*see also* **chi-square—overall**

After a general conclusion is drawn regarding the presence of association in a contingency table by using the usual chi-square test, partitioning is used to obtain a focused conclusion regarding which particular category (or a set of categories) is causing the association. It is also possible that the overall chi-square test indicates no association, but partitioning reveals some association somewhere. We use the data in Table P.1 for illustrating partitioning of chi-square that shows the observed number of AIDS subjects with different blood groups (O, A, B, AB) from a population where these groups are in the ratio 6:5:8:1. These ratios provide $H_0$: $\pi_1 = 6/20 = 0.30$, $\pi_2 = 5/20 = 0.25$. $\pi_3 = 8/20 = 0.40$, and $\pi_4 = 1/20 = 0.05$. Expected frequencies are based on these probabilities. The objective is to find whether or not the blood group pattern in AIDS cases is the same as in the population.

In this example, df = $K - 1 = 4 - 1 = 3$. Calculations are also presented in Table P.1, which show $\chi^2 = 4.91$. A relevant statistical software package automatically compares the calculated value of $\chi^2$ with its known distribution for 3 df and gives $P = 0.178$. Thus, the value $\chi^2 = 4.91$ obtained for these data is not all that unlikely when $H_0$ is true. That is, the frequencies observed in different blood groups in the example are not very inconsistent with $H_0$. The sample values do not provide sufficient evidence against $H_0$ and so cannot be rejected. A preponderance of any blood group in cases of AIDS cannot be concluded on the basis of this sample when this method is used.

**TABLE P.1**
**Calculation of Chi-Square**

| | Blood Group | | | | |
|---|---|---|---|---|---|
| | **O** | **A** | **B** | **AB** | **Total** |
| Observed frequency ($O_k$) | 57 | 36 | 51 | 6 | **150** |
| Expected frequency under $H_0$ ($E_k$) | 45.0 | 37.5 | 60.0 | 7.5 | **150.0** |
| $O_k - E_k$ | 12.0 | –1.5 | –9.0 | –1.5 | **0** |
| $(O_k - E_k)^2/E_k$ | 3.20 | 0.06 | 1.35 | 0.30 | **4.91 = $\chi^2$** |

Examination of the data in this example reveals that the observed frequency in blood group O is much higher than expected from the pattern in the general population (57 versus 45), and the other differences are not as large. To find out that this really is so, check whether the pattern in blood groups A, B, and AB (combined) is nearly the same as expected, and then check the difference in blood group O. The corresponding null hypotheses are

$H_{01}$: A, B, and AB are in the ratio 5:8:1, and
$H_{02}$: $\pi_1 = 6/20 = 0.3$ for blood group O, $\pi_2 + \pi_3 + \pi_4 = 14/20 = 0.7$ for the other three groups combined.

The former ratio is the same as in our example, and the latter ratio combines A, B, and AB. Not stating $H_{01}$ in terms of π is deliberate because that might give rise to confusion. The sum of π's in all contingency tables should be 1, and therefore the same π's cannot be used for the three cells covered by $H_{01}$.

For these two null hypotheses, calculations for $\chi^2$ are shown in Table P.2. The division of the earlier four-cell table into two tables as shown is called **partitioning**. The first partition gives $\chi^2_{\text{I}} = 0.38$ with 3 – 1 = 2 df, and from a software package, $P = 0.83$ for this value of $\chi^2$. Since it is more than 0.05, $H_{01}$ cannot be rejected at 5%

**TABLE P.2**
**Partitioning of Table P.1 and Calculation of Partitioned Chi-Square**

| | Blood Group | | | |
|---|---|---|---|---|
| **I.** | **A** | **B** | **AB** | **Total** |
| $O_k$ | 36 | 51 | 6 | **93** |
| $E_k$ | 33.2 | 53.1 | 6.6 | **93** |
| $(O_k - E_k)^2/E_k$ | 0.23 | 0.09 | 0.06 | **0:38 = $\chi^2_{\text{I}}$** |
| | **Blood Group** | | | |
| **II.** | **O** | | **Others** | **Total** |
| $O_k$ | 57 | | 93 | **150** |
| $E_k$ | 45.0 | | 105.0 | **150** |
| $(O_k - E_k)^2/E_k$ | 3.20 | | 1.37 | **4:57 = $\chi^2_{\text{II}}$** |

level of significance, i.e., the evidence is not sufficient to conclude that the pattern of blood groups A, B, and AB in AIDS cases is not the same as in the general population.

Part II of the table has only two cells, so $\chi^2_{II}$ has only one df. This gives $\chi^2 = 4.57$ and $P = 0.033$. Being less than 0.05, this is statistically significant, and it can be concluded without much chance of error that the pattern in part II is not the same as in the general population. Since the categories now are blood group O versus the others, it can be safely concluded that blood group O is *more* common (note that the observed frequency 57 is more than the expected 45) in AIDS cases. Nothing specific can be said about the other three blood groups.

The conclusion reached after partitioning is different from the one reached earlier when all the cells were considered together. This is because the lack of difference in A, B, and AB groups masked the difference in the O group also. Partitioning helped to uncover this difference.

Note the following: When $n$ is large, the values of $\chi^2_I$ and $\chi^2_{II}$ based on the partitioned table should add *approximately* to the overall $\chi^2$ based on all the cells. In this example, $\chi^2_I + \chi^2_{II} = 0.38 + 4.57 = 4.95$, which is only slightly different from 4.91 obtained earlier when all four cells were considered together. For this reason, this is also called partitioning of chi-square.

## partogram

A partogram is used by midwives in field conditions, especially in developing countries, for preventing prolonged labor in childbirth. Progress of labor is recorded in a graph in terms of cervical dilation against time. Observations are recorded at regular time intervals, say, every hour. The partogram contains an alert line and an action line (Figure P.2).

Crossing the alert line is associated with fetal distress. Neonatal resuscitation is more likely if the alert line is crossed. If the action line is also crossed, the chances of stillbirths are higher. The function of a partogram is to provide early warning for detection of abnormal progress of labor. Dujardin et al. [1] found the partogram useful and efficacious in a study in Senegal. Less postpartum sepsis was reported [2] after implementation of the partogram in a multicenter trial done in Indonesia, Malaysia, and Thailand.

## path analysis

Path analysis works on the correlations of each predictor with the outcome in observational studies and decomposes them into two components: (i) due to direct effect and (ii) due to indirect effect through another predictor, such as of body mass index (BMI) through diet. Thus, a path is traced through a diagram as illustrated in Figure P.3 for the size of prostate and other factors. This helps in investigating the interrelations of the variables and tries to segregate causation from mere correlation. However, a causation model must be postulated for path analysis to work. Although the target may be one particular variable, all other variables are also considered stochastic in this setup, as opposed to regression where only the target variable is stochastic and the regressors are considered fixed. The observed correlations are considered fixed in path analysis in the sense that whatever values of correlations are obtained, they are taken on face value without worrying about the measurement errors.

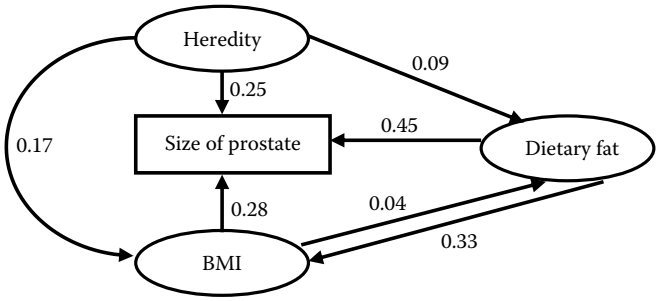

**FIGURE P.3** Example of path analysis of size of prostate affected by heredity, dietary fat, and BMI.

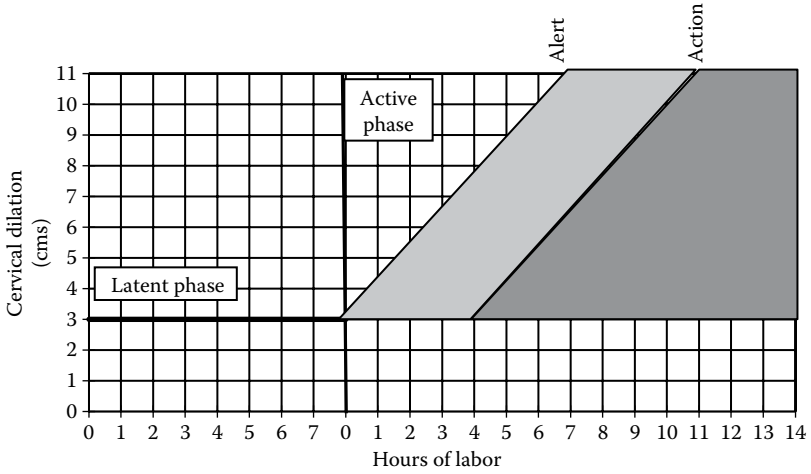

**FIGURE P.2** Partogram.

Despite its strength, path analysis cannot prove causation and its direction—it is just indicative. It provides a good graphical depiction of the extent and direction of the relationships on the basis of the correlations, and highlights the role of **mediators and moderators**. Note that this kind of exercise is not needed in experimental studies since there the design is such that causation comes up upfront anyway.

For example, in a study of the role of heredity, diet, and obesity on the size of the prostate gland, the first method of choice is ordinary regression, provided they are all quantitative. Suppose a heredity score can be developed on the basis of the proportion of male family members who have had prostate problem, diet measured for fat content, and obesity quantified by BMI. Ordinary regression may tell you, for example, that the net effect of heredity on determining the size of prostate is 12%, that of diet is 20%, and that of BMI is 15%, but the role of obesity through diet would remain obscure because diet and BMI are related. The results of path analysis can resolve this complexity as shown in Figure P.3 for this example.

Arrows and quantities in Figure P.3 indicate that heredity is not affected by any of the predictors considered in this figure, but it is affecting both fat intake and BMI—almost twice (0.17) as much BMI as fat intake (0.09). BMI has little effect on dietary fat (0.04), but fat has substantial (0.33) effect on BMI. Fat intake affects the size of prostate (0.45) more than BMI (0.28) does, whereas the effect of heredity (0.25) and BMI (0.28) is nearly the same. These values are path coefficients and interpreting them as "effects" is not necessarily appropriate, although that is how the literature describes the results of path analysis.

The path diagram is already looking complex with only three predictors in this example, and it can become difficult to comprehend if there are more predictors. It is for the researcher to postulate a right model for path analysis. In this example, the postulation is that the size of prostate is affected by dietary fat, BMI, and heredity, and nothing else. If the postulated model is wrong, correct results cannot be expected. Path analysis only provides an algorithm for decomposing the effect into direct and indirect within the postulated model, although one can test how well the postulated model fits to the correlation structure. As in the case of regression, a good fit does not preclude other models with better fit. Secondly, in Figure P.3, ovals are used for *regressor* variables and rectangle for the dependent variable. Sometimes ovals are reserved for latent traits when those also are considered.

The actual mathematics of path analysis are intricate and beyond the scope of this section, but they can be undertaken by a suitable statistical software package that uses various path models such as direct, independent, recursive, and nonrecursive. The above brief is just to apprise you of situations where path analysis can be tried, and the type of results expected from this analysis.

As mentioned earlier, path analysis requires each variable to be quantitative. The variables must be actually observed so that their measurements are available. If some variables are qualitative and others are unobserved underlying traits, also called latent traits of the type seen in factor analysis, **structural equation models** (SEMs) may be appropriate as they consider all these aspects and find out which variable should leave free and which of the others should be constrained or fixed. SEM assumes that the observed correlations are subject to measurement errors—path analysis does not. Details of path analysis and structural equation modeling are given in Loehlin [1]. A good example of where path analysis has been used is given by Tae et al. [2] on depression in Korean women with breast cancer–mediating effects of self-esteem and hope.

## pattern recognition

Pattern recognition is the area of research that deals with the operation and design of systems that recognize patterns within a set of data. Pattern-recognition technology is changing the way we do things as it is being used to evaluate, for example, speech, fingerprints, handwriting, and images, giving valuable insights with useful application to health and medicine as well.

While pattern recognition in its purest form is only possible using the human eye and a discerning mind, a computer system designed for the purpose is extremely useful and is very quick. When properly programmed, such a system can be relied on to provide consistent results. Validity, however, will depend on whether adequate dimensions of the problem have been visualized and properly accounted for in the program. This system is put through a training phase, and key known patterns are run through the program. The program initially guesses the answers; each guess is labeled correct or not correct, thus giving weights to the possible answers. The more weight assigned to an answer, the more the program will recognize the weighted pattern as the one it has been directed to find.

In clinics, physicians often learn to recognize disease patterns by knowledge and experience. A patient may present with a number of symptoms that all point to one disease, or they may not be so specific. Lacking expertise, the physician might create a differential diagnosis that is too large, or too small, and without assigning correct probabilities to the various potential diagnoses. Eventually, the physician learns to quickly determine the most likely diagnosis based on known disease patterns and as seen in a clinic by him or her. It is important, though, that the physician does not become sloppy and superficially misinterpret patterns by rushing to a diagnosis. A computer-aided diagnosis (CAD) can help in this respect.

CAD programs use pattern recognition methods to examine signs–symptoms, radiological images, and laboratory investigations for typical disease patterns. Each of these investigations should ideally have disease-specific definitive pattern for pattern recognition to be successful. The number of parameters for assessment may be huge, perhaps many more than a human mind can comprehend in one go, but that is not an issue with the present-day technology. In so doing, CAD allows one to spot possible patterns more quickly than by examining all the information manually.

Several types of reasoning are used by physicians during the diagnostic process: pattern recognition, algorithmic (using flow charts and algorithms) arguments, hypotheticodeductive (generating and rejecting hypotheses as more data are collected), exhaustive (gathering every possible piece of data to make the diagnosis), etc. Each is appropriate for certain situations and inappropriate for others. These are mostly done inadvertently in mind than on paper. Pattern recognition is an important ingredient and can be formally done using established methods. An example from the current literature is the article by Tiwari and Bhargava [1] for digital cancer diagnosis from chemical imaging data.

Statistically, **cluster analysis** is the method for pattern recognition in the data. This method groups subjects in clusters such that

the clusters are internally homogeneous and externally isolated. Several methods of **hierarchical clustering** are discussed in this volume such as average linkage, single linkage, and complete linkage. Farshad et al. [2] studied polymerase chain reaction–restriction fragment length polymorphism pattern for the gene of *Shigella sonnei* strains isolated from children with bloody diarrhea in Iran using the cluster analysis method.

## Pearsonian correlation, *see* correlation coefficient (Pearsonian/product–moment)

## pedigree charts

Pedigree charts show ancestry, sibship, and progeny after arranging them in an organized manner. They are used by those interested in examining family tree to research the effect of heredity. This chart enables scientists to better understand the role of heredity and to make choices for manipulating future breeding that preserve or select specific strains. Information about the trait of each person of the selected families is charted for two, three, or more generations. Appearances (phenotypes) are used to study the genotypes. If the pedigree chart is about a particular individual patient, the chart will list that patient's parents, grandparents, and other known ancestors, as well as children and grandchildren if present, besides siblings in some situations.

Pedigree charts are commonly used for studying genetic diseases. One example is shown in Figure P.4 [1]. The pattern in such a chart helps to identify a trait as autosomal dominant or recessive since a dominant trait (e.g., familial hypercholesterolemia) shows a vertical pattern of inheritance (parents and children affected), whereas the recessive traits (e.g., beta thalassemia) show a horizontal pattern of inheritance (siblings affected). Males are represented by squares and females by circles, just in case the trait is sex-linked. Affected persons are represented by filled squares or circles and unaffected ones by hollow squares or circles. Carriers are represented by half-filled and half-hollow squares or circles. Pedigree charts can help to investigate X-linked disorders such as hemophilia A and color blindness.

Dwivedi and Aggarwal [2] studied pedigree charts of index cases of coronary artery disease (CAD) in India and forwarded the hypothesis that an individual's genetic profile functions as soil while various environmental factors such as physical inactivity, smoking, stress, etc. act as seeds in the etiopathogenesis of CAD. Another example is given by Pour-Jafari et al. [3] on oculocutaneous albinism Type1A (OCA1A) in an Iranian family.

## penalized likelihood, *see* Akaike information criterion (AIC) and general AIC (GAIC)

## percentiles and percentile curves, *see also* growth charts

Percentiles are the values of the variable that divide the total number of subjects into ordered groups of 100 divisions. This is a form of **quantile**. See that topic for details of how it is calculated. For $n$ = 200 subjects, 35th percentile = (35 × 200/100) = 70th value after ordering from minimum to maximum.

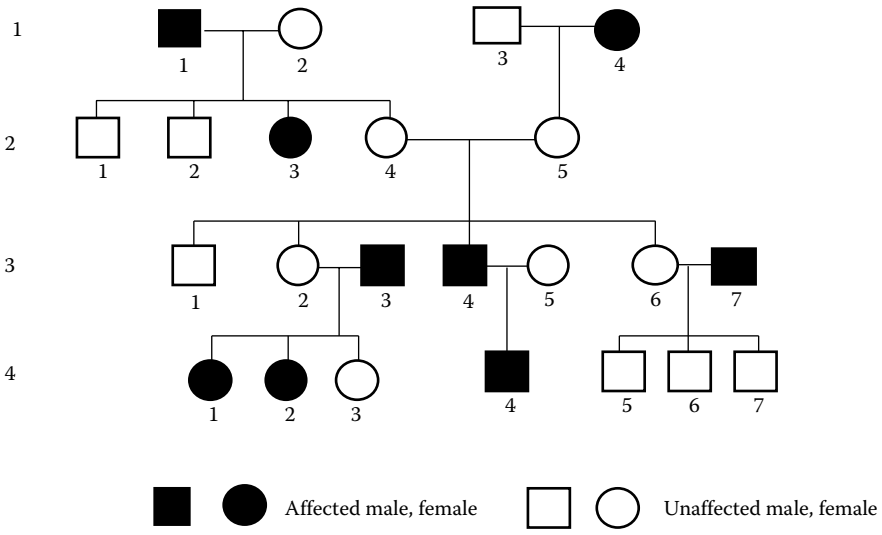

**FIGURE P.4** Pedigree chart.

Note that percentiles are very different from percentages. For example, the 90th percentile of esters in cholesterol could be 58%. This means that 90% of the people have esters less than or equal to 58%. Although theoretically we can have a 99.9th percentile, practically the highest is 99th percentile (better than 99%). No one is ever 100th percentile. Another feature worth noting for all quantiles, including percentiles, is that quantile of $(x + y) \neq$ quantile of $x +$ quantile of $y$. This needs to be understood in the context of mean since mean$(x + y)$ = mean$(x)$ + mean$(y)$.

A common use of percentiles is in growth charts of children for dimensions such as weight, height, and head circumference. Each can be assessed against age or against each other. See the topic **growth charts** for details and Figure P.5 for illustration. This shows various percentiles of height and weight of US girls at different ages from 0 to 36 months. Such charts use percentiles based on measurement of a large number of healthy children at each age and sex. The 50th percentile is like the median that can be used as a reference, and the 3rd and 97th percentile curves are often taken to define the lower and upper limits for healthy growth.

A good use of percentiles is in assessing the risk of heart disease in those who were thin at birth but gained weight fast—that is, initially at the lower percentile then became a part of the higher percentile in a matter of a few years—a phenomenon called *crossing the centiles*. There is a growing evidence that such children are at a greater risk of coronary heart disease [2].

Drawing percentile curves in these charts is not as simple as it looks. Intricate methods such as **LMS** and **BCPE** are used to calculate percentiles depending on the skewness and kurtosis in the data. Smoothing is done by **spline** functions, and measures such as **Akaike information criterion** are used to test the goodness of fit. The objective of all this complex methodology is to come up with valid percentile values and to obtain a trend that is close to the actual pattern of growth without missing any age of real slow or fast growth.

## periodogram

A periodogram is a plot of the behavior of a **time series** when broken down to different periods. The assumption behind this is that most time series tend to repeat the behavior of low and high values after certain periods of time, although there may be an increasing or decreasing secular (long-term) trend. Thus, a time series can be viewed as the sum of waves with different amplitudes and frequencies. This oscillatory behavior may occur once a day (circadian rhythms), once in four weeks (menstruation-related parameters), once a year (seasonal diseases), once in 6 years (influenza epidemics), etc. For some medical measurements, such periodicity is not known or is quite fuzzy. For example, this can happen in a patient with irregular heartbeats. A periodogram can help in extracting information on the dominant periodicity.

A periodogram estimates a particular behavior of time series, called spectral density, versus the frequency, where the latter is explored for all possible segments. It can identify the more common frequencies or the most common one. In simple terms, *spectral density* can be understood as proportional to the squared correlation between the observed series and waves with frequencies $r/n$ ($r = 1, 2, \ldots, n$). If there are $n$ values in the series, frequencies under examination would be $1/n$, $2/n$, $3/n$, etc. Generally, only the first few frequencies are examined. A peak in the periodogram indicates that an oscillation component exists near the frequency value corresponding to the peak. Some periodograms may exhibit multiple peaks—one dominant and the other recessives.

Consider brain cortex activity measured 128 times every 2 s for 256 s when a stimulus was applied for 16 time periods (of 2 s each) and not applied for another 16 time periods (of 2 s each). A time series plot of this (Figure P.6a) follows a regular pattern that seems to repeat about every 30 or so time periods in this example [1]. This is not surprising as the stimulus was applied in this fashion, and a repeating pattern every 16 + 16 = 32 time periods is expected. The periodogram (Figure P.6b) shows a dominant spike at a low frequency. It is hard to judge the exact location of the peak, but exact values reveal that the peak value of the periodogram corresponds to a frequency of 0.03125. The period for this value = 1/0.03125 = 32. That is, it takes 32 time periods for a complete cycle, as expected [1].

The example just mentioned is only to illustrate the features of periodogram, but the results were on expected lines because of the way the measurements were taken. In practice, the oscillations would not be easily discernible, and a periodogram can help in locating a common frequency if it exists.

## perinatal mortality rate/ratio, *see* mortality rates

## permutation tests

Permutation is the rearrangement of available values into distinct sequences. It is different from bootstrap because permutation is without replacement. Different permutations of the sample values to different groups allow us to compute the sampling distribution of a statistic in situations where it is too complex to find mathematically. This complexity occurs when the requirements of the regular sampling distributions are not met, such as when the values have not come from an established distribution (e.g., Gaussian or exponential), or the sampling scheme is too complex and does not fall into known models.

A permutation test is a statistical method of testing hypotheses based upon all potential permutations of subjects to groups. This test assesses whether, under the null hypothesis of no difference among groups, chance might account for the observed difference(s) in the samples. Say that we have a one-way analysis of variance (ANOVA) design with $K$ groups. If the null hypothesis is true, observations are just as likely to fall in one group as in the other. So we can permute the observations across the groups, calculating an $F$ value for each permutation. Repeat these steps approximately 5000 times, and calculate the percentage of repetitions in which the calculated $F$ values exceed the $F$ value obtained from the original data. This will give the $P$-value under the null hypothesis. This is a nonparametric procedure as this does not require any specific pattern of the distribution of values and is also called *randomization test*. A permutation test is exact when all possible permutations are considered.

There is a need to review the requirements underlying this approach. With observational studies, it is clear that we cannot randomly assign subjects across the groups. So we must assume that the observations are *exchangeable* in the sense that it is reasonable for a value to fall in either group under the null. This is the case if observations are statistically independent and if errors come from the same distribution, i.e., if they are identically and independently distributed.

This is straightforward with a one-way ANOVA as illustrated but not so with a two-way design because it is not always obvious what should be permuted and over what cells the permutation should take place. Also, there may be an interaction between the factors in a two-way experiment that could disturb in case of random permutation. In addition, permutation tests are computationally intensive, and they generally do not have as much statistical **power** as the regular tests when the conditions of the regular tests are fulfilled. Thus, permutation tests are recommended for only those setups that do not meet the established distributional requirements.

## personal probability, *see* probability

## person-time

It is sometimes not possible to observe each person in a **cohort** for the same duration. Also, the duration of exposure may vary from subject to subject. For example, persons in a stressful environment for different periods may be observed for incidence of peptic ulcer disease. One person may be under stress for 12 years, another person for 5 years, another one for 8 years, etc. These durations are totaled and called *person-years*. If the $i$th person is exposed for $x_i$ years, then

$$\text{total person-years of exposure for } n \text{ persons} = \Sigma x_i;\ i = 1, 2, \ldots, n.$$

This can be used as a base for the calculation of incidence per year of exposure or can be used as stand-alone for various indexes or scores, although there are limitations as mentioned later in this section. For example, for assessing smoking, cigarette-years are used as a stand-alone indicator as a measure of exposure to smoking, and for risk of diseases, it would be cases per 100 person-years of exposure. That is,

$$\text{incidence rate per 100 person-years} = \frac{\text{new cases occuring in the observed period}}{\text{person-years observed}} * 100.$$

In this setup, a uniform follow-up is not needed to calculate the incidence rate, although a follow-up is required in any case. The multiplier in the formula given in the above equation is not necessarily 100 and can be chosen per convenience.

Person-years is the most frequently used form of person-time, but this could also be calculated in terms of person-months, person-weeks, etc. For example, in the case of use of oral contraceptives, person-months are used, and incidence of a complication or of pregnancy is calculated per 100 person-months of use. For incidence of acute respiratory virus infections after an intense exposure, the follow-up may be a few weeks, and then the incidence will be worked out per 100 person-weeks.

The concept of person-time is valid only when the initial period is as important or as unimportant as the later period, and only if cumulative exposure is what matters and not the actual duration. In the case of a complex surgery, the risk of death in the first few days or weeks could be very different from the subsequent period when the patient stabilizes. In such a situation, person-time can lead to misleading results. A blatant and common misuse of the person-time tool is in calculating smoking exposure in terms of **pack-years**. Pack-years for a person smoking 2 packs of cigarettes a day for 5 years is the same as for a person smoking 1/2 pack a day for 20 years. Both are 10 pack-years. Intensity of smoking as measured by the number of cigarettes per day may have different implication as compared to duration for, say, incidence of cardiovascular disease. This is ignored when pack-years is used as done by Chatkin et al. [1] for assessing abdominal fat in smokers. Green et al. [2] reported incidence of primary outcome (cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, or hospitalization for unstable angina) per 100 person-years of follow-up in patients of type-2 diabetes and cardiovascular disease to determine whether sitagliptin was noninferior to placebo when the patient follow-up was nonuniform with a median of 3 years. This is valid only if the incidence of outcome has nothing to do with the duration of follow-up.

## pharmacokinetic parameters ($C_{max}$, $T_{max}$) and pharmacokinetic studies, *see also* area under the concentration curve (AUC curve), half-life of medications

Pharmacokinetics is the study of the movement of drugs in the body arising from absorption in the first phase, distribution in the second phase, and elimination in the last phase due to metabolism and excretion.

In order to undertake a pharmacokinetic study, the concentration of a drug in the body (mostly plasma or serum) is measured at a series of time points after ingestion to find how much is in the body and how much has been metabolized or excreted. Different drugs take different times to reach the peak concentration and its clearance. Thus, the primary presentation of pharmacokinetic data is the plot of concentration versus time—called the concentration curve. Sometimes the logarithm of concentration gives a more amiable picture. **Area under the concentration (AUC) curve** is just about the most important statistical parameter used to assess the

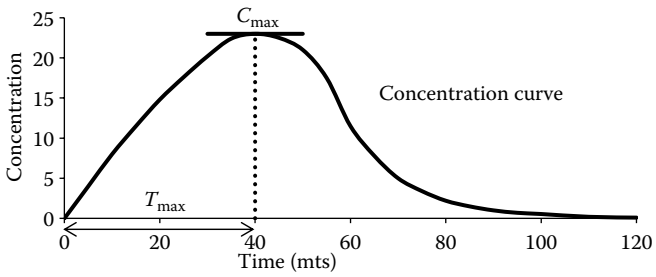

**FIGURE P.7** Concentration curve, peak concentration ($C_{max}$), and time to reach peak ($T_{max}$).

mechanical property of the drug that measures the total amount of drug that got into the body. Biological property is in terms of the efficacy and the side effects. Other pharmacokinetic parameters are peak concentration ($C_{max}$), time to reach peak concentration ($T_{max}$), and **half-life** that characterize the absorption phase. AUC curve and half-life are separately explained, and $C_{max}$ and $T_{max}$ are illustrated in Figure P.7. These parameters can be empirically estimated by drawing a concentration curve as in Figure P.7, where $C_{max}$ = 23 (in whatever units) and $T_{max}$ = 40 min. The elimination phase can take one of several forms, but generally, elimination is proportional to the existing level in the plasma/serum. This leads to exponential decline that converts to linear form in logarithmic units.

If there are 10 subjects for a study on pharmacokinetic properties of a drug, these parameters are obtained for each subject, and mean standard deviation are calculated as usual. The concentration curve can also be based on the average of these subjects, but that, as any average, can mask important age–sex and other variations that could tell a lot more about how drug works in different groups of subjects. Thus, analyze relevant groups separately if the number of subjects is adequate for this division. This may also be obtained separately for patients with mild disease than for patients with a severe form of disease, and may also be studied to depend on nutritional and other characteristics of the subject. If that is what you are interested in, a concentration curve should necessarily be drawn for each subject separately, and the area or any other parameter can be studied for the factors influencing these parameters by statistical methods such as **regression**.

Although the concentration curve empirically will be like a polygon with lines joining different points, it may be useful in some situations to model this as a smooth curve by means of an equation. That could be postulated as the population average. The population does not have to be the general population but can be restricted as always in statistics to a specific segment or specific type of cases.

An important use of pharmacokinetic parameters is in assessing **bioequivalence** of two or more drugs. You may be aware that this is generally assessed in terms of AUC curve and $C_{max}$. AUC can be misleading as two very different curves can give the same area.

For more details and pharmacokinetic models, see Ratain and Plunkett [1].

## phases of (clinical) trials

Drug development is a complex process and requires a lot of research and extreme care. Before trying it on human subjects, the biochemical properties of a new drug are studied in a well-equipped laboratory, and then experiments are undertaken on a suitable animal model. Only after success at these two preclinical phases does the drug go into clinical trial. At clinical stage also, it is generally divided into phases. The purpose of phasing is to gradually increase the exposure and plough back the learnings while proceeding to advanced stages. This allows the developer and the regulatory authorities to supervise the development of the drug effectively. Details are provided later in this section, but in a nutshell,

- The focus of phase I is to assess the safety (tolerability) of the new drug by running a small clinical trial with graded doses on healthy volunteers (except when the nature of the drug precludes its administration to healthy subjects).
- Phase II determines the optimum dose and assesses the efficacy of the new drug in treatment of the target disease/condition.
- Phase III is a large comparative clinical trial to demonstrate the safety and efficacy of the new treatment with respect to the standard treatments available. This is needed to support product license applications.
- Phase IV is surveillance after the drug is released into the market.

The basic features of various phases of a clinical trial can be described as follows. Although these phases are used in some other setups, all these phases must be conducted with convincing success for developing a new therapeutic regimen. Such phasing is sometimes waived for a therapy or its variation that is already in use for some other condition, and the trial is conducted to examine its use in a new set of conditions.

### *Phase I Trial*

Phase I is usually undertaken on healthy human volunteers to study the pharmacologic properties of the regimen, such as concentration–time profile, food interaction, toxicity, and major side effects, and most of all to delineate the maximum tolerated dose. Thus, dose escalation may be done in this phase. It may not be easy to find volunteers for this phase of trial except courageous, healthy people who agree to participate for some compensation. The compensation should be proportional to the expected discomfort and not excessive that could be frowned upon as coercive or as unnecessary inducement. Except for regimens for diseases such as cancer that compromise tolerance, healthy subjects are preferred in this phase because therapeutic efficacy is not an issue at this stage. This phase generally needs less than 20 participants for each dose. A large number are not desirable since serious ethical issues arise due to the perils that volunteers may face. There is no control group in this phase.

If diseased cases are included for some specific reason, see that their varying severity does not affect the outcome. Since comorbidities can spoil this phase, it is necessary to rule out not only symptomatic diseases but also asymptomatic conditions such as low hemoglobin level and high triglyceride level so that the side effects are not unfairly attributed to the drug.

### *Phase II Trial*

Phase II of a trial is conducted on patients for whom the test regimen may be eventually indicated. The objectives of this phase are to (i) get an initial idea of potential clinical efficacy, (ii) assess short-term incidence of side effects, (iii) identify a dose schedule for various kinds of cases (such as for mild, moderate, severe, or for children and adults), (iv) investigate interaction with other drugs or effect of comorbidities, and (v) collect further pharmacologic data.

Phase II also establishes or refutes that the new regimen is likely to meet at least the minimum level of efficacy. If this level is not met, there is no use pursuing the regimen any further. This is a crucial phase that really establishes whether or not the regimen is likely to be clinically useful. Thus, it also provides the *proof of concept*. The number of participants in this phase is generally 100–200 and may be in a randomized trial mode with a control group on the pattern of a phase III trial.

Phase II can help in learning more about the treatment regimen and about the type of patients and kind of symptoms for which the treatment is beneficial. An appropriate dose and the appropriate subjects are identified for the phase III trial. Phase II may have to be stopped early if the regimen is found beyond tolerance in patients and serious side effects are seen. Failure of phase II may help to identify the problems with the regimen, which may indicate a need to go back to the basics for improving the formulation.

When interpreting the results of a phase II trial, keep in mind that the efficacy and toxicity might be interdependent. Thus, the error rate may be higher than that apparently obtained by considering them independently. In this phase, comorbidities are generally not excluded because applicability would suffer; sometimes subjects with potentially interacting comorbidities are intentionally included to avoid confusion. Comparison of efficacy and side effects in patients with and without comorbidities helps in defining the exclusion criteria for phase III trial.

### *Phases IIA and IIB*

There are times when there is a need for even more refinement in the development process by dividing phase II into phase IIA and phase IIB. For example, vaccine trials need even more precaution due to the applicability of vaccines to a large segment of populations who are not sick but are at risk, as opposed to therapeutics that is applied only to patients and administered under close supervision. A feature of vaccines is immunogenicity, which might be an important consideration in some diseases, in addition to protective efficacy. In other diseases, duration of protection may be important. Quality and quantity of immune responses required for protection against infection and against development of disease are scientific challenges. In the case of HIV, for example, there would be a vaccine that inhibits HIV infection, and there could be another that inhibits or retards development of disease—AIDS—in those already infected.

In view of the complexities involved in vaccine trials, an additional phase called phase IIB is sometimes advocated. This is also called the *test of concept* phase. The aim of phase IIA could be to establish the schedule of administration for different age groups as it would be most likely a factorial experiment with dose level as one factor and age group as the second factor. Thus, four phases are required for vaccine trials instead of the usual three for other regimens. The objective of phase IIA is to evaluate whether the vaccine has any efficacy at all, and in phase IIB, this objective shifts generally to at least 30% efficacy. The participants in phase IIB are not necessarily representative of the target population, whereas a representative sample is strongly indicated for phase III. Phase IIB also assesses the operational efficiency, whereas the objective of phase III is to produce compelling evidence of efficacy.

### *Phase III Trial*

The stage is set for a phase III trial once the early trials establish the overall safety of the regimen, its basic clinical pharmacology, its therapeutic properties, and its most important side effects. There must be a valid parallel control group and allocation of subjects fully randomized in this phase to various **arms of the trial**, including the control. For this reason, this is called a **randomized controlled trial** (RCT). The control arm should ideally get the best available treatment or, if no treatment is available, a placebo. Selection of the right cases and the appropriate controls, and randomization are important for this phase as it is through these that a phase III trial can provide compelling evidence of the efficacy and safety of the regimen or lack thereof. When benefits are explored, proper assessment of harm is equally crucial. In fact, these days, safety is an overriding consideration in many trials, particularly when efficacy of the existing regimen is already exceeding 80%. Phase III is also a prerequisite to meet the regulatory standards of license; for this reason, they are sometimes termed as *pivotal* studies.

For a vaccine, a phase III trial has to be on a larger scale so that adequate numbers developing the outcome, particularly in the control group, are available. The outcome may be in terms of immunogenicity and not necessarily the disease. Nevertheless, the total number of subjects may run into thousands, and the follow-up too may go for a long time. Since phase III is an expensive trial for vaccines, phase IIB becomes a highly desirable proposition for indicating whether or not to proceed to phase III. Phase IIB, however, increases the time frame because this too can take at least a couple of years.

### *Phase IV*

Phase IV are postmarketing studies after the drug has received the approval of the regulatory agency. For details, see **postmarketing surveillance**.

## phi coefficient, *see* association between polytomous characteristics (degree of)

## physical quality of life index, *see also* quality of life index

This is a composite index for measuring the quality of life at the *community level* by combining measures of child mortality, longevity, and education. These three are considered the cardinal components that govern the quality of life at the macro level. Note that these are the outcome indicators and not the inputs to the system. Thus, physical quality of life index (PQLI) measures performance or achievement rather than the resources. The components of PQLI reflect that the quality of life in less-developed countries is simply a "work-in-progress" version of that in industrialized countries. Comparison across countries or populations is considered valid since the same set of indicators is used. Morris [1] proposed PQLI in 1978.

At the individual level, the quality of life is mostly the subjective component of well-being. It can be defined as a composite measure of physical, mental, and social well-being as perceived by each individual or by a group of individuals. It includes aspects such as happiness and satisfaction as experienced in life, for example, in health, marriage, finances, education, and creativity. The quality of life can be evaluated by assessing a person's subjective feeling of happiness or unhappiness about various concerns of life. Attempts are made to reach one composite index by combining a number of health indicators.

The PQLI at the community level consolidates three community level indicators, namely, infant mortality, life expectancy at age 1 year, and literacy. Life expectancy considered for this index is at 1 year instead of the usual "at birth" since infant mortality is already included as a separate indicator. For each of these three components, the performance of individual countries or communities is placed on a scale of 0 to 100, where 0 represents an absolutely defined worst performance and 100 represents an absolutely defined best performance. This is similar to how the **human development index** (HDI) is derived and is called **normalization**. In the case of *positive* indicators of life expectancy and basic literacy, the best is shown by the maximum and the worst by the minimum. In the case of infant mortality, which is a negative indicator, the best is denoted by the minimum and the worst by the maximum. These are normalized as follows: achieved level = |minimum value – actual value|/(maximum value – minimum value). The composite index is calculated by averaging these three normalized indicators, giving equal weight to each of them so that each of these three receives equal importance. The resulting PQLI is also rescaled 0 to 100.

As just mentioned, PQLI can be compared over populations and over time to find the difference from one population to another and from time to time, but has been criticized since the three indicators are closely related to one another [2]. The index value has been found to be relatively high for some countries such as Sri Lanka that do not have high income—thus, it does provide an alternative way to look at development away from just income. The index is used more for assessment of social health than for physical health. An example of the use of PQLI in the Philippines is given by Disanayaka and Danuningrat [3].

## PICO method, *see* population, intervention, comparison, and outcome (PICO) method

## pie diagram (exploded and wedged)

A pie diagram is a circular diagram divided into segments, each segment representing proportion in a category of the "whole." If the frequency in a category is $f_k$ out of $n$, the angle of the corresponding segment is $(360^* f_k/n)^\circ$. It is necessary that $\Sigma f_k = n$, that is, the categories must be mutually exclusive and exhaustive. A pie diagram cannot correctly display a **multiple response**.

As in the case of a histogram, percentages can replace frequencies in the case of a pie diagram also. In addition, the categories can be nominal or ordinal, which are not admissible for a histogram—thus increasing the scope of a pie diagram. Grouping of continuous data, as in the case of a histogram, is also required for a pie diagram if not already present, but discrete data may or may not be grouped. This means that a pie can be drawn for all datasets, which could be represented by a histogram, as well as in some other situations. When the metric data are in categories, the functional difference

between a pie and a histogram is that the pie is not adequate to depict the frequency distribution (the pattern) over various values. In addition, a pie does not provide a good representation when there are a large number of categories, although an adequate histogram can be drawn in that situation. However, a pie diagram is generally better in depicting the concentration of values in one category *relative* to the other categories.

Figure P.8a is a pie diagram for causes of death of children of age under 5 years in the world in the years 2000–2003 [1]. Acute respiratory diseases and diarrheal disease were the predominant causes. Figure P.8b is for Asia-Pacific region. Figure P.8c depicts the **disease spectrum** with the help of a series of pie diagrams that are linked to a segment of the previous pie [2]. In this diagram, manifestation of disease in mild, moderate, serious, and critical proportions is shown besides the proportion of survival and death in the case of critical manifestation of the disease.

As far as possible, each segment of pie must be labeled and must show the number or percentage of subjects it represents.

One useful application of a pie diagram is in comparing the relative distribution of two unequal groups of subjects divided into the same categories. Figure P.8a is based on 11 million deaths of children of age less than 5 years in the world per year during 2000–2003, whereas Figure P.8b is based on 4 million such deaths in Asia-Pacific. The higher number of death in the whole world is represented by a proportionate increase in the size of the pie. The segments are still comparable, and the greater predominance of malaria in the world relative to the Asia-Pacific is clear. Such comparability in groups of unequal size is rarely achieved by any other type of diagram.

Another useful feature of a pie diagram is wedging. When attention is to be specifically drawn to one particular category or a set of categories, the segments representing those categories are wedged out as shown for neonatal deaths in Figure P.8a and b. A pie can also be exploded so that all segments are wedged out. This is not shown in these figures.

## Pillai trace

Pillai trace is one of the multivariate test statistics utilized in **multivariate analysis of variance (MANOVA)** that is transformed into an *F*-ratio for assessing the significance level of the effect of the factors under study. This was proposed by Sreedharan Pillai in 1955 [1].

Sreedharan Pillai

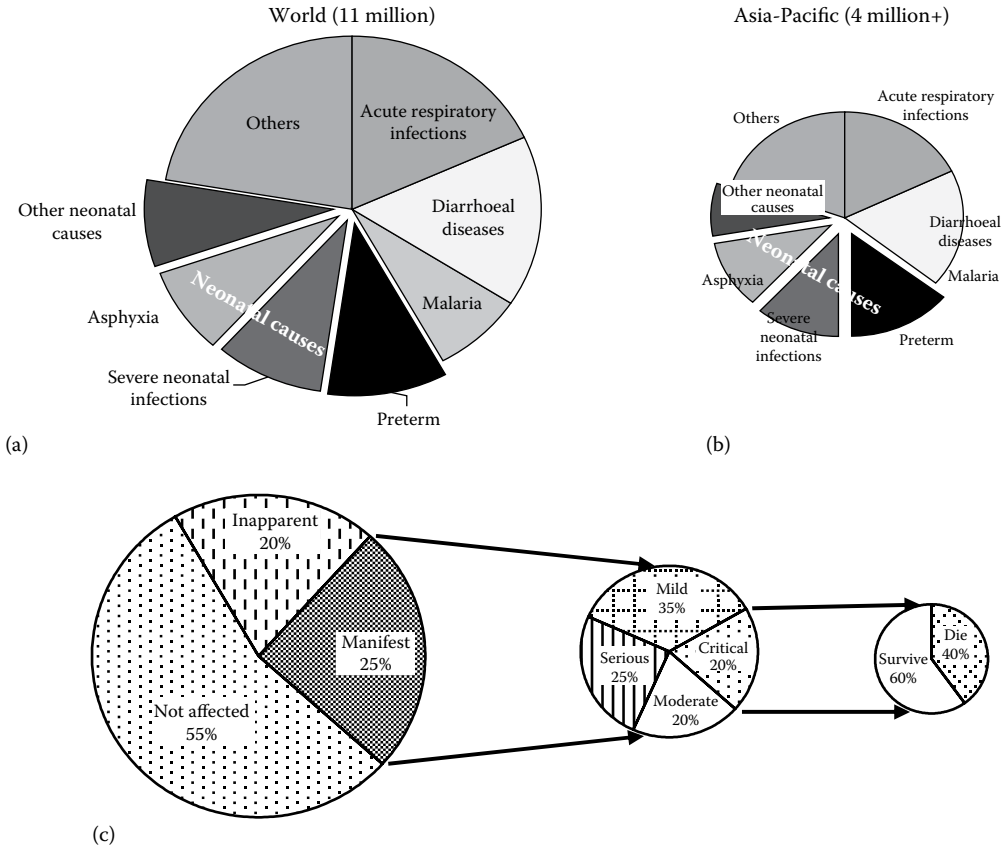

**FIGURE P.8** Pie diagrams: (a) causes of under-five mortality—world; (b) causes of under-five mortality—Asia-Pacific 2000–2003; ([a and b] From WHO. *World Health Report 2005.* World Health Organization, 2005.) (c) spectrum of disease by connected pies. (From Indrayan A. *Basic Methods of Medical Research*, Third Edition. AITBS Publishers, 2008: p. 202.)

MANOVA can be directly compared with the analysis of variance of univariate data, except that the groups are compared on *K* response variables simultaneously. In the univariate case, *F*-tests are commonly used to assess the hypotheses of interest. In the multivariate case, however, no one test statistic can be constructed to be optimal in every case. The most widely used of the available test statistics are Wilks lambda and Pillai trace. Both are obtained from eigenvalues of a matrix that comes up in case of multivariate analysis.

While Wilks lambda gives more accurate results when the requirements of multivariate Gaussian distribution and homogeneity of dispersion matrices are met, Pillai trace is generally more robust to the violation of these requirements. This works reasonably well for relatively small sample sizes also. It calculates the amount of variance in the dependent set of variables accounted for by the greatest separation of the independent variables, just as in discriminant functions. Most standard statistical software packages give a *P*-value based on Pillai trace that can be directly used to draw conclusions. As the sample size increases, the **central limit theorem** starts operating and the two tests tend to give the same result. Both can give the same result in some other specific situations also.

An example of the use of Pillai trace is given by Sánchez-Morla et al. [2]. They compared multivariate neuropsychological function between patients with schizophrenia and the control group using MANOVA and found Pillai trace = 0.493 that corresponds to F = 34.3 and yields P < 0.001.

## pilot study and pretesting

It is generally considered highly desirable that all questionnaires, schedules, laboratory procedures, etc., are tested for their efficacy before they are finally used in the main study. This is called **pretesting**. Many unforeseen problems or gaps can be detected by such an exercise, and the tools can be accordingly adjusted and improved. This pretesting can reveal whether the items of information are adequate, feasible, and clear; that the space provided for recording is adequate; that the length of the interview is within limits; that the instructions are adequate; etc. This also serves as a rehearsal of the actual data collection process and helps to train the investigators. Sometimes pretesting is repeated to standardize the methodology for eliciting correct and valid information.

A study on a small number of subjects before the actual study is called a pilot study. This simulates the actual study and provides a preliminary estimate of the parameters under investigation. Such a preliminary estimate may be required for the calculation of sample size. If the phenomenon under study has never been investigated earlier, the pilot study is the only way to get a preliminary estimate of the required parameter. A pilot study may also provide information on the size of the clusters and sampling units at various stages that could be important in planning cluster or multistage sampling for large-scale surveys. In case of clinical trials, a pilot study can give an idea of the recruitment rate, duration of follow-up, and practical constraints on the blinding [1].

Sometimes observations on the first few cases of a study are used as constituting a pilot study, in which case this is called an *internal* pilot study. The objective in this setup is mostly to get a preliminary estimate of the parameter of interest so that the sample size can be projected. An internal pilot study is applicable only if the design of the study and instruments are final and need no modification. In other words, this presumes that pretesting has been done, and all changes as required have already been incorporated.

A pilot study is not undertaken to investigate statistical significance of the result, nor will the small scale of this study be adequate for estimation of the effect or to judge its practical utility. It only provides a preliminary estimate of the relevant factors for designing a full study when prior data are not available and helps to reduce the areas of uncertainty in the final investigation. In a rare case, when the effect size is really large and a pilot study carried out with proper selection of subjects, the results may even be conclusive, although many would question the conclusion based on a pilot study.

## placebo

A placebo is an inert substance or a procedure that is supposed to neither help nor harm the subjects. Saline injection, colored water, pills containing inactive substance, and sham surgery are examples. This is often used for comparison with the active regimen under test in a clinical trial. The objective of using a placebo is to simulate the conditions of the test regimen and make the patient believe that he/she is getting the treatment.

As in all medical experiments, clinical trials can have one or more treatment regimens, but a parallel or concurrent control group is almost invariably required except in crossover or before–after setups. Real controls are those that are similar but follow the natural course of disease without any intervention, but such subjects would be aware that they were receiving no treatment and that could influence the outcome. For this reason, a placebo is preferred over no treatment. In practice, thus, the reference control group is either treated with an existing regimen or administered a placebo.

The placebo is important because some subjects tend to behave or respond differently when no treatment is given compared with when a sham treatment is given. Although the phenomenon is well recognized and documented, the actual mechanism of how and why this happens is poorly understood. This is surmised to happen due to activation of mu-opioid reception in the brain by the *expectation* of relief [1]. As far as possible, a placebo should be indistinguishable from the active therapeutic agent under trial in terms of appearance, size, color, taste, smell, etc., but it is not always possible to make it absolutely identical. Also, it should be given in a parallel dose so that the **masking** is complete.

There is always an ethical question about using a placebo on patients who are known to have the disease because they need an active ingredient to cure their ailment. However, placebos can be justifiably used in the following situations, although using placebos may affect **randomization** in some of them.

- No standard treatment is available, i.e., the existing treatment modality has very doubtful results—perhaps no better than a placebo.
- New evidence has emerged regarding the doubtful efficacy of the standard therapy.

- Existing regimen is too costly or is rarely available to the patients at large.
- On patients who have already been given standard treatment and have not benefited, and no second line of treatment is available for them.
- Test regimen is an add-on to the existing regimen. This means that all patients in the trial, including those on placebo, would receive the normally prescribed therapy anyway.
- Patients refuse to accept existing therapy but are willing to be part of a trial where they know that they can receive a placebo.

In situations where these conditions are not met, and for procedures for which a placebo group is nearly impossible such as in renal dialysis and fitting of an artificial limb, a group on existing therapy can serve as control. But control is now widely considered as a scientific necessity. Whether existing treatment or placebo, the control group should undergo the same medicinal rituals, such as dietary regulations, as the treatment group. This is more easily said than done.

There is a debate whether surgical trials need a group with sham surgery as the placebo. Perhaps evidence is not enough that sham surgery has the same psychological benefits as a placebo in a drug trial. Because of the major ethical issues, studies in humans involving sham surgery are rarely performed. There is a debate as to whether a surgical trial needs a sham surgery group at all as there is a theoretical argument that the placebo effect of sham surgery may be even more operative than with placebo medications. Nevertheless, a sham surgery group can be adopted for a setup where it is not too expensive and is harmless to the participants. This can be easily adopted in animal experimentation as done by Losey et al. [2] on mice because of far fewer ethical concerns in this setup. For an example of sham surgery on patients, see Hunter et al. [3].

## point-biserial correlation

We try to address four questions in this section: (i) What is the point-biserial correlation coefficient? (ii) How is this coefficient calculated? (iii) How is this coefficient related to other **correlation coefficients**? (iv) How is this coefficient used in practice? Brief answers are as follows.

The point-biserial correlation coefficient ($r_{pb}$) is a measure of the degree of relationship between a naturally occurring **dichotomous** scale and a **metric scale**. For example, you might want to investigate the degree of relationship between gender (male/female) and hemoglobin level (a metric scale). This process is different from finding the mean difference between males and females. The dichotomous categories are coded as 0 and 1. Let the quantitative variable with which this correlation is to be computed be denoted by $x$.

$$\text{Point-biserial correlation: } r_{pb} = \frac{\bar{x}_1 - \bar{x}_0}{s}\sqrt{pq}$$

where

$\bar{x}_1$ = mean of $x$ for those with code 1
$\bar{x}_0$ = mean of $x$ for those with code 0
$s$ = standard deviation of $x$ for both the groups combined (with denominator $n$ and not $n-1$)
$p$ = proportion of those with code 1
$q$ = proportion of those with code 0 ($p + q = 1$)

Consider the shock index in male and female patients with ST-segment elevation myocardial infarction (STEMI). Suppose we have 28 male and 19 female patients. Let their shock index values be as follows:

mean shock index in 28 male patients = 0.83
mean shock index in 19 female patients = 0.72
SD of shock index in the total of 47 patients = 0.065

These give a point-biserial correlation coefficient between sex and shock index $= \frac{0.83-0.72}{0.065}\times\sqrt{\frac{28}{47}\times\frac{19}{47}} = +0.83$. Since the sign is positive, the higher the code (in this example, males), the higher the shock index; and the degree of relationship is an impressive 0.83 on the 0 to 1 scale. Figure P.9 supports this strong relationship. More compact values of the variable $x$ in each group give a higher value of the point-biserial correlation.

In fact, the point-biserial correlation is the same as the Pearsonian **correlation coefficient** ($r$) between $x$ and $y$, where $y$ is now recorded as 0 and 1. The Pearson formula reduces to what is just given for this setup. The interpretation of the coefficient is also similar. Like $r$, $r_{pb}$ can range from 0 to +1 if the two scales are related positively (i.e., in the same direction) and from 0 to –1 if the two scales are related negatively (i.e., in opposite directions). Confidence interval can be easily obtained, and test of significance can be easily done when $x$ follows a Gaussian distribution.

How is the point-biserial correlation coefficient used in practice? Say we are interested in the degree of relationship between being male or female, and the degree of anxiety as measured by the hospital anxiety and depression score (HADS score). The point-biserial correlation will help you to get the answer. Most

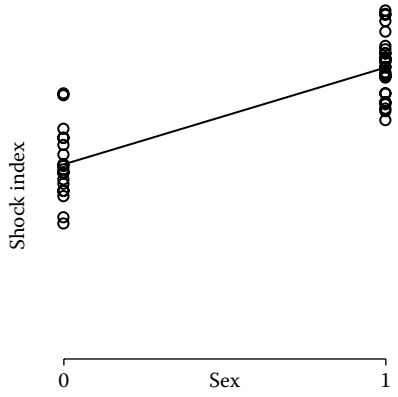

**FIGURE P.9** Relationship of shock with sex of STEMI cases.

commonly, however, researchers use $r_{pb}$ to calculate the item–total score correlation as another, more accurate, way of estimating item discrimination. The $r_{pb}$ shows the degree to which each item is separating the stronger subjects on the whole from the weaker ones. The higher the $r_{pb}$, the better the item in discriminating. Consider a setup where you are assessing some newly developed quality of life index of people with some chronic disease (code = 1) versus those without any disease (code = 0). If our index is good, those with code 1 (higher value) will have a substantially lower score than those with code 0 (lower value). Thus, the point-biserial correlation will be negative. If the correlation is not high on the minus side, you can conclude that the quality of life index used in this exercise fails to discriminate between cases with and without the disease under study. This way, point-biserial correlation can be used for item analysis.

If the dichotomous categories are artificial such as anemia <10 g/dL and nonanemia ≥10 g/dL, then this correlation is called just *biserial* instead of *point-biserial*. Such dichotomy of a metric scale, though, is not desirable. **Biserial correlation** may still fall in the comfort zone of some researchers. If this is so, realize that, in this case, you have ordered categories—you know that the category <10 g/dL is less than the category ≥10 g/dL. They can be legitimately coded as 0 and 1. This is not the case when the categories are male and female. The formula changes slightly in that the point-biserial correlation is further divided by the height of the standardized normal distribution at the point $d$, where $P(z < d) = q$ and $P(z > d) = p$ when the underlying distribution is Gaussian. Statisticians know that this height is $\frac{1}{\sqrt{2\pi}} e^{-d^2/2}$. This is the additional factor in the denominator of biserial correlation. The biserial correlation coefficient is always greater than the point-biserial correlation coefficient since the divisor is always less than 1.

## Poisson distribution

You may be aware that the **binomial** variable $x$ *counts* the number of successes out of $n$ independent trials. If $n$ becomes extremely large and the probability of success becomes extremely small, ultimately in the limit we get a Poisson distribution. Application wise, if migraine occurs 3 times in a year on average in established cases, the probability that it will occur 6 or more times in a year in a random case can be obtained by Poisson distribution. This distribution is given by

$$\text{Poisson distribution: } P(x|\mu) = \frac{e^{-\mu}\mu^x}{x!};\ x = 0, 1, 2, \ldots,$$

where μ is the mean. In the migraine example,

$P(x \geq 6|\mu = 3) = 1 - P(x \leq 5|\mu = 3)$ by the complementary rule of probability

$$= 1 - \left( \frac{e^{-3}3^0}{0!} + \frac{e^{-3}3^1}{1!} + \frac{e^{-3}3^2}{2!} + \frac{e^{-3}3^3}{3!} + \frac{e^{-3}3^4}{4!} + \frac{e^{-3}3^0}{5!} \right)$$

$$= 1 - e^{-3}\left(1 + 3 + \frac{9}{2} + \frac{27}{6} + \frac{81}{24} + \frac{243}{120}\right)$$

$$= 1 - (0.0498 \times 18.4)$$

$$= 0.084.$$

Thus, the chance is nearly 8.4% that a random migraine patient from this "population" will have 6 or more attacks during 1 year. Poisson tables are available in statistics books that give these probabilities, and statistical packages in any case have provision to give exact Poisson probabilities. The value of μ, being the average, does not have to be an integer. In most situations, this will be in decimals.

The mean μ of Poisson is estimated by the sample mean $\bar{x}$ as usual, and the variance of Poisson is also μ so that its estimate is also $\bar{x}$. Equality of mean and variance is considered a defining property of Poisson. In any set of data on rate where mean and variance are nearly equal, you should especially look for Poisson distribution. Examples of Poisson variables are (i) number of deaths occurring in a cardiac hospital per day; (ii) number of myocardial infarction cases arriving in a general hospital per day; (iii) number of measles cases occurring in a city per year; and (iv) number of handicap persons per 1000 population. The standard error of mean can be easily obtained as usual, and the exact confidence interval on population mean can be obtained by Poisson distribution.

In most practical situations where Poisson is applicable, the mean would be small, possibly less than 1. If it gets bigger, say more than 10, the Poisson too tends to behave in the same manner as Gaussian. For example, if μ = 20, then for Poisson $\sigma^2 = 20$, and by Gaussian approximation, the chance that this number is 15 or less in a specific case is

$$P(x \leq 15) = P(x < 15.5) \text{ with } \textbf{continuity correction}$$

$$= P\left(z < \frac{15.5 - 20}{\sqrt{20}}\right)$$

$$= P(z < -1.01)$$

$$= 0.156 \text{ from Gaussian distribution.}$$

The exact answer with Poisson distribution is 0.157. The Gaussian approximation is not far off.

Poisson distribution has been used extensively for medical conclusions. For example, Morris [1] has used this distribution for deleterious mutations in zygotes to study their genomic load in view of their relevance to death in infancy and childhood. A simple example is obtaining standard errors and 95% confidence limits of age-specific incidence rates of pediatric retinoblastoma in India by sex group in each population-based cancer registry using the Poisson distribution [2].

## Poisson regression

Refer to the topic **Poisson distribution** and the topic **regression** while reading this section. Poisson regression is a type of **generalized**

**linear model** (GLM) where the random component is specified by the Poisson distribution. A GLM has the following structure:

$$y = \beta_0 + \beta_1 x_1 + \beta_1 x_2 + \ldots + \beta_K x_K + \varepsilon.$$

The random component here is ε, which is ordinarily considered to have a Gaussian distribution with mean 0 and variance $\sigma^2$. However, in case the dependent variable $y$ is a count or a rate, such as the number of myocardial infarction cases arriving in a general hospital in a day, Gaussian distribution does not hold and Poisson distribution works better. When ε is considered to have a Poisson distribution, this is called Poisson regression.

You may be aware that all regression models are for the mean of $y$ than $y$ itself, and this mean could be a fraction even when individual values of $y$ are the counts. As with any kind of regression, a Poisson model is also fitted to the data values, the coefficients are estimated, and they are interpreted for conclusions. But the mathematics and the underlying theory are different from ordinary least squares regression, which makes Poisson regression a separate topic. It is generally observed that most counts of events have the feature of being mostly around the mode, but occasional value can be large and can also be exceedingly large on rare occasions. To correct this skewness, Poisson regression models the natural logarithm of the mean count instead of the count itself. After this transformation, negative values would occur corresponding to the mean counts between 0 and 1 (counts themselves cannot be negative). The logarithm is called the **link function** since this transforms counts to the values that can be considered to have Gaussian distribution. The logarithm of the response variable is linked to a linear function of regressor variables such that $\ln(y) = \beta_0 + \beta_1 x_1 + \beta_1 x_2 + \ldots + \beta_K x_K$. In other words, the typical Poisson regression model expresses the log outcome as a linear function of a set of regressors. However, this is valid in certain conditions: (i) as the regressor variables increase in equal increments, the logarithm of the dependent changes by the same amount; (ii) the combined effects of different regressors change the dependent in a multiplicative manner; (iii) at each level of the regressor, the dependent has variance nearly equal to the mean; and (iv) observations are independent.

Poisson regression can also be used to model the rates based on the person-time. This may be useful when all individuals are not followed for the same length of time. So, instead of having $\ln(y) = \beta_0 + \beta_1 x_1 + \beta_1 x_2 + \ldots + \beta_K x_K$, you can have $\ln(y/t) = \beta_0 + \beta_1 x_1 + \beta_1 x_2 + \ldots + \beta_K x_K$, where $t$ is the person-time such as 1000 for per thousand rate. This can be written as $\ln(y) = \ln(t) + \beta_0 + \beta_1 x_1 + \beta_1 x_2 + \ldots + \beta_K x_K$— only the intercept changes.

Poisson-distributed data are intrinsically integer-valued, which makes sense for count data. That said, a Gaussian distribution can be a good approximation to a Poisson when the mean value is 10 or greater. This may be easier to fit and would actually be more general, since the Poisson regression requires that the mean and the variance are equal, while Gaussian-based usual regression can deal with unequal means and variances. For a count data model with means different from variances, one could also use a **negative binomial distribution**, for instance.

An example of the use of Poisson regression is given by Pocock et al. [1]. They used it for predicting the 3-year mortality rate in heart failure patients on the basis of the data in 30 studies. The predictors in this model were age, lower ejection fraction, New York Heart Association class, serum creatinine, diabetes, etc. Pereira et al. [2] used Poisson regression to find the factors influencing prevalence of dyslipidemia in a section of Brazilian population.

## polynomial regression, *see* curvilinear regression

## polytomous categories, *see* categories of data values

## ponderal index, *see also* body mass index (BMI)

Ponderosity is about the body heaviness and so is directly related to weight. Ponderal index measures the weight in relation to the size of the body, particularly the height. This term is primarily used for neonates. The corresponding term for adults is obesity.

Although ultrasonographic measurements can be used to assess the growth of the fetus, the first measurement of physical health of a child after birth is the weight. This generally declines for a few days after birth and then regained. If the weight immediately after birth cannot be recorded, as in some underdeveloped countries, the weight on the seventh day in many cases would be a good approximation. The normal range is 3.2–3.7 kg. A birth weight less than 2.5 kg is conventionally considered low in many countries. A low birth weight not only has been found to be associated with increased risk of early mortality but also is surmised to affect growth and development during adolescence and trigger diseases in adulthood such as coronary artery disease and diabetes. Similarly, high weight can be precursor to obesity in adulthood with all its adverse consequences. Thus, it is important to assess ponderosity in neonates. A useful index for neonatal weight is the ponderal index:

ponderal index for neonates:

$$\text{PI} = \text{weight in kg}/(\text{crown–heel length in m})^3$$

A child with a ponderal index of 30 or greater can be considered overweight, but in some conditions, such as in maternal smoking, reduced length may also be implicated. An index between 25 and 30 is considered normal, and that between 20 and 25 is considered marginal; a child with an index less than 20 is classified as *small for gestational age* (SGA). The index can be used as a prognostic indicator and to advise the family to take special care. When weight and length are both low, this index may not reveal the deficiency, but the prognosis is poorer. Such a symmetric SGA child is generally classified as *intrauterine growth retarded* (IUGR). This is identified by a very low weight but a nearly normal ponderal index. Some organizations do not distinguish between SGA and IUGR children, and both are identified only by low weight, generally below the 10th percentile point for the gestational age, irrespective of the length of the child.

The Ponderal index as just defined can also be used for adults, but the normal range will be different. Moreover, for this age, body mass index is a well-established index of obesity.

A general form of ponderal index is weight/$(\text{height})^b$, where $b$ is estimated from the simple linear regression of ln(weight) on ln(height) separately for each age. This can be used for any

age—only the value of $b$ changes from age to age. Freeman et al. [1], for example, found that $b = 2.08$ for boys of 7 years, $b = 2.20$ for girls of 7 years, $b = 2.44$ for boys of 16 years, and $b = 1.75$ for girls of this age in the United Kingdom. This varies from one population to another. Generally speaking, the value of $b$ declines from 3.0 for neonates to 2.0 for adults as we move up for age.

## pooled chi-square, *see* Mantel–Haenszel procedure

## pooled OR, *see* Mantel–Haenszel procedure

## pooled RR, *see* Mantel–Haenszel procedure

## pooled variance

This is the variance in two or more groups combined and can be obtained on the basis of the variance in individual groups. The objective in case of samples is to get a better estimate of the variance because of a large combined sample size when pooling is permissible. The only requirement is that the sample variances in different groups do not differ significantly. Pooling of widely dispersed variances may lead to wrong results.

Consider the scenario where you have two sample means from two independent samples. The standard error (SE) of the difference between the two sample means is given by

$$\mathrm{SE}(\bar{x}_1 - \bar{x}_2) = \sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}},$$

where $s_1^2$ is the sample variance in the first sample with size $n_1$, and $s_2^2$ is the sample variance in the second sample with size $n_2$. If the variances are nearly equal (see the **Levene test**), you can pool the variances of the two samples and get a better estimate. Then

$$\mathrm{SE}(\bar{x}_1 - \bar{x}_2) = s_p \sqrt{\frac{1}{n_1} + \frac{1}{n_2}},$$

where $s_p^2 = \dfrac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$ is the pooled variance. This is better in the sense that this is now based on $n_1 + n_2$ values. The pooled variance (two independent samples) can also be written as

$$s_p^2 = \frac{\Sigma_{i=1}^{n_1}(x_{1i} - \bar{x}_1)^2 + \Sigma_{i=1}^{n_2}(x_{2i} - \bar{x}_2)^2}{n_1 + n_2 - 2}.$$

Such pooled variance is commonly used in the two-sample **Student *t*-test** for significance of difference in means of two independent groups. The test changes to the Welch test in case the variances are unequal and cannot be pooled. This is also used for finding the confidence interval for the mean difference in the population when the variances are equal.

The method can be easily extended to many samples. In this case, the pooled variance for $K$ independent samples is

$$s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2 + \ldots + (n_K - 1)s_K^2}{n_1 + n_2 + \ldots + n_K - K}.$$

This may look like a new expression, but those familiar with one-way analysis of variance (ANOVA) know that this is the same as **mean square error (MSE)**, alternatively written as MSE = $\dfrac{\Sigma_{k=1}^{K}\Sigma_{i=1}^{n_k}(x_{ki} - \bar{x}_k)}{n - K}$, where $n = n_1 + n_2 + \ldots + n_K$, although in the case of ANOVA, slightly different notations are used. This is valid only if the sample variances are not significantly different across groups—commonly understood as the **homoscedasticity**. In this case, the pooled variance is the estimate of the variance of the errors in the ANOVA model. As abundant caution, note that this is not the same as the variance of all $n$ values combined for all the groups because that uses overall mean whereas MSE uses group means.

## population (the concept of)

Population in common parlance is the collection of people residing in a defined area, but it has a special meaning in statistics. It can be understood as the target group to which the findings of a study would apply. This is primarily understood as the **target population**. This is not necessarily a population of human beings—it could be a population of blood samples, of animals, of cases of kidney diseases, of healthy children in a school, of hospitals, etc.

In a descriptive study of acute respiratory infection (ARI) in a country, the target population could be all existing cases of ARI in that country. For a cervical cancer control program, the target population could be all married women of age more than 40 years. For studying risk factors of enlarged prostate, the population of interest could be all men of age 50 years and above in an area. In a laboratory experiment, this could be the population of mice or the population of histological specimens. In a clinical trial setup, the inclusion and exclusion criteria define the population of interest.

For most medical studies, the number of subjects in the population, called the size of the population, is large. Cost and logistic considerations seldom allow the study of all the subjects in a population. Therefore, sampling becomes a natural choice. However, sampling should be such as to provide representative cross-section of the population so that the results can indeed be generalized to the entire target population. This is what makes the **sampling techniques** so important.

In rare situations, all subjects in the target population can also be investigated. Then such a study is called complete enumeration or **census**. However, even if all existing cases are surveyed, there is no guarantee that the results would apply to *future* cases. Thus, the concept of population in the context of medicine is more hypothetical than real. When all existing cases are indeed included, it still remains a sample considering that future cases as well as those who have died are not included. Medical empiricism implies that the findings on the existing cases are used for future cases, and sampling is a prerequisite for this paradigm. Nonetheless, if the objective is to find the prevalence of diabetes mellitus in 2016 among females of age 40 years and above residing in a particular city, complete enumeration is possible. Similarly, if a complete registry of cancer cases in a defined population is available, perhaps sampling is not needed for assessing the existing situation.

A futuristic perspective brings in the concept of statistical **universe**. A universe could be larger than the target population that has

implications for the result. Future cases are part of the universe but not of the population.

## population attributable risk and population attributable fraction, *see also* attributable risk

**Attributable risk (AR)** due to a particular factor is the difference in risk of disease in subjects with that factor and the subjects without that factor when other factors remain constant. This factor is generally termed as exposure, although this can be any, such as low hemoglobin level, high obesity, and adverse family history. Attributable risk can be expressed as

$$\text{AR} = R_1 - R_0,$$

where $R_1$ is the risk (or incidence) in the exposed group and $R_0$ is the nonexposed group. This measures how much risk increases due to the exposure.

In view of the public health importance of AR, it is sometimes of interest to estimate the excess rate of disease attributable to the exposure in the *total population* under study. This excess is called the population attributable risk (PAR) and is calculated as

PAR = **incidence rate** in the total population (including exposed subjects) – incidence rate in the nonexposed subjects.

This can also be called population risk difference. The first component of this equation can be estimated only when the sample contains the exposed and the nonexposed subjects in the same proportion as in the total population. Otherwise, an extraneous estimate would be needed. Note that PAR is the rate of disease in the population minus the rate in the unexposed group. This is different from AR because the population comprises both the exposed and the nonexposed groups of people. In fact, it can be shown that PAR = AR*$p$, where $p$ is the **prevalence** of exposure. This measures the impact of eliminating the exposure from the entire population—and thus helps in developing strategies for control.

The PAR fraction measures the proportion of disease in the population that is attributable to the exposure and is the proportion of incidence that could be eliminated if the exposure were eliminated. This can be directly obtained from the **relative risk** (RR) as follows when the proportion of persons with the given risk factor is known:

$$\text{PAR fraction} = \frac{p(\text{RR}-1)}{p(\text{RR}-1)+1},$$

where $p$ = the proportion of persons having the given risk factor and is the same as the prevalence of exposure. The PAR fraction is also called the **etiologic fraction**. Whenever RR can be approximated by odds ratio (OR) (this requires low prevalence of disease), PAR can be estimated on the basis of case–control data. For a method of doing so with multiple risk factors in case–control studies, see Bruzzi et al. [1].

As an example, suppose oral cancer has a 10-year risk of 0.0002 among nonchewers of tobacco and 0.015 among the chewers. If only 2% are chewers, there are 2000 chewers and 98,000 nonchewers in a population of 100,000. At the risk presumed above, 20 among nonchewers and 30 among chewers are expected to develop oral cancer in a 10-year period. These two together amount to 50 per 100,000 or 0.0005 as the risk in the total population. Thus, PAR = 0.0005 – 0.0002 = 0.0003. If chewing of tobacco is completely eliminated from the population through educational campaigns or otherwise, 3 cases per 10,000 population would be saved at the end of a 10-year period. A health administrator may not view this as a substantial improvement considering the cost involved in the educational campaign and the fact that 2 cases per 10,000 would in any case occur among nonchewers.

The result may look dramatically different if PAR *fraction* is calculated. Using the formula given earlier, since RR = 0.015/0.0002 = 75 in this example,

$$\text{PAR fraction} = \frac{0.02(75-1)}{0.02(75-1)+1} = 0.60.$$

This means 60% of the risk of oral cancer in the population is attributable to chewing of tobacco. This is the same as PAR = 0.0003 out of population risk of 0.0005.

PAR is extensively used in epidemiological studies. Suhrke and Zahl [2] estimated the population attributable fraction of 8.2% of breast cancer incidence in 2006 due to use of hormonal therapy in Norway. Azimi et al. [3] have highlighted how sum of PAR fractions for different exposures can exceed 100% when sufficient care is not taken in its calculation.

## population growth model and curve

Population growth refers to the changes in population in a particular area brought about by births, deaths, and residents moving into and out of an area. This can be modeled to produce a population growth curve. Knowing the size of the population and its projection allows the governments and businesses to make decisions to meet the expectations. Besides humans, these models are also used for bacterial colonies and viruses.

According to the World Population Clock [1], at the dawn of agriculture, about 8000 BC, the human population of the world was approximately 5 million. Over the 8000-year period up to 1 AD, it grew to 200 million with a growth rate of under 0.05% per year. A tremendous change occurred with the industrial revolution: whereas it had taken all of human history until around 1800 for the world population to reach 1 billion, the second billion was added in only 125 years (1927), the third billion in less than 35 years (1960), and the fourth billion in 14 years (1974). It has slowed down a bit since then and it takes nearly 12 years each time to add a billion. The world population in 2016 is estimated as 7.5 billion.

The preceding data may have convinced you that all populations, in general, tend to grow in exponential fashion—multiplying per unit of time instead of adding. That is, they double—the doubling time could be a day, a year, or 100 years depending upon the organism. This is particularly true for bacteria and viruses when allowed to grow unhindered, and for them, the doubling

time is short. The corresponding statistical model that depicts this pattern is **exponential curve**. This model is applicable when the population grows as a proportion of itself, such as 8% each day of what it was at the beginning of the day. If the growth rate is 0.01% per day, it will take 6930 days for population to double; if the growth rate is 1%, it will take 70 days to double; and if the growth rate is 3%, it will take only 23 days to double. If you have some data on a population for some time points, exponential curve (Figure P.10a) can be easily obtained as a regression on time after taking the logarithm of the population. As opposed to an exponential pattern, the populations that tend to limit themselves for whatever reason will automatically relent and stabilize. This gives a logistic type of curve (Figure P.10b). An important feature of this curve is that it shows slow initial growth, then increasing growth rate, rapid growth during the middle period, declining growth rate a little later, and plateauing thereafter. The third pattern could rise fast to a point after which the population tends to plateau (Figure P.10c).

Human populations have recently seen widespread interventions such as contraception. Thus, this requires a relatively complex model of the following type:

$$\text{human population growth model: } y_t = \frac{a}{1+be^{-ct}},$$

where $y_t$ is the population at time $t$, and $a$, $b$, and $c$ are the parameters in this model that would vary from population to population. No transformation of variables $y$ and $t$ can reduce this equation to a linear form. Thus, this model is genuinely nonlinear in parameters. The parameter $a$ mostly defines the baseline, $b$ is the growth rate, and $c$ is the limiting parameter. This is shown in Figure P.10c for specific values of the parameters, which we call classical.

Growth in many populations across the world is primarily due to high birth rate relative to death rate such as in India, but in countries such as the United States, this would be mostly due to immigrants and their descendants [2]. Some countries such as Russia and Belarus have negative population growth as the death rate exceeds the birth rate [3]. This is rare in natural course but can happen in specific situations.

## population, intervention, comparison, and outcome (PICO) method

When researching medical literature, questions often come to mind that makes finding answers a real challenge. With regard to each of these questions, the way forward is to dissect the question into its component parts and then to restructure it in such a way that it is easy to find answers. For example, the most common clinical questions in **evidence-based medicine** are about how to treat a disease or condition. Many such questions can be divided into the following four components, summarized by the acronym PICO: P—population, patient; I—intervention, indicator; C—comparator, control; and O—outcome. The details are as follows.

P: What is the population, patients, or participants for whom the answers are sought?
I: What is the intervention (diagnostic test, exposure, or the treatment regimen) that you are interested in?
C: Is there a control or alternative test or exposure for comparison, also known as the comparator?
O: What are the patient-relevant outcomes of interest of the intervention?

Restructuring the research question as above makes way for a lucid answer. In medical research, this is used for selecting relevant articles for a **systematic review**. These reviews are considered the backbone of evidence-based medicine. For example, Patel et al. [1] studied cervical spine collar clearance in the obtunded adult blunt trauma patient by using PICO as follows: population—obtunded adult blunt trauma patient; intervention—cervical collar removal with adjunct imaging; comparator—cervical collar removal without adjunct imaging; and outcome—peri-clearance events. This helped them to select appropriate studies for a systematic review. Zou et al. [2] used PICO structuring of a clinical question regarding astragalus in the prevention of upper respiratory tract infection in children with nephrotic syndrome, and searched several medical literature databases for relevant papers. PICO seems to be gaining wide acceptance for choosing studies for systematic reviews.

## population pyramid

This is a special bar diagram for showing age–sex distribution in a population. Population pyramid is commonly used in demography but can also be used in a large-scale study to depict the age–sex distribution of the subjects of the study. This diagram shows the number or percentage of males and females in different age groups in a population. Figure P.11 shows the changing age–sex distribution of the population in a developing country such as Bangladesh over a long period. Such pyramids can be used to study the population dynamics. The details are as follows.

The vertical axis running down the center is age, and horizontal bars on the left side are the percentage or number of females and those on the right side are the percentage or number of males. *The age groups must be equal for this kind of depiction*. Note the striking difference between the shapes of the population pyramids for the different periods. The shape initially in 1975 is triangular with a broad base, showing the predominance of the child population. The decline in the population for each age group shows that deaths occurred at almost every age in 1975. Fifty years later (2025), due to slow transition, the pyramid may take a conic shape. After that, the transition is expected to be fast and the projected distribution of the population up to the age of 60 years is nearly uniform for the year 2050. Practically, no deaths occur in age groups up to 60 years because almost everybody tends to live longer. After that age, the deaths are fast and frequent. As the population evolves, the women of old age groups increase: the width of the right-hand side (females) is broader than that of the left-hand side (males). As of now, men die earlier than women, and this is reflected in the projections into 2050 and 2075: it is clearly visible in the pyramid projected for the year 2075 that there will be many more females of old age than males.

Population pyramid can be an effective tool in studying epidemiological impact of diseases. Belle et al. [1] presented population pyramids of Lesotho in the years 1976, 1986, 1996, and 2006 to show impact of HIV/AIDS on the demographic profile of that country. Iani et al. [2] used this to draw a proportionate stratified sample according to the age–sex structure in Italy.

## positive health

Positive health can be understood as the ability to cope with physical, biological, psychological, and social stress [1]. This can become far too abstract. Yet, measurements such as hemoglobin (Hb) level, high-density lipoprotein (HDL) level, immunity level, vital capacity, and pain-bearing capacity can be possibly used to assess positive health. The same is inversely true for low cholesterol, low sedimentation rate, and low bleeding time. Thus, an index of positive health can indeed be developed. Measurement of positive health has remained unexplored and requires the attention of researchers. The profile of persons who rarely fall sick and are able to do more work than others while leading an enjoyable life can be studied to identify factors that contribute to positive health. It is possible, though, that psychological factors such as personality profile, absence of stress, and carefree attitude contribute more to positive health than physiological parameters. This needs to be explored. This is a flagship concept mooted by Indrayan and Sarmukaddam in 2001 [1], and has been picked up by others for exploration such as by Seligman [2].

Assessment of the level of health and disease in individuals can be very subjective. Perfect health can seldom be defined, and the meaning of well-being changes from person to person. The subject's own perception also changes from time to time, and health becomes an unattainable ideal in a true sense. This, however, does not distract scientists, and they always make efforts to measure the level of health. The focus so far, though, remained on lack of health rather than on its presence. Thus, there is a need to define and pursue the idea of positive health.

Note that the way positive health is explained in this section by us is very different from positive health outcomes, positive health behaviors, positive health benefits, etc. These terms have been in use for a long time. Our concept of positive health is the state of health of an individual for a sustained period of time in the sense of capacities and abilities albeit restricted to psychosomatic health. This needs to be explored for proper assessment.

## postmarketing surveillance, *see also* phases of (clinical) trials

A regimen, a drug, or a device can be released for marketing after getting the license from the regulatory authorities on the basis of successful completion of the phase III trial. However, the monitoring continues for the effects and side effects. This is called postmarketing surveillance, and many consider it the phase IV of a clinical trial.

Phase IV is generally carried out in an observational studies mode than in a trial mode. The drug is used in a routine setup and not intentionally ingested by the experimenter. The efficacy and adverse reactions are observed as they occur, and the conditions are not controlled. Under this surveillance, all adverse reactions and other events attributable to regimen are monitored, and the effectiveness is also evaluated. Patient preferences are studied, and health professionals and the public are encouraged to voluntarily share their experiences of any unexpected occurrence. This helps to uncover side effects not seen in a controlled trial and those that require sustained exposure to the regimen. Findings about tamoxifen carrying a risk of endometrial cancer [1] and arthroscopic surgery not beneficial for osteoarthritis of knee [2] are results partially attributable to such surveillance. Appropriate actions are taken to address the problems including risk management of the cases who unwittingly suffer. Investigations are launched to find if the manufacturers adhere to the terms and conditions of approval and that the drug or device is produced in a consistent and controlled manner as stipulated. Sometimes unannounced inspections are also carried out. Companies in any case are required to report any such events.

Any evidence of compromise on safety is a sensitive issue that can be easily hijacked by the media without gathering sufficient evidence. Pharmaceutical companies may have to react swiftly to investigate any such report because its damages can be irreversible.

### *Pharmacoepidemiology*

A whole new science of pharmacoepidemiology has emerged to study postmarketing issues of medical products, including drugs. A good reference on this subject is the book by Strom [3]. Pharmacoepidemiologic research is the study of the use and effects of health care products (e.g., pharmaceuticals, devices, and vaccines) after they are in practice for a while. It has now expanded to include clinical, economic, and other health outcomes, requiring new study methods. Pharmacoepidemiology is being used increasingly to evaluate health care systems, interventions, and health-related behaviors when actually used in practice. This now is considered the core science of therapeutic risk evaluation and management since these risks many times emerge after the product is marketed and used for a sufficiently long time.

The Guidelines for Good Pharmacoepidemiology Practices (GPP) [4] are intended to address these activities and other pharmacoepidemiologic studies. The GPP are intended to apply broadly to all types of pharmacoepidemiologic research, including feasibility studies, validation studies, descriptive studies, and etiologic investigations, as well as all related activities beginning from design through publication. The GPP also support risk management activities.

## poststratification

This is stratification of the sample after the selection is complete and all the data have already been collected. This is used when strata are not envisaged before the sampling but become clear after the data collection. Thus, the strata sizes here are random variables, as opposed to conventional stratified random sampling where strata and strata sizes are generally known before sampling is done.

Say that you have collected all your data but then find that unforeseen confounding has occurred. Confounding is said to exist when a factor affects the outcome as well as the antecedent under study. Confounding factors compete with the hypothesized risk factor as an explanation for the observed response. Frequent egg eaters generally have raised lipid levels. If these subjects are found to be at higher risk of coronary artery disease, it is difficult to say that this is due to eating eggs per se or is contributed, at least partially, by the raised lipid level that can occur for other reasons as well. To evaluate their separate effects, special care should be taken to include egg eaters with normal lipid profile and noneaters with raised lipid levels. When the stratification is known, this can be done beforehand. Unforeseen confounding can also occur or relevant strata might not have been visualized before the study. If one or both of these occur, a poststratification can be tried after the data are collected. This is also done if a particular group turns out to be of some special interest because of exceedingly good or exceedingly poor outcome. A sufficient number of cases may or may not be available in each group after this kind of stratification. If there were very few cases in one or more groups, the validity of the results would suffer.

It is quite common for researchers to use poststratification techniques in survey data analysis when it is discovered that some group or groups are grossly overrepresented or underrepresented. In this case, the estimate can be accordingly adjusted, and a relatively unbiased estimate can be obtained. The adjustment weight is often called the poststratification weight. This is obtained as $\pi_k/p_k$ for the $k$th stratum, where $\pi_k$ is the proportion in the population and $p_k$ is the proportion in the sample. If the weight for any stratum is 2, it really means that each sample value in this stratum will count as two values. These can be calculated only if the strata sizes (or the proportions) in the population are fairly well known. All these weights are always positive and nonzero.

The method to obtain these weights when population percentages are known is illustrated in Table P.3. In this example, strata A and B were underrepresented in the sample compared with the

**TABLE P.3**
**Calculation of Poststratification Weights**

| Stratum | Percentage in the Population | Percentage in the Sample | Poststratification Weight |
|---|---|---|---|
| A | 32 | 21 | 32/21 = 1.5238 |
| B | 45 | 33 | 45/33 = 1.3636 |
| C | 13 | 37 | 13/37 = 0.3514 |
| D | 10 | 9 | 10/9 = 1.1111 |
| **Total** | **100** | **100** | |

population, and stratum C was overrepresented. Stratum D was just about right. Poststratification weights correct this imbalance. When these weights are used for calculating something like mean (i.e., obtain the **weighted mean**), the value obtained will be a much better estimate of the population mean. The strata could be age–sex, blood group, disease severity, or any other. They must, however, be **mutually exclusive and exhaustive**.

Poststratification is also used by epidemiologists while analyzing health survey data. For example, certain diseases, e.g., cancer, are more common among older populations. When comparing the prevalence rates among geographic regions with different age structure, it is necessary to make adjustments according to such demographic categories and to compute relative prevalence rates of the diseases.

Poststratification is like data dredging since this is done after seeing the sample. Thus, this should be done only when it becomes necessary. Any modification done after seeing the data has potential to introduce bias. For example, imbalance in the sample could be due to differential nonresponse that may affect the outcome. Try to obtain the self-weighted data right at the outset. Poststratification weights work well for mean and proportion but not for something like median and quartiles. Extreme weights, which can arise due to gross underrepresentation or overrepresentation of strata, can produce unstable results. In this case, consider if collapsing the categories can help. You may have to exercise caution and make provisions for weights in analyses such as regressions and analysis of variance. Also, different characteristics can give very different weights, and obtaining a combined weight could be an uphill task. In this case, obtain the cross-classification of the population and think of considering each category as a stratum. This is possible only when the distribution of the population subjects is available by all combinations of these characteristics and will give reasonable results only when the sample size is large.

## potential-years of life lost (PYLL), *see also* disability-adjusted life years (DALYs)

Also called *person years of life lost*, potential-years of life lost (PYLL) is defined as the sum total of the years of life lost due to "premature" deaths in a population. Years of life lost for one person is the **expectation of life** at the age at death. This is the additional years he/she might have lived on average if he/she does not die at that age. If a person dies at age 74 years and the expectation of life at age 74 is 16 years, years of life lost is 16 for that person. For this calculation, expectation of life can be for the country of that person but is mostly taken for the population with the highest expectancy. Japan is the country where the expectation of life is the highest. In Slovakia, their expectation of life at 74 may be 7 years, but if expectation of life in Japan at age 74 is 16 years, the years of life lost will be considered 16 and not 7. This helps in obtaining the years of life lost on comparable scale across countries. PYLL is estimated by drawing up a **life table**: by linking life table data to each death of a person of a given age, sex, and race.

PYLL is generally calculated per year. If there are n deaths in a population in one particular year, the years of life lost in the population = x1 + x2 + … + xn, where xi is the years of life lost of the ith person. For comparability, this is also calculated per 1000 population. If PYLL in India is 182 years per 1000 population in 2016, and in 2011 it was 196 years, you know that improvement has taken place. If this is 75 years in Germany in 2016, you know how much ahead of India this country is with respect to this indicator.

What has just been mentioned is for all causes of death, but PYLL can also be calculated for any particular disease. For example, one can conclude from PYLL that cancer causes more person-years lost than do all the other diseases combined. Understanding the concept is also quite exacting: we can draw upon an example contained in a cancer trends progress report—2015 update [1]. PYLL caused by cancer helps to describe the extent to which life is cut short by cancer. On average, in the United States, each person who died from cancer in 2012 lost an estimated 15.7 years of life. This loss has been calculated per person who died of cancer and not per 1000 population. Average years lost due to a disease is the PYLL divided by the number of deaths by that cause. This is potentially a better method, or at least a complementary method, of measuring the burden of lives lost than death rates alone. Soneji et al. [2] were able to conclude by using PYLL that cancer burden increased as a result of decline in cardiovascular mortality, and observed that prior assessments have underestimated the impact of cancer interventions.

PYLL can be a useful metric for comparison of diseases also. If PYLL from cancer is 42 per 1000 population in a country and PYLL from coronary diseases is 38, you know that both are afflicting nearly the same loss of life in that country on average. (These values are illustrative and not real.) In another country, the affliction by coronary disease may be early in life, which would result in higher years of life lost by this disease in this country. You can also calculate this separately for men and women and get the idea which disease causes more early deaths in females than males. For example, when deaths are restricted to age 0–69 years, PYLL in 2012 from all causes was 2.048 in the females of Austria per person but was 3.578 in Hungary, whereas these values in males were 3.835 and 7.507, respectively [3]. Note the disparity between males and females. Among others, this provides another evidence that males are dying early in both these countries.

PYLL can be used for morbidity also when equated to death by some weightage as mentioned for **disability weight**.

## poverty index

Poverty is generally equated with lack of income, but Oxford Poverty & Human Development Initiative (OPHI) [1] uses a multidimensional

**TABLE P.4**
**Components of Multidimensional Poverty Index**

| Indicator | Weight of the Major Component | Division of Weight into Subcomponents |
|---|---|---|
| I. Education | 1/3 | |
| Ia. No one has completed five years of schooling | | 1/6 |
| Ib. At least one school-age child not enrolled in school | | 1/6 |
| II. Health | 1/3 | |
| IIa. At least one member is malnourished | | 1/6 |
| IIb. One or more children have died | | 1/6 |
| III. Living conditions | 1/3 | |
| IIIa. No electricity | | 1/18 |
| IIIb. No access to clean drinking water | | 1/18 |
| IIIc. No access to adequate sanitation | | 1/18 |
| IIId. House has dirt floor | | 1/18 |
| IIIe. Household uses "dirty" (dung, firewood, charcoal) cooking fuel | | 1/18 |
| IIIf. Household has no car and owns at most one of: bicycle, motorcycle, radio, refrigerator, telephone, or television | | 1/18 |

approach to measure it. They define it as experience of deprivation and take it to constitute poor health, lack of education, inadequate living standard, lack of income, disempowerment, poor quality of work, and threat from violence. Under this formulation, lack of income is one of the many constituents of poverty.

The United Nations Development Program (UNDP) [2] has adopted a multidimensional poverty index (MPI) as per the details provided in Table P.4. This includes measures of health, education, and living standard—each making up one-third of the index. The yes/no type of information, with a score of 1 and 0 for yes and no, respectively, is compiled for the households but applied to each individual of the household. For example, health component has nutrition measured by "at least one member of the household is malnourished" and "one or more children have died." If one of these occurs in a household, all members of the household get the score of 1. For this, information on household size is also recorded.

Note that living conditions have six indicators, and all get the same weight. MPI is the weighted average of the number of the "yes" answers. This index can be considered as an inverse of what **human development index (HDI)** measures. The higher the MPI, the greater the poverty. The UNDP divides it also into headcount ratio and intensity of poverty. For details, see their latest HDI report.

## power (statistical) and power analysis

The following discussion on power presumes that you are familiar with the terms **Type I error**, **Type II error**, and **level of significance**. If not, you may like to review these topics.

The complementary of the probability of Type II error is called statistical power and is denoted by $(1 - \beta)$. Thus, the power of a statistical test is the probability of correctly rejecting a null hypothesis $H_0$ when it is false. In other words, this is the proportion of times that repeated samples of similar nature would give *P*-values less than $\alpha$ when the effect specified by the alternative hypothesis $H_1$ is present. Thus, this is the ability of a test to detect the specified difference or any other measure of effect. The power of a test is high if it is able to detect a small difference and can easily reject $H_0$. Suppose the mean peak exploratory flow rate (PEFR) in workers in a tire manufacturing industry is 296 L/min and that in workers in a paint varnish industry is 307 L/min so that the mean difference is 11 L/min. This difference seems small relative to the PEFR values. A test with high power is needed to detect this difference when present and to call it statistically significant. A test with low power will not be able to reject the $H_0$ of equality in this case and will lead to the conclusion that the difference is likely to have arisen by chance in the samples studied. Power measures the degree of assurance that the specified difference will not be missed even when clouded by high variability in the measurements.

Statistical power becomes an especially important consideration when the investigator does not want to miss a *specified* difference. For example, an antihypertensive drug may be considered useful if it reduces diastolic blood pressure (BP) in certain type of cases by an average of at least 5 mmHg after use for, say, 1 week. A sufficiently powerful statistical test would be needed to detect this difference with high probability. Thus, the magnitude of $(1 - \beta)$ is an important consideration in this setup. However, one would like that the minimum **medically important difference** (5 mmHg in this case) is chosen on some objective basis. The choice may not be easy in some situations since this is determined on *clinical* considerations based on benefit to the subjects. Do not confuse it with the actual effect size, which could be more or less.

The number of subjects in the study that determines the standard error is the most important consideration for power when all sources of bias and uncertainties, such as lack of knowledge and inadequate design, are in control. The best approach to achieve good power for detecting a minimum medically relevant difference is to increase the number of subjects in the study. Formulas are available that can give this number for different settings (see the **sample size** formulas in this volume). Power calculation depends on whether the characteristic under assessment is quantitative or qualitative, the form of its statistical distribution in the target population, the variance across subjects, the minimum difference between groups that can be considered medically relevant, and the chosen level of significance. A power of 0.80 or 0.90 seems to have become the norm for medical studies. For analogy with statistical significance, it is customary to call successful detection of a medically relevant difference as **medical significance** of results.

There is a trade-off between Type I and Type II errors in all statistical tests of hypothesis setups. In the court analogy also, which is popularly quoted in this context, eagerness to convict a guilty person has a direct bearing on the risk of an innocent being convicted. A Type II error (not being able to punish a guilty person because of lack of evidence) is preferred over a Type I error in a court to uphold civil rights if the evidence is not sufficiently convincing. Thus, power has a kind of direct relationship with the **level of significance**. The lower the level of significance, the lower the power. Using 1% level

of significance instead of the conventional 5% will make it difficult to reject a false null, and the power will be reduced. The relationship between significance level α and power (1 – β) can be obtained in terms of a receiver operating characteristic (ROC) curve similar to the one between sensitivity and (1 – specificity). However, utility of such ROC is limited since α is mostly fixed in advance.

Also, the power is low if the variance is high. You can intuitively realize that when values are highly variable from subject to subject, the difference between two or more groups will be difficult to detect. In addition, irrespective of α and variance, a smaller difference is difficult to detect, and the corresponding power will be low. The larger the minimum medically relevant difference, the greater the power. For example, in the case of the difference between capillary (by stick) and venous random blood sugar, the difference of possibly as much as 20% could be tolerated. In this case, medically important difference is large. The basic statistical consideration in determining the power is the sample size. An adequately large sample can override the limitation of low level of significance, high variance, and small medically relevant difference for detection.

In the case of large *n*, when **Gaussian conditions** prevail, it can be shown for one-tailed test that

$$\text{power} = P(Z \geq z_\alpha \text{ when the specified medically important effect is present}),$$

where $Z$ is the criterion under the null, assumed Gaussian here, and $z_\alpha$ is the value of $z$ corresponding to the α level of significance. The sample size $n$ would occur on the right side of the above equation. This can be solved to obtain $n$ when everything else is specified. However, the criterion may not be $Z$ and would depend on the kind of data you have. If the power is to be 99% for detecting a specified difference, obviously a larger sample size is required than for a power of 80%. Power and $n$ have a direct relationship for any fixed level of significance. The following example illustrates the power calculation in a simple situation.

The ratio of heart rate and the systolic BP is called the shock index. Suppose you measure this for 100 patients of ST-segment elevation myocardial infarction at the time of admission to test the null hypothesis that the mean is $\mu_0 = 0.70$ and the alternative is $\mu_0 > 0.70$. If the sample mean is 0.73 and $\sigma = 0.16$, what is the power of the study to find statistical significance when actually the mean is $\mu_1 = 0.75$ and the level of significance is 5% for one-tailed test? For many tests, such a calculation is difficult, but it is easy in this case since the sample size is large and the mean can be assumed to follow a Gaussian pattern even when the original values do not. Statistical significance in this case will be achieved when $Z \geq 1.645$ under the null hypothesis, where 1.645 is the Gaussian value for one-tailed probability 0.05. Under the null, $Z = \dfrac{\bar{x} - \mu_0}{\sigma/\sqrt{n}} \geq 1.645$ gives $\bar{x} \geq 1.645 \times 0.16/10 + 0.70$, i.e., $\bar{x} \geq 0.7263$. Power is the probability of this when mean $\mu_1 = 0.75$. That is,

$$\begin{aligned}
\text{power} &= P(\bar{x} \geq 0.7263 \text{ when the actual mean is } 0.75, \\
&\quad \sigma = 0.16, \text{ and } n = 100) \\
&= P\left(\frac{\bar{x} - \mu}{\sigma/\sqrt{n}} \geq \frac{0.7263 - 0.75}{\frac{0.16}{10}}\right) \\
&= P(Z \geq -1.48) \\
&= 0.93.
\end{aligned}$$

In this example, there is a 93% chance that the null of $\mu_0 = 0.70$ will be rejected when the actual mean is 0.75. In practice, we rarely calculate power; we calculate $n$ for the desired power so that the study can be planned accordingly. This exercise is done at the planning stage before the data are collected and the required sample size is mentioned in the protocol on the basis of the power calculations. For this, see the following and the topic **sample size**.

### *Power Analysis*

Good researchers determine the sample size on the basis of power required to detect a specified minimum difference, and try to do their study on the size so determined. Power is specific for the difference or effect size we wish to detect. Because of some exigencies, sometimes it becomes difficult to study as many subjects as calculated. This reduces the power. Sometimes a study is done on specific $n$ without worrying about power.

There is a considerable overlap in the literature about the term **power analysis**. It is used for the calculation of power for a given $n$ as well as for the calculation of $n$ for a specified power. Both calculations require prior specifications of the effect size to be detected based on literature or previous experience. The real utility of power analysis is in designing a study and not so much in interpreting nonsignificance of the result once obtained. Nonetheless, midcourse power calculation (**interim analysis**) can be done on the basis of the observed data and can tell you how much more $n$ you need. Post-hoc calculation can tell you what might have gone wrong. Use this experience for planning a better study next time. Post-hoc power can also be used to assess the ability of the study to discern a false hypothesis.

There is another exception, though. If the study throws up very different values of the parameter estimates such as the proportion $p$ and the standard deviation (SD) $s$ than assumed earlier for calculation of the sample size, and the effect size is found statistically not significant, recalculation of power with new $p$ or SD is justified and can give you better leads about the strength of your result. This can lead to **sample size re-estimation**. See also **adaptive clinical trials**.

## power transformation, *see also* Box–Cox power transformation

A number of statistical analysis methods for testing of hypothesis, such as the Student *t*-test, regression, and analysis of variance (ANOVA), require that the data have a Gaussian distribution. This distribution also helps in obtaining the correct confidence intervals easily. When the data are not distributed in a Gaussian manner, specific features of non-Gaussianity are explored, and appropriate remedial actions are taken. Data transformation is one of those remedial actions that may help to make the data Gaussian. An understanding of the concept of transformation may prepare you better to work with non-Gaussian data.

Transforming data means performing the same mathematical operation on each value in the original data. An example from daily life is converting temperature from degrees Celsius to degrees Fahrenheit. This transformation is called a linear transformation because the original data are simply multiplied or divided by a particular coefficient, or a constant is subtracted or added. But linear transformation does not change the shape of the data distribution, and it remains as non-Gaussian as before the transformation. Thus, nonlinear transformations are examined for achieving Gaussianity.

**TABLE P.5**
**Common Power Transformations**

| Power | –2 | –1 | –0.5 | 0 | 0.5 | 1 | 2 |
|---|---|---|---|---|---|---|---|
| Transformation | $1/y^2$ | $1/y$ | $1/\sqrt{y}$ | $\log(y)$ | $\sqrt{y}$ | $y$ | $y^2$ |

These transformations can also stabilize the variance in case that is needed. In many situations, both non-Gaussianity and variance heterogeneity go hand in hand. One set of these transformations is $y^{\lambda}$, where the $\lambda$ value is the power to which all the values should be raised. This is the reason that it is called power transformation. The value of $\lambda$ varies from one situation to another and depends on the nature of departure from Gaussianity. For example, $\lambda < 1$ is for correcting right skewness and $\lambda > 1$ is for correcting left skewness. The higher the skewness, the greater the power of $\lambda$. For aberrations other than skewness, such as sharp or flat peakedness, this transformation may not work. Also note that these apply only to nonnegative values. If there are negative values in your data, add slightly more than the maximum negative value to all the values so that none is negative.

See Table P.5 for some common transformations. The user may explore the data using several of these and other transformations and then select the most appropriate one.

Box and Cox [1] proposed a family of slightly different transformations that could correct non-Gaussianity in a variety of situations. These are given by

$$\text{Box–Cox power transformation:}$$
$$W(\lambda) = (y^{\lambda} - 1)/\lambda, \text{ for } \lambda \neq 0; \quad \text{and} \quad \ln y, \text{ for } \lambda = 0;$$

where $W(\lambda)$ is a continuous function of $y$. The value of $\lambda$ is chosen in a manner in which the transformed values have Gaussian distribution. A modification of the method of maximum likelihood is used for estimating the value of $\lambda$ for any given dataset. See the topic **Box–Cox power transformation** and Sakia [2] for further details.

Using a power transformation is not in itself a guarantee for achieving Gaussianity. You must check Gaussianity by using one or more of the methods listed under the topic **Gaussianity (how to check)** after the data are transformed.

## pragmatic trials

These are those trials that give high importance to the practical feasibility of the regimen. A regimen may have 90% efficacy, but what is it worth if it is extremely difficult to implement? Effectiveness under practical conditions has brought pragmatic trials into focus. The patients recruited for this kind of trial are not homogeneous as in a regular clinical trial but reflect variations that occur in real clinical practice. Strategies such as **randomization** and **control** are also not structured in this trial. Instead, patients receiving existing regimen or not receiving any treatment serve as control. Because of a large number of intervening factors in this setup, the interpretation could be difficult. Statistically, the standard deviation could be relatively large. For details of pragmatic trials, see Roland and Torgerson [1].

**Clinical trials** are generally done in ideal conditions that do not exist in practice. The subjects are carefully chosen with strict inclusion and exclusion criteria, administration is done in standard conditions, efforts are made for full compliance, patients get full attention, the results are adjusted for dropouts and other missing observations, and the response is carefully assessed by experts. These steps help to draw a causal inference and establish the efficacy of the regimen under trials. However, the actual performance of the regimen in practice may differ. Efficacy of a treatment is what is achieved in a trial that simulates optimal conditions, and effectiveness is what is achieved in practical conditions when the treatment is actually prescribed. For clarity, the latter is sometimes called use-effectiveness. Effectiveness could be lower than efficacy because of lack of compliance of the regimen due to cost or inconvenience, inadequate care, nonavailability of the drugs, etc. These deficiencies do not occur in a trial. Experience suggests that nearly three-fourths of the patients, in general practice, do not adhere to or persist with prescriptions. Thus, patients and maneuvers adopted during a trial do not translate their results for patients at large. Generally, such external validity of the trial results is not high. But clinical trials do establish the potency of a regimen to effect a change. Effectiveness, on the other hand, is a suitable indicator to decide whether or not to adopt that regimen in practice, or what to expect. The concept of effectiveness in contrast to efficacy has given rise to pragmatic trials.

In the absence of blinding and placebos in a pragmatic trial, the results could be biased because of the **Hawthorne effect**. The expectation of participants could be favorable or unfavorable, and that will determine the actual bias. If patients are allowed to choose a treatment as can occur in practice, a further bias may creep in. Causal inference, which says that the effect is due to certain regimen, suffers. Thus, a better approach would be to do a pragmatic trial for assessing usefulness in a real-life situation *after* efficacy in ideal conditions has been established by regular clinical trials.

## precision, *see also* reliability

Imagine you are shooting a gun at a target and that the aim of your gun causes shots to be displaced to one side or the other from the bull's eye. As your shooting proceeds, the shots form a group. The dispersion of this group is the precision. How close the mean of these shots is to the bull's eye is the validity, and not the precision.

It is easy to translate this into the realm of clinical measurements. When repeated measurements of the same characteristic under same conditions give the same value, you know that it is precise. Precision is the same as repeatability or reliability. Measurement of body temperature is quite precise, but that cannot be said about alkaline phosphatase level. Even if you split the sample and analyze separately in the same laboratory in a blind manner, the phosphatase level may differ. This measurement is not as much precise.

Statistically, the term *precision* is used for estimates we generate on the basis of sample values. High precision of estimates (by which

it is meant that the estimates from sample to sample are more tightly grouped) mainly results from a good sample size. When the sample size is large, summaries such as mean and proportion in different samples from the same population would be close to one another. You can intuitively imagine that the means based on two samples of size 100 are likely to be close to one another than the means based on a sample size of 10 each. In clinical trials, the underlying theme with regard to sample size considerations is precision. Imprecision of an estimated effect such as a mean, proportion, and difference is a consequence of measurement error, person-to-person variability, etc. These are factors that are mostly beyond human control; however, the sample size is within our control. By specifying quantitatively the precision of measurement needed in an experiment, the investigator is implicitly outlining the sample size.

Population parameters are seldom known and cannot be calculated (if they were known, there would be no need of a sample). They are almost invariably *estimated* from the corresponding values in the sample. The **standard error** (SE) of these estimates is the inverse measure of precision. This measures sampling error. You may have noted that $\sqrt{n}$ appears in the denominator of most SEs. The higher the *n,* the lower the SE and the higher the precision. This underscores the importance of sample size and explains why statisticians are so particular about the sample size. Precision frequently defines the credibility of the research you do and report.

However, caution is needed in interpretation of the SEs, particularly for proportions. For example, consider $\mathrm{SE}(p) = \sqrt{\frac{\pi(1-\pi)}{n}}$. You may like to check that SE($p$) is maximum when $\pi = 0.5$ and smaller when $\pi$ is either small or large. It would appear that the precision is lowest at $\pi = 0.5$. But its interpretation requires additional care. For $n = 100$ and $\pi = 0.5$, SE($p$) = 0.05, but for same $n$ and $\pi = 0.25$, SE($p$) = 0.043. In absolute terms, the SE in the second case is less than what it is in the first case, but, in relative terms, the second SE is almost one-fifth of $\pi$ while the first is one-tenth of $\pi$. Thus, the precision in the second case is lower in a relative sense. These are referred to as the *absolute precision* and *relative precision*, respectively, of *p.* The difference is more apparent while considering the confidence intervals (CIs). A CI from 0.02 to 0.12 around 0.07 may have smaller width than 0.42 to 0.58 around 0.50; however, the former provides more imprecise information about the value of $\pi$, whereas the latter is not so imprecise.

Distinction between precision and validity is important just as between reliability and validity. In terms of shooting, you can be far away from the target, yet very precise. Shooting is precise if all shots are very close to each other even if all of them are far away from the target. When this happens, you know how to adjust your angle of shooting so that the shots hit the target. This has a direct relation with statistical precision. The estimate may be very precise but highly biased. Bias in statistics implies that the average is far away from what you aimed. Bias can be corrected by adding or subtracting a constant from each value—precision cannot be corrected this way. For medical studies, bias is corrected by framing correct questions, by standardized laboratory results, by randomization or matching, etc.

## predicted value and prediction interval in regression

In 2012, statistician Nate Silver created a furor by predicting the correct results of all 50 states for the presidential election in the United States [1]. Nobody believed that this could be done. Such is the power of prediction. If you can predict the years of life remaining for a patient of cancer, and your prediction turns out correct for many such patients, you will be idolized. However, medical predictions are fraught with enormous uncertainties, surpassed only by attitude and behaviors among human endeavors. The mortals among us use empiricism to predict the future. They are guided by what has actually happened in the past or what is happening in the present and what can possibly affect the outcome. Many researchers take recourse to statistical models for prediction. **Regression** models are just about the most common statistical tools for prediction of medical outcomes. The following discussion is restricted to prediction based on these models.

A regression model can be written as

$$\hat{y} = f(x_1, x_2, \ldots, x_K),$$

where function $f$ is a rule that relates the values of ($x_1$, $x_2$,…, $x_K$) to a variable $y$, and $\hat{y}$ is the predicted value. In case the purpose of the regression is prediction, the $x$ variables are called the predictors of $y$. Their number is $K$ in this model. The function $f$ is chosen in a manner that specific values of the $x$'s uniquely predict the value of $y$. Ordinarily, each value of $y$ must be independent of other values of $y$ for valid regression; for example, they cannot belong to different sites of the same body.

The relationship $\hat{y} = f(x_1, x_2, \ldots, x_K)$ may take any of several different forms. One that is relatively simple to comprehend and most commonly studied is the **linear** form. For $K$ predictors, this is expressed as

$$\hat{y} = b_0 + b_1x_1 + b_2x_2 + \cdots + b_Kx_K.$$

Any of the $x$ variables can be a function of another $x$ variable. For example, $x_3$ could be $x_2^2$, or $x_4$ could be $\ln(x_1)$—thus, this model includes curvilinear regressions. The regression coefficients ($b_1$, $b_2$, …, $b_K$) are obtained by the method of **least squares** or by the method of **maximum likelihood**. When these coefficients are known, the values of the $x$'s can be substituted in the model to predict the value of $y$. Remember though that prediction models are not necessarily the same as explanatory models. For prediction, choice of the $x$ variables is not important—one set of $x$'s may be as good as another set of $x$'s for predicting $y$, but in explanatory models, $x$'s must be those that are biologically or functionally related to $y$.

One of the important functions of regression is to provide an estimate or to predict the value of $y$ for a given set of $x$'s. There is a fine statistical distinction between an estimated value and a predicted value. The former term is generally used for the *mean* of $y$ for a group of individuals with a specific value of ($x_1$, $x_2$, …, $x_K$), and the latter is used for the value of $y$ for a single individual. The former has less variance than the latter, although both have the same value. Because the estimated and predicted values are the same, these terms are sometimes interchangeably used in the literature.

The predicted value of $y$ will be the best that the regression model can predict, but it may still be far from reality. Correct prediction depends on the proper choice of predictors. These should include all those that are associated with the outcome $y$, although they may or may not be causally associated with $y$ as this is not important for prediction models. The difficulty is that for many medical outcomes, all associated factors are rarely known—nobody knows, and we work within the limitation of our knowledge. Such epistemic gaps are the most pronounced stumbling blocks for correct prediction. In addition, a linear model is not necessarily the most appropriate even when it is extended to include curvilinear forms. Most medical phenomena are not as simple, and many times nonlinear models provide better prediction. Linear models were

a favorite because of the ease of computation and understanding, but now computation is not a restrictive feature—understanding remains a block that is still to be overcome by many researchers.

Consider the problem of predicting body surface area (BSA) (in $cm^2$) by weight (in g) of well-proportioned children using simple linear regression [2]. If the regression is BSA = 1321 + 0.3433(Wt), it tells what BSA to expect in children of different weights. If this regression is good, the predicted BSA of a child of 20 kg is (1321 + 0.3433 × 20,000 =) 8187 $cm^2$. The actual value would most likely differ from this predicted value. If the actual BSA of a child of 20 kg is found to be 8093 $cm^2$, then the difference from the expected is –94 $cm^2$, and if another child of 20 kg has BSA 8214 $cm^2$, then the difference is +27 $cm^2$. Thus, prediction is never perfect. Statistically, the error in the long run depends on the standard error (SE) of the estimate.

The SE of $\hat{y}$ is different when it is for the mean of $y$, earlier called as the *estimated value* of $y$, and when it is for individual values of $\hat{y}$, earlier called as the *predicted value* of $y$. Prediction of individual values has a much larger SE. These SEs have complex forms for multiple regression, but they can be easily stated for a simple linear regression. Under certain general conditions, for a simple linear regression of $y$ on $x$,

$$\text{SE (predicted individual value of } y_x) = \sqrt{\text{MSE}\left[1+\frac{1}{n}+\frac{(x-\bar{x})^2}{\Sigma(x-\bar{x})^2}\right]},$$

and

$$\text{SE (predicted mean value of } y_x) = \sqrt{\text{MSE}\left[\frac{1}{n}+\frac{(x-\bar{x})^2}{\Sigma(x-\bar{x})^2}\right]},$$

where $y_x$ is the value of $y$ at a given $x$. MSE is the mean square error and is always generated by the regression package. If the dependent of interest is duration of analgesia ($y$) in min induced by different doses of a drug ($x$) in μg, and $n$ = 15, MSE = 6.50, $\bar{x} = 11.2$ μg, and $\Sigma(x-\bar{x})^2 = 18.07$, then for $x$ = 8 μg, SE(predicted individual value of $y$ at $x$ = 8) $= \sqrt{[6.50\{1+1/15+(8-11.2)^2/18.07\}]} = 3.26$ min by the above equation. The SE of the estimated mean is 2.03. The SE of the predicted value is much higher than the SE of the estimated value of $y$. Prediction of the individual value of $y$ is always less precise than the estimation of the mean of $y$. This has direct bearing on the **prediction interval**, which is the same as the confidence interval for the predicted value.

## predictive validity, *see* predictivities (of medical tests)

## predictivities (of medical tests)

Predictivities of medical tests are their ability to correctly identify presence or absence of a disease or any health condition. Positive predictivity refers to the ability to detect presence of disease, and negative predictivity is the ability to detect absence of disease. These are also called predictive value of a positive test and of a negative test, respectively. These are kind of the opposite of what **sensitivity and specificity** are. Sensitivity and specificity are also indicators of the validity of a test, but they do not measure the diagnostic value of the test. Sensitivity and specificity are based on the correct identification of the cases when it is known that the groups of subjects have disease or do not have disease, i.e., the disease status is already known. Diagnostic value of a test is obtained in terms of predictivities.

### *Positive and Negative Predictivity*

The actual problem in practice is detecting the presence or absence of a suspected disease by using a test. The diagnostic value of a test is measured by the probability of actual presence of disease among those who are test positives and the probability of actual absence of disease among those who are test negatives. Besides the names just mentioned, these can also be understood as posttest probabilities and measure the utility of a test in correctly identifying or correctly excluding the disease. Positive predictivity can also be understood to measure how good the test is as a marker of the disease. In terms of notations,

$$\text{positive predictivity } P(+) \text{ or } P(D+\,|\,T+) = \frac{\text{TP}}{\text{TP}+\text{FP}}$$

and

$$\text{negative predictivity } P(-) \text{ or } P(D-\,|\,T-) = \frac{\text{TN}}{\text{TN}+\text{FN}},$$

where $D$+ is for presence of disease, $D$– for its absence, $T$+ is for positive test and $T$– for negative. TP, TN, FP, and FN are given as in Table P.6.

Suppose that 4700 patients coming to a cardiac clinic with some complaints had ECG done. Out of these, 425 had positive ECG and 275 negative ECG. All these were further investigated, and 416 of 425 ECG positives were found to have myocardial infarction (MI) (Table P.6), and 104 of 275 ECG negatives were found to have MI.

**TABLE P.6**
**Myocardial Infarction (MI) and ECG in Cases of Acute Chest Pain**

| | MI | | |
|---|---|---|---|
| **ECG** | **Present** | **Absent** | **Total** |
| Positive | 416 (TP) | 9 (FP) | **425** |
| Negative | 104 (FN) | 171 (TN) | **275** |
| **Total** | **520** | **180** | **700** |

Then, the predictivity of a positive ECG for the presence of MI in such cases is

$$P(+) = \frac{416}{425} \times 100 = 98\%,$$

and the predictivity of a negative ECG for the absence of MI is

$$P(-) = \frac{171}{275} \times 100 = 62\%.$$

The diagnostic value of a test is not reflected by sensitivity and specificity but is reflected by predictivities. These also are indicators of the validity of a test. If these 700 subjects in this example are considered good representatives of such cases, the specificity is high at 95% (171/180), yet the test is poor in excluding MI—only 62% are correctly ruled out. This happens in this case because many subjects with negative ECG have MI (i.e., 104 out of 275). What it tells us is that the ECG can be safely used to detect the presence but not to detect the absence of MI, as far as this example is concerned.

A screening test should have high negative predictivity, whereas a confirmatory test should have high positive predictivity. When both are equally important, use

$$\text{predictive validity} = \frac{\text{TP} + \text{TN}}{\text{total subjects tested}}.$$

**Predictive validity** combines the two predictivities assuming that both are equally important. If they are not, an index can be devised that gives differential weight as needed. This equation is similar to

$$\text{inherent validity of a test} = (\text{TP} + \text{TN})/n,$$

but the interpretation is different since the denominator in the latter equation is the total subjects with and without disease and in the former equation is the total subjects who are test negative and test positive.

### *Predictivity and Prevalence*

You can see that the concepts of sensitivity and specificity work in an inverse direction. They move from disease to the test. The predictivities do provide assessment in the right direction, but they are severely affected by the prevalence of disease among those tested. This is illustrated in the example below. The advantage of sensitivity and specificity is that they are absolute and do not depend on prevalence.

Out of the 700 tested, let the number with MI in Table P.6 be changed to 300 rather than 520 (the prevalence is now 43%, i.e., 300 × 100/700). If the sensitivity and specificity remain as before at 80% and 95%, respectively, then the different numbers would be as shown in Table P.7. Now,

$$\text{positive predictivity} = \frac{240}{260} \times 100 = 92\% \text{ and negative predictivity}$$

$$= \frac{380}{440} \times 100 = 86\%.$$

These values are very different from the ones obtained earlier because of the entirely different prevalence rate. The previous prevalence rate was 520/700 = 0.74 or 74%, and now it is 43%.

**TABLE P.7**
**Increased Prevalence of Disease Than in Table P.6**

| | *D*+ | *D*– | Total |
|---|---|---|---|
| *T*+ | 240 | 20 | **260** |
| *T*– | 60 | 380 | **440** |
| **Total** | **300** | **400** | **700** |

When the prevalence rate is available, denoted by $P(D+)$, we can calculate predictivities from sensitivity–specificity as follows. From **Bayes rule**, positive predictivity is given by

$$P(+) \text{ or } P(D+ \mid T+) = \frac{P(T+ \mid D+)P(D+)}{P(T+ \mid D+)P(D+) + P(T+ \mid D-)P(D-)}$$
$$= \frac{S(+) * p}{S(+) * p + [1 - S(-)] * (1 - p)},$$

where $p$ is the prevalence rate per unit, and $S(+)$ is the sensitivity and $S(-)$ the specificity. When sensitivity and specificity are constants, it is easy to see from the above equation that positive predictivity increases as prevalence increases. Similarly, it can also be shown for negative predictivity that

$$P(-) \text{ or } P(D- \mid T-) = \frac{S(-) * (1 - p)}{S(-) * (1 - p) + [1 - S(+)] * p}.$$

As prevalence increases, the negative predictivity decreases. Dependence of predictivity on prevalence arises from putting the information in its proper context. A patient with high fever and shivering might be diagnosed with influenza in Europe but malaria in West Africa [1].

The predictivities for some specific values of sensitivity and specificity and for different prevalences are shown in Table P.8. As

**TABLE P.8**
**Predictivities for Some Specific Values of Sensitivity, Specificity, and Prevalence**

| Sensitivity *S*(+) | Specificity *S*(–) | Prevalence | Positive Predictivity *P*(+) (%) | Negative Predictivity *P*(–) (%) |
|---|---|---|---|---|
| 0.20 | 0.20 | 0.10 | 3 | 69 |
| | | 0.50 | 20 | 20 |
| | | 0.90 | 69 | 3 |
| 0.20 | 0.90 | 0.10 | 18 | 91 |
| | | 0.50 | 67 | 53 |
| | | 0.90 | 95 | 11 |
| 0.90 | 0.20 | 0.10 | 11 | 95 |
| | | 0.50 | 53 | 67 |
| | | 0.90 | 91 | 18 |
| 0.90 | 0.90 | 0.10 | 50 | 99 |
| | | 0.50 | 90 | 90 |
| | | 0.90 | 99 | 50 |

P

the prevalence increases, the positive predictivity also increases, and this increase is more pronounced when the specificity is low. Higher prevalence leads to less negative predictivity, more so when sensitivity is low.

The two equations just mentioned also express the relationship between sensitivity–specificity and predictivities. If prevalence is known, predictivities can be obtained by using sensitivity and specificity. Herein lies the importance of these two somewhat reversed indices. Based on confirmed cases, sensitivity and specificity are easy to obtain. Use them to calculate diagnostically important positive and negative predictivities with the help of these equations. Direct calculation of predictivities requires follow-up studies to find the confirmed cases with and without disease among those that have shown positive and negative tests. Such follow-up studies can be expensive and can be avoided for predictivities when prevalence is known and sensitivity–specificity easily obtained.

## predictors

A predictor variable is the one that is useful for predicting the value of the response variable. It may not fully predict the value but helps at least partially when chosen with care. Obviously, this would be used in a setup where response is not known or is difficult to observe or measure. Otherwise, why would one want to have a predictor? Predictors need not be biologically or causally related to the response, and they may have an indirect relationship. The stronger this relationship is, the better the predictor becomes. Among statistical methods, predictors are used predominantly in a **regression** setup that exploits the relationship between these so-called predictors and the response. In this setup, variables with high correlation with the response would be good predictors.

The general form of regression is $\hat{y} = f(x_1, x_2, \ldots x_K)$, which expresses a variable $y$ in terms of another set of variables $x_1, x_2, \ldots, x_K$. Whether or not this relationship is adequate is another question. When the objective of the regression is prediction of $y$ based on observed values of $x's$ (see **explanatory and predictive models**), then $\hat{y}$ is the predicted value of $y$ and $x's$ are the predictors. In case of multiple linear regression, this takes the form $\hat{y} = b_0 + b_1x_1 + b_2x_2 + \ldots + b_Kx_K$, where $x's$ are the $K$ predictors; and in case of logistic regression, this becomes $\hat{\lambda} = b_0 + b_1x_1 + b_2x_2 + \ldots + b_Kx_K$, where $\hat{\lambda} = \ln\frac{p}{1-p}$ and $p$ is the proportion of subjects with positive response. The response variable in this case is $\hat{\lambda}$, which is called the logit of $p$. In both ordinary and logistic regressions, the predictors could be dichotomous, polytomous, continuous, standardized, etc., and the interpretation of the regression changes accordingly. The details are as follows. Also see the topic **regression coefficients**.

### *Types of Predictors*

Continuous predictors are those that can have any value within the specified range. Age, blood pressure, bilirubin level, and creatinine level are the examples. In the case of linear regression, which we are considering in this section, the effect of continuous predictors on the response is that it increases by $b_k$ per unit increase in the value of $x_k$. Thus, the predicted value of $y$ depends on whether $b_k$ is small or large, positive or negative. This is adjusted for other predictors in the model. If you want to compare the effect of two predictors to find which of them has more influence on the response, it is necessary to standardize the predictors. A predictor that has a value in hundreds such as cholesterol level may have small $b_k$ but will still have large effect compared with, say, creatinine level, which is generally less than 1 when measured in mg/dL units. Thus, it also depends on the units. Weight (of, say, an infant) measured in kg will have a different meaning compared to weight in g.

Response will be in logit units in case of logistic regression, and the effect of a continuous predictor has to be assessed with a degree of caution. If a predictor is continuous such as age in years, a logistic coefficient of 0.15 would imply odds ratio (OR) = $e^{0.15}$ = 1.16, indicating that each year of increase in age increases the OR by a factor of 1.16. A 10-year increase in age would increase the OR by a factor of $(1.16)^{10}$ = 4.41. You can say that a 10-year increase in age increases the OR by 341%. In this case, the OR may look only slightly more than 1.0, but it can translate into an enormous effect. The argument can be turned on its head for another predictor such as waist–hip ratio that can rarely increase by 1 unit.

Interpretation of dichotomous and polytomous predictors is not so straight. Dichotomous predictors are those that have just two categories such as male or female, healthy or sick, prescription followed or not followed, discharged or died, etc. These categories are customarily coded as 0 and 1. Consider a simple example of linear regression for predicting systolic level of blood pressure (sysBP) in healthy adults with age and sex as the predictors. This regression could be sysBP = 112 + ⅓*Age – 4*Sex, where Sex is coded as 1 for males and 0 for females. Sex is a dichotomous predictor in this example. When these codes are substituted in the equation, you get sysBP = 108 + ⅓*Age for males and sysBP = 112 + ⅓*Age for females. Coding in this case gives two equations—one for males and the other for females. The case of polytomous predictors is more complex. First, they could be nominal or ordinal, and these two types require separate treatment. For nominal predictors, **indicator variables** are used as predictors as explained for that topic. For ordinal predictors, see if you can convert them into linear or nonlinear **scores**. Whereas the interpretation of polytomous predictors is simple in case of ordinary regression, logistic regression requires some explanation.

Interpretation of logistic coefficients for predictors with three or more categories depends on the coding system adopted. If a particular predictor is polytomous ordinal such as disease severity categorized as none, mild, moderate, serious, or critical, many types of coding can be done. The simplest can be 0, 1, 2, 3, 4 when the number of categories is five. This kind of coding quantifies predictor values and works like a score. In this case, the corresponding $e^b$ is the factor by which OR multiplies when the category moves one up in terms of this score. If $e^b$ = 1.15, this means that the odds for category $x$ = 1 (mild disease) are 1.15 times the odds for category with $x$ = 0 (no disease), and the odds for category $x$ = 2 (moderate disease) are 1.15 times the odds for category $x$ = 1 and 1.15 × 1.15 = 1.32 times the odds for $x$ = 0 (no disease).

This interpretation of the logistic coefficient is valid for ordinal predictors. For a predictor in real nominal categories, suitable **contrasts** of interest should be defined. They are generally defined in terms of the difference of one group from one or more of the others. If the objective is to examine 5-year survival with site of malignancy, you can have one particular site, say lung, as the reference category and compare this with oral, prostate, esophagus, etc., by forming contrasts such as (lung – oral), (lung – prostate), etc. Each of these contrasts would appear in the predictor set of the logistic model. If you consider it more appropriate, you can have "prostate cancer" as the reference category. In this case, all other sites will be compared with this cancer. This requires coding accordingly. The advantage with these kinds of contrasts is that each contrast will have its own logistic coefficient, and the coefficient for one contrast can differ from that of another contrast. Thus, differential effects of the categories on the

response, if present, will emerge. It is possible to find out if one particular category, say category 2, is a significantly higher contributor to the response than category 3 or category 1. The serial coding 0, 1, 2, 3, 4 mentioned in the preceding paragraph does not have this feature.

For interpretability, it is necessary that each category of each predictor is explicitly defined. For example, the "others" category that includes leftovers as in a kitchen sink is not admissible. In cases where reference category is used for all comparisons, conclusions are more reliable when the number of subjects in the reference category is reasonably large.

## pretesting, *see* pilot study and pretesting

## prevalence and prevalence rates

In our context, prevalence is the presence of morbidity, and incidence is its fresh occurrence. Thus, prevalence is computed on the basis of the existing cases and incidence on the basis of the new cases. They can be obtained either by counting the subjects affected or by counting the episodes that have occurred. Prevalence is considered to measure the load on health care services, and incidence is considered to measure the risk of getting the disease. In its simplest form, prevalence is governed by incidence (how much new cases are added), duration of disease (due to which accumulation occurs), **case fatality** (how many people with the disease are dying), and recovery (what percentage of cases recover) (Figure P.12).

Depiction of prevalence in Figure P.12 is rather too simplistic. In fact, the prevalence increases when

- Incidence increases: This can happen either because people become more susceptible due to change in lifestyle, because of the increase in expectation of life that can increase the proportion of the vulnerable section, or because the causative agent such as bacteria has increased. If people become healthier and more resistant, the incidence will decrease.
- Duration of disease increases: See Figure P.13 where prevalence on day 7 is only 1 case when the duration of disease is short and is 9 when the duration of disease is long (for both the diseases in this figure, the onset [incidence] is the same). This will happen when better knowledge and technology are available to save lives—the patients remain sick for longer time but are not allowed to die.
- Recovery rate reduces: This is rare but can happen when the disease starts afflicting mostly old-age people who may have a slower rate of recovery. Fast recovery due to early detection and availability of better treatment regimens can decrease prevalence.
- Detection improves either because of better surveillance or because of the availability of more sensitive tools.
- Better reporting occurs due to more awareness.
- There is immigration of cases.

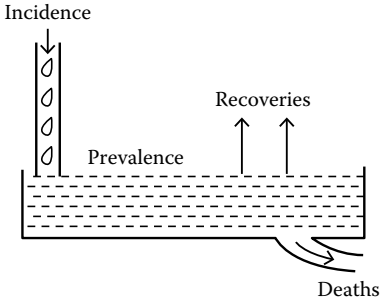

**FIGURE P.12** Accumulation of prevalence.

The last three indicate artificial increase and not the real increase. Cancer is the disease where most of these factors are operating almost all around the world.

By its nature, incidence is related to a period such as a week, a month, or a year, but prevalence is related to a point of time. Yet, there are concepts of point prevalence and period prevalence.

### *Point Prevalence*

Point prevalence is the number of cases existing at a specific point in time. Some cases may be preexisting, and some may have occurred on the day of inquiry. Thus, many texts define this as old and new cases. A survey to identify affected cases in a population generally takes weeks or months, but the count obtained is a point prevalence when the inquiry is with regard to the presence or absence of morbidity at the time of contact or a particular reference time point. This can be obtained by a cross-sectional survey. Point prevalence for the episodes would be the same as for the subjects because, at any point of time, a person cannot have two episodes of the same illness. In any case, point prevalence is generally obtained for chronic conditions rather than for acute illnesses.

For the purpose of comparison between groups, areas, diseases, etc., it is customary to calculate the prevalence rate (percent, per thousand, or per million persons) at a particular point in time. *It is actually a proportion but is conventionally called a rate.* It does not measure the speed of occurrence that a rate should. Persons counted

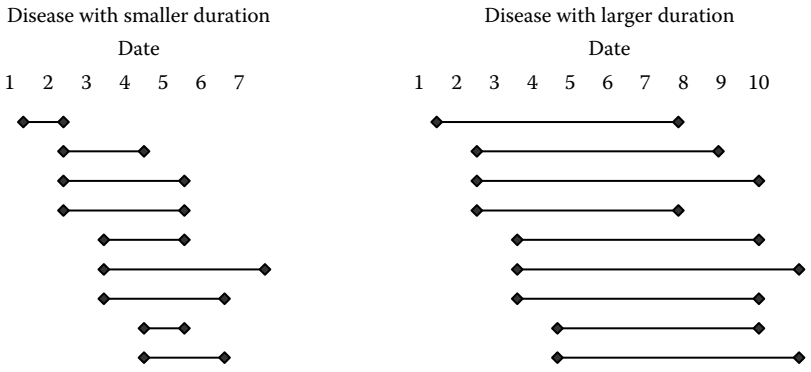

**FIGURE P.13** Effect of duration of morbidity on prevalence.

for the denominator are those who are exposed or at risk for the disease in question; others are excluded. For example, for smoking, children below the age of 12 years can be excluded. A prevalence rate can be calculated for a specific age, gender, occupation, etc. The prevalence rate estimates the probability of the presence of morbidity in a randomly selected person from that group. This has also been called a pretest probability in the context of **predictivities** of medical tests, although there prevalence is calculated among those suspected. If peptic ulcer is found in 5% of the cases of hypertension, this is the prevalence rate of peptic ulcer among cases with hypertension.

### *Period Prevalence*

For calculating period prevalence, the number of persons affected or the number of episodes of illness present during a specific period such as 1 week or 1 month in a defined population is counted. This includes the number of cases arising before but extending into or through the period as well as those arising during that period. The information sought from the respondent in this case is whether he/she is suffering from the disease at the time of inquiry or had suffered at any time during the last 1 week, 1 month, etc. For measuring period prevalence, generally only a short duration is considered, and it is mostly obtained for acute conditions.

### *Prevalence Rate Ratio*

If prevalence of a disease in males is 17% and in females 24%, it could be useful to say that the prevalence in females is nearly 1 ½ times of that in males. The ratio of prevalence in two mutually exclusive groups is called the prevalence rate ratio (PRR). Thus,

$$\text{PRR} = \frac{\text{prevalence rate in one group}}{\text{prevalence rate in another nonoveralapping group}}.$$

If $n_1$ is the number of subjects with diabetes and $a$ of them are also hypertensive, the prevalence of hypertension among diabetics is $a/n_1$. If $n_2$ is the number of subjects without diabetes and $b$ of them are hypertensives, the prevalence in this group is $b/n_2$. In this case,

$$\text{PRR} = \frac{a/n_1}{b/n_2}.$$

This is useful in measuring how commonly a condition is present in one group relative to the other.

## primary sampling unit

In studies that involve a population of largesize, it is sometimes helpful to draw samples in stages (see **multistage random sampling**). If the subjects spread all over a state are the target, you may select a small number of districts or counties in the first stage; then some blocks, colonies, or hospitals in the second stage from the selected districts or counties; and finally the subjects from the selected colonies/hospitals. Thus, there are sampling units of various sizes. The large unit used in the first stage is called the primary sampling unit (PSU). For example, the National Health and Nutrition Examination Surveys in the United States use counties as the PSUs. From each selected PSU, they select segments, households, families, and individuals in stages [1].

In a study to find the prevalence of smoking in females of age 20 years and above in a particular state with, say, a million families, you may, for example, first select 4 counties by the random method, then 12 census blocks within each selected county, and 50 families within each selected block. All females of age 20+ years in the selected families could be the unit of inquiry, although the sampling units are counties, blocks, and families. Some families may have two or more units of inquiry and some none at all, but most may have just one. If there are many families with two or more eligible females, this can produce a **clustering effect**.

When the size of the PSUs is not large, i.e., when they generally contain a small number of subjects, then it is sometimes advisable that these units are not sampled further. All the elements in the selected primary units are then surveyed. This tends to increase the total number of subjects in the sample without a corresponding increase in the cost. Since many subjects in close proximity are included in this kind of sample, the travel time and the cost are saved. When this is done, it is convenient to understand a primary unit as a **cluster**. The units within each cluster are likely to be similar in some sense. The **design effect** arising from including clusters of units in the sample will depend on the size of the clusters and the homogeneity of units within clusters. The estimates and particularly their variance will be affected accordingly.

## primordial factors

According to conventional wisdom, a primordial factor is the one that is used at the very beginning of your study: its inclusion marks a beginning to that process. In our context, primordial factors are those underlying factors that start serial changes in health. The sequence generally is that primordial factors prepare a fertile ground for generation of risk factors, and these risk factors trigger the disease process when a suitable environment is available. Primordial factors have an important place in the etiology of disease; when they are controlled, the disease would not occur—this is called primordial prevention.

For most health conditions, social and environmental conditions are considered primordial. In the case of coronary diseases, obesity and hypertension are risk factors, but their origin may lie in improper diet and physical inactivity. They may have started to make changes at the beginning of life, perhaps even during pregnancy, because of imprudence, lack of awareness, traditions, attitudes, and practices. Thus, awareness could be the main primordial factor. Some of these may lie within—attitudes, personality traits, beliefs, and behaviors may be notable contributors. We can go further down and note that lack of awareness may be rooted in lack of education of parents, awareness in people around, universal lack of knowledge regarding the effect of these factors, and the like. For some cancers, primordial

factors may be environmental pollution, pesticides and chemicals in the food we eat, carcinogens in beauty products we regularly use, etc. There is a growing realization that control of risk factors is difficult unless primordial factors are targeted. For many diseases, these are not fully known, and the search for such factors has given rise to the science of primordialism in health that was earlier mostly restricted to philosophy.

Statistical methods that can investigate primordial factors may require complex modeling such as multilevel models because the effect of primordial factors is many times indirect and mediated through other cofactors that work at different levels. For example, environmental pollution is a macro variable, whereas the use of cosmetics is a micro variable. These can be studied together by multilevel models. Moreover, the statistical properties of most such variables would rarely be Gaussian, and methods such as generalized linear models with suitable link function may be needed to study them.

## principal components

If you are dealing with a really large number of variables that need to be considered together, a statistical method called principal components (PCs) can be used to reduce their number in many situations without losing much information. That can make them manageable and possibly also more meaningful for subsequent analysis. The aim of PC analysis is to reduce the dimensionality of the data.

It should be clear that PC analysis is used for multivariate data and not for univariate data. The original variables are transformed into new ones that are uncorrelated and that account for major proportions of the variance in the data. The new variables are the PCs and are defined as linear functions of the original variables. These are obtained in stages. For $K$ variables, the first PC may be $y_1 = a_0 + a_1x_1 + a_2x_2 + \ldots + a_Kx_K$. This will be the combination that can capture higher variation among $x$'s than any other linear combination. The second PC would be the one that is independent of the first (called *orthogonal*) and captures more of the remaining variation than any other combination. This can be written as $y_2 = b_0 + b_1x_1 + b_2x_2 + \ldots + b_Kx_K$. Similarly, other PCs are obtained. A complex method based on matrices and eigenvalues is used to obtain these PCs. Theoretically, one can obtain as many PCs as the number of variables, but generally only the first few are enough. If the first few PCs account for a large percentage of the variance of the observations (say above 80%), they can be used to simplify subsequent analyses and to display and summarize the data in a more parsimonious manner.

The loss of information in extracting just a few PCs in most cases would be small. But the PCs so derived are purely statistical and would not generally have any biological meaning. These are artificial variables and can make interpretation very difficult. They are sometimes "rotated" (see **varimax rotation**) to be able to attach meaning. PCs are commonly used for psychometric evaluations of questionnaires (see, e.g., Bian et al. [1]) but rarely for medical investigations. If you are looking for meaningful extracts in medical context, use the method of **factor analysis**. This also is based on PCs. That possibly is the most pronounced use of PCs in medical studies.

Among sparing uses of PCs in medical research, one is by Caine et al. [2] on the study of cognitive profile of prion disease. Their PC analysis showed a major axis of frontoparietal dysfunction that accounted for approximately half of the variance observed. This correlated strongly with volume reduction in frontal and parietal gray matter on magnetic resonance images. Tareque et al. [3] developed a wealth index on the basis of PC analysis of socioeconomic data to study the association of diabetes and hypertension with socioeconomic status.

A tutorial on PCs is given by Shlens [4] for those who want to know more.

## principles of experimentation, *see* experimentation (statistical principles of)

## prior probability and posterior probability

The probability of any event without availability of any particular information is called the **prior probability**, and the probability after that information is available is called the **posterior probability**. The latter obviously depends on the kind of information available to alter the prior probability.

When a patient comes with a certain presentation, several possible diagnoses may flash into mind. The clinician mentally works out the chances of each specific diagnostic category and assigns the patient to the most likely category. The diagnosis, thus, is essentially a probabilistic entity. Until sufficient information is available to objectively evaluate probability, personal probabilities can be used. **Personal probability** is a measure of one's belief in a statement. If you believe on the basis of experience or otherwise that among the patients who present with long-standing complaints of abdominal pain, vomiting, and constipation simultaneously, only 16% are cases of abdominal tuberculosis, your personal probability of abdominal tuberculosis given these three complaints (and nothing else) is 0.16. This is the prior probability. It alters as and when additional information on the patient becomes available such as the laboratory test results and x-ray findings.

Posterior probability is the chance of occurrence of an event when part of the information governing its occurrence is known; for example, high fever, rigors, splenomegaly, and presence of the malarial parasite in the blood are the stages that progressively confirm malaria. As the information increases, the diagnosis of malaria becomes firm, and the probability of absence or presence of the disease becomes concrete. This probability depends on what information is already available. The chance part is restricted to the uncovered information.

In an antecedent–outcome setup, if outcome is denoted by $O$ and antecedent state by $A$, the probability to be calculated is $P(O|A)$. This is conditioned on $A$ being present and is called the posttest probability with the same meaning as the posterior probability. $P(O)$ by itself without knowledge of the presence or absence of $A$ is the prior probability. The other prominent use of prior probability is in **discriminant analysis**—to run this analysis, we need to assign group probabilities upfront.

Prior and posterior probabilities are the backbone of **Bayesian inference**. See this topic for details. **Bayes rule** gives the method to convert posterior probability of one kind to another kind. For example, you can convert $P(A|O)$ to the more useful $P(O|A)$. The first is the probability of particular signs–symptoms in a disease, whereas the second is the probability of disease for given signs–symptoms. The first is how our books generally describe the disease, and the second is the way you use for establishing a diagnosis in clinics.

Brase and Hill [1] give a review of this topic.

## PRISMA Statement

PRISMA stands for preferred reporting items for systematic reviews and meta-analyses. It is an evidence-based minimum set of items for reporting in **systematic reviews** and **meta-analyses**. This is an effort to improve the conduct and report medical research so that more objective decisions can be made. The details are available at the PRISMA website [1]. A brief is given as follows.

You may be aware that diverse medical literature is regularly systematically reviewed to extract a common theme so that a more plausible conclusion can be reached regarding efficacy of a regimen or its side effects, its effective implementation, etc. Meta-analyses are their numerical counterparts for combining the evidence. Many times, both go hand in hand. These were being reported in the literature with varying format, sometimes missing the vital information. The aim of the PRISMA statement is to help authors improve the reporting of systematic reviews and meta-analyses. This is primarily designed for reviews of randomized trials, but PRISMA can also be used as a basis for reporting systematic reviews of other types of research, particularly those evaluating interventions.

The PRISMA Statement consists of a 27-item checklist and a four-phase flow diagram. The checklist is divided into Title, Abstract, Introduction, Methods, Results, and Discussion as is usual in the IMRAD format, and states what each of these should contain. For example, the checklist wants that full electronic search strategy for literature should be described, including any limits used, in a manner that it could be repeated. It also wants that results of any assessment of risk of bias across studies should be presented, and limitations fully discussed. There are several others. All these are pretty much the same as known to the researchers, but availability of checklist helps in ensuring that nothing is missed. More important from the statistical viewpoint is the flow diagram (Figure P.14). This shows how many articles have been identified, removed, screened, assessed, and finally included.

PRISMA Statement is an evolving document that is subject to change periodically as new evidence emerges. In fact, the present PRISMA Statement is an update and expansion of the now outdated QUOROM Statement.

## probability, *see also* laws of probability (addition and multiplication)

Uncertainties in medical decisions are profound. These can be minimized but not eliminated, and we must learn to live with them. Measurement of their magnitude is the first step in this direction. An accepted measure of uncertainty is probability. The term has everyday meaning, but its computation can be nerve-wrecking in some intricate cases. Mathematically speaking, an event that cannot occur, such as a human male giving birth to a child, has probability 0. This is as low as it can get. An event that is certain to occur, such as death, has probability 1. No probability can be negative, nor can it exceed 1.

As opposed to mathematics, statistical definition of probability is based primarily on empiricism and thus is milder. If a woman of age 58 years has never conceived in the history of a community, the statistical probability of occurrence of such an event in that community is 0. It does not necessarily imply that the event is impossible. Probability may seem ludicrously abstruse to some clinicians but is pervasive in all medical decision processes. See the two topics on **medical uncertainties** in this volume to be convinced that this really is so.

This section is concerned with statistical probabilities. In simple terms, if oral cancer is seen to occur in 8% of a *large number* of habitual tobacco chewers for more than 10 years, the probability *P* that a randomly picked tobacco chewer of this type will get oral cancer is 0.08. An interpretation of probability is the relative frequency in a large number of cases. Thus, it measures the likelihood of an event and is complementary to uncertainty. Their calculation is illustrated in an example later in this section. In an etiologic investigation, this probability is referred to as risk—a term extensively used to delineate the hazards of a disease on exposure to an unfavorable factor. If the risk of oral cancer among nonchewers is 0.005, then the risk in chewers in our example is 16 times of that in nonchewers.

Beside empirical approach to measure probability as just mentioned, statistical probabilities are also obtained on the basis of mathematical formulation of the statistical **distributions**. These are obtained as area under the curve in the specified range. Thus, for example, we can obtain the probability that a Student *t* statistic with 12 df is more than, say, 4.53, or a chi-square statistic with 28 df is less than 7.81. Such probabilities are routinely obtained for testing a statistical hypothesis. We have separately explained the method for this for the popular Gaussian distribution in the topic **Gaussian probability (how to obtain)**. Similar method is used for all other distributions.

Although probabilities can be exactly obtained in many situations, they are many times interpreted in a subjective manner. One such overlapping classification is as follows: virtually certain 99–100% probability, very likely 90–100%, likely 66–100%, about as likely as not 33–66%, unlikely 0–33%, very unlikely 0–10%, exceptionally unlikely 0–1%. Additional terms (extremely likely: 95–100%, more likely than not >50–100%, and extremely unlikely 0–5%) may also be used when appropriate [1]. In statistics, though, we like to use exact values in place of such subjective interpretations.

### *Personal and Imprecise Probabilities*

In many medical setups, precise probabilities are difficult to obtain. Many clinicians work with what is called **personal probability**. This is based on personal perception of chance of occurring of an event—the rate at which a person is willing to bet. Thus, this is also known as subjective probability. Ramsey [2] published an article in 1926 in which he interprets probability as related to individual knowledge that formulates personal beliefs. This led to the notion of personal probability. Savage [3] has also discussed these probabilities in some details.

In medicine, personal probability is the belief of the doctor in the occurrence of an event—a patient having a particular disease, efficacy of a treatment regimen, a patient getting fully relieved, not surviving for more than a year, etc. This is based on personal experience with the type of case in hand as evaluated from signs, symptoms, investigation results, etc. As more and more information becomes available by way of additional results, response to the treatment, etc., the personal probability changes. The difficulty with personal probabilities is that these are not objectively determined and may substantially vary from one clinician to another. Thus, these are not used for research.

Coined by Peter Walley in 1991 [4], the term **imprecise probability** signifies the absence of exact information that one needs to calculate precise probability. When precise probability cannot be obtained, imprecise probability, marked by lower and upper limits, can help in some cases. Another term used for the same is *interval probability*. Long-term chance of occurrence of cancer in a person with a specific trait would be rarely known. Imprecise probability is a term in relation to this kind of occurrence. Such a probability could be based on personal belief or other considerations that are fuzzy and have an element of gambling. Probability is imprecise when stated in interval such as between 10% and 15%. Such probability arises when the information is scarce, vague, or conflicting, and where the preferences are of the "may be" type. There is no bar in using imprecise probability where precise probability is not available, but note that a decision based on imprecise probability can only be tentative. Remember also that the output of any model cannot be more precise than the inputs. If at all, the output will be less precise. Thus, do not expect a model to work wonders when it is based on imprecise probability. It is better to use precise probabilities wherever possible.

To illustrate it further, suppose a patient comes to you with longstanding complaints of pain in abdomen, vomiting, and constipation. These are considered cardinal complaints, but how confidently can you say that the person has abdominal tuberculosis or, for that matter, any other related disease? Incomplete information propels the use of imprecise probability. Such instances are galore in critical care setup, where the patient requires immediate help and is not in a position to provide history. Even when full information is available, precise probability of a disease or of prognosis is difficult due to omnipresence of **epistemic uncertainties** in health and medicine. In addition, *risk* and *safety* are terms with inherent uncertainty, which are so commonly used in health and medicine setups. It is easier in these setups to think of a range of values of probability that allow greater flexibility for uncertainty quantification to take care of the missing information. One can even postulate that precise probability framework is more of a mirage than reality. It is apparent that weaker expertise is required for specifying imprecise probability compared with the expertise required for precise probability. However, full range of imprecise probability models has not been developed yet, and it is in the pipeline.

Not many researches that have used imprecise probability are available in medical literature. One is by Zaffalon et al. [5] that has successfully used imprecise probabilities arising from incomplete data for diagnosis of dementia and discriminating it with Alzheimer disease. Gurrin et al. [6] have discussed use of imprecise probabilities in randomized clinical trials.

### *Conditional, Marginal, and Complementary Probabilities*

The probability we assign to occurrence of an event A depends on what is known about the situation at that time. If we come to know more subsequently, this probability is revised. This revised probability is statistically called the conditional probability and is denoted as $P(A|B)$, where B is the additional information now available. The original probability is called the unconditional probability. These can also be understood as **prior and posterior probabilities**. This happens all the time in any medical setup such as revising the chance of disease when the test results are available, radiological findings are known, the patient reports improvement or deterioration, or new knowledge becomes available. The conditional probability is defined as

$$\textbf{conditional probability}: P(A|B) = \frac{P(A \cap B)}{P(B)},$$

where ∩ refers to simultaneous occurrence and is called the intersection. This probability really means that out of those with event B, what is the chance that A will occur? This can be easily explained with the help of an example of a cross-sectional study on disease and test results (Table P.9).

For the data in Table P.9, $P(D+) = 160/400 = 0.40$, $P(D–) = 240/400 = 0.60$, $P(T+) = 310/400 = 0.775$, and $P(T–) = 90/400 = 0.225$, where the + sign is for presence and the – sign for absence. Because of their division in this table, these will now be called *marginal probabilities* instead of original probabilities. The intersection probabilities are as follows: $P(D+ \cap T+) = 120/400 = 0.30$, $P(D+ \cap T–) = 40/400 = 0.10$, $P(D– \cap T+) = 190/400 = 0.475$, and $P(D– \cap T–) = 50/400 = 0.125$. Note that the sum of all these intersection probabilities is 1 since these are **mutually exclusive and exhaustive categories** in this example. Now the conditional probabilities can be obtained. For example, $P(D+ | T–) = P(D+ \cap T–)/P(T–) = 0.10/0.225 = 0.444$. This is the same as 40 disease positives among 90 test negatives (40/90 = 0.444). This particular conditional probability is the chance that a test negative patient has the disease.

Note that the conditional probability can be very different from the unconditional probability. For example, probabilities of death at different ages will add to 1. Conditional probabilities do not have this feature. The conditional probability of death between 80 and 84 years may be 0.6, and the conditional probability of death between 85 and 89 years may be 0.7. These are conditioned on the person being alive at that age. These probabilities add to more than 1. This cannot happen with unconditional probabilities.

The scheme of medical knowledge is sometimes to provide probabilities of the form $P(\text{complaints}|\text{disease})$, whereas the probabilities actually required in practice are of the form $P(\text{disease}|\text{complaints})$. For simplicity and for generalizability, denote the set of complaints and investigation results by $C$ and the particular disease by $D$. When some additional information is available, $P(D|C)$ can be obtained from $P(C|D)$ by using **Bayes rule**.

A word about *complementary probability*: When probability of occurrence of an event A is $P(A)$, the complement is the probability of nonoccurrence of A. This is $1 – P(A)$. In our example, $P(T–)$ is the complementary probability of $P(T+)$ assuming that if test is not negative, it has to be positive, when the third possibility of indeterminate is ruled out.

**TABLE P.9**
**Test Results and Disease Status in 400 Subjects Attending a Clinic**

| | Test Positive | Test Negative | Total |
|---|---|---|---|
| Disease | 120 | 40 | **160** |
| No disease | 190 | 50 | **240** |
| **Total** | **310** | **90** | **400** |

### *Further on Probabilities*

Probabilities are the foundation of statistics. You must have a good grasp of its different features to be able to correctly interpret the statistical results. This includes the **laws of probability** such as law of multiplication, which helps to calculate the probability of joint occurrence of two or more events, and the law of addition, which helps to calculate the probability of one or the other event. Refer to that topic for more details. Probabilities play an important role in wide-ranging clinical activities as described for **probabilities in clinical assessment**.

## probabilities in clinical assessment

**Probabilities** play an important role in wide-ranging clinical activities. When a diagnosis is reached on the basis of the complaints and physical examination, this is generally only the most *likely* diagnosis. As the investigation reports become available or the response to a therapy is known, the probability changes and sometimes even the most likely diagnosis also changes. *If they do not change the probability, then there is no use of these investigations and they are a waste of effort.*

Prospects of recovery after a therapeutic intervention are almost always stated in terms of probability. When the first heart transplantation was done, the chances of success were rated as 80%. The probability of recovery of a patient from tetanus after clinical manifestation is often considered less than 60%. The probability of survival for more than 5 years after detection of acute lymphoblastic leukemia is generally assessed as less than 30% despite therapy. Thus, probabilities have extensive usage in clinical assessments as illustrated next.

### *Probabilities in Diagnosis*

Consider the following for the process of diagnosis. A set of signs, symptoms, and other evidence, occurring together more often than expected by chance and generally found useful in treatment and

prognosis, is given a name, and the process is called diagnosis. It requires discovering clusters such that similar patients fall within the same cluster, but the clusters themselves remain relatively distinct from one another.

There are two kinds of diagnostic entities. First are those that are based mainly on the value of a set of particular measurements. Diagnosis of essential hypertension depends almost exclusively on levels of systolic and diastolic blood pressures, diagnosis of glaucoma on intraocular pressure, and diagnosis of diabetes mellitus on serum glucose level. Once a defined cutoff point is available, the diagnosis is immediately obtained in these cases. Nevertheless, because of the wide-ranging variability even among healthy subjects and the distinct possibility of overlap between measurements found in healthy and ill subjects, a diagnosis based on such clear-cut definitions does not always remain above board. Probabilities play a preeminent role.

The second type of diagnostic entities is essentially multifactorial. They depend on signs and symptoms, and on findings of laboratory and radiological investigations. Most cardiopulmonary disorders and hepatic dysfunctions fall in this group. Even though gold standards are available in some cases, such as positive cerebral angiography in embolism, the facility to carry out such an investigation may not be immediately available. In some cases, the gold standard itself can be in error. Positive histological evidence in carcinomas is considered confirmatory, but negative findings sometimes fail to correctly exclude the disease. When diagnosis depends on a multitude of factors, the clinician's personal judgment becomes important. Childhood leukemia and abdominal tuberculosis are examples of such diagnoses. When a patient presents with complaints of pain in the right hypochondrium, anorexia, and dyspepsia, liver disease is suspected. Liver function tests are then performed, and various enzymes in the blood are estimated. They too, in many cases, fail to provide a differential diagnosis on cirrhosis, malignancy, or hepatitis. Looking at the totality of the presentation, only the most probable diagnosis is made.

Suppose the analysis of records shows that 70% of patients with abdominal tuberculosis (abdTB) present with long-term complaints of abdominal pain, vomiting, and constipation. Then, $P$(pain, vomiting, constipation|abdTB) = 0.70. Because of the restriction to a specific group, which is mentioned after the vertical slash (|) sign, namely, the cases of abdTB in the above equation, such a probability is called the **conditional probability**. Note that the probability herein is of very little value to a clinician. It tells what is seen in the patients but does not tell about the presence or absence of the disease when these complaints are reported. The inverse probability $P$(abdTB|pain, vomiting, constipation) is useful to a clinician because it gives the diagnostic value of the complaints. The difficulty, however, is that the hospitals maintain records disease-wise and not complaint-wise. Thus, the records to compute the probability in the first equation above are easily located. This requires only screening the records of cases of abdTB with regard to those complaints. But to compute the probability in the second equation, records of all the cases need to be screened irrespective of the disease, and the cases separated according to the reporting of these three complaints. Among these, the cases with abdTB need to be counted. This is relatively a big exercise. One way to get around the problem is to use **Bayes rule** that converts $P$(A|B) into $P$(B|A).

### *Probability in Treatment*

Choice of treatment is a complex process and includes single or multiple therapy, dosage and duration, surgery, etc. It is known that the progress of disease and its severity differ from patient to patient and that a patient's response to a treatment always remains uncertain. When a choice of treatment modalities is available, that modality is prescribed, which is *most likely* to result in best relief for the patient according to the assessment of the treating clinician. Thus, the choice of the treatment too is a matter of probability, so is its effectiveness. This probability again is conditional on a priori information regarding patient characteristics, disease prognosis, facilities available, cost, etc. Although the efficiency, efficacy, and effectiveness of various treatment regimens are established with the help of clinical trials, in many cases, a physician is again guided by his/her or others' experience and uses **personal probabilities** to choose a particular treatment.

### *Assessment of Prognosis*

In prognosis, the effort is to correlate the outcome (survival with or without residual effect, or death) with the antecedent state (disease severity with reference to agent, host, and environment factors). The relationship depends, among other things, on correct diagnosis, promptness of treatment, type of treatment, facilities available, cooperation of the patient, attention of medical personnel, their expertise, etc. Because of the variability in all these factors, not all patients with a given similar antecedent state have the same outcome. Again, the probabilities are helpful in making a decision. As in the case of diagnosis, the probability here is also conditional on the antecedent state.

If the outcome is denoted by $O$ and the antecedent state by $A$, the probability to be calculated is $P(O|A)$. In fact, long-term follow-up studies of patients of different types and with different severities are needed before $P(O|A)$ can be objectively evaluated. Books and other literature may carry information on such probability of a specific outcome for a particular antecedent state. In the absence of such studies, the clinician's own experience of the percentages of patients who in the past have recovered, been disabled, or died can be used. So far, the prognosis lacks much of such quantification.

## probability proportional to size (PPS) sampling

This sampling method applies to situations where blocks of units are to be selected and where larger blocks are given higher chance of selection. This presumes that the blocks vary greatly in their size. Blocks can be villages, schools, or hospitals, whereas the units can be persons, students, and patients, respectively. PPS is best understood using the following example. This example has a feature of systematic sampling woven into it.

Consider **cluster random sampling** (CRS) for assessing prevalence of poor vision in old age. For a survey on prevalence of poor vision (visual acuity <6/36 in the better eye with corrective glasses if any) in persons of age 50 years and above (50+) in a district with half a million population divided into census blocks, suppose 20 clusters (one cluster per block) of size 30 each are selected as per the following scheme:

(a) A list of census blocks is prepared along with the population of each, and this is cumulatively added.
(b) A sample of 20 clusters in half a million population means that the sampling fraction is one cluster per 25,000 population. One number less than or equal to 25,000 is randomly selected. Then 25,000 is sequentially added every time in a systematic fashion, and thus a sample of 20 numbers is obtained. Twenty blocks containing the chosen 20 numbers are selected from the list made in (a). These blocks are now in the sample.

**TABLE P.10**
**Illustration of PPS Sampling**

| Block Number | Block Size (Population) | Cumulative Block Size | Selected Blocks by PPS (Random Number) |
|---|---|---|---|
| 1 | 4387 | 4387 | |
| 2 | 12,275 | 16,662 | |
| 3 | 8931 | 25,593 | 3 (18,789) |
| 4 | 5365 | 30,958 | |
| 5 | 7987 | 38,945 | |
| 6 | 2361 | 41,306 | |
| 7 | 4580 | 45,886 | 7 (43,789) |
| 8 | 15,439 | 61,325 | |
| 9 | 9438 | 70,763 | |
| 10 | 6753 | 77,516 | 10 (68,789) |

Let us illustrate this procedure for selection of initial three blocks where the block sizes are as in Table P.10. The first random number selected is 18,789. Since all numbers from 16,663 to 25,593 are in block number 3, this would be selected. Now add 25,000 to the first random number and get 43,789. This number falls into block number 7. This is the second block selected. Again add 25,000 and get 68,789. This falls into block number 10, and this is selected. This process goes on till 20 blocks are selected.

(c) Home visits are made from a geographically random point in each of the selected blocks, and the first 30 persons of age 50+ residing in contiguous houses are listed and examined for visual acuity. This gives one cluster of 30 subjects from each selected block.

The scheme in this example of CRS is similar to the one recommended by WHO for surveys to assess immunization coverage in developing countries, but is not exactly the same. Among several features of the CRS, note the following in this example.

The selection of blocks is based on the size of the population in these blocks. This is inherent in step (b). Blocks with a larger population have a higher chance of being included in the sample. This is what is called sampling with probability proportional to size (PPS). The size in this case is the population in the census blocks, and the subjects are the persons of age 50+. It is reasonable to expect that this age group would have nearly the same proportion in each census block. The technique was suggested by Hansen and Hurwitz [1] in 1943.

This sampling becomes self-weighting because of PPS, and this makes estimation easier. Weighted calculations, as done for **stratified random sampling**, are not required when this kind of PPS sampling is done. The sampling strategy we have given in our example has the feature that you can choose the size of clusters as per your convenience, such as being able to manage the cluster within a day. In this example, the cluster size is 30, which could be covered by one team in 1 day. This would make it easier to complete the survey in a more efficient manner. If you think that a size of 40 could be covered by one team in a day, you can choose clusters of size 40. However, there are limitations as well. First, PPS can be adopted only when the **primary sampling unit** is a block containing several units of inquiry. Second, it requires that the information on size of all blocks in the population is available. In many situations, this would be a challenge, and a surrogate may have to be used. In our example also, we have used population as the size, whereas the actual requirement was people of age 50+. Similarly, for example, when the number of patients admitted in a hospital is not directly available, the bed strength can be used as a surrogate for the number of patients in the hospital. Using estimated size in place of the actual size introduces some complication in the estimates, but this is surmountable. For details, see Cochran [2].

PPS sampling is quite common in surveys. For example, O'toole et al. [3] report data on two cities in the United States from a community-based, probability populations-proportionate sample of randomly selected homeless adults to compare substance-abusing to non-substance-abusing respondents with respect to not just sex and education but also characteristics such as stealing and the need to learn how to manage money.

## probability sample, *see* sampling techniques

## proband

A proband is a person who is the first affected within a family and through whom attention is first drawn to a pedigree of particular interest to human genetics. Here *pedigree* is a term used for any grouping of related individuals, for example, pairs such as twins and spouses, and larger groups such as nuclear or extended families. Probands help in the general understanding of genetic disorders—how they pass on to the siblings and progeny.

Proband studies are quite common in human genetics. Sun et al. [1] studied a proband in China who had typical homozygous phenotype of familial hypercholesterolemia to identify the gene defect. They did not study a series as is generally done in this setup. Messinger et al. [2] examined sex differences in autism spectrum disorder (ASD) outcome and in the development of ASD symptoms and cognitive functioning among the high-risk younger siblings of such probands and low-risk children, in view of female protective effect hypothesis for this disease.

The concept of proband is also loosely used in calculating the secondary **attack rate** of a communicable disease, although a more appropriate term is *index case*. This rate measures how many people are affected by the probands on average. When a proband affects others, those become proband for others. Secondary attack rate measures the intensity of spread of infection or risk among the susceptible contacts after exposure to an infective case. When the primary case (proband) is infective for a long period as in tuberculosis, the duration of exposure becomes important. Secondary attack rate then is computed per 100 person-weeks, person-months, or person-years of exposure.

Study of probands and their progeny poses a statistical challenge because of the clustering effect. For something like regression in such a study, you may have to use the method of **generalized estimating equations** because of possible clustering. Luckily, genetic studies seldom require study of the factors contributing to the outcome (as in regression) because genetic factors can be directly studied in many situations.

## probit transformation

The acronym for probability integral transformation, probit is the value of standard **Gaussian** (normal) $z$ corresponding to the specified probability. For example, probit = 0 for $P = 0.5$ since $P(z < 0) = 0.5$ for this distribution. The expression $z < 0$ indicates that $P$ is the cumulative probability. As another example, it is well known that for $P = 0.975$, $z = 1.96$, and for $P = 0.025$, $z = -1.96$. These are the probits. Sometimes, 5 is added to the values of $z$ so that none is negative. When we add 5 to such value of $z$, the probit of 0.975 is $5 + 1.96 = 6.96$ and probit of 0.025 is $5 - 1.96 = 3.04$. The negative value $z = -1.96$ for $P = 0.025$ explains how adding 5 is helpful. This addition of 5 is needed when doing calculations by hand and not needed when working with computers. Computer software packages on probit generally do not add 5.

Probit transformation is helpful when the category for which the probability $\pi$ is obtained is based on a continuous variable such as for systolic blood pressure <140 and ≥140 mmHg, and this continuum, in this example blood pressure, follows a Gaussian distribution. When this transformation is used in the case of simple linear regression, the target regression is

$$\text{probit of } \pi = \alpha + \Sigma\beta_k x_k \, (k = 1, 2, \ldots, K)$$

for $K$ regressors. This is an alternative to logistic regression and uses the Gaussian property of the underlying variable. The logistic does not use this property—and thus has applicability to non-Gaussian setups as well. Sometimes, probits are considered more relevant for problems of estimation of relative potency in bioassays. Methods are available to find the estimate of $\alpha$ and $\beta$ for standard and test preparations—thereby obtain the relative potency. However, the method is complex. See Finney [1] for details.

## profile analysis

This is the term used for analysis of the characteristics of the subjects to find what kind of subjects are more commonly affected and what kind are not affected. It can also tell which type of cases get severe form of disease and which ones get away with mild form only, or which type of cases suffer for longer duration and which ones do not.

The easiest and most common is the profile of cases in a study that gives their age–sex distribution, their socioeconomic status, their distribution by severity of disease, from where they came (geographical area, the institutions, or the like), etc. This is a **descriptive analysis** just to apprise the reader about the basic information of the subjects. This contextualizes the study and helps to assess where the results could be applicable. Profile analysis can go deeper into cross-classifications so that predominance or underrepresentation of particular type or types of cases can be highlighted. However, for this, the comparison should be with a valid group. For example, if you find that the age group 30–39 years is dominant among accidental deaths you are studying, compare it with the age distribution in the population from which these cases are coming.

This kind of analysis also helps in confirming or denying that the groups in clinical trial or any other experiment under study were similar to begin with. If the profile of subjects in different groups under study is the same and significant differences in outcome after an intervention are present, you would have more confidence in assigning these differences to the intervention. This may require using the Student $t$-test for two groups or analysis of variance (ANOVA) for multiple groups in case of quantitative data, and chi-square for qualitative data. Help from graphical displays is also taken to compare profiles of two or more groups.

Medical uses of the term *profile analysis* seem to be greatly varied. Gribskov et al. [1] used the term profile analysis for a method of detecting distantly related proteins by sequence comparison. Shen and Richards [2] mentioned profile analysis in the context of spectral processing of two harmonic complexes. Ghosh and Chinnaiyan [3] talked of genomic outer profile analysis. Whereas the last one is statistical, the previous two are not.

There is another term called *latent profile analysis*. This is a pattern statistical technique discovered in quantitative data, similar to the cluster analysis. (For qualitative data, this is called *latent class analysis*.) Cluster analysis is a nonparametric technique, but latent profile analysis uses distributional properties (such as multivariate Gaussian distribution) to apportion data values into natural categories such that the values within categories are similar and the values in other categories are dissimilar. Thus, latent profile analysis is very different from profile analysis we mentioned earlier. For details of this method, see Hagenaars and McCutcheon [4].

## propensity score approach

The interest in many regression situations is in finding the effect of one exposure or an antecedent on one outcome. The exposure could be an intervention such as a treatment, or a preexisting risk factor such as obesity, or any other of interest. However, several covariates or confounders are also considered in this setup so that the net

relationship can be identified when other factors are under control. When the covariates are almost equally divided among the comparison groups, such as by randomization in clinical trials, these do not cause much of a problem. But in observational studies, they are generally not balanced. This hinders causal inference. Propensity score approach helps in adjustment of these covariates particularly when the number of covariates is large and subjects with exposure (or without exposure) are few.

Under this approach, all covariates are converted into a single value, called propensity score. Let the exposure of interest be denoted by $x_1$ and covariates by $x_2, x_3, \ldots, x_K$. It is sometimes possible to find a combination of multiple covariates that together reasonably determine the exposure level, or the probability of exposure if it is of the yes/no type. That is, $x_1$ can be determined mostly by $x_2, x_3, \ldots, x_K$. This would be the propensity score, which summarizes the covariate information into a single value.

The propensity score is obtained by running a regression of the actual variable of interest $x_1$ on the covariates $x_2, x_3, \ldots, x_K$. If $x_1$ is binary (exposure status: exposed/not exposed), logistic regression is obtained, and if $x_1$ is quantitative (exposure level: quantitative such as the degree of exposure), quantitative regression is obtained. If this scoring is successful in terms of high $R^2$ or percentage correctly predicted, you can use this score as a regressor in place of $x_2, x_3, \ldots, x_K$. Now a regression with only two regressors is required—$x_1$ and the propensity score. The method assumes that you have sufficient, valid, and reliable data on these covariates, and these covariates are able to reasonably predict the exposure level or exposure status. Note that the exposure level (or exposure status) continues to be in the regression. In the case of binary exposure, for example, the exposure is adjusted for the propensity, and that can be a big help in causal inference. However, the propensity score method is purely statistical and may not have much biological interpretation. The method was first proposed by Rosenbaum and Rubin [1] in 1983.

In most experiments, the subjects are randomly and equally allocated to the test and control group so that they have equal "propensity" to be in any group. Because of random allocation, all covariates and confounders (known and unknown) are expected to be equally divided. This is not so in observational studies. You cannot allocate who will smoke and who will not—thus, there is no random allocation. Covariates are not equalized. Here you can match them for propensity score. In a case–control setup, generally an equal number of subjects are selected by the outcome; but cases may have 70% exposed, while control may have 40% exposed. For example, 70% of patients undergoing kidney transplant (cases) may be relatively young and nutritionally better, and only 40% of those on conventional treatment (controls) may be so. The success rate (say, living for at least 10 years after the treatment) in these two groups depends not just on receiving or not receiving transplant but also on their age and nutrition status, among other factors. These are the covariates in this setup. The outcome is the success rate. The conventional method to adjust for such covariate differential is by including these in the regression (in this case, logistic since the outcome is binary). One can also think of matching for the covariates. Both these options are practical for a small number of covariates. What if the number of covariates is large, say 10, even 50? Matching is not feasible for so many covariates, and logistic would require an extremely large sample at the rate of at least 8 events (not subjects) per covariate [2]. The propensity score approach can be helpful in this situation as this does not require such a big sample. If you have a sufficient number of positive outcomes, do the analysis by both approaches: (i) by using $x_1$ and all the covariates as such and (ii) by using $x_1$ and the propensity score. If the propensity scoring is successful, you will get nearly the same result. In this case, you may like to prefer propensity score as this makes the regression so simple.

The propensity scores can also be used for matching or for stratification of the subjects. Matching is easier with these scores compared to matching on 10 covariates because now the matching is to be done for just one variable. Subjects with the same propensity score are likely to have similar effect of the set of covariates. Stratification can be done on subjects with high and low scores (or by **quantiles**) that really are now a surrogate for the level of exposure. Matching, as always, is able to take care of the known factors whereas randomization takes care of the unknown factors in the epistemic domain also. As for any regression model, the following precautions may be helpful in using propensity scores. These are mentioned for the setups where there are many regressors of interest besides a large number of covariates that are reduced to propensity score.

- Use a parsimonious approach as is always the case with regression.
- Test all the regressors for statistical significance.
- Examine all regression coefficients carefully for their proper interpretation.
- Perform regression diagnostics regarding its applicability and adequacy.
- Examine the residuals with care.
- Hold out a part of your data for cross-validation, performing external validation on a new sample of data.
- Ensure that the propensity model has not missed any important factor determining the exposure status.

## prophylactic trials, *see* clinical trials

## proportional hazards, *see also* Cox regression

This section presumes that you are familiar with the concept of hazards. If not, review the topic **hazard rate**. This is the same as risk but has a time dimension. Since measured per unit of time, this becomes a rate.

Proportional hazards imply that the ratio of hazards in the test and the control group remains the same over the entire survival time. For example, if a person of age 60 years with hypertension has hazard of myocardial infraction (MI) 1.25 times (i.e., 25% higher) that of the person without hypertension, this ratio should continue to be 1.25 at 70 years and at age 80 years if these ages are in your data. This means that the hazard of MI increases with age in the same proportion in hypertensives as in nonhypertensives. This may not hold, for example, for intricate surgery (compared with, say, medical treatment) because of the high risk of death at early stages due to perioperative causes and relatively lower risk of mortality at later stages of recovery when the surgery is seen as successful. When proportionality holds, no correction is required for the varying length

of follow-up of different subjects. This is the basic advantage of proportional hazards. Also, this makes the analysis independent of the statistical distribution of survival as shortly explained.

In terms of notations, consider two groups defined by indicator variable $x_1 = 0$ for control and $x_1 = 1$ for the treatment group. For simplicity, suppose this is the only variable under consideration. In this case, this gives $h(t) = h_0(t)$ for $x_1 = 0$ and $h(t) = h_0(t)\, e^b$ for $x_1 = 1$, where $h(t)$ is the hazard at time $t$ when covariates are present and $h_0(t)$ is the hazard again at time $t$ when no covariate is in operation. Thus, the ratio of these two hazards is $e^b$ for all $t$. It does not depend on time. The form of $h_0(t)$ does not matter for this ratio. This is what proportional hazards imply. This simple and useful interpretation has made the hazard ratio so popular. It is because of this proportional property that the method of analysis is independent of the pattern of the survival curve. Proportional hazards in the two groups would mean the plot of logarithm of hazards versus survival time would be parallel (Figure P.15). This is an important requirement for validity of **Cox regression**, where the logarithm of the hazard ratio is modeled to depend on a linear combination of the regressors. This essentially implies that the effect of covariates on the hazard rate is multiplicative instead of the usual additive.

There could be situations where proportionality does not hold. While comparing a short-acting regimen with the one with continued action for a long time, the hazards will not be proportional (Figure P.16) because hazard rises fast after the active phase of the short-acting regimen is over, whereas it remains low for substantial period with the long-acting regimen.

How does one check that the hazards are indeed proportional? For this, divide the total time period of follow-up into two or three plausible segments, and run the usual Cox regression after including an interaction term between time segments and other risk factors in the model. If any interaction term is statistically significant, conclude that the requirement of proportional hazards is violated. As for any test, detecting significance will also depend on the size of the sample—thus, this must be adequate for this procedure.

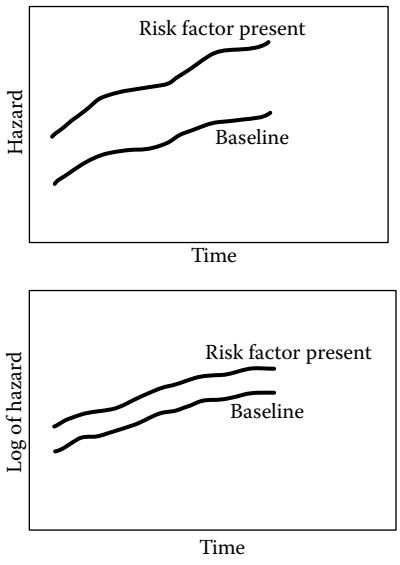

**FIGURE P.15** Hazards and proportional hazards in terms of logarithm.

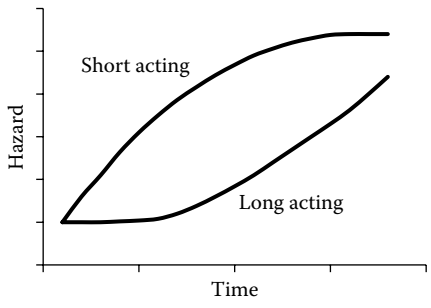

**FIGURE P.16** Nonproportional hazards.

## proportional reduction in error (PRE)

PRE is one of the measures of strength of relationship between two qualitative characteristics, but it has more useful interpretation in some specific situations. The primary purpose of PRE is to measure the utility of one characteristic in predicting the other: the higher the PRE, the more useful the predictor, and it is directly dependent on the strength of the relationship. The PRE ranges from 0 to 1 and can be interpreted from no association to perfect association. But there is no negative association. The basic principle underlying PRE is easily explained with the help of an example.

Table P.11 contains data on age and visual acuity (VA) of 1000 patients coming to a cataract clinic. Based on these data, if a guess is to be made about the visual acuity of a random person coming to the same cataract clinic, the best guess (with least error) is (6/60 > VA ≥ 1/60) because this is the most commonly (657/1000 = 65.7%) occurring acuity in such subjects. This guess can be wrong in the other 100 – 65.7 = 34.3% of the cases. This is the error of prediction. If we know that the age of the patient is between 60 and 69 years, then this guess is strengthened further because 325 out of 460 (70.7%) is a higher proportion in this acuity category than for any other age group. The error is now reduced to 29.3%. The PRE by knowing the age in this case is (34.3 – 29.3)/34.3 = 0.15 or 15%. This measures the utility of age in predicting VA category. However, knowing age on the whole is not helpful in predicting the VA category in the data of Table P.11 because the most common VA category is always (1/60, 6/60) whatever the age may be.

A study was carried out on 80 subfertile men with varicocele on spermatozoal morphology with the objective of finding whether head abnormalities can be used to predict neck abnormalities in spermatozoa. Suppose the data obtained are as shown in Table P.12.

If head abnormality is present, the best prediction is that neck abnormality is doubtful because this is the most commonly observed (24 cases) category in the head abnormality group. This prediction will be wrong in 44 – 24 = 20 cases. Table P.13 has been constructed

**TABLE P.11**
**Age and Visual Acuity (VA) in Patients Coming to a Cataract Clinic**

| Age-Group (Years) | Visual Acuity (VA) | | | Total |
|---|---|---|---|---|
| | ≥6/60 | 6/60–1/60 | <1/60 | |
| –49 | 19 | 69 | 22 | **110** |
| 50–59 | 39 | 142 | 29 | **210** |
| 60–69 | 46 | 325 | 89 | **460** |
| 70–79 | 21 | 98 | 51 | **170** |
| 80+ | 7 | 23 | 20 | **50** |
| **Total** | **132** | **657** | **211** | **1000** |

**TABLE P.12**
**Head and Neck Abnormality in Spermatozoa in Subfertile Men**

| | Neck Abnormality | | | |
|---|---|---|---|---|
| **Head Abnormality** | **Present** | **Doubtful** | **Absent** | **Total** |
| Present | 11 | 24 | 9 | **44** |
| Absent | 3 | 7 | 26 | **36** |
| **Total** | **14** | **31** | **35** | **80** |

**TABLE P.13**
**Calculation for PRE in Table P.12**

| **Head Abnormality** | **Best Prediction for Neck Abnormality** | **Extent of Error** |
|---|---|---|
| Present (44 cases) | Doubtful (24 cases) | 44 – 24 = 20 cases |
| Absent (36 cases) | Absent (26 cases) | 36 – 26 = 10 cases |
| If not known (total 80 cases) | Absent (35 cases) | 80 – 35 = 45 cases |

with similar arguments. The extent of error stated in the last column is obtained by subtracting the maximum in the row from the corresponding total. By knowing that the head abnormality is present or absent, the error is reduced from a total of 45 cases to a total of 20 + 10 = 30 cases. Thus,

$$\text{PRE (by knowing the head abnormality)} = \frac{(80-35)-[(44-24)+(36-26)]}{80-35} = 0.33.$$

Knowledge about the presence or absence of head abnormality reduces the error in predicting neck abnormality by 33%. This reduction is not really high in this example and shows that the association of head abnormality with neck abnormality in spermatozoa is not really strong.

In terms of notations, the PRE in predicting the column category when the row category is known can be written as

$$\text{PRE} = \frac{(n - \overset{max}{C}\, O_{\bullet c}) - \Sigma_r (O_{r\bullet} - \overset{max}{C}\, O_{rc})}{n - \overset{max}{C}\, O_{\bullet c}}, r = 1,2,\ldots,R,\ c = 1,2,\ \ldots, C,$$

where
the order of the table is $R \times C$.
$O_{rc}$ is the frequency in the cell in the $r$th row and the $c$th column.
$O_{r\bullet}$ is the marginal total in the $r$th row.
$O_{\bullet c}$ is the marginal total in the $c$th column.
$n$ is the total number of subjects.

The notation $\overset{max}{C}$ is for the maximum value among the columns.

For PRE in the formula given in the above equation to be interpretable, it is necessary that one variable is considered dependent on the other in the sense that one can be predicted by the other. In this example, neck abnormality is treated as dependent because it is sought to be predicted from head abnormality.

The formula given in the above equation assumes that the column category is to be predicted by the row category. The notations will change if the row category is to be predicted by the column category. The PRE considers all categories nominal. If categories are ordinal or metric, and if the order is important, then other measures of association should be used. These are discussed by Freeman [1]. Yamamoto et al. [2] have discussed PRE for ordered categories.

## proportionate sample

This is used in stratified sampling. A sample is called proportionate when the number of subjects from each stratum is in proportion to the size of the stratum. If the $k$th stratum has $N_k$ subjects in the entire target population, the sample size from the $k$th stratum should be $n_k \propto N_k/N$ for it to be proportionate. In exact terms, this is $n_k = n^*(N_k/N)$, where $n$ is the total sample size. Consider the following example.

Evidence has accumulated that a large waist–hip ratio (WHR) may be a health risk. In a study of 100 hypertensive males, the subjects are divided into thin, normal, and obese according to WHR ≤ 0.89, 0.90 ≤ WHR ≤ 1.09, and WHR ≥ 1.10. With this categorization, the **simple random sampling** (SRS) of 16 subjects happens to contain 2 thin, 11 normal, and 3 obese subjects. However, the actual numbers of thin, normal, and obese in the population according to this categorization are 14, 38, and 48, respectively. Thus, the obese are clearly underrepresented in the sample. If you calculate any summary such as mean cholesterol level in these 16 subjects, the sample mean would be biased because possibly high values of cholesterol levels of obese subjects would not be as many as they should due to their underrepresentation in the sample. If you divide the population in the first instance and then take a **stratified random sample**, the result could be very different. A commonly adopted strategy in this case is to take a proportionate sample from each stratum. When this is done, the sample mean, sample proportion, etc., would be unbiased without any correction.

If the sample sizes in different strata are not proportionate, an adjustment would be needed to get an unbiased estimate. In our example, the strata sizes are 14, 38, and 48, respectively. For obtaining the right sample mean, these are multiplied by the means in the respective strata and divided by the population size, i.e.,

$$\bar{x}_{st} = \sum N_k \bar{x}_k / N,$$

where $N_k$ is the size of the $k$th stratum and $\bar{x}_k$ is the mean obtained for the $k$th stratum. The stratum size is now the "weight" for calculation of the mean. Such weighting is necessary to get a valid estimate and is regularly done for stratified samples when not proportionately chosen. The same weighting procedure is used for obtaining the sample proportion, sample standard deviation, etc.

In the case of proportionate samples, the probability of selection of each subject is the same in different strata. The advantage with this is that the sample becomes self-weighting. This can be explained as follows. In our example, 16 out of 100 gives a sampling fraction of 0.16. Applying this to the strata sizes gives a sample of 2 from the first stratum, 6 from the second stratum, and 8 from the third stratum. Proportionate sample implies that the sample from each stratum is in the same proportion as in the population. This means

$$\frac{N_k}{N} = \frac{n_k}{n} \text{ for all the } k \text{ (i.e., for each stratum).}$$

When this is substituted in the formula earlier given for the sample mean, we get

$$\bar{x}_{st} = \sum n_k \bar{x}_k / n.$$

This can be easily seen to be the same as the usual sample mean without any weights. Thus, in the case of proportionate samples, the mean for the stratified sample can be calculated just as a usual unweighted mean is calculated.

## proportion-by-probability (P-P) plot

This is the plot of empirical cumulative proportion versus cumulative probabilities based on any hypothesized distribution and is used to check whether or not they agree. If they agree, the plot would be a straight line. If the plot is not a straight line, consider that the data do not follow the hypothesized distribution. This check is visual and not fully scientific because minor variations would always occur.

For a P-P plot, the observed values of the variable are first sorted into ascending order from minimum to maximum as $x_{[1]}, x_{[2]}, \ldots, x_{[n]}$. The $i$th observation is plotted as $i/n$ (i.e., the observed cumulative proportion) against the other axis as $F(x_{[i]})$, where $F(x_{[i]})$ stands for the value of the theoretical cumulative probability for the respective observation $x_{[i]}$. If they approximate well, all points in this plot should fall onto the diagonal line. Table P.14 contains survival years of 10 patients after the detection of a cancer. Does it follow a Gaussian distribution? The mean of the survival years is 12.3, and the sample standard deviation (SD) is 8.29 years. We used these to calculate the standardized deviate $z$. This is shown in the third column of Table P.14. The Gaussian probabilities obtained from software for these values of $z$ are in the last column. The plot of the probability versus proportion is in Figure P.17. Diagonal line is also shown for comparison. The P-P plot is away from the line—remains below the line all the time. Thus, the distribution of survival years is not Gaussian.

The P-P plot considers all aspects of Gaussianity including **kurtosis**. In place of P-P, you can also try the **quantile-by-quantile (Q-Q) plot**. However, both these methods are approximate. More exact methods require calculations and checking statistical significance of the departure from Gaussian. Such significance tests based on

**TABLE P.14**
**Calculations for P-P Plot**

| *i/n* | Survival Years (*x*) | *z* = (*x* – Mean)/ SD | Gaussian Probability |

**Anderson–Darling**, **Shapiro–Wilk**, and **Kolmogorov–Smirnov test** are discussed in their respective topics.

## proportions

Proportion is the fraction of the whole. When we say that 30% of those affected had mild form of disease, the proportion is 0.30. Proportion is always out of 1, but many times, it is expressed in terms of percentage.

Proportion is best understood when the categories are **mutually exclusive and exhaustive** so that there is no overlap and nothing is left out when all categories are considered. Proportion of cases with mild, moderate, serous, and critical form of a disease is a good example. In this case, proportion tells how big or small the slice of a pie is. Best graphical representation of a proportion is indeed a **pie diagram**. You can show many proportions of the same pie by this diagram, although it becomes too cluttered if the number of categories is large. Since something like site of injury after an accident does not form mutually exclusive categories since one person can have injury at multiple sites, the pie diagram is not appropriate. Nonetheless, it is perfectly valid to say that 22% of all fatal accidents have head injury. This example may have also alerted you to distinguish between these two kinds of proportions—the overlapping and nonoverlapping. Nonoverlapping proportions give you a total equal to 1 when all possible categories are considered. Overlapping categories will give a total of more than 1.

The most prominent clinical application of proportion is in expressing the efficacy of a treatment—generally expressed as, say, 85%—and in expressing how common side effects are. Many times, probabilities of disease, or of recovery, or of death are also expressed in terms of proportions. For example, you may tell the patient that 4 out of 5 such patients recover within 7 days. This is just another method to say that the proportion recovering within 7 days is 0.80. However, proportions are different from odds. In our example of 4 patients recovering within 7 days out of 5, the odds of recovering within 7 days are 4:1. But odds can be converted to proportion: odds $a_1$:$a_2$ are the same as probability $\pi = a_1/(a_1 + a_2)$. Some statisticians and researchers also make a distinction between a proportion and a probability. Proportion is what you observe in a sample, whereas probability is what is seen in the corresponding population. The term *population* here is the statistical **population**

and not the general population. Probability is the proportion in the population and is applicable to individuals when randomly chosen or randomly arriving. In other words, probability is the long-term manifestation of the proportion: the expectation when the proportion is based on an exceedingly large sample, theoretically an infinite sample. Customarily, probability is denoted by $\pi$ and the sample proportion by $p$.

Probability of a sample proportion exceeding any given value, limiting (less than) to a given value, or lying between a specified range, is generally obtained by binomial distribution. The only condition is the probability in one case should be known and it should remain constant from person to person. Restricting to fatal accidental injuries, for example, we can find the probability that the number of persons with head injury will be between 20 and 30 out of 120 fatal accidents in a year in a city when the probability of this in one person is $\pi = 0.22$. Since $20/120 = 0.1667$ and $30/120 = 0.2500$, this translates to $P(0.1667 \le p \le 0.2500)$, where $p$ denotes the proportion of head injuries in fatal accidents in the sample subjects. The method to obtain this probability is given under the topic **binomial distribution**. When **Gaussian conditions** prevail, this probability is easily obtained by Gaussian approximation rather than by using the tedious method of binomial distribution.

In most situations, probability or the population proportion $\pi$ is not known and has to be estimated: the best estimate of $\pi$ is the sample proportion $p$. See the topic **confidence interval (CI) for proportion** and exact **confidence intervals (CIs)** for the methods to obtain interval estimates of $\pi$. We have also presented the method for obtaining the **confidence interval (CI) for difference between proportions**. See **$z$-test** for test of hypothesis on $\pi$ for large samples. For small samples, binomial distribution is used for this purpose as already indicated.

For comparing proportions in two groups, the groups are classified either as independent or matched pairs. Independent groups imply that the two samples taken are independent, that is, sample values selected from one population are not related in any way to sample values selected from the other population. Males and females are a common example of independent samples. Matched pairs consist of two samples that are dependent. Proportion of patients with a particular symptom before the treatment and after the treatment is an example of matched pairs. The method of choice for testing equality of two proportions in independent samples is **chi-square**, but that is applicable for large samples only. For small samples, the **Fisher exact** test is used. Exact methods are available in many statistical software packages for CI also for the difference between two proportions in small samples. If the samples are matched pairs, a large sample test is **McNemar**, and a small sample **exact test** is based on binomial distribution.

For proportions in multiple categories (polytomous), see **goodness of fit** test and **chi-square for trend in proportions** for large samples, and **multinomial distribution/test** for small samples.

## prospective studies, *see also* retrospective studies, case–control studies

Statistically, a study is called *prospective* when it investigates the outcome for a given set of antecedents. Antecedents could be exposure, intervention, or risk factors. Since outcome takes time to appear after the exposure, this generally requires a follow-up of cases forward in time. This could be a few minutes, a few hours, a few days, or a few years depending on whether the outcome is quick or slow to appear. There is a convention not to consider studies with a short follow-up as prospective. Thus, a study assessing the effect of anesthesia is not prospective in that sense. As we would shortly explain, the follow-up does not have to be in the future—it can also be in the past, called the *retrospective follow-up*. The follow-up can be just at one time point or at multiple time points. We also cite examples later of rare prospective studies that do not require actual follow-up in time frame. The defining feature remains that prospective studies are those that move from the antecedent to the outcome. Recruitment of subjects in the future as they come to a clinic or otherwise does not make it a prospective study since this refers to the recruitment only and not for the design.

Prospective studies can be contrasted with **retrospective studies** that move from the outcome to the antecedent, and **cross-sectional studies** that elicit both the antecedent and the outcome together.

*Prospective* is an umbrella term that includes various types of studies based on follow-up of the subjects: a cohort study with concurrent or historical cohort, repeated measures, and longitudinal study are all prospective studies. **Repeated measures studies** are separately described because of their special importance in medical and health setup; the others are explained in this section. **Before–after studies** too are technically prospective studies, and these also are separately discussed as they are commonly used. Some researchers use the term *prospective study* as a synonym of cohort study, but this is not entirely correct. A study of antenatal women for birth outcome, coming to a clinic staggered over a period of time at different gestations, is a prospective study but would not be called a cohort study. A cohort is a predefined group of subjects followed up for one or more outcomes. In view of its special importance in health and medical investigations, **cohort studies** are discussed as a separate topic in this volume.

It may be clear that prospective, cohort, longitudinal, and repeated measures are not mutually exclusive terms. A prospective study can be **longitudinal** comprising observations of each subject at several points of time or can have only two assessments: one at the beginning and the other at the end. In most longitudinal studies, measurements are taken at different points in time such as the patients are investigated before surgery, during surgery, and 1, 2, and 3 h after surgery. Another patient could be measured before, immediately after, and 90 min after surgery. The same characteristics such as extent of pain can be measured at these points of time. The objective is to assess change over time, and often the outcome of interest is the time taken to reach a particular end point such as the time when pain score is 1 or less on the scale of 0 to 10. In some situations, the interest may be in the pattern of change such as whether pain is high initially and then declines either rapidly or slowly, or declines initially and increases thereafter. In this case, the interest may also be in time at which the pain is the highest or lowest.

The primary objective of a longitudinal study is to track the trend over time, generally of a quantitative measurement. This means that the time points are an important consideration. For example, a **pharmacokinetic study** that evaluates peak concentration of a drug and time to reach the peak would require a longitudinal study since observations at several time points are needed for this kind of study. Similarly, a study on growth of children would need a longitudinal study to track their trajectory. In both these setups, the outcome is quantitative, but that is not a prerequisite for a study to be longitudinal. Time-invariant risk factors such as sex and family history may be measured only at the baseline, and other associated risk factors may be measured repeatedly over time.

Whereas longitudinal studies are mostly forward in time requiring follow-up, they could also be backward in the sense that the cases are investigated regarding their history at different points in time in the past. Smoking history of cancer cases that includes how many cigarettes were smoked for what duration in the past is the

classic example. Prospective studies could be based on past cases also. For example, Sokal et al. [1] carried out a cancer risk study in 1992 on the basis of the records of women sterilized with transcervical quinacrine hydrochloride pellets in Chile between 1977 and 1991. Traceable women were also interviewed. Despite being based on past records, it is not a retrospective study since the direction of investigation is from the antecedent to the outcome. Terms such as *retrospective follow-up* and *historical prospective* are also used for this kind of methods. This requires that past records are fully available.

Exceptional prospective studies can be cited that do not require any follow-up in actual time frame. In a study on the effect of profession on smoking habits, a cohort of people joining different professions in one particular year can be followed up for a 10-year period. This would be a standard prospective study. But the effect can also be studied by selecting people who have been in different professions for nearly 10 years and noting their present smoking habit at the end of the 10-year period in the profession. This also is a prospective study since the direction of the study is from the antecedent (in this case, profession) to the outcome (in this case, smoking), but there is no follow-up of the subjects in a conventional sense.

Among the most popular longitudinal studies is the **Framingham Heart Study** in the United States that has repeatedly measured initial cohort for their lifetime. Recent publication on this by Pencina et al. [2] asserts that investigation of apolipoprotein B improves risk assessment of future heart disease beyond LDL-C and non-HDL-C. Tarnanas et al. [3] carried out a longitudinal study on ecological validity of virtual reality daily living activities screening for early dementia.

Analysis of data from prospective studies is mostly done in terms of **relative risk (RR)** and **attributable risk (AR)**. These refer to the occurrence or nonoccurrence of an event of interest such as recovery, a medical parameter reaching to a threshold, and death. The outcome must be qualitative for these measures to be applicable. If the outcome of interest is quantitative such as actual creatinine level, and when the average over subjects at different time points is sensible, think of regression with time as a factor of interest for analyzing such data. You can have other covariates also in this model. All limitations of **regression models** apply. When the data at different time points are required to be considered together, **generalized estimating equations** may be a better method, particularly when the objective is to study the contribution of various factors to the outcome. This allows correlated values (in this case, values at different time points are correlated) that most other methods prohibit. When the duration of appearance or occurrence of an event at different points in time is the variable of interest, including whether the event occurred within the follow-up period or not, the data are analyzed by **survival analysis** methods. This considers survival (or event-occurrence rate) at different points in time.

### *Selection of Subjects for a Prospective Study*

An important consideration in the selection of subjects for any study is the feasibility of obtaining data on them. This means that the subjects must be approachable and cooperative. For a prospective study, especially, accurate and complete information must be available on them at baseline so that they can be correctly classified into exposed and nonexposed groups, and the effect of other characteristics on the outcome can be properly assessed. It is natural to expect that the subjects included in the study truly represent the target population. Thus, the target population must be clearly defined. It could be, for example, patients attending a particular group of diabetes clinics who are observed for development of retinopathy, or those exposed to a carcinogen in a particular district. Note the geographic limitation associated with the definition of a population as is nearly always done.

In a prospective study, generally only one **risk factor** will be of primary interest, but other risk factors to be concurrently studied also need to be properly identified. For example, in a study of maternal complications, these could be parity, nutrition status, hemoglobin level, and the nature of natal care. Decide in this case whether the study is to be restricted to women who are currently pregnant or will include all married women of reproductive age. Such specification also is important for any study.

A basic feature of a prospective study is that the incidence of outcome such as disease or relief is evaluated in those subjects who are exposed. It is often helpful to study a parallel group, also called a *control*, which is not exposed, so that a proper comparison can be made. Thus, case–control nomenclature can also be applied to prospective studies, which otherwise is restricted to retrospective studies. However, in this case, they are exposed and unexposed groups, and not diseased and nondiseased groups.

### *Comparison Group in a Prospective Study*

Proper selection of the comparison group enhances the validity of conclusions from a prospective study. Quite often, the control group comes from within the cohort, in whom some subjects are naturally exposed and some are not. For a valid comparison, the exposed and unexposed groups must be similar at baseline, particularly with regard to the factors that can influence the outcome not under study. If the objective is to study the effect of recently acquired central obesity on the electrocardiogram changes over time, factors such as age, gender, personality traits, stress conditions, and smoking need to be matched between the study group (with central obesity) and the control group (without central obesity). If complete matching is not possible, as would generally happen in practice, statistical methods are used to do the required adjustment at the time of analysis. Such an adjustment can become incomprehensible if done for a large number of factors and should be done for a few factors that are more relevant than others.

An external group can be used for comparison in some situations. An adequate number of nondiabetics may not be available in a diabetes clinic for assessing the development of coronary events. External controls can be included in such a situation; however, they should come from the same milieu and should preferably be matched for all the factors except the exposure. In a rare situation, when an appropriate external group is also not available, comparison can be done with the outcome rates in the general population. For example, the incidence of birth defects in babies born to women of age 45 years and above can be compared with that in births to women of childbearing age in the general population. The actual control group in this setup should be births to women of age less than 45 years, but a separate incidence of birth defects in them may not be easily available. The incidence in births to women of age less than 45 years may not be much different from that in all women of childbearing age since births after that age are rare. However, in many situations, the rate in the general population is not comparable with the rate in the unexposed group, and a great degree of precaution is required in using such a general group as control.

In some prospective studies, it is useful to have multiple groups for comparison. For example, the effect of profession on smoking habits can be investigated by including several categories of profession in the same study where none would be the control group in the conventional sense. Subjects with different exposure levels can also

be chosen for follow-up that would also provide multiple groups for comparison of the outcome.

It is sometimes impossible to find a group that is completely nonexposed. An example is exposure to dichlorodiphenyltrichloroethane (DDT). Even people in remote locations, such as Canada's Baffin Island, harbor traces of DDT. In such cases, the comparison effectively would be between the less exposed and the more exposed.

### Potential Biases in Prospective Studies

A large number of biases are listed under the topic **bias in medical studies**, and all those should be considered in a prospective study. Biases typically occurring in a prospective study setup are the following.

*Selection bias*: A prospective study group is rarely a random sample from the population of subjects, although this is highly desirable. Selection bias is said to have occurred when the study group has a different composition with regard to etiologic factors such as heredity, age, gender, nutrition status, and addictions compared with the composition in the target population. Studies on volunteers or on clinic subjects almost invariably suffer from such a bias. A method of selection that has a random component is considered insulation against this kind of bias. But such selection fails to take cognizance of special bias that can result from extraneous sources such as improper definition of the population. In a study on causes of psychiatric illness in old age, if the subjects are those who are single and of age 70 years or above at the time of enrollment, the bias occurs because some with severe illness may have already expired before attaining the age of 70 years. Those who remain are the ones who are robust or have minor illness.

*Bias due to loss in follow-up*: A major task in prospective studies is to accomplish successful follow-up of all the subjects. Loss occurs due to change in residence to an unknown or remote address, unrelated death, severe illness other than the one under study so that the required investigations cannot be done, loss of motivation of the patient to cooperate, fault developing in machines such as treadmill whose rectification takes time, absence of a trained technician, etc. In a clinic-based follow-up, when the patients are advised to report at periodic intervals, some may not come on the required day, and one or two follow-ups may be missed. Such loss constitutes a threat first because the size of the group shrinks and second because those lost are seldom a random subgroup. They are generally typical, for example, subjects who are seriously ill and are not hopeful of living long, or those who are mildly affected and who consider continuation in the study not worth taking the risk. If the rate of disease and the rate of severity are different in the subjects who have discontinued, it would affect the validity of the results. Where possible, a random subsample of the discontinued subjects should be investigated intensively to evaluate their characteristics versus the characteristics of those who have not discontinued. If they are really different either with respect to outcome or even with respect to the baseline information collected at the time of first contact, an adjustment may be required at the time of analysis to remove the effect of such bias. When nonrespondents could not be contacted despite best efforts, the baseline information can still be used for adjustment.

*Assessment bias and errors*: Human error can occur in assessing the condition of the patient. This can be due to either carelessness or lack of expertise of the observer. The physician may lack competence and the recording clerk may lack training or motivation. Assessment during the later part of a longitudinal study may be less accurate as fatigue sets in or may be more accurate due to learning effect.

*Bias due to change in the status*: In a prospective study on central obesity and coronary artery diseases, it is possible that some subjects of the nonobese group become obese while the follow-up is still in progress. In a study on effect of smoking, a nonsmoker at the initial stage may start smoking in the middle of the study, or a smoker may quit smoking. Exclusion of such cases is one option but is feasible only when their number is small. A long-term cohort is also affected by the environmental changes such as introduction of a new drug in the market that can influence the incidence of the disease under study.

*Validity bias*: Some prospective studies try to develop criteria to distinguish subjects with greater risk of disease from those with less risk. If sufficient distinguishing features are detected, then these criteria could indeed be developed. Such criteria may work wonderfully well on the group from which they have been derived, but they need to be externally validated on another group of similar subjects. Although statistical principles say that criteria based on representative sample should work nearly equally well on another sample from the same population, evidence of external validation is considered essential before such criteria are accepted. This validation could be done on another sample from the same population or even on a sample from a different population. The latter, of course, provides evidence that the results could be valid for other populations too.

All such biases and errors in assessment can be reduced simply by being more careful and by using precise instruments, measurements, and classification criteria that have been pretested for their validity. The identification and resolution of bias are primarily a matter of epidemiological judgment. The success of a prospective study often depends on the care taken by the investigator in recognizing and correcting these biases. Although some bias can be handled at the time of data analysis by using appropriate statistical techniques, the applicability of these techniques depends on validity considerations, particularly on the adequate number of cases with the outcome of interest in groups and subgroups. This cannot be ensured beforehand in this situation. Precautionary steps are preferable wherever feasible.

### Merits and Demerits of Prospective Studies

The advantages of prospective studies will be clearer if you are clear about other designs—retrospective and cross-sectional—of observational studies. Nevertheless, it is evident that the temporal sequence between exposure and disease can be more easily established by prospective studies than by any other format. Risk of outcome such as of disease or the chance of getting cured can be directly measured. Also, the incidence of an outcome cannot be assessed by any other method. Prospective studies are particularly well suited for assessing the effect of rare exposure such as of a specific chemical or of a new therapeutic modality because the cohort is expected to start with an adequate number of subjects. These studies allow for examination of multiple effects of a single exposure. If the outcome

of interest is death and the records are not adequate, a prospective design is the only choice.

There are several demerits too. Sometimes an outcome, such as carcinoma, may take years to appear after the exposure. It may occur only in a small percentage of subjects, which could mean a very large cohort to obtain an adequate number of subjects having the disease. Thus, prospective studies tend to be heavy on time and resources. In some situations, the natural course of the disease or the characteristics of the subjects may change during the follow-up period. As already stated, obesity, dietary pattern, and smoking can all change in a long-term follow-up. In a prospective study, subjects know that they are being observed, and this awareness may change their behavior and outcome, called the **Hawthorne effect**. If the study spans several years, it is difficult to maintain motivation and retain the trained staff. Supervision may also lose sharpness. Notwithstanding these difficulties, prospective studies are technically the most correct design because they move in the natural direction from exposure to outcome.

## protective effect

The concept of protective effect arises when considering the **relative risk (RR)**. RR < 1 for any factor is an indication that this is a protective factor for the outcome being studied in the sense that the incidence of disease is lower in those with the "risk factor." RR = 1 for any factor implies that it is neither a risk factor nor a protective factor, and RR > 1 implies that it is a risk factor. These terms are being used in the usual sense as applicable to any adverse outcome. For example, eating plenty of fruits and vegetables has a protective effect on coronary events. If you calculate the RR for this factor for coronary events, you will find RR < 1. If the outcome is relief such as early discharge from the hospital, the same factor may give RR > 1 but is still protective as it increases the chance of early discharge. Thus, RRs should be cautiously interpreted. The same applies to odds ratio (OR) as well. Regression coefficients in logistic and ordinary regression may also be similarly interpreted.

Ghorbani et al. [1] have talked about protective effect of selenium on cisplatin-induced nephrotoxicity and concluded that selenium could probably prevent such injury when added to hydration therapy in cancerous patients. Akhavan et al. [2] have discussed early protective effect of hydroxychloroquine on the risk of cumulative damage in patients with systemic lupus erythematosus. There are a large number of such examples of protective effect in the literature.

## protocol (research) and its contents

In our context, a protocol is the document that delineates the research plan for a study. The protocol is the backbone that supports a study in all steps of its execution. Thus, sufficient thought must be given to its preparation. On many occasions, it gradually evolves as more information becomes available and is progressively examined for its adequacy. The most important aspect of study protocol is the statement of the problem, objectives, and hypotheses. Formulating a feasible scientific question is a challenge, as well as ensuring availability of resources (expertise, funds, patients, time) to complete the task. A useful first step in preparing a complete research protocol is developing a one- or two-page document that summarizes the key scientific and clinical features of the study. This document helps to structure the final protocol and can be used to communicate the scientific aspects of the study and elicit the feedback.

### *Research Problem*

It is often said that research is half done when the problem is clearly visualized. There is some truth in this assertion. Thus, do not shy away from devoting time in the beginning for identifying the problem, to thoroughly understand its various aspects, and to choose the specifics you would like to investigate.

A problem is a perceived difficulty, a feeling of discomfort about the way things are, the presence of a discrepancy between the existing situation and what it should be, a question about why a discrepancy is present, or the existence of two or more plausible answers to the same question [1]. Among the countless problems you may notice, identifying one suitable for study is not always easy. Researchability of course is a prime consideration, but rationale and feasibility are also important. Once these are established, the next important step is to determine the focus of the research. This can be done by reviewing the existing information to establish the parameters of the problem and using empirical knowledge to refine the focus. Specify exactly what new the world is likely to know through this research.

The title of research by itself is not the statement of the problem. The statement of the problem is a comprehensive statement regarding the basis for selecting the problem, the details of lacunae in existing knowledge, a reflection on its importance, and comments on its applicability and relevance. The focus should be sharp. For example, if the problem area is the role of diet in cancers, the focus may be on how consumption of meat affects the occurrence of pancreatic cancer in males residing in a particular area. For further focus, the study may be restricted to only nonsmoking males to eliminate the effect of smoking. For more depth, meat can be specified as red or white. Additionally, one can also include the amount of consumption of red and white meat and its duration. The role of other correlates that promote or inhibit the effect of meat in causing cancer can also be studied. The actual coverage of the study would depend on the availability of relevant subjects on one hand and the availability of time, resources, and expertise on the other. Such sharp focus is very helpful in specifying the objectives and hypotheses, in developing an appropriate research design, and in conducting the investigation.

### Objectives of the Study

The focus of the study is further refined by stating the objectives. These are generally divided into broad and specific. Any primary medical research can have two types of broad objectives. One is to describe features of a condition such as the clinical profile of a disease, its prevalence in various segments of the population, and the levels of medical parameters seen in different types of cases. This covers the distribution part of epidemiology of a disease or a health condition, such as what is common and what is rare, and what is the trend. It helps to assess the type of diseases prevalent in various groups and their load in a community. However, a **descriptive study** of this type does not seek explanation or causes. Evaluation of the level of $\beta_2$ microglobulin in cases of HIV/AIDS is an example of a descriptive study. A study on growth parameters of children or estimating prevalence of blindness in cataract cases is also a descriptive study.

The second type of broad objective could be to investigate the cause–effect type of the relationship between an antecedent and an outcome. Whereas cause–effect would be difficult to ascertain unless certain stringent conditions are met, an association or correlation can be easily established. Studies that aim to investigate association or cause–effect are called **analytical studies**.

A broad objective would generally encompass several dimensions of the problem. These dimensions are spelt out in specific objectives. For example, the broad objective may be to assess whether a new diagnostic modality is better than an existing one. The specific objectives in this case could be separately stated as (i) positive and negative predictivity; (ii) safety in case of an invasive procedure, or side effect of a medical treatment; (iii) feasibility under a variety of settings such as field, clinic, and hospital; (iv) acceptability by the medical community and the patients; and (v) cost-effectiveness. Another specific objective could be to evaluate its efficacy in different age–sex or disease-severity groups so that the kinds of cases where the regimen works well are identified. Specific objectives relate to the specific activities, and they identify the key indicators of interest. They are stated in measurable format.

Keep the specific objectives as few and focused as possible. Do not try to answer too many questions by a single study especially if its size is small. Too many objectives can render the study difficult to manage. Whatever objectives are set, stick to them all through the study as much as possible. Changing them midway or at the time of report writing signals that enough thinking was not done at the time of protocol development.

### Hypotheses under Investigation

A hypothesis is a precise expression of the expected results regarding the state of a phenomenon in the target population. Research is about replacing existing hypotheses with new ones that are more plausible. In a medical study, hypotheses could purport to explain the etiology of diseases; prevention strategies; screening and diagnostic modalities; distribution of occurrence in different segments of population; and the strategies to treat or to manage a disease, to prevent recurrence of disease or occurrence of adverse sequel, etc. Consider which of these types of hypotheses or any other can be investigated by the proposed study.

Hypotheses are not guesses but reflect the depth of knowledge of the topic of research. They must be stated in a manner that can be tested by collecting evidence. The hypothesis that dietary pattern affects the occurrence of cancer is not testable unless the specifics of diet and the type of cancer are specified. Antecedents and outcome variables, or other correlates, should be exactly specified in a hypothesis. Generate a separate hypothesis for each major expected relationship.

The hypotheses must correspond to the broad and specific objectives of the study. Whereas objectives define the key variables of interest, hypotheses are a guide to the strategies to analyze data. Besides objectives and hypotheses, a protocol is generally structured as described next. Most funding agencies and universities prescribe a particular format on these lines.

### Structure of the Protocol

Realize that a protocol is the focal document for any medical research. It is a comprehensive yet concise statement regarding the proposal. Protocols are generally prepared on a structured format with an introduction, containing background that exposes the gaps needing research; a review of literature, with details of various views and findings of others on the issue including those that are in conflict; a clear-worded set of objectives and the hypotheses under test; a methodology for collection of valid and reliable observations, and a statement about methods of data analysis; and the process of drawing conclusions. It tries to identify the uncertainty gaps and proposes methods to plug those gaps.

Administrative aspects such as sharing of responsibilities should also be mentioned. In any case, a protocol would contain the name of the investigator, academic qualification, institutional affiliation, and the hierarchy of advisers in the case of masters and doctoral work. The place of the study such as the department and institution should also be mentioned. The year the proposal is framed is also required. An appendix at the end includes the proforma of data collection, the consent form, etc. The main body of a protocol must address the following questions with convincing justification.

*Title*: What is actually intended to be studied and is the study sufficiently specific?

*Introduction*: How did the problem arise? In what context? What is the need of the study—what new is expected that is not known so far? Is it worth investigating? Is the study exploratory in nature, or are definitive conclusions expected? To what segment of population or to what type of cases is the problem addressed?

*Review of literature*: What is the status of the present knowledge? What are the gaps? Are there any conflicting reports? How the problem has been approached so far? With what results?

*Objectives and hypotheses*: As already described.

*Methodology*: (i) What exactly is the intervention, if any—its duration, dosage, frequency, etc.? What instructions and material are to be given to the subjects and at what time? (ii) Is there any comparison group? Why is it needed and how will it be chosen? How will it provide valid comparison? (iii) What are the possible confounders? How are these and other possible sources of bias to be handled? What is the method of allocation of subjects to different groups? If there is any blinding, how will it be implemented? Is there any matching? On what variables and why? (iv) On what characteristics would the subjects be assessed—what are the antecedents and outcomes of interest? When would these assessments be made? Who will assess them? Are these assessments necessary and sufficient to answer the proposed questions? (v) What exactly is the design of the study? Is the study descriptive or analytical? If analytical, is it observational or experimental? An observational study could be prospective, retrospective, or cross-sectional. An

experiment could be carried out on biological materials or animals, or humans, in which case it is called a trial. If experimental, is the design one-way, two-way, factorial, or what? (vi) What is the operational definition of various assessments? What methods of assessment are to be used—are they sufficiently valid and reliable? (vii) What information will be obtained by inspecting records, by interview, by laboratory and radiological investigations, and by physical examination? Is there any system of continuous monitoring in place? What mechanism is to be adopted for quality control of measurements? What is the set of instructions to be given to the assessor? (viii) What form is to be used for eliciting and recording the data? (Attach it as an appendix.) Who will record? Will it contain the necessary instructions? (ix) What is to be done in case of contingencies such as dropout of subjects or nonavailability of the kit or the regimen, or development of complications in some subjects? What safeguards are provided to protect the health of the participants? Also, when should one stop the study if a conclusion emerges before the full course of the sample? (x) What is the period of the study and the time line?

*Study sample*: What are the subjects, what is the target population, what is the source of subjects, how are they going to be selected, how many in each group, and what is the justification? What is the minimal effect you are looking for that would be considered clinically relevant, and how is this determined? What would be the statistical power or expected confidence interval, with what error? What are the inclusion and exclusion criteria? Is there any possibility of selection bias, and how is this proposed to be handled?

*Data analysis*: What estimations, comparisons, and trend assessments are to be done at the time of data analysis? Will the quality and quantity of available data be adequate for these estimations, comparisons, and trend assessments? What statistical indices are to be used to summarize the data—are these indices sufficiently valid and reliable? How is the data analysis to be done—what statistical methods would be used and are these methods really appropriate for the type of data and for providing correct answer to the questions? What level of significance or level of confidence is to be used? How are missing data, noncompliance, and nonresponse to be handled?

*Reliability and validity of results*: What is the expected reliability of the conclusions? What are the limitations of the study, if any, with regard to generalizability or applicability? What exercises are proposed to be undertaken to confirm the internal and external validity of the results?

*Administration*: What resources are required, and how are they to be arranged? How are responsibilities to be shared among investigators, supporting units (e.g., pathology, radiology, and biostatistics), hospital administration, funding agency, etc.?

In short, the protocol should be able to convince the reader that the topic is important, the data collected would be reliable and valid for that topic, and that contradictions, if any, would be satisfactorily resolved. Present it before a critical but positive audience and get their feedback. You may be creative and may be in a position to argue with conviction, but skepticism in science is regularly practiced. In fact, it is welcome. The method and results would be continuously scrutinized for possible errors. The protocol is the most important document to evaluate the scientific merit of the study proposal by the funding agencies as well as by the accepting agencies. Peer validation is a rule rather than an exception in scientific pursuits. A good research is the one that is robust to such reviews.

You can see that a protocol should consist of full details with no shortcuts, yet should be concise. It should be to the point and coherent. The reader, who may not be fully familiar with the topic, should be able to get clear answer about the why, what, and how of the proposed research. To the extent possible, it should embody the interest of the sponsor, the investigator, the patients, and the society. The protocol also is a reference source for the members of the research team whenever needed and therefore should be complete and easy to implement.

The protocol is also a big help at the time of writing of the report or a paper. The introduction and methods sections remain much the same as in the protocol, although they are in an elaborate format. The objectives as stated in the protocol help to retain the focus in the report. Much of the literature review done at the time of protocol writing also proves handy at the time of report writing.

Whereas all other aspects may be clear by themselves, special emphasis should be placed on the impartiality of the literature review. Do not be selective to include only those pieces of literature that support your hypotheses. Include those that are also inconsistent with or oppositional to your hypotheses. Justify the rationale of your research with reasons that effectively counter the opposite or indifferent view. *Research is a step in the relentless search for truth, and it must pass the litmus test put forward by conflicting or competing facts*. The protocol must provide evidence that the proposed research would stand up to this demand and would help minimize the present uncertainties regarding the phenomenon under study.

## proximal and distal measures of health and disease, *see also* primordial factors

Proximal measures of health are those that directly measure the state of health in a person or a community. Common examples are various morbidity and mortality rates. Physiological and pathophysiological processes that lead to disease and infirmity are also included among proximal measures. Distal measures are those that indirectly measure health. These are the measurement of those factors that predispose the health condition and give rise to proximal measures, such as diet, smoking, and hygiene. Genetic and environmental factors such as pollution and water supply contribute to this process of reaching to proximal from distal. Assessment of social factors such as income, occupation, and education is also included among distal measures.

Proximal measures of health such as **morbidity indicators** and **mortality rates** are described separately in detail. We have also discussed **growth indicators of children** and indicators of **adolescent health**, **adult health**, and **geriatric health**. These are all proximal measures, although many of these apply to communities and not to individuals. Distal measures are also discussed separately under the topics **social health (indicators)** and **mental health (indicators of)**. Holistic definition of health includes these two aspects, among others. **Dietary indices** and **smoking index** are also presented in this volume. Among environmental indicators, the most relevant for health and medicine is **health infrastructure**. There is a full section devoted to these indicators.

## *P*-values

In the context of statistical tests of significance, the *P*-value represents the probability that our sample gives the observed effect (or more extreme) when, in reality, such an effect does not exist in the concerned population. Nonexistence of the effect is called the null hypothesis, denoted by $H_0$. Thus, the *P*-value indicates how compatible your sample values are with the $H_0$. In notations, *P*-value = $P$(sample values|$H_0$). If this probability is far too small, the null is considered implausible. Statistically, this is termed as the probability of rejecting the null when it is true. Some of you know that this is the probability of **Type I error**. The concept of *P*-value was introduced by Fisher in the 1920s, possibly to judge whether or not the evidence is significant in the sense that it requires a second look, but it has imbibed into a solid framework for evidence-based medicine. He used the lowercase *p* to denote this probability [1], which many continue to use, but we prefer the uppercase *P* to distinguish it from sample proportion *p*.

*P*-values are an integral part of hypothesis testing as a means for statistical inference from sample to population. Hundreds of papers and blogposts have been written about what some statisticians deride as "null hypothesis significance testing" [2]. They are being widely used and also widely abused. Sufficient precautions should be exercised in interpreting a *P*-value. First, the null is not necessarily zero effect. It could be equal to a certain quantity, at least this much, or at most this much. Second, this is not the probability of the null being true given the sample values, i.e., this is not $P$($H_0$ true/sample values). If you notice what we mentioned earlier, *P*-values are its statistical inverse. Thus, it is not correct to say that this is the chance that the null is true. Third, it only tells whether to reject or not reject but does not say what to accept. This is one of the severest criticisms of *P*-values. Fourth, the *P*-value is customarily compared against an arbitrary threshold such as 0.05, called the **level of significance**, and conclusions are made. Purists do feel concerned about such "arbitrary" inferences. Despite all these problems, *P*-values seem to have come to stay as the main consideration to draw data-based inferences.

### *One-Tailed and Two-Tailed* P-*Values*

*P*-values depend on whether a test is for **one- or two-tailed alternatives**. Hemoglobin (Hb) level after giving a hematinic to anemic patients is a situation where a one-tailed test is appropriate because biological knowledge and experience confirm that iron supplementation cannot reduce Hb level at least on average. Use of the two-tailed test in this case makes it unnecessarily restrictive and makes rejection of $H_0$ more difficult. However, in most medical situations, assertion of one-sided alternative is difficult and a two-sided test is needed. Most statistical packages provide two-tailed *P*-values as a default, and many workers would not worry too much about this aspect. Scientifically, a conservative test does not do much harm, although some real differences may fail to be detected when a two-tailed test is used instead of a one-tailed test. It is advised to use a one-tailed test only where a clear indication is available in its favor, but not otherwise.

### *General Method for Obtaining the* P-*Value*

Step 1. Set up a null hypothesis and decide whether the alternative is one-sided or two-sided. Also decide the level of significance $\alpha$ and thus fix the threshold of Type I error that can be tolerated for the problem in hand.

Step 2. Identify a criterion, such as Student *t* and chi-square, suitable for the setup in hand. These criteria are also called **tests of significance**. The distributional form of these criteria has been obtained and is known. The exact criterion for obtaining the *P*-value depends mostly on (i) the nature of the data (qualitative or quantitative); (ii) the form of the distribution such as Gaussian or non-Gaussian when the data are quantitative; (iii) the number of groups to be compared (two or more than two); (iv) the parameter to be compared (it can be the mean, median, correlation coefficient, etc., in case of quantitative data; it is always a proportion $\pi$ or a ratio in case of qualitative data); (v) the size of the sample (small or large); and (vi) the number of variables considered together (one, two, or more). All this is analogous to saying that the criterion for assessing the health of a person depends on the age, gender, purpose, general health or organ-focused health, etc.

Step 3. Use sample observations to calculate the value of the criterion *assuming that the null hypothesis is true.*

Step 4. Compare the calculated value with its known distribution, and assess the probability of occurrence of a value of the criterion that is *as extreme as or more extreme toward* $H_1$ than that obtained in step 3. This probability is the *P*-value. This is calculated for both the negative and positive sides when the alternative is two-sided. Since the comparison is with the distribution under $H_0$, a probability that is not very low indicates that the sample is not inconsistent with $H_0$, and thus $H_0$ cannot be rejected. In this case, sampling fluctuation cannot be ruled out as a likely explanation for the values observed in the sample. A very low probability indicates that the observed values are very unlikely to have come up from a population where the null is true—thus $H_0$ is rejected.

Statistical tables give different values of various criteria for popular threshold $\alpha$, particularly 0.05. These are called the **critical values**. In fact, what is required is the *P*-value for each value of the criterion, but that is difficult to tabulate in most cases. Most statistical software packages give exact *P*-values associated with the value of the criterion obtained.

Step 5. Reject $H_0$ if *P* is less than the predetermined level of significance. Generally, $P < 0.05$ is considered low enough to reject $H_0$. Statistical significance is said to have been achieved when $H_0$ is rejected. Such a result can be stated in a variety of ways:

- The evidence against the null hypothesis is sufficient to reject it.
- Sample values are not consistent with the null hypothesis.
- Sampling fluctuation is not a likely explanation for the hypothesized effect.
- The alternative hypothesis is accepted.
- The *P*-value is less than a predetermined threshold such as 0.05.
- The probability of wrongly rejecting $H_0$ (Type I error) is very small.
- The result has achieved statistical significance.

### P-*Values for Nonrandom Sample*

Remember that all statistical methods of inference such as confidence interval and test of significance require random sample of subjects. Patients coming to a clinic during a particular period can be considered a *random* sample from the population of patients that are currently coming to that clinic. But this limited definition of

population is sometimes forgotten, and generalized conclusions are drawn on the basis of *P*-values. This is quite frequent in medical literature and mostly accepted without question.

Two more points need to be stressed in this context. First, a sample can rarely be fully representative of the target population in a true sense. Thus, the risk of a wrong conclusion at $\alpha = 0.05$ is, in fact, slightly more in many cases than it is in case of truly random samples. This probability can also be affected by, for example, non-Gaussian distribution of the measurement under consideration. Second, *P*-values have no meaning if no extrapolation of findings is stipulated. Conclusions based on a sample *for the sample subjects* can be drawn without worrying about *P*-values.

### P-*Value Threshold: The Level of Significance*

A threshold of 0.05 in the Type I error is customary in health and medicine. Except for convention, there is no specific sanctity of this threshold. There is certainly no cause for obsession with this cutoff point. A result with $P = 0.051$ is statistically almost as significant as one with $P = 0.049$, yet the conclusion reached would be very different if $P = 0.05$ is used as the threshold. Borderline values always need additional precaution.

A value close to the threshold such as $P = 0.06$ can be interpreted both ways. If the investigator is interested in showing the presence of difference, he/she might argue that this *P* approaches significance. If the investigator is not interested, this can be easily brushed aside as not indicating significance at $\alpha = 0.05$. It is for the reader to be on guard to check that the interpretation of such borderline *P*-values is based on objective consideration and not driven by bias. The authors generally interpret $P = 0.06$ or 0.07 as encouraging though not quite good enough to conclude a difference. They can be called marginally significant. If feasible, wait for some more data to come and retest the null in this situation.

The second problem with threshold 0.05 is that it is sometimes used without flexibility in the context of its usage. In some instances, as in the case of a potentially hazardous regimen, a more stringent control of Type I error may be needed. Then $\alpha = 0.02$, 0.01, or 0.001 may be more appropriate. It is not necessary to use $\alpha = 0.01$ if a threshold less than 0.05 is required. The value $\alpha = 0.02$ can also be used. In some other instances, as in examining the presence of differences in social characteristics of the subjects, a relaxed threshold $\alpha = 0.10$ may be appropriate. For most physiological and pathological conditions, however, the conventional $\alpha = 0.05$ works fine, and that is why it has stayed as a standard for so long.

The practice now generally followed is to state exact *P*-values so that the reader can draw his/her own conclusion. A value of *P* around 0.10 can possibly be considered weak evidence against the null hypothesis, and a small *P*, say less than 0.01, as strong evidence. Any *P*-value more than 0.10 is considered as no evidence of any consequence.

### *Other Problems with* P-*Values*

Statistical *P*-values seem to be gaining acceptance as a gold standard for data-based conclusions. However, biological plausibility should not be abandoned in favor of *P*-values. Inferences based on *P*-values can also produce a biased or incorrect result just as misdiagnosis and missed diagnosis happen in clinical setting. Also see the topic **misuse of statistical tools** for examples of misuse of *P*-values.

Attempts are sometimes made to dramatize the *P*-values. James et al. [3] stated $P < 0.00000000001$ for difference in seroconversion rate against Epstein–Barr virus between patients with lupus and controls. It is pulling out a number from a computer output without being careful about its implications. Such accuracy is redundant. It really does not matter whether $P < 0.001$ or $P < 0.000001$ as far as its practical implication is concerned. Many statistical software packages rightly stop at three decimal places under default and give $P = 0.000$ when it is exceedingly small. It only means that $P < 0.0005$, and this is enough to draw a conclusion. Further decimal places are rarely required. But do not interpret $P = 0.000$ as $P = 0$ as no *P*-value can be zero.

## publication bias

There is a tendency for studies with positive results to find their way preferentially into the literature and studies with negative results not finding their place: this makes for the phenomenon named publication bias. Publication bias is a form of selection bias for studies that yield a particular type of result. This phenomenon has been convincingly demonstrated by several authors (for example, see Boulesteix et al. [1]). When published literature is solely used as the basis for drawing conclusions about a treatment, it is possible that a biased impression in favor of the treatment could result. This is possible for both informal reviews of the literature and more quantitative ones such as meta-analyses.

The fact remains that the literature is unduly loaded with positive results. Negative or indifferent results are either not sent for publication or are not published by the journals with the same frequency. Many journals are much too keen to publish reports that give a positive result regarding efficacy of a new regimen compared with the negative trials that did not find any difference. If there are 20 studies—8 with positive and 12 with negative results—may be 7 with positive results will be published, but possibly only 2 with negative results. Thus, you will get the impression that 9 studies were conducted and 7 have positive results. If a vote count is done on the basis of the published reports, positive results would hugely outscore the negative results, although the fact may be just the reverse. Thus, any conclusion based on commonality in publications can magnify this bias.

In principle, publication bias should not happen. If a trial yielding a negative finding but addressing an important therapeutic question has been conducted rigorously, and it is written up as it should be, then the resulting information will be useful to other researchers and practitioners. It deserves to be published as much as the studies with positive results that appear to show a therapeutic advance. Investigators, however, often lose enthusiasm for trials with negative results because they seem less glamorous than positive ones and may be viewed as failures by the research team and sponsors. If this happens, then it can lead to weaker reports. Song et al. [2] report a meta-analysis of different types of research studies for publication bias. The pooled odds ratio of publication of studies with positive results, compared to those without positive results, was 2.78 in studies that followed from inception, 5.00 in trials submitted to regulatory authority, 1.70 in abstracts, and 1.06 in other manuscripts. Thus, the problem seems more severe for clinical trials. Some journal editors seem to prefer to publish positive studies because in so doing

they might improve the standing of the journal. This is paradoxical, however, because if we assume that true treatment advances are uncommon, then positive reports are more likely to be in error than negative ones.

There is no one way for the readers of a report to correct for publication bias. You must recognize that selection bias may exist and retain some skepticism about a conclusion with positive results. In a few cases, readers might be aware of unpublished studies that fail to support a particular finding: these can be used to soften enthusiasm. It may be useful to ask if the paper in question would have been published if it was actually a negative trial. In other words, is the quality of the study good enough to convey externally valid information consistent with no effect? Even so, there is no way to separate true from false positive results without replicating the study several times. When conducting exhaustive quantitative overviews in systematic reviews and meta-analyses, it is important to include data from both the published and the unpublished trials to counteract such publication bias whenever unpublished reports of the trials are available. That meta-analysis tends to provide more valid and reliable results by pooling results from different publications is accepted as a good statistical technique, but the validity of the results depends on proper representation of studies with all kinds of results.

## purchasing power parity dollars

The most widely used measure of the level of income of a community is the per capita gross domestic product, popularly called the per capita income. Almost all countries compute this for the nation as a whole and usually also for each of their states separately. Further subdivisions may not be easily available. It is to be expected that the higher the level of income of a community, the healthier that community.

Income per se in the national currencies is seldom comparable across countries because of huge differentials in purchasing power. A Singapore dollar cannot buy as much in Singapore as the Yuan equivalent can in China. The World Bank has done considerable work in this sphere and obtained incomes of various countries in terms of purchasing power parity (PPP) in international dollars. An international dollar has the same purchasing power in the country as the US dollar has in the United States. Thus, an average per capita income of nearly 50,000 rupees per annum in 2013 in India was equivalent to Int$5350 [1]. That is, an Indian rupee in India is worth nearly 10 cents in the United States in terms of purchasing power. For Austria, the per capita income is Int$45,040. You can say that the average income of a person in Austria is nearly 8 times of that in India. Note, however, that income is mostly a family trait rather than of an individual because children are not supposed to earn. If the average size of family is four, the average family income is four times the per capita income.

PPP comes in handy for comparing cost of health care. If a cancer treatment costs Rs 500,000 in India and US$50,000 in the United States, they are nearly the same in terms of purchasing power. PPP is also used for assessing income across countries and its impact on health infrastructure or its utilization. Alkire et al. [2] have used PPP for projecting the value of lost output due to surgical conditions across 128 countries for which the data were available. Kalo et al. [3] have worked out the financial benefits of clinical trials in Hungary in terms of PPP dollars.

## purposive sample, *see* sampling techniques

## putative factors

"Putative" has the meaning of being part of conventional wisdom: "generally considered or reputed to be" such as putative father. This is related more to "reputation" than real. You can see that putative factors may not be the actual operational factors but are those that are widely considered to affect an outcome. These are perceived, believed, or assumed to affect an outcome, may not be necessarily supported by hard evidence, and may not be biologically related to the outcome. The term is mostly used for risk factors. On many occasions when the actual risk factors are not known, a beginning can be made with putative factors. In some situations, the interest may be restricted to putative factors to find if any or some of them are for real, have supportive evidence, and can be explained with biological mechanism.

Putative factors can best be understood by reference to the examples given by Mascheretti et al. [1] and Fechner et al. [2]. In the former, the authors found that although dyslexia runs in families, several putative risk factors, which could not be immediately identified as genetic, predicted reading disability in dyslexia patients in Italy. Putative factors they considered are younger parental age at child's birth, lower parental education, and risk of miscarriage. These factors significantly increased the odds of belonging to the dyslexia group. These findings supported the result that reading disabilities are a multifactorial disorder and may bear some importance for the prevention and/or early detection of children at heightened risk for dyslexia. In the second paper, the authors studied putative risk factors for colorectal cancer such as fecal mass, transit time, fecal pH, and secondary bile acid concentration. In so doing, they tested the hypothesis that high intake of dietary fiber has been associated with a lower risk of colorectal cancer. It was concluded that enhancing dietary fiber intake through consuming blue lupin fiber up to about 50 g/day can be recommended.

# Q

## Q–Q plot, *see* quantile-by-quantile (Q–Q) plot

## *Q* test, *see* Cochran *Q* test

## quadratic regression, *see* curvilinear regression

## qualitative measurements, *see also* quantitative measurements

The measurements that do not have a metric, such as site of injury ("measured" as head, chest, abdomen, etc.) and blood groups (measured as O, A, B, and AB), are called qualitative measurements. This is in contrast to quantitative measurements such as blood pressure, hemoglobin, creatinine, and size of kidney, which are measured in numeric metric. Qualitative measurements could be dichotomous or polytomous depending on whether the number of categories is two or more than two, and polytomous could be further divided into ordinal (such as the severity of disease being mild, moderate, serious, and critical) and nominal (with no order, such as site of cancer).

Ordinal qualitative measurements are statistically quite challenging since they actually are a manifestation of the underlying continuum. If an appropriate scale is available, we would like to measure them quantitatively. Disease severity in critical patients can be possibly measured by the APACHE score, but such scoring is not available for many diseases, and the validity of available scores is questionable in some cases. When no such scale is available, signs–symptoms and investigations are used to classify the subjects into one of the many possible ordinal groups. Even when a clear quantitative scale is available, many clinicians prefer to label their patients as mild or moderate or serious. This possibly helps them decide how to manage the patient. The most prominent examples of this are univariate diseases such as hypertension, diabetes, and anemia, which are the names of conditions indicating that a particular measurement has crossed a threshold. Problems in this are apparent since a person with a fasting blood sugar level of 119 is not diabetic and a person with a fasting blood sugar level 121 is if the threshold is 120 mg/dL. Such categories defy statistical logic, but at the same time, there is no denial that clinicians do need a threshold beyond which a treatment must be instituted.

In addition to what is just stated, note that a variable such as birth weight is also quantitative but is treated as qualitative when the interest is in knowing the percentage of newborns with weight <2500 g, 2500–3499 g, and ≥3500 g. This is an example of a quantitative variable converted to a qualitative one, where the concern is with the proportions of subjects in different categories and not mean or median. The actual scale can be metric, but the variable becomes qualitative when such categories are formed and the interest shifts to proportions. There is a rider though. For the interest in proportion to sustain, the number of such categories must be small. If, instead of three broad categories, the birth weight is divided into a large number of 100-g categories such as <2000, 2000–2099, 2100–2199, and so on, the interest would rarely be in a proportion of births in these categories and would mostly be in parameters (such as mean, median, standard deviation, percentiles, etc.) of birth weight. The categories are not qualitative then.

Statistical inferential methods for qualitative variables are different from those for quantitative variables. This is analogous to the assessment methods that are different for cardiovascular diseases from those for gastrointestinal tract diseases. These methods are based on **binomial distribution** for dichotomous categories and on multinomial distribution for polytomous categories. Dichotomous categories, where a quantitative measurement is divided into two groups, are a class apart from the nominal dichotomous categories. Examples of nominal dichotomous are male–female, case–control, and cancer of prostate or cancer of esophagus. These have no order—no single category is better or superior to the other. These are the situations where binomial distribution can be legitimately applied with full authenticity when the categories are **mutually exclusive and exhaustive**. Quantitative dichotomous can also be handled with binomial distribution, but sometimes the underlying distribution can also be used to provide additional information. For example, if you know that fasting blood glucose level follows a Gaussian (Normal) distribution, the threshold 120 mg/dL is not simply a yes/no type but has additional information such as how far this is from the mean or mode in absolute value or in SD units. The same applies to multinomial distribution for polytomous ordinal categories based on quantitative measurements.

## qualitative research, *see also* focus group discussion

This term refers to the research almost entirely based on **qualitative measurements** with an additional feature that the qualities are far too disperse and varied. This type of research does not focus on quality of instruments but generally concentrates on behavioral and mental aspects such as opinion, perception, belief, motivation, expectation, satisfaction, and reaction that cannot be easily measured in terms of quantities. The focus in qualitative research is on the why and how of the decision process instead of the what and where. Such characteristics may defy hard measurement but are important to provide the context and may help in explaining the reasons behind controversies.

The most common tool of qualitative research is **focus group discussion**, where a knowledgeable group of people is assembled and engaged in a discussion on a topic of interest. The theme of the discussion is captured by the terms and concepts most commonly used. The methodology is still developing, and it basically remains descriptive and exploratory, if not anecdotal. Many consider this unscientific because the same results cannot be obtained if the discussion is repeated; repeatability is a sheet anchor of scientific research. The extent to which biases and prejudices affect this evidence is still an area of conjecture.

Qualitative research on an audience is usually audio-recorded and transcribed. The transcriptions form the data that are then analyzed by the moderator. Group discussions can be video-recorded

and can also be observed in real time at venues specially designated for that purpose.

In many situations, medical decisions are taken on soft considerations that can be assessed only by qualitative research. Issues such as refusal to undergo a surgery that has demonstrable benefits have heavy personal overtones and can rarely be explained by hard facts. Ignoring such social issues can be perilous in some situations. The challenge is that these contexts are highly variable from person to person and can quickly change within a person also from time to time depending on the context. Experience and circumstances sometimes play an important role in determining such reactions.

Qualitative research rarely give statistically sound findings since the methods used in this kind of research, such as focus group discussion, in-depth interviews of a small, nonrandomly selected key persons, observation of activity, and reactions in a specified situation, are highly subjective. Thus, this is not a substitute for quantitative research, although it can be a useful adjunct in studies that require *soft data*. For example, in-depth interview in an intimate environment may allow the participant to talk openly about obscure issues such as about competitors with whom discussion in a group cannot be held. This can unravel facets that would otherwise rarely come to the fore.

There is no denying that we need qualitative research in health and medicine. This is a science that has profound impact on psychosocial aspects and is also deeply affected by such factors. The methodological standards and the guidelines for qualitative research in medicine and health care remain too sketchy to help one conduct such a study with conviction and critically evaluate a qualitative study. Better methodologies may develop in the future, but till such time, the results of qualitative research must be interpreted with caution. For a review of this topic, see Poses and Isen [1]. For an application, see Vazquez et al. [2] who did qualitative research to understand the phenomenon of nonadherance to dental treatment by adolescents in Brazil.

## quality control in medical care, *see also* control charts, lot quality assurance scheme

Quality in the statistical sense means meeting a specified standard. It is always desirable to aim at perfection, but that is quite often elusive. For example, it would be wonderful to have a hospital that discharges fully cured patients all the time without any death or disability, but that is impossible to achieve. Thus, a lower standard of, say, a 90% cure rate in casualty cases and 98% in routine admissions may have to be fixed. Limitations of knowledge and cost considerations often determine this feasibility level. Once a standard—high or not so high—is fixed, everything possible should be done to achieve it, and this is best done by controlling errors.

Errors are distinct from variation, the latter being endogenous whereas the former being exogenous. Variability remains; it is only their impact that can be minimized. On the other hand, the errors themselves can be largely avoided by being sufficiently careful, although it may not be easy to eliminate them fully. A standardized mercury manometer would still give variable readings in different individuals, but occurrence of air bubbles in the mercury column produces an error. Clinicians may genuinely differ on the dose of a drug to be given to a particular patient, but giving the drug two times when the prescription says three times a day is an error.

### *Statistical Quality Control in Medical Care*

Medical care is a big industry in many parts of the world. Providing good care is a prerequisite for this industry to maintain and increase clientele and perhaps profits, but the primary concern is with the humanitarian aspect of doing the best to prolong life and reduce suffering in an activity that deals with the life and health of people. In this context, quality of medical care assumes importance much more than in other industries. Perhaps millions of episodes of illness and deaths around the world every year can be attributed to medical errors. According to one estimate, nearly one in three patients encounter problems due to medical errors during their hospital stay [1].

A patient sometimes has to undergo an array of steps while seeking treatment: the patient describes complaints, responds to questions about the history of the problem, talks about environmental exposures, discusses extent of disabilities, and so on. The attending clinician gears questions to meet the requirement of the situation in terms of the condition of the patient, the type of complaints, and the intelligence level of the patient. The clinician also examines the patient as required and obtains data on body temperature, heart rate, blood pressure, and weight. An interim therapy is sometimes started, and laboratory and radiological investigations are ordered, if considered desirable. The laboratory and radiological units carry out these investigations and report findings. The clinician reassesses and sometimes the cycle restarts. In a hospital setup, outpatients receive their supply of medicines from a pharmacy according to the prescription and ingest the drug, whereas inpatients are administered prescribed dosages by the nursing staff. Some patients undergo surgery where a series of steps are undertaken in the preoperative ward, operation theater, and postsurgical care unit. A hospital does all this for a large number of patients day after day. It is unrealistic to expect that all steps will be correctly done in all cases all the time. Errors do occur. The question is whether these errors are far too many or too large, or are within a tolerance limit. This tolerance has a statistical nature because it is determined by the experience. Before this is discussed, a brief overview of steps that could enhance the quality of medical care may be helpful.

Edward Deming is among those who were outstanding in promoting quality control. He suggested many steps to keep a check on quality. Some of these, in the context of medical care, are as follows [2]:

- Prepare operational definitions of the services to be provided, specify the standards of service, and formulate clear guidelines about the identification of patients to be served and to be excluded by referral or otherwise.
- Refuse to accept a higher level of mistakes in diagnosis and treatment for any reason including inadequate instruments, inappropriate technology, lack of expertise, expired drugs, substandard chemicals, and so on.
- Instead of depending on ad hoc inspection, depend on statistical evidence of quality of incoming material such as pharmaceuticals, testing kits, and blood. The meaning of statistical evidence is given later in this section.
- Implement a system of self-detection of errors and do not wait for complaints to come.
- Continually update the doctors and technicians on rapidly growing developments and encourage them to acquire new skills.

- Have the objective not of finding cases of fault but of diagnosing the fault so that remedial steps can be taken.
- Drive out fear so that employees feel free to make suggestions. Assign failure to the lacuna in the system rather than to the individuals.
- Instead of setting numerical targets, set work standards in terms of quality. Thus, do not count the patients treated but assess the percentage of patients who were cured and satisfied.
- Top management must be committed to quality and should earnestly implement the preceding suggestions.

A large number of issues related to quality of medical care can be discussed. The focus here is on statistics-based issues rather than on medicine-based issues, and the following discussion is limited to some specific aspects that *illustrate* the help statistical methods can provide in improving the quality of medical care. The same kind of methodology can be used to control other kinds of errors.

If a patient with a disease, the treatment of which is known, is not cured, it would be generally correct to assume that this failure is a consequence of error on the part of the medical care chain. This can be due to carelessness or inadequate expertise of the attending personnel or to the faulty tools and equipment—in some cases to the carelessness of the patient. The present discussion is restricted to deviation such as from the prescription or from the specified procedures so that such errors can be called as medical care errors. In admitted patients, these could be in terms of administration of doses at times other than specified, wrong amount of doses, omission of a dose or giving an extra dose, administration of an unprescribed drug, and so on. Such errors can also occur with other procedures such as obtaining the history; establishing the diagnosis, measurements, and assessments; attending to the complaints of the patients; acting on warning signals; consulting a specialist; carrying out a laboratory investigation; and identifying the side effects.

Medical care errors are difficult to identify. They come to notice mostly when the outcome of a therapy is a sudden deterioration of the condition of the patient rather than gradual improvement. Listed next are some common adverse patient outcomes [3] that indicate that an error has occurred somewhere in patient management, including a clinician's error in judgment about the patient's condition.

- Admission due to adverse results of outpatient management
- Admission for complication of a problem on previous admission
- Perforation, laceration, or injury to an organ incurred during an invasive procedure
- Adverse reaction to a drug or transfusion
- Unplanned return to the operation theater
- Infection developing subsequent to admission, including infection occurring after operation
- Transfer from a general care to a special care unit
- New complications occurring after the start of therapy

This list may convince one that errors in medical care are not uncommon. It is preferable to keep separate track of each type of adverse outcome so that corrective steps can be taken accordingly. For care in the hospital, the indicators can be listed as follows:

- Medication errors per 100 patient days
- Transfusion reactions per 100 units
- Surgery site infection rate per 100 surgeries
- Ventilator-associated pneumonia per 100 ventilator days
- Incidence of bed sores per 100 patients
- Incidence of needle stick injuries per 100 patient days
- Percentage of emergency patients who had to wait for more than 30 min

A hospital's ability to provide the best care for certain types of patients can be difficult to measure because each patient's case is different and outcomes cannot always be predicted. In addition, the collection of data for health care facilities is a challenging, continuously changing science. This makes it important to compare as many quality measurement types as possible so as to form the most complete picture of a hospital's total quality of care before making a final decision.

*Monitoring Fatality*: The adverse outcomes just listed assume that the patient is alive, but some events are bound to be fatal in a hospital despite the best care. **Case-fatality** per 1000 patients admitted can be an indicator of the quality of care in a hospital. Because some hospitals are specialized to treat serious and terminal cases, interhospital comparison on the basis of gross fatality may not be valid. The same is true for different units of a hospital. However, trend within a hospital can certainly be monitored over time using this indicator. Mortality within 48 h in many cases is determined by the condition of the patient at the time of admission instead of the quality of medical care. When this is excluded, the rate is called the *net fatality rate*, a relatively more valid rate for comparison between units or between hospitals. Case-fatality rate, when calculated separately for each disease or condition, may also provide a good indication of the quality of care in different departments of a hospital and may reflect the ability to manage critical patients with different diseases. The other useful indicators of hospital mortality are general anesthesia death rate, which is based on the deaths related to general anesthesia per 1000 patients administered anesthesia. Other indicators are postoperative death rate, hospital maternal death rate (maternal deaths per 100,000 antenatals admitted), hospital early neonatal death rate, and so on. These focus on specific aspects that can be targeted for remedial steps.

It is often difficult to identify a single error that has caused a particular adverse outcome, but if the management is sufficiently careful and the staff is cooperative, analysis of each case of adverse outcome may successfully pinpoint the major cause. Thus, errors of different types can indeed be monitored. For limits of tolerance and related issues, **control charts** that can guide one on how to statistically control such errors are prepared. We have also separately discussed the method of **lot quality assurance scheme** to assess quality of lots such as laboratory kits. Also, see **six-sigma methodology**.

## *Quality Control in a Medical Laboratory*

Besides errors in analysis of the specimen, errors in a laboratory can occur due to incomplete preparation of the patient before sampling, collection of specimen in an inappropriate container, mislabeling or mishandling, delay in transport, improper storage, mistakes in data entry, and, above all, misinterpretation of the physician's order for the test. All these can add up to a formidable chance of error. Imagine the cost of these errors to the patient and medical care system. Wrong reporting can cause immense discomfort and can even cost a life. Ethics is compulsive in this activity as in all others involving health and well-being of people. If you are interacting with a laboratory where a large number of specimens are processed everyday, see if the laboratory is keeping count of such errors and has a mechanism to address the quality issues.

Laboratories differ in their methods, chemicals, skills of the staff, and so on, and thus results for aliquots of the same specimen may differ from laboratory to laboratory. Part of this variability can

be eliminated by standardization across laboratories. Differences also occur within the laboratory from time to time. If such differences are substantial, it shakes the clinician's confidence in the values reported. Quality control helps keep a check on and maintain a high level of performance. This can be done with the help of a **control chart** as discussed under that topic.

Because of widespread computerization, much of the data required for quality control are available online these days. Programs are prepared to issue warning signals when the system seems to derail. This, as well as issues related to multivariate control of quality, is discussed by MacGregor [4], although in the context of manufacturing industry. The application to medical setups is immediate.

## quality of data and of measurements, *see also* fallacies (statistical)

Quality of data refers to their **reliability** and **validity**, which includes aspects such as care in obtaining and recording the data; minimization of missing values, misreporting, and biases of the observer; standardized definitions and procedures; and so on. Correct statistical decisions depend not just on choosing the right method of analysis and right interpretation but predominantly on right data so that the **garbage-in garbage-out (GIGO) syndrome** does not operate. Even the most immaculate statistical treatment of data cannot lead to correct conclusions if the data are basically wrong. Before starting an analysis, everything possible should be done to ensure that the information is correct. This mostly depends on the validity and reliability of the tools and instruments (including manpower) used for the collection of information and on the quality of data actually obtained through these instruments.

Since there are a large number of steps a patient or a subject has to pass through after entering a health care web, expertise and attention of the people doing this assessment are critical. For example, in a clinical setup, health is assessed by eliciting the history, conducting a physical examination, carrying out laboratory or radiological investigations, and, sometimes, longitudinally monitoring the progress of the subject, all of which require care and expertise. Health assessment generally requires the use of a questionnaire or a schedule for systematically eliciting and recording information; medical instruments such as a stethoscope, a blood pressure instrument, and a weighing machine; laboratory chemicals, reagents, and methods including machines such as analyzers; x-ray, ultrasound and other imaging devices, and all that go along with them; diagnostic criteria and definitions including scoring systems, if any; and prognostic indicators. Generically, all these are instruments in the statistical sense because data are obtained through them. Various procedures for patient management such as endoscopy, surgery, and treatment regimens also fall under this general term. Under certain conditions, these procedures can also be called tests instead of instruments. No medical instrument is perfect in practice because the performance of the instrument also depends, to a degree, on the human input, besides its own intrinsic properties. The quality of medical decisions depends very substantially on the dependability of these instruments in actual use. This is assessed in terms of the **validity** and **reliability** of the instruments, but quality has other dimensions as well, such as ease in use, simplicity, and being readily interpretable.

Valid and reliable instruments can also give erroneous results when not used with sufficient care. In addition, some errors creep in inadvertently because of ignorance. Sometimes, data are deliberately manipulated to support a particular viewpoint. Also remember what Tukey said: availability of set of data and aching desire for an answer do not ensure that a reasonable answer would be extracted.

### *Errors in Measurement*

Errors in measurement can arise due to several factors as listed below.

*Lack of Standardization in Definitions*: If it is not decided beforehand that an eye will be called practically blind when VA < 3/60, VA < 1/60, or any other, where VA stands for visual acuity, then different observers may use different definitions. When such inconsistent data are merged, an otherwise clear signal from the data may fail to emerge, leading to a compromised conclusion. A similar example is of the variable definition of hypertension used by different workers. In addition, special attention is required for borderline values, for example, Chambless et al. [1] use blood pressure (BP) ≥ 140/90 for hypertension, and Wei et al. [2] use BP > 140/90, where one considers BP = 140/90 hypertensive and the other normotensive. The other such example is age, which can be recorded in completed years (age last birthday) or as on the nearest birthday. These two are not necessarily the same. A difficulty might arise in classifying an individual as anemic when the hemoglobin level is low but the hematocrit is normal. Guidelines on such definitions should be very clear, and all observers involved in a particular research should follow the same definition.

*Lack of Care in Obtaining or Recording Information*: This occurs when, for example, sufficient attention is not paid to the appearance of Korotkoff sounds while measuring BP by a sphygmomanometer or to the waves appearing on a monitor for a patient in critical condition. This can also happen when responses from patients are accepted without probing and some of them may not be consistent with the response obtained on other items. If reported gravidity in a woman does not equal the sum of parity, abortions, and stillbirths, then obviously some information is wrong. A person may say that he/she does not know anything about AIDS in the early part of an interview but states sexual intercourse as the mode of transmission in the latter part of the interview. This is an example of inconsistent responses that require further probing. The observer or the interviewer has to exercise sufficient care so that such inconsistencies do not arise.

Then, there is the question of correct transfer of data in completed forms to the spreadsheet where the collection of data is not online. We have often detected errors in data entry when intimately checked after a suspicion arose. It is mostly for investigators themselves to carefully check the data and ensure that the data are correctly entered. Here is a sample of what we could detect: (i) In one instance, codes for males and females were reversed for some subjects. Such errors are difficult to detect till you find a pregnant male! (ii) In another case, the pretest values were unwittingly swapped with posttest values for some cases at the time of data entry. (iii) In yet another instance, the values for case number 27 were exactly the

same as those for case number 83, which could have occurred as a result of repeat recording of the same subject by two different workers or by wrong renumbering of forms.

To give you a few more practical examples, at the time of entering change from pre- to post-values, the minus sign was inadvertently omitted in some cases. In another instance, calculation of scores was based on wrong columns F, G, H, M, and N in the spreadsheet where the columns actually needed were F, G, H, N, and O, and the scores that turned out did not arouse suspicion. Only when a third person examined the data for some other purpose was this error detected. All these are actual instances and can happen in best of setups. Thus, proper scrutiny of data is a must for valid results. Some such errors may have crept in this book as well and we will fake it as if nothing serious has happened.

Now, some tips on how to check the data. For large data sets, double entry by two independent workers and matching may help in detecting errors that could be subsequently resolved either by going back to the forms or by reasoning. The second method is the range check. If hemoglobin level is typed as 3.2 mg/dL, birth weight as 6700 g, or age at menopause as 67 years, you know these are improbable values and need to be double checked. Whether qualitative or quantitative, frequency tabulation can help in detecting such outliers. The difficulty is in detecting age 32 years wrongly typed as 23 years—when both are equally plausible. If the stakes are high, it is a good idea to double check all the entries with the forms (assuming that information in forms is correct). If the entries are direct online, one source of errors is eliminated but the chance of detecting any error in entry steeply declines. Everything possible should be done for correct entries since these cannot be disowned later when detected.

*Inability of the Observer to Get Confidence of the Respondent*: This inability can be attributed to language or intellectual barriers if the subject and observer come from widely different backgrounds. They may then not understand each other and generate wrong data. In addition, in some cases, such as in sexually transmitted diseases, part of the information may be intentionally distorted because of the stigma or the inhibition attached to such diseases. An injury in a physical fight may be ascribed to something else to avoid legal wrangles. Some women hesitate to divulge their correct age, and some refuse physical examination, forcing one to depend on less valid information. Correct information can be obtained only when the observer enjoys full confidence of the respondent.

*Bias of the Observer*: Some agencies deliberately underreport starvation deaths in their area as a face-saving device and overreport deaths caused by calamities such as flood, cyclone, and earthquake to attract funds and sympathy. Improvement in condition of a patient for reasons other than therapy can be wrongly ascribed to the therapy. Tighe et al. [3] studied observer bias in the interpretation of dobutamine stress echocardiography and concluded that the potential for observer bias exists because of the influence of ancillary testing data such as angina pectoris and ST-segment changes. Lewis [4] found that psychiatric assessments of anxiety and depression requiring clinical judgment on the part of the interviewer are likely to suffer from observer bias. These examples illustrate some situations in which observer bias can occur.

*Variable Competence of the Observers*: Quite often, an investigation is a collaborative effort involving several observers. Not all observers have the same competence or the same skill. Assuming that each observer works to his fullest capability, faithfully following the definitions and protocol, variation can still occur in measurement and in assessment of diagnosis and prognosis because one observer may have different acumen in collating the spectrum of available evidence than the others.

Many inadvertent errors can be avoided by imparting adequate training to the observers in the standard methodology proposed to be followed for collection of data and by adhering to the protocol as outlined in the instruction sheet. Many investigations do not even prepare an instruction sheet, let alone address adherence. Intentional errors are, however, nearly impossible to handle and can remain unknown until they expose themselves. One approach is to be vigilant regarding the possibility of such errors and deal sternly with them when they come to notice. Scientific journals can play a responsible role in this respect. If these errors are noticed before reaching the publication stage, steps can be sometimes taken to correct the data. If correction is not possible, the biased data may have to be excluded altogether from analysis and conclusion.

It is sometimes believed that bad data are better than none at all. This can be true if sufficient care is exercised in ensuring that the effect on the conclusion of bias in bad data has been minimized, if not eliminated. This is rarely possible if the sources of bias are too many. Also, care can be exercised only when the sources of bias are known or can be reasonably conjectured. Even the most meticulous statistical treatment of inherently bad data cannot lead to correct conclusions.

For quality of statistical models, see the topic **robustness**.

## quality of life index, *see also* physical quality of life index

This index measures quality of life of individuals either as per their own perception or on some objective basis. Thus, this section is restricted to assessment of quality of life of individuals rather than of communities. For communities, see **physical quality of life index**. The focus here is on patients, particularly those suffering from chronic conditions who are not able to lead a normal life.

Myocardial infarction (MI), breast cancer, multiple fractures, and peritoneal surgery are examples of conditions that have many survivors, but quite a few of them are not able to lead a normal life of a healthy person. The disability may be apparent, such as in walking and talking, or more subtle as in doing heavy work for long hours. Quality-of-life assessment is gaining importance as more and more people are able to live longer due to medical intervention but retain residual disability of one kind or the other. It is being increasingly assessed for the general population as well, or for patients of various other types with no disability. This is also commonly used as an outcome measure in research on the relative benefits of different treatment methods.

Quality of life is generally equated with hopes and ambitions matched by experience. It involves a person's own perception and values. Note that this is quite abstract and thus is difficult to measure. Physical, psychological, and social well-being, including functionality in daily living, are generally included in a quality-of-life assessment. In the case of chronic patients, this may contain items on sleep, appetite, sexual functions, social participation, work performance, and so on. It is often considered convenient to divide the quality-of-life questionnaire into domains such as physical health and psychological well-being and to divide a domain into facets, such as psychological well-being into negative and positive feelings, self-esteem, and memory. As the quality of life is mostly the perception of the subject, the rating sometimes may be inconsistent with the actual physical condition such as tumor stage. A patient in an advanced stage of malignancy may still report a good quality of life if he/she has learnt to live with it.

Several instruments that claim to measure quality of life in different kinds of subjects, particularly in patients with chronic ailments, are available. For cardiovascular disease, a multidimensional index based on 35 questions on different domains of quality of life was developed by Avis et al. [1]. For cancer, there is a quality-of-life questionnaire, called EORTC QLQ-C30, containing 30 items of inquiry [2]. Ferrans and Powers [3] developed a quality-of-life instrument whose different versions can be used for a variety of health disorders. Seattle Quality of Life Group has given a big list of adult and children instruments for different conditions on their website [4]. All of them translate quality into an index that can be used for statistical purposes.

For the general population, the World Health Organization has devised a quality-of-life (WHO-QOL) questionnaire with 100 items [5]. This questionnaire is considered too detailed and difficult to answer. More popular is the short form with 36 items called *SF-36*. This measures functional health and well-being. Such questionnaires can be easily downloaded from various websites such as www.sf-36.org but may have to be adapted to the local conditions. A brief questionnaire (WHO-QOL-BREF) [6] with 26 items is also available. There are other indices that measure contextual quality of life such as activities of daily living index [7] for elderly people.

Reliability and validity of such instruments have always been a concern. Reliability is statistically assessed in terms of **Cronbach alpha** for internal consistency and **test–retest** correlations for stability. All types of **validity** (face, content, concurrent, construct, etc.) are also tested in a variety of conditions before such instruments are actually used.

## quantal assays, *see also* bioassays

These are **bioassays** for quantal response. Quantal response are of the yes/no type, such as whether death occurred or not (within the chosen time frame), the person recovered or not, the subject developed side effects or not, the subject developed disease or not, and so on.

The response observed at different doses of a test and a standard regimen is essential to an assay. In the case of quantal assays, the response is the percentage of subjects who developed the intended outcome. For example, this could be of the type that when the dose is 5 mg, 56% responded; when the dose is 10 mg, 69% responded; when the dose is 20 mg, 88% responded; and so on. The initial objective is to find the dose–response relationship using such data. Obviously, the regimen for such assays should be such that a higher dose elicits a progressively higher or progressively lower response but not an erratic response. This would happen with insecticides and such other toxic substance, but this can also happen with drugs when the dose is given between certain limits—for example, the higher the dose between 5 and 15 mg, the higher the response, but beyond 15 mg, the dose is harmful and not tried, and less than 5 mg may be ineffective and not worth giving it a try. Anesthetic agents also have this property—the higher the dose, the more the response, although it can be lethal beyond a point.

As in all bioassays, there is a test and a standard preparation, and the ultimate objective is to obtain an estimate of the **relative potency** as done for parallel-line and slope-ratio assays for quantitative response.

Essentials of quantal assays are explained next in this section. These should make it clear what a quantal assay is and why this is called a quantal assay. We also give an outline of how to estimate relative potency with quantal assays and what are the validity conditions.

### *Setup for Quantal Assays*

As already mentioned, the basic setup in quantal assays is that different doses of a test and a standard preparation are each given to a group of subjects and the percentage who responded with different doses is noted. For example, give 2 mg to 12 subjects, 5 mg to 7 subjects, 10 mg to 20 subjects, and so on, and the number who responded could be 4, 3, and 16, respectively. In this example, the quantal response is $100 \times 4/12 = 33.3\%$ with a 2-mg dose, and similarly, 42.9% with a 5-mg dose and 75.0% with a 10-mg dose. The dose that yields response in 50% of the subjects is called effective dose 50 and denoted by $\mathbf{ED_{50}}$. If the response is death, this is called lethal dose 50 or $LD_{50}$. This is also called **median effective dose** or median lethal dose as the case may be, and this could also be a quantity of interest in addition to the relative potency.

For simplicity, consider only one preparation for the time being. Let the dose metameter be denoted by $x$ as before, which could be the dose itself or log dose or any other transformation, called metameter. The subscripts $s$ and $t$ will be introduced later for standard and test preparations. Let the $k$th dose be denoted by $x_k$ ($k = 1, 2, \ldots, K$), which means that the regimen is tried in $K$ different doses. In the example in the preceding paragraph, $K = 3$ since there are three doses, and $x_1 = 2$ mg, $x_2 = 5$ mg, and $x_3 = 10$ mg. Assume that these are arranged in ascending order so that the first group received the lowest dose, the next group received the next higher dose, the third group received the next higher dose, and so on. The first dose

is tried on $n_1$ subjects, the second on $n_2$ subjects, and so on, and the $K$th dose is tried on $n_K$ subjects. In our example, $n_1 = 12$, $n_2 = 7$, and $n_3 = 20$. Let the number of subjects who responded positively to dose $x_k$ be denoted by $r_k$, which, in our example, are $r_1 = 4$, $r_2 = 3$, and $r_3 = 16$. You can see that doses $x_k$ and number of subjects for each dose $n_k$ are fixed by the experimenter as per the design but the numbers positively responding $r_k$ depend on the sample observations and are not fixed. You can also imagine that quantal assays require many more subjects than quantitative assays because each dose is tried in a *group* of subjects of reasonable size and not just two, three, or four subjects. Thus $n_k$'s would be large.

With these notations, we move on to the usual test and standard preparation setup. Consider a hypothetical example where egg is considered a standard source of dietary protein and rice is the test preparation, both assessed for their digestibility in terms of some scoring. Suppose a digestibility score of at least 15 is considered necessary for the protein to be considered sufficiently good. This is quantal response when assessed as <15 or ≥15. The data obtained are shown in Table Q.1. In this example, there is no blank dose but some assays can have this also. It may or may not be there. For standard preparation, 5 g of egg protein was given to 20 subjects and 8 of these had a digestibility score ≥15. And so on.

For dose–response relationship, the regression required is between probabilities of positive response and the doses. This takes the form

$$\text{(A)} \quad \pi_k = \alpha + \beta x_k \, (k = 1, 2, \ldots, K),$$

where $\pi_k$ is estimated by $p_k = r_k/n_k$. In other words, $p_k$ is the sample analog of $\pi_k$. This regression is restricted to a simple linear form for simplicity of our discussion but can be more complex in some actual situations. We keep those complex situations out of our purview in this book for medical professionals.

As mentioned earlier, the dose metameter could be dose itself or its transformation such as log dose. Response is in terms of percentage (or probability), and we necessarily need a transformation to get an appropriate response metameter that could convert the probability on the left-hand side of Equation A to a continuous quantity whose distribution is known or can be conjectured and easily handled and, more importantly, to achieve linear relationship. Experience has shown that the relationship between $\pi_k$ and dose is rarely linear—it generally takes a shape of what is called a **sigmoid** (S-shaped) curve, particularly because probability has restriction to be between 0 and 1. **Probit** or **logit** transformation is commonly used to achieve linearity. Probit is preferred when the response is continuous with Gaussian distribution such as digestibility in our example and logit is preferred for genuinely binary responses. Most people use logit these days because it can be used for both setups without much compromise on the distributional properties.

**TABLE Q.1**
**Sufficiently Good Response (Digestibility Score ≥15) for Different Doses of Egg and Rice Protein**

| | Receiving Egg Protein (Standard) | | | | Receiving Rice Protein (Test) | | | |
|---|---|---|---|---|---|---|---|---|
| | Dose 1 | Dose 2 | Dose 3 | Dose 4 | Dose 1 | Dose 2 | Dose 3 | Dose 4 |
| $x_k$ | 5 g | 10 g | 15 g | 20 g | 5 g | 10 g | 15 g | 20 g |
| $n_k$ | 20 | 30 | 32 | 24 | 11 | 16 | 23 | 25 |
| $r_k$ | 8 | 12 | 15 | 17 | 3 | 7 | 15 | 20 |

### *Estimation of Relative Potency*

For two preparations, the test and the standard, you will have one logistic regression line of the type mentioned at Equation A for the test preparation and one for the standard preparation. These would take the following form:

$$\lambda_{tk} = \alpha_t + \beta_t x_{tk} \, (k = 1, 2, \ldots, K) \text{ for the test preparation}$$

$$\lambda_{sk} = \alpha_s + \beta_s x_{sk} \, (k = 1, 2, \ldots, K) \text{ for the standard preparation,}$$

where λ is the logit of the corresponding proportion. To keep notations simple, we are describing these for symmetric assays where the number of doses of test preparation is the same $K$ as for standard preparation. However, in these equations, the actual doses of test preparation can be different from the doses of standard preparation. For example, the doses of test preparation can be 2, 5, and 10 mg, and those of standard preparation can be 4, 7, and 12 mg. These correspond to the values of $x_{t1}$, $x_{t2}$, and $x_{t3}$, and of $x_{s1}$, $x_{s2}$, and $x_{s3}$, respectively, in this example. They are not necessarily the same doses but both have three doses each.

When sample values are used, these regressions can be written as

$$y_{tk} = a_t + b_t x_{tk} \, (k = 1, 2, \ldots, K) \text{ for the test preparation}$$

$$y_{sk} = a_s + b_s x_{sk} \, (k = 1, 2, \ldots, K) \text{ for the standard preparation,}$$

where $y_{tk}$ = logit of $p_{tk}$ ($p_{tk} = r_{tk}/n_{tk}$ is the proportion of positive response to the $k$th dose of test preparation) and $y_{sk}$ = logit of $p_{sk}$ ($p_{sk} = r_{sk}/n_{sk}$ is the proportion of positive response to the $k$th dose of standard preparation). The difference between λ and $y$ is that λ is the notation for the population value and $y$ is the corresponding sample value when α's and β's are replaced by their estimates $a$'s and $b$'s.

In the case of quantal assays, the convention is to restrict investigations to **parallel line assays** where the regressions are such that the lines have the same slope but different intercepts as is expected in this setup. The relative potency is estimated as (in log doses if logarithm has been used)

$$\text{Relative potency: } R = \frac{a_t - a_s}{b},$$

where $a_t$ is the estimate of $\alpha_t$ and $a_s$ is the estimate of $\alpha_s$, and $b$ is the common estimate of the regression coefficient β. The common estimate is obtained by using the data on both the preparations under a parallel-line assumption. If the dose metameter is log(dose), then this relative potency is for the log dose, and a conversion back to the original dose would be needed in this case. When the values of $a_t$ and $a_s$ are substituted (see **simple linear regression** for these values), this can also be written as

$$\text{Relative potency: } R = \left(\bar{x}_s - \bar{x}_t\right) - \frac{\left(\bar{y}_s - \bar{y}_t\right)}{b}.$$

You can use either of these expressions to estimate the relative potency. However, this is valid only when the slope of both the lines is the same and the linearity is affirmed. We illustrate this with an example.

Following are the data of a quantal assay of a test and standard insecticide showing the proportion of insecticides killed by different doses using log(dose) as the dose metameter. For simplicity in calculations, we have taken the same number of insects (1000) for every dose of the standard as well as the test preparation. In practice, they can differ—in which case, the formulas will alter. Also, in this example, only three doses of standard preparation and three doses of

test preparation are under trial, although there is no such theoretical restriction.

Plots of proportion responding ($p$) versus dose, as presented in Table Q.2, are shown in Figure Q.1a. Note two things about these: one, they are not straight lines; and two, the plots do not differ much. For the first, Figure Q.1b shows plot of logit of $p$ versus log(dose) (logit of $p$ is not shown in Table Q.2). Now, the plots are nearly a straight line. For the second, we would soon see how the results turn out in case the plots of standard and test preparations are not much different.

For estimating the relative potency, we need the estimate of the intercepts of the two regressions and an estimate of the common slope. Exact logistic calculations require a computer software that give

$$b = 3.5020 \quad \text{and} \quad R = 1.05.$$

Relative potency close to 1 indicates that there is minor difference in potency of the two preprations, if at all. This was quite evident from Figure Q.2 also since the plots for standard and test preparations hardly differed.

### *Checking the Validity of Conditions of a Quantal Assay*

As mentioned earlier, the calculation of relative potency in this case is valid only when the two regression lines have the same slope and the regressions are indeed linear. For this, the hypothesis $\beta_t = \beta_s$ (earlier called parallelism) and the hypothesis for linearity are tested using sum of squares similar to those used for ordinary regression. In the case of quantitative assays, the sum of squares is directly used as chi-square variables and tested for significance as any other chi-square with the requisite df's provided that the sample size is large. For the data in Table Q.2, a software package gives between-preparations sum of squares = 0.4585 that follows $\chi^2$ distribution with 1 df since there are two groups. The critical value of $\chi^2$ at 1 df at the 0.05 level is 3.84. Since the calculated value is less, between-preparations sum of squares is not significant, and the preparations are not different with respect to the killing of insects at different doses. This conclusion corroborates an earlier finding that relative potency of test preparation is 1.05 (nearly the same as of standard preparation).

A statistical software package gives the following for the data in Table Q.2:

Sum of squares due to regression = 6.0046 with 1 df ($P < 0.05$); that is, the slope is statistically significant.
Sum of squares for equality of slopes = 0.0139 with 1 df ($P > 0.05$); thus, equality of slopes can be assumed.
Sum of squares due to linearity = 0.0717 with $(2K - 4) = 2$ df in this example ($P > 0.05$) so that the hypothesis of linearity cannot be rejected.

Thus, this assay fulfills the condition of equality of slopes (parallelism) and linearity of regression, and the procedure followed for the calculation of relative potency is valid.

**TABLE Q.2**
**Data of a Quantal Assay on Insecticides**

| | Standard Insecticide Dose (μg) | | | Test Insecticide Dose (μg) | | |
|---|---|---|---|---|---|---|
| **Particulars** | **100** | **200** | **400** | **50** | **150** | **300** |
| Log(dose)—dose metameter ($x$) | 2.00 | 2.30 | 2.60 | 1.70 | 2.18 | 2.48 |
| Number of insects ($n$) | 1000 | 1000 | 1000 | 1000 | 1000 | 1000 |
| Number killed (response) ($r$) | 200 | 500 | 700 | 100 | 400 | 600 |
| Proportion response ($p$) | 0.2 | 0.5 | 0.7 | 0.1 | 0.4 | 0.6 |

## quantile-by-quantile (Q–Q) plot

This is a plot of **quantiles** of one data set with the quantiles of another data set, mostly to check whether or not the two data sets follow the same distribution. Quantile is the value below which a specified fraction (or percent) of points lie. That is, for example, the 40% quantile is the value below which 40% of the values fall and 60% fall above, and the 65% quantile is the value below which 65% of the values fall and 35% fall above. If the two data sets follow the same statistical distribution, the Q–Q plot should form a diagonal line. The greater the departure from this reference line, the stronger the evidence of difference in the distribution. The two distributions could be either two groups such as males and females, or one could be sample values and the other could be theoretical population values. In the latter case, the Q–Q plot will indicate whether the sample values conform to those expected in the corresponding population.

The Q–Q plot is essentially a large sample method since these quantiles can be unstable for small samples. For this plot, instead of conventional quantiles such as deciles and quartiles, the quantiles are obtained for each value in the data set after arranging the values in ascending order. Quantiles are obtained after standardization so

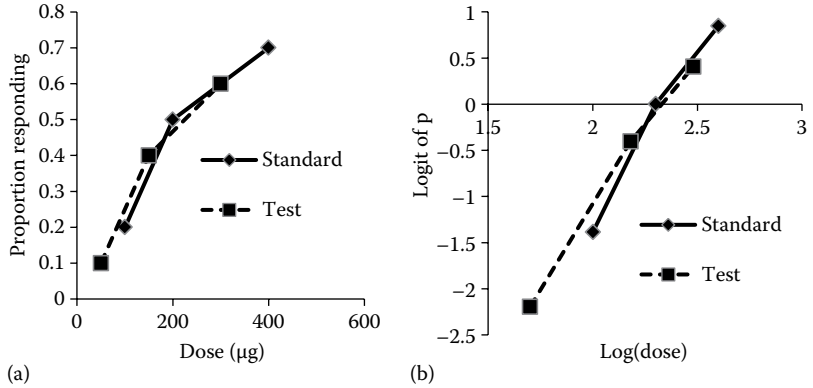

**FIGURE Q.1** Plots for the data in Table Q.2. (a) Proportion versus dose and (b) logit versus log(dose).

that the values in the two groups become comparable. This is of two types: normal Q–Q plot and detrended Q–Q plot.

### *Normal Q–Q Plot*

The feature of this plot can be best illustrated with the help of figures obtained for different types of distributions (Figure Q.2). When the sample sizes from the two distributions are the same, a Q–Q plot is essentially a plot of the sorted values in the two data sets. In case of unequal sizes, the quantiles of the larger data sets are obtained only for quantiles of the smaller data set.

It is customary to consider the plot of a Gaussian (Normal) distribution as standard for comparison. In all these figures, the horizontal axis depicts the observed values. The Q–Q plot for data being Gaussian would be a straight line as shown in Figure Q.2b except for some fluctuations due to sampling. What is important is the trend and not the individual points.

The Q–Q plot is quite sensitive to many types of differences between the two distributions under comparison. If they have different means but have the same shape, the points will still lie on a straight line but that line is displaced up or down from the reference line. For a positively skewed distribution, the plot will bend upward in the middle (Figure Q.2e), and for a negatively skewed distribution, the bow will be the reverse (Figure Q.2h). If the data are symmetric but have a flat peak and shallow tails (low kurtosis) relative to a Gaussian distribution, the plot will have its bottom end downward and its top end upward (see Figure Q.2k) and will have the reverse for relatively high kurtosis. Thus, both skewness and kurtosis can be examined by a Q–Q plot, and outliers can also be detected. Many statistical software packages have provision to provide a Q–Q plot.

Our illustration is in reference to the Gaussian distribution, but that is not a requirement. You can also compare two distributions of any shape. If these are samples, the size need not be equal as already stated. They will essentially yield the same kind of plots as just discussed, and you will be able to judge whether these distributions differ or not and in what respect. It is helpful to keep the vertical and horizontal axis on the same scale so that the diagonal is clearly demarcated at 45°.

A Q–Q plot is just an exploratory graphical device that assesses whether the two distributions have differences and, if so, locates where the differences are. This is not used for conclusive evidence. For conclusion, you would need statistical tests such as **Kolmogorov–Smirnov** and **Anderson–Darling** tests.

### *Detrended Q–Q Plot*

The detrended Q–Q plot shows the differences between the standardized values of the two distributions against the standardized values of one of the distributions. The differences remove the trend and become detrended. These are also popularly known as **worm plots**. If the distributions match, the differences will be randomly distributed along the line at difference = 0 (Figure Q.2c). Any other pattern is a clear indication of deviation from the theoretical distribution. For examples, see Figures Q.2f, i, and l. These detrended plots are even more sensitive to detect departures than the Q–Q plots.

For a useful application of these plots to child growth data, see the WHO report [2].

## quantile regression

Quantile regression aims to estimate a specific **quantile** of a continuous response (dependent) variable in place of mean that an ordinary **regression** estimates for given $x$'s. Just change the mean of $y$ to any specific quantile of $y$ for quantile regression. The quantile can be the 95th percentile, the first quartile, the 7th decile, the 2nd tertile, or any other value. Besides genuine interest in quantile of some measurement, quantile regression can also be used when there are outliers in the data set that make mean unreliable, or when the distribution of $y$ is highly skewed. This kind of regression was introduced by Koenker and Bassett in 1978 [1]. Figure Q.3 shows regressions for 5th, 25th, 50th, 75th, and 95th percentiles versus age for children with sedentary habits. These are linear, but one can examine a quadratic form or any other form as considered appropriate.

There are situations where the interest is not in the mean but a particular quantile. For a highly skewed distribution of the dependent variable, the median may be a better indicator of the central value, and this would be the target for regression. The median is also a quantile. For growth of children, the interest may be in the factors contributing to the 90th percentile of weight of children at any particular age, and in case of terminal diseases, the interest could be in finding the factors responsible for high duration of survival reached by the top 10% of patients or in factors of critically low duration of survival. You may also like to compare the factors contributing to the 50th percentile of heart size versus those contributing to the 80th percentile of heart size. In some situations, the relationship with mean may be weak but that with quantile may be strong. All these situations would require quantile regression. These are examples of univariate regression, but you can also run regression of first, second, and third quartiles together on the same regressors by using multivariate methods. This may be the case with body mass index where both low and high values are watched. This will tell which regressors are important for which quartile. However, methods for this kind of multivariate regression are not fully developed yet.

For the sake of generalizability, let us consider the $q$th quantile. The method of quantile regression is different from comparing, say, the $q$th quantile in two or more groups such as males and females, or those receiving treatment 1, treatment 2, and treatment 3. This can be tested by an analysis of variance–like method with $q$th quantile values as dependent on the groups, keeping in mind that quantiles do not generally follow a Gaussian pattern. For small samples, **permutation tests** can be used and the confidence intervals can be obtained by other nonparametric methods such as those based on bootstrap. This will tell you whether $q$th quantiles are significantly different or not across groups but will not reveal the factors responsible for the difference. For delineating the role of factors, quantile regression can be of definite help.

The method of quantile regression is intricate but can be easily carried out with the help of appropriate software. An outline of the method of quantile regression is as follows. The least squares method followed for estimation of the regression coefficients in ordinary regression is modified to minimize the sum of squares of deviations from the concerned quantile. The solution may have to be obtained by an iterative process. Regression coefficients in quantile regression are interpreted almost the same way as in ordinary regression; for example, for a binary predictor, the intercept in quantile regression is the $q$th quantile of $y$ for the category coded as zero.

## quantiles, *see also* percentiles and percentile curves

Quantiles are the values of the variable that divide the total number of subjects into ordered groups of equal size. These are also called **fractiles**. This means that each group so formed will have the same number of subjects. In general, the values dividing subjects into $S$ equal groups may be called the $S$-tiles. The total number of $S$-tiles is $(S - 1)$ as the last $S$-tile is the maximum value itself. For example, the median is the value such that the number of subjects with a value more than the median is the same as the number of subjects less than the median—this is a quantile that divides the subjects into two equal groups. **Tertiles** divide the subjects into 3 equal groups, **quartiles** divide the subjects into 4 equal groups, **quintiles** divide the subjects into 5 equal groups, **deciles** divide the subjects into 10 equal groups, vigintiles divide the subjects into 20 equal groups, and **percentiles** divide the subjects into 100 equal groups. For example, the 9th decile is the minimum value below which at least 90% of the values lay and not more than 10% values will be greater.

Evidently quantiles are primarily meant to be used with quantitative, particularly continuous data. A value $x_p$ is the $p$th $S$-tile if $P(x \le x_p) = p/S$. For example, for a standard Gaussian (Normal) distribution, the 97.5th percentile is 1.96 since $P(z \le 1.96) = 0.975$, and the second tertile is that value of $a$ for which $P(z \le a) = 2/3$. Normal distribution gives $a = 0.43$. Note the equality sign. If the values are quantitative but discrete such as parity, months of gestation, and ranks, quantiles may not be fully defined. This can happen with continuous values also in samples, especially when the sample size is small. Quantiles in ungrouped data are obtained simply in the following manner:

$p$th $S$-tile = $(p^*n/S)$ the value in ascending order of magnitude,

where $n$ is the total number of subjects. For $n = 200$ subjects,

35th percentile = (35 × 200/100) = 70th value
7th decile = (7 × 200/10) = 140th value
3rd quintile = (3 × 200/5) = 120th value
1st quartile = (1 × 200/4) = 50th value
2nd tertile = (2 × 200/3) = 133rd value

in ascending order of magnitude.

Percentiles can be denoted by $P_1$, $P_2$, $P_3$, and so on; deciles can be denoted by $D_1$, $D_2$, $D_3$, and so on; and quartiles can be denoted by $Q_1$, $Q_2$, and $Q_3$. A feature worth noting for all quantiles is that quantile of $(x + y) \ne$ quantile of $x$ + quantile of $y$. This needs to be understood in the context of mean since mean$(x + y)$ = mean$(x)$ + mean$(y)$.

Consider the following 18 values:

23, 12, 56, 25, 34, 43, 12, 7, 49, 27, 34, 45, 28, 14, 19, 17, 16, 28.

After ordering, these are 7, 12, 12, 14, 16, 17, 19, 23, 25, 27, 28, 28, 34, 34, 43, 45, 49, 56. Thus, the 3rd quartile is the 18 × 3/4 = 13.5th value. Since the 13th value is 34 and the 14th value is also 34, the 3rd quartile is (34 + 34)/2 = 34. Similarly, the 4th quintile is the 18 × 4/5 = 14.4th value and obtained as 4/10th away from the 14th value. Since the 14th value is 34 and the 15th value is 43, 4/10th apportion of the difference of 9 between these two values is 3.6, giving the 4th quintile = 34 + 3.6 = 37.6. In most practical applications, decimals are approximated; that is, the 14th value is taken as the 14.4th value.

### *Quantiles in Grouped Data*

In case of grouped data, the calculation is based mainly on the quantile interval—the interval containing the required quantile.

$$\text{Grouped data: } p\text{th } S\text{-tile} = a_{p-1} + \frac{p^*n/\mathrm{S} - C}{f_p} * h_p,$$

where $a_{p-1}$ is the lower limit of the quantile interval. The quantile interval is the one containing the $(p^*n/S)$th observation in order of magnitude

$C$ = cumulative frequency until the quantile interval
$f_p$ = frequency in the quantile interval
$h_p$ = width of the quantile interval

Consider the duration of immobility data in Table Q.3. The 2nd tertile in this data set is approximately 2 × 38/3 = 25th value in ascending order. This is 8 days. Also, the 85th percentile = (85 × 38/100)th or the 32nd value in ascending order = 10 days. The same data are grouped in Table Q.4. The 25th value is in the interval

**TABLE Q.3**
**Duration of Immobility (Days) of 38 Patients of Acute Polymyositis**

| | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 7 | 5 | 9 | 7 | 36 | 4 | 6 | 7 | 5 | 8 | 3 | 6 | 5 |
| 7 | 8 | 10 | 7 | 14 | 10 | 9 | 4 | 6 | 11 | 9 | 6 | 5 |
| 8 | 8 | 6 | 7 | 5 | 5 | 12 | 3 | 5 | 9 | 10 | 7 | |

**TABLE Q.4**
**Grouping of Data in Table Q.3 on Duration of Immobility in Cases of Acute Polymyositis**

| Group $(a_{k-1}, a_k)$ | 2.5–5.5 | 5.5–8.5 | 8.5–11.5 | 11.5–14.5 | 36 | Total |
|---|---|---|---|---|---|---|
| Midpoint $(x_k)$ | 4 | 7 | 10 | 13 | 36 | |
| Frequency $(f_k)$ | 11 | 16 | 8 | 2 | 1 | **38** |
| Cumulative frequency | 11 | 27 | 35 | 37 | 38 | |

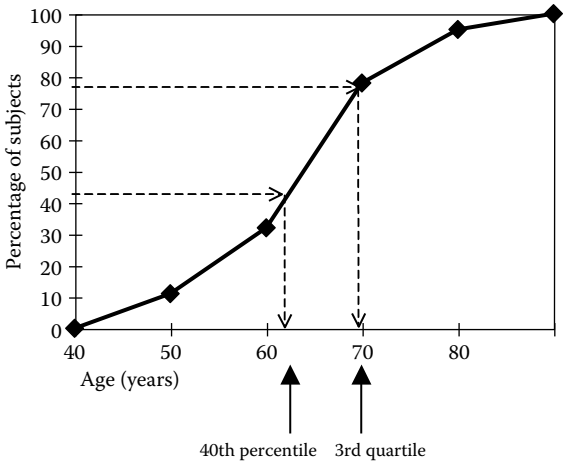

**FIGURE Q.4** Approximate calculation of some quantiles from ogive.

(5.5–8.5) days. Thus, for the 2nd tertile, $a_{p-1} = 5.5$, $C = 11$, $f_p = 16$, and $h_p = 3$. Therefore,

$$\text{2nd tertile (grouped data)} = 5.5 + \frac{25-11}{16} \times 3 = 8.1 \text{ days.}$$

Similarly,

$$\text{85th percentile (grouped data)} = 8.5 + \frac{32-27}{8} \times 3 = 10.4 \text{ days.}$$

The other method for obtaining approximate quantiles in case of grouped data is graphical. For graphical calculation of quantiles, the cumulative percentages of subjects are plotted against the upper end of the data intervals, called the **ogive**. Suppose, for an age distribution, this plot is as shown in Figure Q.4. The cumulative percentages for age 49, 59, 69, 79, and beyond 79 are 11, 32, 78, 95, and 100, respectively. To obtain a *p*th *S*-tile, draw a horizontal line at 100*p*/*S*% and read the value on the *x* axis where this horizontal line intersects the percent-based ogive. Figure Q.4 shows the 40th percentile and the 3rd quartile of age for these data. The calculations in the case of grouped data are, in any case, approximate for quantiles just as for the mean, median, and mode—thus, the graphic method may not be as bad for quantiles too.

### *Interpretation of the Quantiles*

All calculations can be done with the help of computers, but the method of computation helps in understanding quantiles and their proper interpretation. Figure Q.5 on quartiles may provide another perspective. This shows the duration of hospital stay after surgery for 30 patients. See how quartiles are determined. They divide the total number of subjects into four equal groups in terms of frequency. These frequencies may not be exactly equal in the case of the discrete data depicted in Figure Q.5 but would be equal in the case of really continuous data. Other quantiles have similar interpretations.

Quantiles are sometimes used for an objective categorization of the subjects. It may be easier to say in some situations that the bottom one-third values are low, the middle one-third are medium, and the top one-third are high. These are tertiles. In the case of data on the duration of immobility in our example, one may say that the duration of immobility up to 6 days experienced by one-third of the patients is low, that between 6 and 8 days is medium, and that above 8 days is high. A popular use of quantiles is in grading scores in educational testing where it is common to consider the scores in the top decile as excellent because only 10% of the subjects have these high scores. In medicine, scoring is sometimes used to grade the severity of disease as well. A condition with a score less than the first quartile (scored by the least affected 25% of cases) can be considered mild, one with a score between the first and second quartiles can be considered moderate, that between the second and third quartiles can be considered serious, and that beyond the third quartile can be considered very serious. Such nomenclature may or may not agree with the prognosis because the categorization is based on statistical rather than on medical considerations. The argument is that a condition with a score, for example, worse than that of 75% of cases can be safely called very serious. When the categorization is based on quantiles and not on prognosis, the interpretation is relative and not absolute. It is in this sense that percentiles are used in growth charts.

Quantiles are the *points* that divide the total number of subjects into equal groups, but it is colloquially popular to say, for example, that the scores are in the top decile as though the decile is a range. This is not technically accurate but is accepted as long as the meaning is clear.

## quantitative measurements, *see also* qualitative measurements

Any characteristic that is measured in terms of numbers is quantitative. This will have values, levels, and high–low kind of connotations that most qualitative measurements such as blood group do not have. When appropriate instrument is available, it is measured exactly numerically such as blood pressure, hemoglobin, creatinine, and size of kidney. These are the most obvious example of quantitative characteristics and said to be on the metric scale. This is further divided into interval and ratio scale—interval where the difference is more meaningful and ratio where the ratio is more meaningful.

Degree of severity of disease is also intrinsically quantitative, but in the absence of an appropriate scale, this is measured as none,

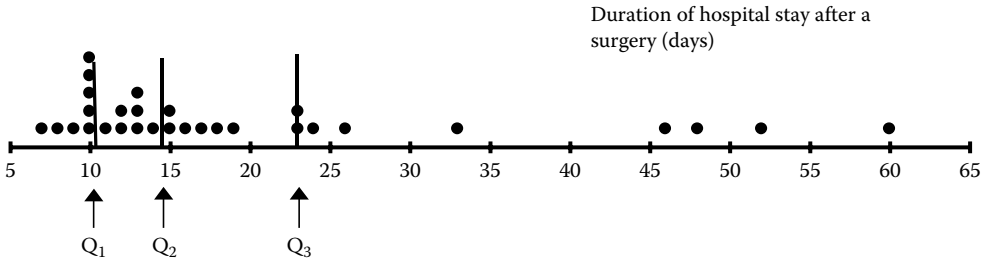

**FIGURE Q.5** Schematic of quartiles.

mild, moderate, or serious. This is called ordinal because an order is present with an underlying continuum. We may not have an adequate instrument as of now to measure them in terms of exact numbers but can hope that some are developed soon. Till such time that this does not happen, they are statistically considered ordinal and not considered quantitative. There are other characteristics that do not have continuum, and these are called nominal. Blood group mentioned earlier is a glaring example. Site of injury, site of cancer, sex, and occupation are other examples. Nominal and ordinal together form, what are called, qualitative characteristics. These are discussed in details with a different perspective under the topic **scales of measurement (statistical)**.

Characteristics that are quantitatively measured are called quantitative variables. As discussed for **variables**, these are divided into continuous and discrete. Age and blood pressure level are continuous as they can be 36.432 years and 132.57 mm/Hg, respectively, if an instrument for this kind of accuracy is available. Number of family members affected by a genetic disorder is discrete as this cannot be 2.57. Yet, both types of quantitative variables have a special place in statistics because of their amenability to mathematical manipulations. Their mean and standard deviation can be calculated, methods such as Student *t* and analysis of variance can be used, and correlation coefficient, ordinary regression, and so on can also be worked out. Durations are also quantitative, which lend themselves to survival analysis, whereas the variable that counts such as the number of persons attending a busy clinic is discrete, yet is statistically considered continuous because of the large range of values.

Even for quantitative variables, caution should be exercised when an apparently minor change in the value of a variable is highly sensitive. Body temperature may have a small range from, say, 97°F to 106°F, but a difference of 2°F or 3°F can have a profound impact on health. Also in terms of percentage, a drastic change may look miniscule in this case. This may not be so with alkaline phosphatase level—thus, biological context can never be ignored. Second, clinicians like to divide the continuum into categories that are considered relevant for patient management. For example, systolic blood pressure level may be divided as ≥140 mmHg and <140 mmHg, and body mass index (BMI) is divided into thin, normal, overweight, obese, morbid obese, and super obese categories. This categorization may look like a convenient way to decide about what to do but has undesirable statistical implications. Depending on how these categories are defined, a BMI = 29.7 kg/m$^2$ can fall into the overweight category and BMI = 30.2 can fall into the obese category. A marginal difference of 0.5 makes a big difference. View it in the light that a BMI = 25.1 and a BMI = 29.9 are both in the same category despite a relatively large difference. Moreover, one researcher may define morbid obese category to start from BMI = 40.0 and the other from BMI = 35.0. Such discrepancies are quite common in medical literature. When the values are grouped into intervals such as this, and the actual values are not available, statistical methods would consider all values concentrated at the midpoint of the interval. You can see that this is unrealistic and introduces an avoidable artifact. Because of this, statistical advice suggests that you do all the analysis on actual exact values, but for reporting in a tabular form, use categories. There are instances, though, that categorical data lead to more valid conclusions than the corresponding ungrouped data. For an example of this, see Welch et al. [1].

## quartiles, *see* quantiles

## quasi-experimental design, *see also* before–after design/study

A design is called quasi-experimental when an experiment's key element—randomization—is missing although the objective remains to find the effect of one or more interventions. In a conventional experiment, the subjects are allocated to the interventions in a random manner that tends to equalize the groups under different interventions not just for known factors but also for the unknown factors. In the absence of randomization in quasi-experiments, baseline equivalence of the groups receiving various interventions is in doubt and comparability suffers. The internal validity of the experiment takes a hit and the results are rarely conclusive. Despite these limitations, a quasi-experimental design is useful in some situations.

A quasi-experimental design is used when randomization cannot be done, either due to ethical reasons or because of lack of feasibility. Suppose the study is on the effect of age on recovery after a treatment regimen, where one group is composed of subjects of age around 60 years and the other group is composed of those of age around 70 years. These groups may or may not be randomly selected. Nonrandom selection does not preclude it to be called quasi-experimental—nonrandom allocation of treatment does. Let these two groups be measured before the intervention and after the intervention. The **difference-in-differences** approach will give the estimate of the effect—in this case, the effect of age. However, this estimate will be valid only if all other factors that can affect the outcome are the same in both the groups. For example, they should have the same sex composition, the same obesity, the same nutritional level, and so on. The effect of all these factors will have to be eliminated by an appropriate analysis to reach a valid conclusion in case there is a difference.

In our example, there are two age-groups, but any **before–after design**, even for one group, is quasi-experimental because of lack of random allocation. In fact, most quasi-experimental studies are on one group with no parallel control where before treatment values serve as control, but the effect observed, purported to have been caused by the intervention, cannot be wholly ascribed to the intervention despite the same subjects being observed before and after. This is because (i) placebo effect would be confounded in this type of study; (ii) subjects at baseline may have different levels to begin with that could affect the outcome (if a person's hemoglobin level is already 13 g/dL, improvement is unlikely); (iii) there might be other concurrent changes that may be affecting the outcome; (iv) strict inclusion and exclusion criteria are needed to ensure that the outcome has not occurred before the intervention, or before the expected duration; (v) attrition during follow-up can introduce artifacts if the loss is related with intervention; (vi) if the gap between before and after measurements is substantial, the nature of measurement may change over time, and there could be regression to the mean effect in the sense that as the time passes, the subjects tend to move closer to the mean. Because of these problems, many equate quasi-experimental studies with **observational studies** instead of **analytical studies**.

Not that there are no advantages of a quasi-experimental design. One, it has wider applicability because it can be used where randomization is not practical. Second, because of nonrandomization, this design can have better generalizability—sometimes being more representative of the actual life situations. Third, if the follow-up is short, measurement of the same subject can rule out the effect of many factors. The effect of the confounding and extraneous factors can be adjusted to provide near noncontaminated results. When this

is adequately done, cause–effect conclusions can indeed be reached. Another alternative is to choose two groups that look similar at baseline, calculate the **propensity score** of each group, and use it for adjustment. Kausto et al. [1] used propensity score matching on age, sex, diagnostic category, and several other factors before intervention to study the effectiveness of legislation on sickness benefits in a quasi-experimental study.

Further details of quasi-experimental studies have been provided by Harris et al. [2]

## quasi-random allocation, *see* random allocation

## questionnaire, schedule, and proforma

These are the types of forms used to record the information regarding a person, a patient, or any other unit of enquiry. The kind of information recorded in health and medical setups is one or more of the following: unique identifier; basic background characteristics such as age, sex, and education; medical history; knowledge, behavioral, attitudinal, and sometimes psychological traits; signs and symptoms; basic measurements such as blood pressure, height, and weight; investigation results; prescription and other advice; follow-up findings; and so on. These forms are generally predevised after a lot of thinking and discussion among stakeholders so that nothing of consequence is missed, and the information is available in a standardized format. Special care is taken to keep focus on the objectives of such records and to ensure that no extra information is collected or recorded. Many times, these forms are **pretested** by actually using them on a subset of cases and revised accordingly.

Many medical studies require physical examination of the subject and investigations in the laboratory or in the radiology unit. The information so received will most likely be recorded on a form containing the items on which the information is required. The recording should be accurate after following the correct and full procedure as required in the protocol, but what needs to be emphasized is the legibility of writing in case of manual forms—more so because most of the schedules for such purposes would be open ended. A computer-generated form, which allows direct entry of data without the help of intermediaries, is a big advantage in this context. However, the quality of information depends on the cooperation of the patient, the skills of the doctor, and the validity of the instruments. Ensuring all of this can be an uphill task in a given situation.

A form is a big help in retaining the focus on the objectives and in ensuring uniformity and also serves as a repository of information for later reference. In view of such important functions, ample time and thought should be invested in designing forms. The format could be a questionnaire or a schedule or a proforma for master chart. There is a considerable confusion among medical fraternity about these terms since the contents of all three formats are basically the same. Their unique features are as follows.

### *Questionnaire*

As the name implies, a questionnaire contains a series of questions that are required to be put to a subject in verbatim at the time of interview. A questionnaire could be self-administered or could be administered by an interviewer. In the case of the former, the education and the attitudes of the respondent toward the survey can substantially influence the response, and in the case of the latter, the skill of the interviewer can make a material difference. The interviewer may have to be trained on how to approach a subject; how to obtain cooperation; when to prompt, probe, pause, or interject; and so on. Some details of these aspects are described in simple language by Hepburn and Lutz [1] for health surveys.

Framing questions is a difficult exercise because the structure of the sentence and the choice of words become important. Some words may have different meanings to different people. In any case, it is evident that the questions must be unambiguously worded in simple language, and they must make sense to the respondent. The sequence must be logical, and the length of the questionnaire should be carefully decided so that all the questions can be answered in one sitting without a feeling of boredom or burden. It is always helpful for the interviewee as well as for the interviewer to divide the questionnaire into sections. Use of features such as italics, boldface, underline, and capitals can help clarify the theme of the question.

Respondents tend to be careless toward the tail end of the questionnaire if it is unduly long and not interesting, and a large number of questions may be a source of attrition for the subjects and can increase nonresponse. Thus, nonessential questions must be avoided. Ask yourself how much you lose if a particular question is not asked. If the answer is negligible, then delete the question; otherwise, do not do so. All the questions should be short, simple, nonoffending, and corroborative. They should be such that the respondent is able to answer.

A questionnaire is called *structured* when the language and the order of the questions are fixed. When the list of possible answers is also given and the respondent has to just tick one or more as applicable, this becomes *close ended*. One possible option can be "Any other (specify)" to cover the possibility of the list not being exhaustive. A question can be framed close ended only when enough is known about the type of responses so that the responses under the "other" category are minimum, say, not exceeding 10%. If they are higher than that, this reflects that the questionnaire was not prepared with sufficient thought. If the responses cannot be anticipated, do a pilot study to find out the common responses that need to be separately listed in a close-ended fashion. If substantial responses occur under the "other" category despite best efforts, invoke the "specify" component and identify which common responses can be separated. Remember that a large number of responses for "other" without identifying what can throw any research out of gear. Also, at the time of statistical analysis and conclusions, this "other" category can cause problems because it contains the assorted leftovers that defy interpretation. The list of responses in a close-ended questionnaire should be designed in such a manner that no choice is forced on the respondent. They should also be preferably mutually exclusive so that one and only one response is applicable in each case. Depending on the question, one of the responses could be "not applicable." For example, the question of results of laboratory investigation does not arise in cases where laboratory investigation was not required. This should be distinguished from cases in which the investigation was required but could not be done for some reason.

The objective of close-ended questions is to make it friendlier to the respondent, as well as for easy data processing and analysis. However, care must be exercised in providing the list of possible

answers in addition to what is already advised. The choices for "How often do you get bouts of depression?" can be never, sometimes, often, and frequent. These are subjective terms. Instead, try "less than once a year," "more than once a year but less than once a month," "more than once a month but less than once a week," and so on. In addition, for a close-ended question, the instruction on how to correct mistakes in a filled-up form without making it ambiguous should be clear.

When the response is to be recorded verbatim, the question or item is called *open ended*. This can present difficulty during interpretation and analysis of data but can provide additional information unforeseen earlier. Also, such open-ended responses can provide information regarding the quality of response and can provide results different from the results of *close-ended questions*. Suppose a question for parents is "What is the most important thing for the health of their children?" More than 60% might say nutrition when this alternative is offered on a list, but only less than 10% may provide this answer when no list is presented.

The phrasing of questions and their sequence are important since these features have potential to change the response. For side effects, for example, asking generally about any problems caused by the treatment may elicit much less response than asking separately for each possible side effect. However, in the latter case, all possible side effects should be known at the time of framing of questionnaire. Also, the last asked side effect is likely to be reported much less than the first asked. Sensitive questions such as on sexual behavior should be asked as late as possible because that can change the course of the interview. Suppose the interest is in finding whether a couple had undergone sex determination of a fetus in relation to their knowledge of legal provisions in this respect. If knowledge about legality is asked first and the respondent says "yes, he knows that it is illegal," he would be bound to say "no" to the question regarding sex determination actually practiced by him. The right sequence is to first ask about any sex determination undertaken and related questions and then ask about his knowledge regarding legal provisions in this respect.

There is also an effect of attitude of the patient toward certain ailments. An older person may perceive poor vision or infirmity as natural and may not report it at all, and a smoker might similarly ignore coughing. On the other hand, mild conditions may be exaggeratedly reported depending on the disturbance they create in the vocational pursuits of the patient. A vocalist may be worried more about the vocal cords than a fractured hand. Thus, interview responses measure the person's perception of the problem rather than the problem itself. Some conditions with a social stigma such as venereal diseases and impotence may not be reported despite their perception as important.

Avoid questions such as "Don't you use pain killers for acute pain?" They suggest an answer and are called leading questions and not recommended. Also, do not seek two pieces of information in one question. The wordings must not be ambiguous. Minimize hypothetical questions on future or regarding attitude because the response to such questions depends on the mental frame at the time of the interview, and the response may change when asked a second time. It is sensible to concentrate on questions on facts rather than on opinion. In place of asking what would he do in a particular situation, ask what he did last time in that situation. For regularity of condom use, for example, do not elicit response as never, sometimes, regular, and always, but ask how many times condom was used in the last, say, four sex encounters. Probing is allowed provided no suggestion is made regarding the reply, and the interviewer is trained.

A self-administered questionnaire must contain all the explanations and instructions for its completion. Use simple language for framing the questions. If the language of the questionnaire is different from the language of the respondent, the translation should be appropriate but that should not lose the context. Despite all these precautions, portions of a self-administered questionnaire are likely to be left blank and be prepared for this eventuality, but more accurate information can be obtained by this method on sensitive issues such as sexual behavior if the questionnaire is anonymous. Face-to-face interview may not yield the same quality of response on such sensitive issues. In postal questionnaires, chance of response can be increased by offering incentives, advance contact, personalized letter, stamped return envelope, follow-up contact, and so on.

### Schedule and Proforma

Schedule contains only the items on which the information is to be collected, and not questions. Framing questions to get that information is left to the interviewer in this case. A schedule will have an item—age. A questionnaire will have "What is your age?" The information can be obtained by observation, by interview, or by examination. Sufficient space is always provided to record the response. A bed-head ticket or a case sheet is a schedule since it contains only the items of information.

Proforma is the prototype or a sample providing the items of information on which the information is to be collected. It is neither a questionnaire nor a schedule. Perhaps this can be used to prepare columns in a register where information for each patient can be recorded in one line as for a database or master chart. The illustration in Table Q.5 would clarify the differences between a questionnaire, a schedule, and a proforma.

### Features of a Form

Whether a questionnaire, a schedule, or a proforma, the following should be kept in mind.

- It should be properly formatted with headings and subheadings, and spaces as required. Use capitals, bold, italics, and different fonts to emphasize the thrust of the information you are seeking. The layout of the form should be aesthetically pleasant.
- A printed form with a logo and an immaculate appearance instills confidence in the interviewer and the respondent alike. Photostat or cyclostyled forms do not do that.
- The unit of recording for each piece of information should be specified, for example, whether duration of symptoms is to be recorded in days or weeks or months. Age of a neonate of 4 h is recorded as 1/6 day if this information is to be used for analysis along with such information on other neonates whose age is recorded in days.
- Specify how the measurement is to be rounded off. If age is 13 years and 8 months, is it to be recorded as 14 years, which is the nearest integer, or in completed years (13) as is generally done all around the world in a medical record? Do not make categories such as 15–19, 20–24, and so on, in the data collection form. Such categories can be made later at the time of analysis or presentation.
- The questions or the items should be framed in a manner that the chance of bias in the responses is minimum.
- Questions or items that need to be skipped for being not applicable in certain cases should be specified. If there is an item on cause of death that is to be asked only if there is a death in the family, the item should have a remark that this is to be skipped in other conditions.

**TABLE Q.5**
**Illustration of Differences between a Questionnaire, a Schedule, and a Proforma**

**Questionnaire**

Unique ID_____
What is your name? _____
What is your age in completed years? _____
What is your gender? _____
What are your complaints?

(i) _____
(ii) _____
(iii) _____
(iv) _____

Does any other member of your immediate family suffer from the same complaints? Yes/No
If yes, what is your relationship with each of them?

(i) _____
(ii) _____
(iii) _____
(iv) _____

**Schedule**

Unique ID_____
Name _____
Age (completed years) _____
Gender _____
Complaints

(i) _____
(ii) _____
(iii) _____
(iv) _____

Immediate family members affected (write None if no family history)

(i) _____
(ii) _____
(iii) _____
(iv) _____

**Proforma**

**Complaints codes: 0. None, 1. Abdominal pain, 2. Vomiting, 3. Acidity, 4. —, etc.**
**Family history codes: 0. None, 1. Mother, 2. Father, 3. Brother, 4. Sister**

| Sl. No: | Unique ID | Name | Age (Years) | Sex (M/F) | Complaints Code (Enter X) 0 | 1 | 2 | 3 | 4 | Family History Code (Enter X) 0 | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | | | | | | | | | | | | | | |
| 2 | | | | | | | | | | | | | | |
| ⋮ | | | | | | | | | | | | | | |
| *n* | | | | | | | | | | | | | | |

- Nonstructured questionnaires are used for informal surveys. For medical research, structured questionnaires are preferred.
- If multiple responses are admissible, this should be clear to the investigator. Multiple responses imply that one question or one item can have more than one answer. Complaints could be many in one person; thus, "complaints" is a multiple-response question.
- The forms can be precoded, which will make computer entry simple. In any case, text responses such as signs and symptoms have to be coded either at the time of recording or later at the time of computer entry. However, remember that codes are not grades or scores, and they cannot be added, subtracted, and so on.
- The form should be comprehensive so that all information on one subject or one patient could be recorded together. Investigation results may have to be obtained separately but they should be transferred to the main form. Postoperative details should be recorded together with preoperative findings, and not in a separate from. Each page of the form should have the same identification number, which would be unique for each subject.
- The information should be elicited only on the items that are really required to meet the study objectives since unnecessary information tends to dilute the quality. An unduly detailed form can be tedious and boring, and wasteful of the time of the interviewer and the respondent. It is difficult to sustain the interest of a respondent for more than half an hour unless there is some encouragement. Nonetheless, obtain all the information committed in the protocol.
- As far as possible, restrict to the collection of objective information. Opinions and attitudes should be minimal and separately identified.
- Standardize the form after pretesting on a small number of subjects from the same target population for which this is going to be finally used. Pretesting helps identify ambiguities or potential biases in the responses. Investigators can be trained accordingly. It also helps assess the time and resources required to administer this kind of instrument to various types of respondents. For a large-scale study, two or more rounds of pretesting may be required.
- One aspect of some questions is the rating scale used for providing the answer. For a question such as "how fit are you after one week of a surgery?", many may rate themselves +3 if the scale is from –5 to +5 but not 8 if the scale is from 0 to 10. Also, see the topics **Likert scale** and **Guttman scale**.
- Sometimes, methods such as **Rasch analysis** are used to develop and evaluate a questionnaire or a schedule. See this topic for details.

- The questionnaire or schedule must always be accompanied by a statement of the objectives of the survey so that the respondent becomes aware. Easy-to-follow instructions for recording responses and explanatory notes where needed are always helpful. Special care may have to be taken concerning possible memory lapse if a question or item requires recall of an event. Whereas serious events such as accidents and myocardial infarctions are easy to recall even after several years, mild events such as episodes of fever or of diarrhea may be difficult to recall after a lapse of just 1 month.

## quota sampling

Quota sampling is one of the methods of **purposive** (nonrandom) **sampling** where a predetermined number of units is selected without adopting any specific procedure. This is generally adopted after the population is divided into strata. For example, one may decide to have 100 males and 200 females in a study on chronic kidney disease, and select them to serve a specific purpose. These quotas are generally decided on the basis of previous experience or perceptions but can also be based on statistical considerations. However, which subjects will be in the sample is left on who comes first, who are readily available, volunteers, or any such consideration. The subjects continue to be recruited till such time that the prefixed quota of subjects is met.

Quota sampling can be quicker and can be carried out without much hassle. It does not require any sampling frame that a **random sampling** does. In contrast to simple random sampling, the researcher can decide to overrepresent or underrepresent any particular group to suit the purpose. For example, it can be decided to have a minimum of 30 subjects of age 90+ years in the sample, or to have not more than 40 subjects of age 40–49 years in the sample.

Statistically, the demerits hugely outscore the merits of this kind of sampling. Because of nonrandom selection, none of the statistical methods of inference such as confidence interval and test of hypothesis would be applicable and the generalizability would suffer.

There are many examples in the medical literature where this kind of sampling has been used. Niedźwiedzka et al. [1] used quota sampling for assessing the validity of self-reported height and weight in elderly people of Poland. Note how random sampling in this kind of study was not a strict requirement. Hongthong et al. [2] also used quota sampling for finding factors that influence the quality of life of elderly people in a rural area of Thailand. Because of purposive sampling, their findings are suspect and cannot be generalized even to the rural area of Thailand studied by them.

# R

## radar graph

A radar graph provides a suitable presentation when the performance of one group on several variables is to be compared with another group. As many axes are drawn as the number of variables, and a polygon is drawn according to the values as shown in Figure R.1. You can see that this looks like a radar. The larger the number of variables, the bigger the radar should be so that all axes can be clearly seen. This depiction seems most appropriate for four to eight variables.

The first figure compares average age, percent females, percent hypertensives, percent obese, and average hemoglobin level in cases and controls at baseline in a randomized controlled trial (RCT). The graph reveals that percent hypertensives are very different in the two groups, but all other values are not much different. The second figure compares male and female diabetic patients for six measurements. Notice the marked difference in percent on diet control and with positive history. If one radar graph portrays general population averages for five or six variables and another graph the same variables for a specific group such as those suffering from cancer, such a graph can highlight the variables, if any, on which the cancer patients exceed the general population and on which variables they have less value.

Radar graph seems like a good tool for multivariate comparisons, although only two groups can be cleanly compared. For three or more groups, this becomes too cluttered. As with almost all other graphs, a radar graph too can mislead depending upon the scale chosen for depiction. In Figure R.1b, the axis for average age at detection can be stretched, and then the difference between the two groups will magnify. Any axis can be stretched or compressed as we wish. The figure is most effective when all variables have the same scale such as percentage or **standardized** score because then all axes can also have the same scale.

Kalonia et al. [1] have effectively used a series of radar graphs to visualize subdivided particle concentration and size data for IgG1 mAb solution, and Oowada et al. [2] have used radar graphs to depict multiple free-radical scavenging capacity in serum of chronic kidney disease patients.

## radix, *see* expectation of life and life table

## random allocation, *see also* block, cluster, and stratified randomization and minimization

This is the method that randomly allocates eligible subjects to different groups such as treatments and control in a trial. The objective is to achieve baseline equivalence of the groups by providing same chance to each subject to be assigned to any of the groups under study and to provide a foundation for the application of a statistical test of significance. A big advantage of random allocation is that the groups tend to have equal distribution not just for the known factors but also for the unknown factors. Thus, it covers the **epistemic uncertainties** as well. Random allocation distributes the effects of concomitant variables (covariates), both observed or unobserved, in a statistically acceptable way. However, baseline equivalence with random allocation is more likely to be achieved with a large sample than with small samples since small samples can have bias even when randomly allocated. If the number of available subjects is

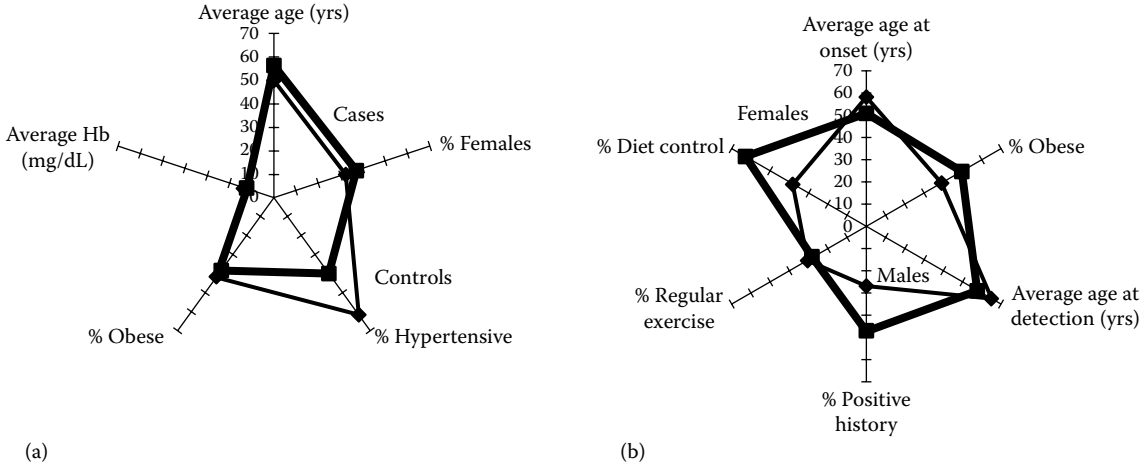

**FIGURE R.1** Radar graphs: (a) compares some characteristics of cases (thick lines) with controls (thin lines) in a randomized controlled trial (RCT); (b) compares some characteristics of male cases (thin lines) of diabetes with female cases (thick lines).

small or the resources do not permit a large trial, consider the strategy of matching instead of randomization, as this at least equalizes the groups for known important covariates.

Random allocation is advocated only when the treatments are harmless—for example, it is not feasible to allocate subjects to smoking and nonsmoking groups as an intervention. It is necessary for random allocation to meet ethical considerations, and it cannot be used if a patient's condition requires a specific treatment.

A large number of methods are available for random allocation as discussed next, but not many of these methods are adequate. The general practice is to conduct a trial on consecutive patients reporting in a clinic after excluding those who are not eligible or do not provide consent. If the patients indeed come in random order and the consent does not introduce any bias, the even-numbered patients can be assigned to one group and the odd-numbered patients to the other group. For three or more groups, the first patient can be randomly allocated to any group by, say, a draw of lots and the remainder allocated in a systematic way. For example, if there are four groups and the first patient is randomly allocated to group 3, then the allocation for the incoming patients will be group 4, 1, 2, 3, 4, 1, etc. This systematic scheme will fail in achieving unbiased allocation if the subjects follow an unknown or known design in the sequence of their arrival. Also, it is difficult to enforce **blinding** with this kind of allocation.

In situations where there are only two groups such as treatment and control, the participants can receive one of these on the basis of the outcome of a chance event, such as tossing a coin behind the curtain. This has the potential to provide an impartial procedure for the allocation of treatment to individuals, free from personal biases. Another method for two groups could be to draw a single digit random number and allocate participants corresponding to odd digits to group 1 and even digits to group 2. If the first two digits are odd, these participants go to group 1; if the third digit is even, this participant goes to group 2; and so on. This process can give an unequal number of participants in the two groups; however, we generally want the groups to be of equal size. This is a worry to researchers who are concerned that the randomization is not as it should be.

It is sometimes considered convenient to include patients who report to a clinic on alternate days or during a specified time of the day. This may introduce bias because some patients may choose a time and day according to the availability of a particular physician, and the management of cases by this particular physician may have prognostic implications. Allocation of subjects on the basis of even or odd date of birth may apparently look random but can be misused. All such methods are called **quasi-random allocation**. As already noted, the biggest problem in such allocation is that it cannot be kept blind, and the chances of bias in assessment remain. The investigator knows which treatment the next patient will receive, and that can influence the decision to enter him/her into the trial. Random allocation can be kept open so that the concerned subjects know that they are randomized to a particular group, but the strategy of **concealment of allocation** is the gold standard in clinical trials.

A more acceptable method is to draw or generate a **random number** between 1 and $K$ (both inclusive), where $K$ is the number of groups. When an eligible subject arrives, assign him/her to the group bearing this number. If the random number drawn is 3, then the subject is allocated to group 3; if the random number is 1, then the subject goes to group 1; and so on. In place of generating a random number between 1 and $K$, it may be convenient to generate a two-digit random number. Divide it by $K$ and add 1 to the remainder to get the group. (This assumes that the number of groups is $K \leq 9$.) If $K = 3$ and the generated random number is 52, then assign the subject to group 2 (remainder of 52/3 is 1, and addition of 1 gives 2). In fact, a small computer program can be developed that randomly allocates subjects to the specified number of groups. This program can be used over and over again to provide fresh allocation whenever a new trial begins. This is called *simple randomization*. However, there are problems with this also as discussed next.

A difficulty in simple randomization is that one particular group may have its full quota of subjects much before the other groups. This is called imbalance since the subjects appearing late will not have the chance to be allocated to the already completed group. In that case, the process of allocation may be continued as follows: The subjects for whom the allocated group as per the existing randomization scheme turns out to be the already completed group are excluded from the trial. Suppose there are three groups, and each is planned to have 30 subjects. It is possible in this scheme that the full 30 are allocated to group 2 when group 1 has only 22 and group 3 has only 26 after allocation of 78 subjects. In this case, ignore the 79th subject if he/she is randomly allocated to group 2. This subject will not be included in any group. If the random number for the 80th subject is 3, then the subject is assigned to group 3. This process continues until each group has its full quota of 30 subjects. This procedure may mean wastage of some eligible subjects, but it ensures fair allocation. It is not considered fair to assign the last few subjects to only one or two groups and deny them a chance to be theoretically in the other groups.

By avoiding purely physical methods, such as the one just mentioned, randomization can be achieved with the help of random number tables, as follows: List the first $K$ participants and assign them numbers from 1 to $K$ if there are $K$ groups. Randomly permute these $K$ numbers to get the group to which these would go. If you have $K = 3$ groups in your trial, the random permutations could be (2,1,3), (3,2,1), (2,3,1), (1,3,2), etc. A total of $n$ such permutations, each a triplet of the type just mentioned, will determine allocation of $3n$ subjects in 3 groups of $n$ subjects each. The easiest way is to use the website *randomization.com*, where you can specify the number of groups and the number of subjects, and get the random allocation.

Note that random allocation is not haphazard allocation. It follows a well thought-out scheme. The most preferred method of randomization is **block randomization**, which is discussed separately under the topic **block, cluster, and stratified randomization and minimization**, where other methods of randomization are also discussed.

## random effects, *see* fixed and random effects

## random effects ANOVA

**Analysis of variance (ANOVA)** of data arising from a setup where all factors have random effects is called random effects ANOVA. This is different from the usual ANOVA where all factors are fixed, particularly in the way the $F$-ratio is calculated. Review the topic **fixed and random effects** if you want to understand these terms. In brief, if the observed levels of a factor represent many other levels not actually observed, it is a random effect factor. Suppose the interest is in finding whether the duration of hospitalization after a particular surgery is the same or not across hospitals. The interest in this case is in finding the hospital effect: whether or not it varies from hospital to hospital. If you select 4 hospitals randomly out of, say, 80 hospitals in a state, these 4 are the levels of the factor "hospital." The interest in this case is not restricted to these 4 hospitals but also in the variability across all hospitals. The analysis of data from such a study would require random effects ANOVA.

The ANOVA for random effects is not the same as for fixed effects, although luckily the computation of the mean sums of squares is the same. In the case of fixed effects, the mean sums of squares due to factors are divided by the mean square error (MSE) to get the *F*-ratio, but this is not the case for a random effects model. Details are as follows.

### *One-Way ANOVA with Random Effects*

In the case of fixed effects, the model for a one-way ANOVA is $y_{ij} = \mu + \alpha_j + \varepsilon_{ij}$ ($j = 1, 2, \ldots, J$; $i = 1, 2, \ldots, n$), where $J$ is the number of levels of factor A, $\mu$ is the overall mean, $\alpha_j$ is the effect of the $j$th level of factor A, and $\varepsilon_{ij}$ is the error term, generally required to have **Gaussian** (normal) **distribution** with mean 0 and variance $\sigma^2$, written as $\varepsilon_{ij} \sim N(0, \sigma^2)$, whereas all other terms in the model are fixed. The $j$th level effect $\alpha_j$ is generally defined such that $\Sigma_j\alpha_j = 0$. When factor A is random, the model changes to $y_{ij} = \mu + a_j + \varepsilon_{ij}$, where $a_j$ continues to be the effect of the $j$th level of factor A, but is now random. This is required to be $N\left(0,\sigma_A^2\right)$. The mean continues to be 0 just as $\Sigma_j\alpha_j = 0$ in fixed effects model, but there is a variance attached to the effects now because they are random. In our example, if the hospitals are purposively selected, the effect of these hospitals can still be studied but the conclusion will be valid for these four hospitals and not for the other hospitals. You would not be able to say anything about the hospitals not in your sample. No general statement regarding whether duration of hospitalization across hospitals in the state is different or not can be made. For this kind of conclusion, the hospitals have to be selected randomly and the analysis done by random effects ANOVA. The difference would be clearer if you look at the null hypothesis in the two setups:

$$\text{Null hypothesis in case of fixed effects: } \alpha_1 = \alpha_2 = \ldots = \alpha_J;$$

$$\text{Null hypothesis in case of random effects: } \sigma_A^2 = 0.$$

The alternative hypothesis in the fixed effects case is that at least one $\alpha_j$ is different from any other, whereas in the random effects case, the alternative hypothesis is $\sigma_A^2 > 0$.

The calculation of mean sum of squares is the same in random effects model as in fixed effects model. The calculation of *F*-ratio also remains the same with the same dfs for one-way ANOVA (but not for higher-way ANOVA): only the interpretation changes. We now explain two-way ANOVA with random effects to highlight the difference.

### *Two-Way ANOVA with Random Effects*

For two fixed factors, the usual ANOVA model is $y_{ij} = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk} + \varepsilon_{ijk}$ with the conditions that $\Sigma_j\alpha_j = 0$, $\Sigma_k\beta_k = 0$, $\Sigma_j(\alpha\beta)_{jk} = 0$, and $\Sigma_k(\alpha\beta)_{jk} = 0$; where we assume that there are same $n$ number of subjects for each combination of factor levels ($i = 1, 2, \ldots, n$), $\alpha_j$ is the effect of the $j$th level of factor A, $\beta_k$ is the effect of the $k$th level of factor B, $(\alpha\beta)_{jk}$ is the interaction, and $\varepsilon_{ijk}$ is the error term with $N(0, \sigma^2)$ distribution. When both factors are random, this model becomes $y_{ij} = \mu + a_j + b_k + (ab)_{jk} + \varepsilon_{ijk}$ where now $a_j \sim N\left(0,\sigma_A^2\right)$, $b_k \sim N\left(0,\sigma_B^2\right)$, and $(ab)_{jk} \sim N\left(0,\sigma_B^2\right)$. In our example of duration of hospitalization in different hospitals after a particular surgery, two-way random effect would be applicable if you want to consider treatment modality also as the second factor. Let there be a large number of treatment modalities practiced in all hospitals. Of all the levels of this factor, include $K$ of them by random selection with the objective of finding whether these treatment modalities differentially affect the outcome. Based on statistical consideration of what is called expected mean squares in this setup, the *F*-ratios are calculated as follows when both factors have random effects:

$$\text{Random effects: } F_A = \frac{\text{MS}_A}{\text{MS}_{AB}},\ F_B = \frac{\text{MS}_B}{\text{MS}_{AB}},\ F_{AB} = \frac{\text{MS}_{AB}}{\text{MSE}},$$

where MS is for mean square. The degrees of freedom for these are as per the respective numerators and denominators in these ratios. The calculation of mean squares remains the same as in fixed effects. For fixed effects, the denominator is MSE in all these *F*-ratios, but not so for random effects. The null hypotheses under tests are $\sigma_A^2 = 0$, $\sigma_B^2 = 0$, and $\sigma_{AB}^2 = 0$, respectively, in random effects. If any of these is rejected, the conclusion is that the effects of different levels of the concerned factor have significant variation. In our example, if $K = 3$ treatment modalities are included randomly, $n = 10$ patients in each cross-tabulation of levels of factor A and factor B, and $F_A = 17.43$ at df = (3, 108), then $P < 0.05$, and thus the mean duration of hospitalization is different across hospitals. This conclusion is for all hospitals in the state and not just for the four hospitals in the sample.

An interesting situation arises when one factor is random and the other is fixed. This can happen in our example when factor A continues to be different hospitals but factor B is sex of the patients, which is fixed anyway. It would be interesting to find whether different hospitals treat males differently than females with respect to duration of hospitalization, called interaction. The data where some factors are fixed and others random are analyzed by **mixed models** ANOVA as per the details mentioned for that topic.

## random errors

These are inherent, unpredictable errors that arise when repeated measures of the same characteristics are taken in identical conditions and exclude bias or man-made error. Random errors occur due to imprecision of the process—in methods, measurements, etc., such as in staining, magnification, rotation, counting, and timing in a laboratory setup; in the environment such as room temperature, humidity, or minor variation in chemicals, reagents; or in the varying care adopted by different observers. All measurements are prone to random error, but they are particularly prominent in health and medicine.

Random errors can also arise due to (i) shifting goal posts so that similar performance is rated differently, (ii) measurements taken in a hurry or too much slackness, (iii) tendency to assign some middling value to most response, (iv) tinkering values perceived as unduly large effects, (v) trying to correlate response to different items when none exist, (vi) tendency to compare one person with others that can modify the reporting or measurement, and (vii) fatigue, boredom, lack of concentration, carelessness, etc. All these errors may occur unwittingly in the subconscious mind without the investigator really knowing.

**Replication** is an effective method of reducing the effect of these errors on the conclusions since these tend to average out in replications. The effect of random errors can be reduced through ordinary statistical methods such as using the mean. If you measure a pharmaceutical tablet eight times with an accurate balance and get slightly different values, the mean weight will be very close to the actual weight of the tablets if these differences are really random. If not, suspect that the errors are systematic.

It may be a surprise to many that random errors are not so random after all. They follow a pattern, called **Gaussian**. This means that most random errors will have a value around zero with a plus or minus sign, and a few will be large. This is also the basic assumption in most statistical methods. For example, in **multiple linear**

**regression**, the errors are $\varepsilon = (y - \beta_0 - \beta_1 x_1 - \beta_2 x_2 - \ldots - \beta_K x_K)$, and they are required to follow a Gaussian distribution with mean zero and variance $\sigma^2$ for validity of the procedures such as confidence interval and test of hypothesis. In case of samples, these errors are called **residuals**. The least squares method finds those estimates of regression coefficients β's that minimize the sum of squares of residuals. Goodness of fit of any statistical model is assessed by the magnitude and nature of these residuals. If many of these residuals are large, the model is not considered a good fit even if the mean is zero. If the mean is not zero, then it is called bias and it will require adjustment in the model.

In the context of experiments, random error is called *experimental error*. This can be controlled by appropriate choice of the experimental design. For example, experimental error could be caused by interobserver variability. Blocking by observers would control this error (see **randomized block design**). If it is due to age, sex, severity of disease, etc., these are controlled by considering them as factors in the statistical analysis so that their effect can be isolated and removed.

Opposite to random errors, there are systematic errors, which are also called **bias**. Systematic errors are reproducible inaccuracies that are consistently in the same direction. They can persist throughout. If you measure vials as part of the process of filling them but the measurements are 0.10 g higher because the scale was not properly tared, it would be a systematic error. If there is an air bubble in the mercury column of a sphygmomanometer, the blood pressure reading will be consistently high than the actual. Systematic errors are difficult to detect; worse, they cannot be analyzed statistically. Spotting systematic error and correcting requires a lot of diligence, and it should be done before starting the formal measurement for the study subjects.

## randomization, *see* random allocation

## randomized block design

A design is called a randomized block when the treatments are randomly allocated to the subjects after dividing them into some homogeneous groups, called blocks. The objective is to reduce the experimental error. Consider an experiment on the effect of three doses on duration of recovery that depends on the severity condition of the patients, among other factors. Divide the condition into mild, moderate, serious, and critical. Note that this division into homogeneous blocks is not random; instead, within each severity, the patients are allocated to receive one of three doses randomly. You may have 12 cases with mild disease, 21 cases with moderate disease, 15 cases with serious disease, and 6 cases with critical disease. We are taking these sizes in multiples of three since there are three doses. It is decided randomly which of the 15 cases with serious disease will get dose 1, dose 2, and dose 3. Thus, the random assignment is restricted to the doses within blocks as illustrated in Table R.1.

**TABLE R.1**
**RBD with Disease Severity as the Block**

| Dose | Mild | Moderate | Severe | Critical |
|---|---|---|---|---|
| Dose 1 | 2, 3, 6, 10 | 4, 8, 9, 12, 13, 20, 21 | 1, 7, 9, 10, 12 | 1, 5 |
| Dose 2 | 4, 5, 9, 12 | 1, 3, 7, 10, 14, 15, 18 | 3, 4, 8, 11, 14 | 2, 4 |
| Dose 3 | 1, 7, 8, 11 | 2, 5, 6, 11, 16, 17, 19 | 2, 5, 6, 13, 15 | 3, 6 |
| **Total number of subjects** | **12** | **21** | **15** | **6** |

*Note:* Table entries are subject numbers.

Sometimes a one-way experiment is repeated two or three times in different groups of subjects to increase the level of confidence in the findings. This is also blocking, where the blocking factor is time. However, one has to make sure that conditions such as reagents, calibration, and environment do not change in such repetitions.

Blocking characteristics can be those associated with subjects, such as age, sex, nutritional status, and severity of disease, or those associated with experimental setting, such as hospitals, observers, time, method of assessment, etc. The former controls intersubject variability, and the latter helps in achieving standardized conditions. In medical setups, blocking by age and sex is common but is useful only if this reduces experimental error—thus, the responses of subjects within each block must be substantially homogeneous. When this is so, the results will be more reliable. If any one particular block is to be excluded because of huge nonresponse or any other spoil, the results for other blocks would still be valid. However, if there are a few missing values in one or more blocks, this causes imbalance due to unequal $n$ and may also cause bias if missing values are related to response. Results from a randomized block design (RBD) can be difficult to interpret if there is an interaction between the blocking variable and the treatment levels. Yet, in some cases, this interaction can provide useful information on how a treatment works in different blocks.

In most applications of RBD, the two factors under study have fixed effects. In our example, the interest could be in just those three doses that are included in the experiment and in those four disease severity levels as included. But that is not necessary, and any or both factors can be random. When both are fixed, analysis of data is done by the ordinary **two-way ANOVA**. However, in this case, if you have just one subject in each combination of factors, you would not be able to study interaction in any ordinary manner. A special method called **Tukey test for additivity** is used for this purpose. If any one of the two factors is random, **mixed effects** ANOVA would be used, whereas if both factors are random, **random effects ANOVA** would be used. In an RBD, usually the interest is in the treatment effect—blocks are just for reducing the experimental error.

Distinguish RBD from a factorial experiment. In the case of the latter, there are two treatments and they can have $J$ and $K$ levels, respectively. This is like using two drugs: drug A in doses 5, 10, and 15 mg and drug B in doses 10, 50, and 100 mg. If it is a factorial experiment, there will be a group receiving 5 mg of drug A and 10 mg of drug B, another group receiving 5 mg of drug A and 50 mg of drug B, etc. The allocation of "treatments" is in combinations rather than one at a time.

When one or more treatment–block combination is missing, this is called *incomplete block design*. For example, you may not have any patient with critical condition receiving treatment 3. Incomplete blocks require a special method of analysis. For details, see Ruxton and Colegrave [1].

When time is used as a blocking variable on the same subjects, beware that the measurements at different points in time in the same subjects would be related. This violates the basic requirement of independence and invalidates the ANOVA unless special methods such as **repeated measures** are involved.

## randomized consent design, *see* Zelen design

## randomized controlled trials (RCTs)

A clinical trial with random allocation of the subjects to the treatment and the control arms is called a randomized controlled trial (RCT). In the case of therapeutic modalities, this is the phase III trial (see **phases of (clinical) trials**) once the early trials (phase I and phase II) have established the overall safety of the regimen, its basic clinical pharmacology, its therapeutic properties, and its most important side effects. This kind of trial sits at the top level of the evidence pyramid (see **evidence (levels of)**) with the most credible and the least biased results. Employing an RCT is also a prerequisite to meet the regulatory standards of licensing for efficacy as well as safety of a new regimen.

For credibility, there must be a valid control group and allocation of subjects should be fully **randomized** in this phase to the test arm and the control arm; also **blinding** is done where feasible. Through such strategies, a phase III trial is expected to provide compelling evidence of the **efficacy** of the regimen or its lack thereof. When benefits are explored, proper assessment of harm is equally crucial—thus, safety is also assessed. In fact, these days, when efficacy of many regimens is exceeding 80%, safety is an overriding consideration in many trials.

An RCT in drug development is a large-scale trial with generally 300–1000 subjects recruited for each arm. The follow-up must be sufficiently long for efficacy and side effects to emerge, and to rule out that any relief is transient. For side effects, a larger sample may be needed then to evaluate efficacy because critical side effects can be rare. An RCT is expected to provide a full picture of the clinical performance of the treatment under test. Specifically, this can include

- Exact identification of the diagnostic group that responds reasonably well, and comparison of the beneficial and adverse effects with those of the existing treatment, if any.
- An increase in patient exposure in terms of both the number of patients and the length of follow-up over phase I and phase II trials so that less common and late side effects can also be identified.
- More evidence on possibility of adverse interaction with other treatment regimens with which the new treatment is likely to be prescribed.
- The ideal dose regimen for different types of patients with regard to age, body weight, severity of disease, etc.
- Further pharmacological studies.
- Acceptability to the treatment regimen of communities with different medical cultures. This last objective can be achieved by conducting a multicentric trial.

Among thousands of studies, just to give you an example, Gianotti et al. [1] performed one in Italy in which a total of 305 patients of cancer of the gastrointestinal tract with preoperative weight loss <10% were randomized to receive either preoperative artificial nutrition supplementation, postoperative jejunal infusion (perioperative group), or no artificial nutrition (conventional group). There are three groups in this RCT including one control (the conventional group). The outcome variables were postoperative infections and length of hospital stay. **Intention-to-treat analysis** and differences between the groups showed that preoperative supplementation was as effective as perioperative administration, and both strategies are superior to the conventional approach. This illustrates how an RCT provides an opportunity to reach to a definitive and useful conclusion. However, among other considerations, the quality of evidence provided by an RCT depends on the proper choice of the cases and controls.

### *Selection of Participants for RCT*

When an inordinately large number of subjects are available that pass the **inclusion and exclusion criteria**, they must be randomly selected for inclusion in the trial. This allows generalizability. When the patients arrive randomly as they ordinarily do and there is no filter except the eligibility, one method of random selection could be systematic (e.g., every fifth), and another method is to include consecutive eligible patients arriving in a clinic or hospital within a specified period. Otherwise, random numbers can be used for selection. *Note that this random selection is different from random allocation.*

**Ethical** considerations such as **informed consent** can preselect a biased group. Some patients or some clinicians may have strong preference for a particular therapy, and they can refuse randomization. Some eligible patients may refuse to participate when they are told that they could be randomized for a **placebo** or a new untested therapy. Some may refuse because it is a trial and not treatment per se. Considerable efforts may be needed to keep such refusals at a minimum.

In addition, the groups should be such that there is an a priori uncertainty about the efficacy of the test therapy in them. This is called patient equipoise and helps to ensure that the patients are homogeneous. Patient equipoise implies guarding against unwitting tendency to include subjects who are likely to benefit from the drug under trial without declaring that the trial is restricted to such specific groups. Sometimes health-conscious people agree to enter a trial while, in fact, participants should be fair representatives of the class of patients that are finally targeted to benefit from the regimen in case the trial is successful. The participants should be genuinely uncertain about the outcome of the trial so that the results are unbiased. See the topic **equipoise** for other such requirements.

Be extra cautious in trials on severe cases. Beside medical surveillance that these cases require, note that some such cases sometimes hardly have scope to deteriorate further in case the drug is ineffective—they can only improve. If the patients have very high blood pressure (BP), they may remain so, whereas patients with relatively low BP can easily show a rise. When comparing cases of high BP with cases of low BP for efficacy of a drug, the drug may be unnecessarily considered to have caused the rise in the low BP group. In some situations, it could be just the reverse.

**Bias** can still occur in subtle or unknown ways in an RCT despite random allocation and blinding. A major source of bias is negligence to follow-up. If the follow-up requires recalling or revisiting the patients, some may not turn up or may refuse to cooperate, some may be untraceable, and some could die from unrelated causes. Even if the outcome assessment is within the hospital stay, some can leave against medical advice. Another factor that could affect a clinical trial is the need to change the treatment modality midway if any patient develops a serious illness. In addition, there could be patients who did not follow the full regimen. This is called partial **compliance**. Take preemptive steps to minimize such losses and plan to adjust the results if needed. Also make sure that the experience gained on previous subjects does not alter the method of assessment of subsequent cases. The fundamental assumption of independence of the subjects must not be violated.

### *Control Group in a Clinical Trial*

As in other experiments, clinical trials can have one or more treatment regimens, but a parallel or concurrent **control group** is almost invariably required except in **crossover trials** and **before–after**

**design**. As the name implies, controls are necessary in an RCT. Real controls are those that are similar but follow the natural course of disease without any intervention. In practice, however, the reference control group is either treated with an existing regimen or administered a placebo so that (i) any **Hawthorne effect** is neutralized and (ii) any psychological effect of a regimen is accounted. See the topic **placebo** for details of the conditions where placebo could be justified. There is a debate whether surgical trials need a group with sham surgery as placebo. Perhaps evidence is not enough that sham surgery has the same psychological benefits as a placebo in a drug trial. Nevertheless, a sham surgery group can be adopted for a setup where it is not too expensive and is harmless to the participants.

For some medical maneuvers such as renal dialysis and fitting of an artificial limb, for which a placebo group is nearly impossible, the existing regimen is given to the control group—now called active control. But the control group is now widely considered as a scientific necessity. Such a group too should have similar baseline and must be subjected to the same maneuvers as the test group, except for the regimen itself. The control group should undergo the same medicinal rituals, such as dietary regulations, as the treatment group. If a nonparallel group is a control, then appearance, schedule of administration, discomfort, etc., may cause differential compliance. Such a trial cannot be **double blind**. Finding a strategy that minimizes bias in such cases can be a challenging task. Whatever bias creeps in will have to be tackled at the time of analysis of data, and this too may not be easy to handle.

An apparently simple approach is the comparison of the current test group with a group previously treated with the required control regimen including placebo. This is called historical control. This may be derived from previous clinical trials or records such as registries and databases. The advantage is that no concurrent control is required—thus, the requirement of cases reduces by half and the cost also reduces accordingly. Ethical issues regarding recruiting and exposing subjects to the control regimen are also avoided. Historical controls may be appropriate for a disease that has a relatively stable natural history, and understanding of prognostic aspects has not changed. Multiple controls in this setup may help increase the level of confidence if the results replicate in each group of controls.

Despite demonstrable equivalence, the results are rarely accepted as definitive when based on historical controls. The flaw is that some factors may have changed over time such as diagnostic techniques, and evaluation procedures may have improved over time. Known changes can be accounted for in the interpretation of results, but there might be some obscure changes that could affect the results. Lack of randomization also compromises the credibility of results in this setup. Historical controls may not have been monitored with the same keenness as one would with concurrent controls, causing bias in the results.

Notwithstanding the strong argument made above for some kind of controls, there might be situations where they are not needed. If a treatment is being tried for a rapidly fatal disease such as tuberculous meningitis, where is the need for a control group? Saving of some cases is enough evidence of efficacy. Drugs with dramatic effects such as penicillin do not need a control. Utility of Pap smear was established without recourse to a controlled trial. However, such instances are rare.

### *Some Subtleties of Statistical Analysis of RCT*

Perhaps it needs to be emphasized that *the difference between treated and control must be statistically significant for it to be medically relevant*. If it is not statistically significant, nobody can be confident that the difference is actually present in the corresponding population. Thus, the first step is to assess statistical significance. If it is not significant and the statistical power is adequate, there is no need to worry about its medical relevance in most cases because it is likely to be there in the sample by chance. If significant, further statistical testing is used to judge if it reaches a medically relevant threshold. This threshold comes from medical acumen, and value judgment is required. In a rare case, statistical nonsignificance can be ignored. If in an RCT, 3 deaths occur in 100 subjects in the placebo group and none out of 100 in the treatment group, the difference is not statistically significant, but would you not try this treatment for your family if everything else has failed? Additional factors such as environment, family condition, and availability of health infrastructure are also considered while taking a final decision regarding the management of a patient.

When considering analysis, **intention-to-treat (ITT)** is an ingenious strategy to partially circumvent the limitation imposed by a specific kind of distortion in the data. This strategy is particularly advocated for RCTs. See that topic for details.

Some professionals feel that an RCT is the only mode to provide scientific evidence of a cause–effect relationship. A moment's reflection will convince you that this is not so. Most accept that cigarette smoking *causes* lung cancer, but no trial has ever been conducted. The controlled experiments do provide direct evidence, but evidence from observational studies can be equally compelling when confounders are really under control and the results replicate in a variety of settings. In any case, an RCT is almost never undertaken for a potentially harmful substance or regimen.

Sample size, $n$, is just about the first thing that comes to mind when planning a trial. It is among the most important considerations that determine the utility of a trial. For a discussion on this aspect, see the topic sample size for study formats, where a subsection about clinical trials is given.

For those who want to know more, Ref. [2] is a seminal text on RCTs. Also see the topic **adaptive designs for clinical trials**.

## randomized response technique

This is a procedure to collect usable information on sensitive items that the respondents are generally hesitant to answer correctly. Such items could be regarding extramarital sex, abortions, consumption of illegal drugs, going to quacks, drunk driving, etc. Many persons are hesitant to reveal their correct income, and for some women even their exact age. They may elect not to reply at all to such questions or reply with incorrect answers. The resulting bias is difficult to assess. It can be removed by allowing the respondent to answer privately through a randomizing response technique (RRT). This is done through a device in his/her control as per the details given next. The method was proposed by Warner [1] in 1965.

Take an example of a survey about abortion. Let the objective be to estimate the proportion of women who have ever had an abortion. This is a sensitive issue and a correct answer may be evasive. Under the RRT, two inverse questions are framed: (a) "Have you ever had an abortion?" and (b) "Have you never had an abortion?" Answer to both is either yes or no. Thus, the answer does not reveal which question has been answered. The RRT is implemented as follows. Ask the respondent to roll a die away from the interviewer and tell her to correctly answer (a) if the die face is 1–4 and answer (b) if the die

is 5 or 6. Assure the respondent that no one will know which question she is answering. Only the respondent knows which question is answered, and the investigator does not know the outcome of the die. But the investigator knows that the probability of answering (a) is $\theta = 2/3$ and that of answering (b) is 1/3. Since the answer to both (a) and (b) is either yes or no, the respondent is assured that her answer would remain confidential and so might answer correctly.

Let $\pi$ be the true proportion in the population that we want to estimate. This means that the probability of a "yes" response to question (a) is $\pi$ and the probability of a "yes" response to question (b) is $(1 - \pi)$. These are mutually exclusive answers. Thus, the probability of "yes" response to either (a) or (b) by addition rule is

$$P(\text{yes}) = \theta\pi + (1 - \theta)(1 - \pi).$$

This gives $\pi = \dfrac{P(\text{yes}) - (1-\theta)}{2\theta - 1}$ and its estimate $p = \dfrac{x/n - (1-\theta)}{2\theta - 1}$, where $x$ is the number of "yes" responses by $n$ women. In our rolling a die method, we know that $\theta = 2/3$. Thus, for this method, $p = \dfrac{x/n - 1/3}{1/3}$. Therefore, the proportion in the population with abortion can be estimated. In place of rolling a die, any other randomized mechanism that protects the privacy can be used, but this method requires that $\theta$ should neither be 0 nor 1 nor ½. Thus, tossing a coin is not an option. When $\theta = 1/2$ as in tossing a coin, another method called innocuous question method [2] is used. Blair et al. [3] have developed a multiple regression technique for analyzing randomized responses and have also proposed power analysis.

Despite the availability of this method for a long time, there is a dearth of substantive applications. Perhaps the reason is the use of an outside method of randomized device that can confuse the respondents. Respondents possibly will not feel confident in answering sensitive questions despite this device.

Chen et al. [4] used randomized response method to estimate commercial sex proportion among men having sex with men and condom use in China. Wolter and Preisendörfer [5] compare the RRT to direct questioning with a survey that contains sensitive questions. Their data came from 552 face-to-face interviews with subjects who had been convicted in a metropolitan area in Germany for minor criminal offences. They found that the RRT does not lead to higher prevalence estimates of sensitive behavior than does direct questioning. Secondly, effects of individual and situational determinants of misreporting differ between the two question modes. The effect of need for social approval is stronger in RRT than in the direct question mode.

## randomness (statistical tests for)

When dealing with data, you might want to determine whether they are indeed random. This kind of problem generally arises while generating random numbers such as for simulations. First, consider just what is meant by **random**. If the data are single numbers, a datum is random when it is drawn from an equally probable set of possible values. Statistically, it will have a **uniform distribution**. Also, if you take a sequence of random numbers, each number drawn must be statistically independent of the others. That is to say that drawing one value does not make that value less likely or less likely to occur again. So with an unloaded die, if you roll a six, that does not mean that the chance of rolling another six changes.

Among many tests available to check randomness of data, runs test is the most popular.

### *Runs Test for Randomness*

In the case of tossing a coin, randomness implies that there are no big sequences of consecutive heads or tails. If a coin shows up 8 consecutive times, would you not doubt the fairness of the coin or of the toss? A consecutive similar outcome is called a run. In the following sequence of 15 tosses, there are 8 runs—4 of heads and 4 of tails:

| T T | H H H | T | H H | T T | H H H | T | H |
|---|---|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |

In case of numerical values, a series of increasing values or a series of decreasing values would be a run. These can also be divided as below median and above median, ignoring the values exactly equal to median (hoping that these are not many) as – and +, or 0 and 1. Too few runs indicate nonrandomness. But there is a problem with too many runs also. The sequence with many runs such as 0 1 0 0 1 1 0 1 is not necessarily random—it could be cyclical. Thus, the number of runs should not be too many either. Runs test for randomness is based on the basic premise that the runs should be neither too few nor too many. For large samples,

$$\text{Runs test for randomness: } t = \frac{R - \bar{R}}{s_R} \text{ with } (n_1 + n_2 - 1) \text{ df,}$$

where

$n_1$ = number of positive runs and $n_2$ = number of negative runs,
$R$ = number of runs in your data ($R = n_1 + n_2$),

$$\bar{R} = \frac{2n_1n_2}{n_1 + n_2} + 1,$$

$$s_R^2 = \frac{2n_1n_2(2n_1n_2 - n_1 - n_2)}{(n_1 + n_2)^2(n_1 + n_2 - 1)}.$$

Reject the null hypothesis of randomness if $|t|$ exceeds the critical value at $\alpha$-level of significance. This could be easily done with the help of software. In the literature, you may find $z$ instead of $t$, although it legitimately is $t$ because of the estimated standard error (SE) of $R$ in the denominator. For large $n$, it really does not make much of a difference. For small samples, there are separate tables [1] to determine critical values that depend on values $n_1$ and $n_2$.

A **Cusum chart**, as described separately in this volume, can also be used as a visual test for randomness. If the plot follows a discernible pattern such as most values on one side or continually increasing or decreasing, the randomness is in doubt. Another test

for randomness uses frequency within a block. This exploits the premise that the number of 0's and 1's expected in different blocks of values should be the same if the data are random. For details, see Kenny and Mosurvski [2]. Despite these tests, it is hard to find that a sequence of numbers is really random. All possible sequences are equally likely, and it is possible to get six zeroes in a row. Some perfectly random sequences may appear nonrandom and may fail the randomness test, but the suspicion rises if many sequences fail the test.

## random numbers

What do we mean by random numbers? These are those numbers that do not follow any predictable pattern. There are a number of methods of building up a series of random numbers for use in selection of cases or otherwise. Apart from all physical methods, the method of building up a sequence from a random number table is conceptual.

With two participants, the tried and tested method, beautiful in its simplicity, is to toss a coin. Other methods are dice, cards, and drawing lots. A different and possibly more scientific method is to use a random number table of the type shown in Table R.2, where three-digit random numbers are arranged in 10 columns and 30 rows. This table can be used to generate one, two, three, or higher digit random numbers. Each digit is random and there are 900 digits in this table. You can start at any random point and pick up one, two, or more consecutive numbers to form a random number of the size you want.

It would be more accurate to call these as pseudo-random numbers as they are generated by a mathematical process. These tables are to be found in statistics books, or they can be produced by computers and some types of calculators.

Although random allocation of subjects to the regimen in an experiment or a trial is directly done by computer programs, this can also be done by the random number table of the type shown in Table R.2. If there a total of 60 subjects for allocation to two groups of 30 each, select the first 30 distinct random numbers beginning at any random point in the table that are ≤60. If any number repeats, ignore this number and also exclude 000. These 30 will be in group I and the remaining 30 in group II. You can move across or downward in the random number table for reading the numbers; that does not matter because the numbers are not just random but also randomly arranged. But decide in advance how you plan to go from one number to the next since no change is permissible after seeing the numbers.

## random sampling, *see* sampling techniques

## random sampling methods

A sample is called random when inclusion or exclusion of a particular eligible subject in the sample depends on chance and cannot be predicted in advance. However, as will be illustrated shortly, the chances are not necessarily equal for all subjects for inclusion in the sample. For this reason, it is sometimes prudent to call it a **probability sampling**.

Random selection is just a strategy to get a representative sample. If representativeness can be achieved by any other method, the same can be adopted. The larger the sample relative to the size of the population, the more the chance of it being representative—random or not. A large number of methods are available for choosing a random (or probability) sample. However, only some are commonly used. For details, refer to the following topics: **simple random sampling**, **stratified random sampling**, **multistage random sampling**, **cluster random sampling**, and **systematic random sampling**. Note that all of these methods include the term "random." This is because choosing a sample at random is an easy way of getting a truly representative sample. Not choosing at random can result in the sample being biased, although this kind of sample may still be applicable in some situations. For an overview of nonrandom methods, see the topic **sampling techniques**. Some of these such as **haphazard sampling**, **snowball sampling**, and **volunteers** are also discussed as a separate topic.

Typically the simple random sampling (SRS) allows the same chance of selection to each unit in the population. Other sampling procedure can have unequal chance despite being random. For example, in stratified random sampling, if you are randomly selecting 20 out of 100 mild cases and 20 out of 40 serious cases, the chance of selection of each mild case is 1/5 and the chance of each serious case is 1/2. These chances are not equal. This can be so with multistage and cluster random sampling also. For this reason, proportionate sampling is sometimes advocated that assigns the same chance to all individuals, but that will have a relatively small sample of cases that are rare in the population—defeating one of the purposes of stratified sampling of adequate size from each stratum.

A visual comparison of some methods of random sampling is shown in Figure R.2. This may help to distinguish among various methods. The method of choice is always SRS unless it is difficult to adopt. The estimate provided by SRS is generally the most precise. Some problems with SRS are the following:

- Nonavailability of **sampling frame**. This is the list of items of subjects to be sampled and is needed to adopt SRS.
- SRS is likely to select widely dispersed subjects, making the approach difficult. In case of choosing people residing all over a state by SRS, they may be too far off from one another.
- It is possible in SRS that specific groups of interest are not adequately represented. For example, you may find after random selection that the females are underrepresented in your sample.
- If you are using a random number table for selection, obtaining so many distinct random numbers may be difficult as the numbers tend to repeat after a while.

The first two problems can be handled by either cluster or multistage sampling. The answer to the third is stratified sampling, and the remedy for the fourth is systematic sampling because it requires only one random number. The systematic method also does not require the full frame. In any case, with the wide availability of computers, generating distinct random numbers is not a problem. Although small-scale studies may use one of the preceding methods, medium- and large-scale studies would generally be based on a mix of two or more methods.

**TABLE R.2**
**Random Number Table Used in Random Number Generation**

| Row # | A | B | C | D | E | F | G | H | I | J |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 939 | 720 | 840 | 376 | 644 | 997 | 729 | 271 | 249 | 224 |
| 2 | 987 | 736 | 804 | 840 | 389 | 290 | 704 | 784 | 115 | 613 |
| 3 | 527 | 613 | 677 | 893 | 900 | 473 | 198 | 448 | 673 | 798 |
| 4 | 142 | 979 | 621 | 927 | 805 | 920 | 993 | 806 | 467 | 438 |
| 5 | 763 | 871 | 634 | 286 | 280 | 535 | 310 | 727 | 711 | 978 |

## random variables, *see* variables

## range, *see* variation

## rank correlation

This is the correlation between **ranks** of quantitative values in two series rather than the values themselves. In some cases, two variables $x$ and $y$ clearly increase or decrease together, but the relationship is not necessarily linear. This is called a **monotonic** relationship (Figure R.3). The dependence of height on age of children is an example of such a relationship. This is not linear but definitely exists. The relation of visual acuity with age after 60 years may be monotonically decreasing with a sharp drop after the age of 80 years. The usual method to measure the strength of *linear* relationship for such data is the Pearson **correlation coefficient**. This is adequate in most situations but not for the situations just listed. The linearizing effect of the product–moment correlation coefficient in such cases amounts to an oversimplification of the relationship. Also it can provide misleading results when outliers are present. Its test of statistical significance is valid only when at least one of $x$ and $y$ has Gaussian distribution. When these conditions are not met, rank correlation is used.

The best known measure of rank correlation is the **Spearman correlation coefficient**. For this correlation, the values of $x$ and $y$ are separately ranked from 1 to $n$ in increasing order of magnitude, and the ordinary product–moment correlation coefficient is computed between ranks of $x$ and ranks of $y$. This simplifies to the following:

$$\text{Spearman rank correlation coefficient: } r_S = 1 - \frac{6\Sigma d^2}{n(n^2-1)},$$

where $d$ = (rank of $y$ – rank of $x$) and where the summation is over all pairs of observations. This coefficient always lies between –1 and +1. When computed for all subjects in the population, it is denoted by ρ. Calculation of rank correlation is illustrated in Table R.3 for the height and weight of eight children. This is $r_S = 1 - \frac{6 \times 0.50}{8 \times 63} = 0.994$. This example illustrates the following:

1. Equal ranks are assigned to the tied observations. In this example, the second child and the fifth child have the same weight. They would have received ranks 4 and 5 but now received a midrank of 4.5 each because of the tie.
2. The ordinary product–moment correlation coefficient between weight and height in this example is 0.967. The rank correlation is slightly higher. This would have been exactly +1 if the weight of the second child were 13 kg and the height the same 92 cm. The rank correlation can sometimes overrate the strength of the relationship because it partially disregards the actual magnitude of $x$ and $y$. This is clear from the explanation given next.
3. The value of rank correlation would not change if, for example, the height of the third child were 114 cm instead of 127 cm. This is because the rank is not changed by such an alteration in this case. Rank correlation, thus, is not fully sensitive to the exact values of the variables.

One big advantage of rank correlation is that it attenuates the effect of outliers. You may be aware that only one outlier can substantially distort the value of the product–moment correlation coefficient. The value of rank correlation is not so much affected because a high value is converted just to the next rank. This is a nonparametric procedure, and the test of its significance does not require a Gaussian pattern of either $x$ or $y$. This correlation is thus preferable when the distribution pattern of both $x$ and $y$ is far from Gaussian.

Rank correlation, being a nonparametric procedure, requires a **permutation test** for checking its statistical significance for small $n$. For large $n$, the same Student $t$-test with df = $(n - 2)$ as used for the product–moment correlation coefficient can be used, namely, $t = r_S\sqrt{\frac{n-2}{1-r_S^2}}$. For the confidence interval, **Fisher $z$ transformation** can be used for large $n$ just as for the product–moment correlation coefficient.

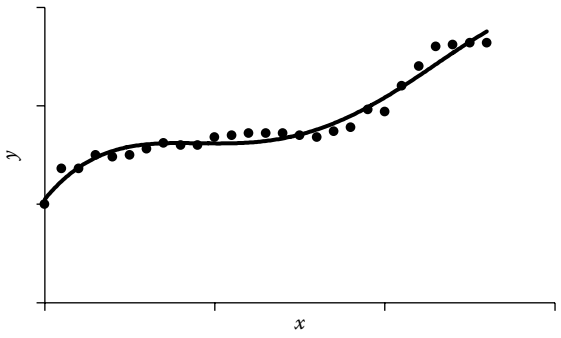

**FIGURE R.3** Monotonic but not linear relationship.

**TABLE R.3**
**Calculation for Rank Correlation Coefficient**

| | Child 1 | Child 2 | Child 3 | Child 4 | Child 5 | Child 6 | Child 7 | Child 8 | |
|---|---|---|---|---|---|---|---|---|---|
| Weight (kg)—$y$ | 10 | 14 | 26 | 6 | 14 | 18 | 32 | 4 | |
| Height (cm)—$x$ | 65 | 92 | 127 | 63 | 95 | 96 | 128 | 55 | |
| Rank ($y$) | 3 | 4.5 | 7 | 2 | 4.5 | 6 | 8 | 1 | |
| Rank ($x$) | 3 | 4 | 7 | 2 | 5 | 6 | 8 | 1 | |
| Difference ($d$) | 0 | +0.5 | 0 | 0 | –0.5 | 0 | 0 | 0 | $\Sigma d^2 = 0.50$ |

## ranking and selection

Ranking of groups is achieved by putting groups in order from minimum to maximum with respect to mean or proportion, marking those that are not significantly different. Selection is identifying the best or the worst or the median. The statistical method for ranking and selection is generally traced to a paper by Bechhofer [1] in 1954.

Ranking and selection problem usually originates from a question such as, "Which diet, out of $K$ available options, is the best to prevent cancer?" and "Which is the next best?" In statistical terms, the objective is to find the order of the groups such that $\mu_1 \geq \mu_2 \geq \ldots \geq \mu_K$ or $\pi_1 \geq \pi_2 \geq \ldots \geq \pi_K$. Whereas some of these can be strict inequalities, others may be equalities only. When such ordering is done, the group with the largest or the smallest mean or the smallest proportion is automatically identified. The constraint imposing the challenge is that we should be able to do this with probability of Type I error less than the level of significance α.

Ranking and selection can also be understood as identifying the best set of alternatives from the given options based on their expected performance. The methods of **order statistics** are used to address the problem. These methods are based on the distribution of any order statistics of interest. For example, $\bar{x}_{[k]}$ is the $k$th-order statistics if $(k - 1)$ means are less than this and the remaining $(K - k)$ are more than or equal to this. Median and percentiles are the popular example of order statistics. Statistical distribution of such statistics is not straightforward and may require some intricate mathematics.

Complexities in ranking can be illustrated as follows. Suppose that the largest sample mean is $x_{[K]}$. Because of sampling fluctuation, this could have come from the population whose mean is just the middling type. What is the chance that this indeed has come from the population with largest mean $\mu_{[K]}$? If values in all groups follow a Gaussian pattern with the same variance $\sigma^2$, this could be shown to be [2]

$$P(\bar{x}_{[K]} \text{ from the population with mean } \mu_{[K]}) = P\left(z_k < z_K + \frac{\mu_{[K]} - \mu_{[k]}}{\sigma/\sqrt{n}}, k = 1, 2, \ldots, K-1\right),$$

where $n$ is the sample size from each population and $z_k = \frac{\bar{x}_k - \mu_k}{\sigma/\sqrt{n}}$. It is with the help of such probabilities that ranking and selection is done.

The situation is illustrated in Figure R.4, which shows the sample means on the lower side and the population means on the upper side. In practice, we will have only the lower half as the upper half on population will be unknown. It is possible that the sample mean of group 2 is much lower than its population mean and becomes substantially larger in another sample.

When considered in an oversimplified manner, ranking can be done on the basis of **multiple comparisons**. If there are five groups A, B, C, D, and E, multiple comparisons methods would determine which groups are significantly different from others, and can provide the results of the following type:

C B E A D

This is the presentation when they are ordered by the values of sample mean, and the mean in group B is found not statistically significant from group E, and group E not significantly different from group A and group D. However, group B is significantly different from group A, and group C with the minimum mean is significantly different from all other groups. In this manner, we are able to rank these groups with respect to their mean. When the results of multiple comparisons are as shown, it is possible to say that group C has minimum mean, and there is no clear ranking between group B and group E: they are in the indifference zone. Similar conclusions can be drawn for ranks of other groups as well. For example, in this case, no clear maximum could be established by the amount of available data.

However, the multiple comparisons just mentioned are oversimplification because the question in selection is identifying the maximum irrespective of statistical significance [3]. Multiple comparisons unnecessarily increase the required sample size. Thus, alternative and more robust procedures are used that consider the minimum specified difference between the "best" and the second best. These are classified as subset selection procedures and

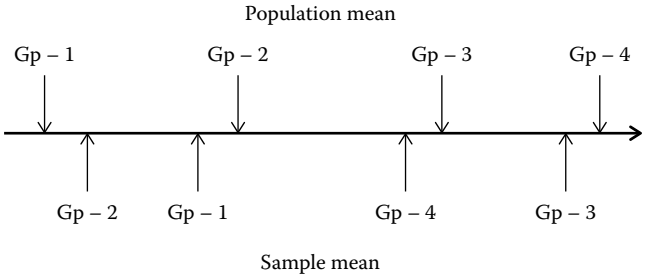

**FIGURE R.4** Order of sample means and population means in four groups.

indifference-zone selection procedures. For details, see Gupta and Panchapakesan [4].

Cui et al. [5] provide a good example of microarray experiments where the interest was in a set of genes with the largest difference in gene expression under different methods—not just in significant genes. Thus, the method of ranking and selection was required for this problem.

## ranks

These are the relative positions of the observation in a sample with respect to their value. The most obvious example can be found in sports: first, second, and third. Similarly, the positions in the examination results are another example. As shortly spelled, such rankings are not rare in medical setup—thus, the idea behind them should be clear. Suppose there is a database that includes some extreme values that would bias the arithmetic mean of these values. The way forward is to rank the data and then use the median to get an idea of the "middle" data point. In addition, for medical measurements that defy exact quantitative measurement or are too expensive or inconvenient, ranks are easy portal for valid inference. It is easier to assess that body burns are extensive than to say that these are 88%. All ordinal measurements are ranks, and these are quite common in medical setups.

Statistical application of ranks is extensive for **nonparametric methods**. Quantitative values are assigned rank after ordering them from minimum to maximum. Consider the following values of fasting blood glucose level (mg/dL) of 12 subjects attending a diabetes clinic:

117, 124, 148, 208, 169, 209, 124, 110, 115, 124, 169, 151.

This would have ranks as in Table R.5 after arranging from the maximum to the minimum.

*Ties* are values that are quantitatively the same and given the same ranks. There are three persons with a value of 124. If they are distinct, they would get ranks 4, 5, and 6. But now because of the tie, they get a rank of 5.0 each. Rank 5.0 is the average of their supposed ranks of 4, 5, and 6. Next rank would be 7. Similarly, two persons with a value of 169 each get the rank of 9.5, which is the average of their supposed rank of 9 and 10. While using nonparametric methods based on ranks, special adjustment is made for such ties.

Realize that the maximum value in our example is 209. Had it been 221, the rank would still be the same. Similarly, the value 148 will continue to get rank 7 even if it is 150, and the value 117 will continue to get rank 3 even if it is 123. Thus, the ranks do lose some information, and this is what makes ranks-based nonparametric methods less efficient in many applications.

## rapid assessment method, *see* cluster sampling

## Rasch analysis

Georg Rasch was a Danish statistician known mostly for the development of a class of measurement models now known as Rasch models. These models are used for analyzing the ability of a test, such as a questionnaire, to measure what it intends to measure. The objective of the Rasch analysis (RA) is that the total score of any test measures the target ability of the subjects and nothing else. That is, the questionnaire or any such test should not be affected by the person's age, sex, or any such characteristics not of interest. For example, the questionnaire should be such that two physicians assessing severity of disease in a patient come up with the same answer.

Georg Rasch

The purpose of RA is to increase the chance of a more able person correctly answering any item compared with a less able person, and to increase the chance of getting a more difficult item correct by a more able person compared with a less able person. In this process, some items of questionnaire may be recalibrated. The procedure has limitations, however, as it depends on who and how many respondents attempt different items. Also, it generally assumes that all items have equal correlation with the latent trait intended to be assessed. RA also helps in reducing redundancy in the items of the questionnaire to yield a more valid and simple questionnaire without sacrificing the requisite information.

The principle that RA follows is that the questionnaire should fit the Rasch model instead of the usual in which the model

**TABLE R.5**
**Ranks of 12 Values of Fasting Blood Glucose Level**

| Value | 110 | 115 | 117 | 124 | 124 | 124 | 148 | 151 | 169 | 169 | 208 | 209 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Rank | 1 | 2 | 3 | 5.0 | 5.0 | 5.0 | 7 | 8 | 9.5 | 9.5 | 11 | 12 |

should fit the data. Rasch is a predetermined model. If the fit is not good, the questionnaire is changed. The reason is that Rasch modeling is seen as the most rational way for measuring ability or trait in a linear and continuous way. It follows the principle that a more able person has a higher chance of correctly responding to more difficult items. Thus, the probability of the correct response solely depends on the person's ability and the difficulty level of an item.

The fit statistics obtained from RA indicate whether to delete, rescore, or reword an item. Answers to items may be ordinal, such as extremely dissatisfied to extremely satisfied, but RA transforms this to exact quantitative measures that can be used for more exact statistical analysis. When properly done on an adequate sample, RA provides a valid measure that can be extrapolated to its population.

General statistical software packages may not have the provision to do RA, and special software packages for this purpose may have to be accessed. This analysis flags the items that do not fit the model. Perhaps no set of items can exactly fit the Rasch model, and the items that do not fit are dropped or modified. Calculations such as mean square fit are used to find out whether the items fit the model or not. This measure is independent of the sample size, whereas the statistical tests of significance are intimately dependent. Those items with mean square fit between, say, 0.7 and 1.3 are considered adequate. A lower value indicates that the item is undesirably correlated with extraneous characteristics, whereas a higher value indicates that the item is too unreliable.

da Rocha et al. [1] give further information on RA. They aimed to present the main characteristics of RA in the context of patient-reported outcomes in psychiatry as follows, using as an example depressive symptoms, measured by using the Beck Depression Inventory (BDI). In fitting data to the Rasch model, the authors aimed to demonstrate the structural validity of the BDI scale. They also illustrate how RA can inform on how best to use scales: the meaning of the numbers therein; the latent traits that such numbers represent; and how best statistical operations could be used to analyze them. They illustrate how fitting data to the Rasch model has become the measurement gold standard for patient-reported outcomes in general and, more specifically, how it facilitates a quality improvement of outcome instruments in the field of psychiatry.

For further details on RA, see Bond and Fox [2].

## rate

Rate is a measure of the frequency of occurrence of a phenomenon. It counts the number of events occurring in a specific period per unit of time. Time is an essential element of this concept—per day, per month, per year, etc. *Since this frequency can change over time, rate is time specific.* If 8 deaths occurred per 1000 population in a particular year, this becomes the death rate for that year. If, on average, 2 new cases of cirrhosis appeared per 1000 population in the year 2012 in an area, we call it the incidence rate per 1000 for that year. When the variation from time to time is not large, the reference to the point in time can be omitted. If the death rate from accidents remains fairly constant at about 14 per million population per year after year in an area, a general statement can be made without mentioning any particular year. But new discoveries and advances in technology can alter any rate even when the ground situation remains the same. Thus, exercise caution in comparing rates over time.

Essential components of a rate are (i) a numerator, (ii) a denominator, (iii) a specification of duration, and (iv) a multiplier such as percent or per thousand. The multiplier helps to convert an awkward-looking fraction to a convenient and nice number. The denominator is generally the number of subjects in the group *at risk* for the events counted in the numerator. Measures such as birth rate per thousand are exceptions because the children born are not part of the entire population, and yet it is called a rate. Since the essential feature of a rate is the frequency of occurrence over time, it is legitimate to call it a birth *rate*.

The main purpose of computing a rate is to be able to validly compare two or more groups, times, places, etc. The denominator is population, patients, subjects, etc., which vary periodically and geographically. Rate makes the denominator uniform and thus allows valid comparison. However, a rate is a valid tool only for stable conditions over the period for which it is calculated. If the population varies within that period, such as the beginning of the year and the end of the year, it is conventional to use the average population, say at the middle of the year. Herein lies the catch. If a city has a population of 10,000 at the beginning of the year and 6000 perish due to a severe earthquake in the month of February, the midyear population would be nearly 4000 (some would die due to routine causes and some births may take place). In that case, the death rate, when based on the midyear population, for that year would be nearly 6000 × 1000/4000 or 1500 per 1000 population, or 1.5 per person: ridiculous! This rate would be entirely different if earthquake deaths occur in the latter half of the year. This dramatic example illustrates that the midyear or average population can be fallacious if deaths, or for that matter any event for which rate is required, do not occur regularly throughout the period at nearly a uniform rate. The concept of rate is not applicable when such unusual spikes or dips occur. Also, when the duration of observation is not uniform for all the subjects, rate per **person-time** is calculated with the limitations mentioned in that topic.

Rates can be averaged so long as the denominator is the same. If the incidence rate of a disease in a vulnerable section of population is 20 per 1000 per year and in robust section is 10 per 1000 per year, the rate for both together will not be 15 unless both groups are equal. If 70% of the population is robust and 30% vulnerable, the average incidence rate is 13 per 1000 population, which is the **harmonic mean**. Similarly, if the incidence rate is 5 per 1000 per year for 2 years and 8 per 1000 per year for 5 years in the same total population, the average for 7 years is not (5 + 8)/2 = 6.5 but is 7.14 per 1000 per year. This can be checked by simple arithmetic by calculating the total number of new cases (10 + 40 = 50 cases per 1000 in 7 years).

When rate is a dependent (outcome) variable in a regression, the ordinary least squares method will not be generally applicable. Instead, use **Poisson regression**.

## rate of homogeneity, *see* design effect and the rate of homogeneity

## ratio

Generally speaking, a ratio is one quantity relative to another. It can be expressed as *a:b* or as *a/b*. In a broad sense, all rates are also

ratios because there is a numerator and a denominator. In practice, the usage of the term *ratio* is restricted to a situation in which the numerator is not a part of the denominator, nor is the denominator a part of the numerator. Both are separate and distinct entities. The ratio of white blood cells to red blood cells is 1:600. The sex ratio in a general population is computed as the number of females per 1000 males, and the dependency ratio as the number of dependents (say, of age –15 and 65+ years) in a population to the working (15–64 years) population. Doctor–population, bed–population, waist–hip, acid output basal to maximal, and albumin–globulin ratios are other examples. All these ratios have biological meaning—they do convey the state of health or disease in some sense.

"Ratio" is also encountered in the term "ratio scale." A scale is an instrument on which the characteristics are measured. Those characteristics that can be exactly measured in terms of a quantity are said to be on a metric scale. The metric scale can be further subdivided into interval and ratio scales. In an interval scale, there is no absolute zero: for example, body temperature. On the other hand, in a ratio scale, a zero point can be meaningfully designated. It is correct to say that the duration of survival of 6 years is twice as much as 3 years, and parity 3 is thrice as much as parity 1. On the other hand, body temperature rise from 100°F to 105°F cannot be called a mere 5% rise.

Among statistical ratios, the most prominent is the *F*-ratio, commonly used in the analysis of variance and regression. Factually speaking, even Student *t* is a ratio of mean and its standard error (SE) adjusted for the degrees of freedom. Odds ratio is frequently used to measure risk in retrospective studies. Relative risk used in prospective studies is also a ratio.

Ratios can rarely be averaged; therefore, be careful if you come across any average ratio or if you want to use average ratio.

## ratio estimator

This topic introduces the procedure for using auxiliary information about the population to estimate a given unknown population parameter of interest with better precision. This auxiliary information may be for a known variable to which the unknown variable of interest is related. The auxiliary information may be straightforward to measure, while measurement of the actual variable of interest might be expensive. Ratio estimator uses the ratio of auxiliary information to the sample values to provide a better estimate of the parameter of interest.

Suppose the variable of interest is *y*, which is strongly (linearly) correlated with another variable *x* through origin. The latter implies that if *x* is zero, *y* also is zero. Suppose *x* is the auxiliary variable whose even population mean $\mu_x$ is known. You observe both *x* and *y* for a random sample of *n* subjects. The usual estimate of mean of interest is $\bar{y}$. But the ratio estimate of mean of *y*:

$$\hat{\mu}_y = \frac{\bar{y}}{\bar{x}} * \mu_x \text{ if } x \text{ and } y \text{ are positively correlated, and}$$

$$\hat{\mu}_y = \frac{\bar{y}}{\mu_x} * \bar{x} \text{ if } x \text{ and } y \text{ are negatively correlated,}$$

would have far more reliability compared with $\bar{y}$ alone. Means can be replaced by totals. The higher the correlation between *x* and *y*, the more the reliability. But this comes at a cost. This estimate requires that (i) *x* is also measured along with *y* for the sample subjects, (ii) the population mean $\mu_x$ of *x* is known, and (iii) the relationship between *x* and *y* is linear through origin. Ratio estimate is used only when the first two pieces of information can be easily obtained without much effort, or when they are already available, and when the third condition holds.

The auxiliary variable (*x*) could be the baseline values, and the variable of interest (*y*) may be the values at the end point after follow-up. Baseline values may be available for all patients admitted to a clinic such as their age. This could be useful if the outcome of interest is intimately related with age. For example, lung functions after the age of 40 years are intimately related to age. Suppose you know from records that the average duration of workers exposed to pollutants in a factory is 12 years and their average total lung capacity at recruitment is 4.6 L. In a sample of 30 such workers, the average duration of exposure was found to be 10 years and their total lung capacity 4.1 L. This sample shows a decline of 0.5 L. How much is the decline on average in all the workers? Here, the duration of exposure is *x* and $\mu_x = 12$ years. In the sample, $\bar{x} = 10$ years, and the average decline in lung capacity in the sample $\bar{y} = 0.5$ L. If the decline is linearly dependent on the duration of exposure, $\bar{\mu}_y = \frac{0.5}{10} \times 12 = 0.6$ L.

This innocuous-looking procedure can mislead if the relationship between *y* and *x* is not linear and is not through origin. In our example, the relationship will not be linear if the decline in total lung capacity tends to be increasingly steep with duration of exposure. That is unlikely in this example, but keep this in mind in applications. Note that this is regression through origin since when the duration of exposure is zero, the decline in lung capacity is also zero.

Jeelani et al. [1] listed a large number of modified ratio estimators for various conditions. For example, Subramani [2] proposes a modified ratio estimator for the estimation of the population mean of the study variable when the population median of the auxiliary variable is known. The bias and mean squared error of the proposed estimator are derived and are compared with those of existing modified ratio estimators for certain known populations. Further, the author has also derived the conditions for which the proposed estimator performs better than the existing modified ratio estimators. From the numerical study, it was observed that the proposed modified ratio estimator performs better than the existing modified ratio estimators for certain known populations.

## recall lapse

A recall lapse is the genuine failure to remember when reporting past events or characteristics. This can introduce bias in a medical setup in a variety of ways.

In a **case–control study**, cases may easily recall past events since they are sick or affected, whereas controls may fail to do so. The opportunity of accurately observing the events as they unfold, as in a prospective study, is not available in a case–control study. Dependence is entirely on the reporting done by the subject or on the records. Recall lapse can occur, and the records may be incomplete,

adversely affecting the results. This is commonly seen in smoking studies where retrospective recall method is used to gather data on daily cigarette consumption [1].

Despite widespread and fairly well-known phenomenon, nothing much seems to have been studied regarding the impact of recall lapse on study findings and how to adjust it. It stands to common sense that the events far back in time would be forgotten more frequently than recent occurrences; that is, recall lapse is directly proportional to the recall gap. It also stands to reason that the events making serious impact on health will be remembered, and the mild events would lapse. Adjustment can be made in situations where the correct values can be obtained by some intensive efforts, but not otherwise.

Wang et al. [1] analyzed smoking history by recall and ecological momentary assessment that records each cigarette as it is smoked. The analysis suggests that recall lapse contributes substantially to the distribution of self-reported cigarette counts. They also found that recall lapse was more common in females than males. Thus, recall lapse can also depend on the host characteristics such as age and sex in addition to the physical features such as recall time and severity of health consequences of the event. Note that recall lapse is different from intentional misreporting. Some details of recall lapse in the context of demographic surveys have been described by Som [2].

## receiver operating characteristic (ROC) curve, *see also* *C*-statistic

This is the plot of **sensitivity** of a quantitative test versus its (1 – **specificity**) (true positive rate vs. false positive rate) for different values of the test as illustrated with an example later in this section. Receiver operating characteristic (ROC) curve is used to assess the overall validity of the test and to find the best threshold that has maximum sensitivity and specificity. It can also be used to compare the validity of two or more quantitative tests.

Medical tests such as white blood cell count for appendicitis are continuous as a range of values are obtained. Tests such as presence or absence of abdominal pain are discrete—mostly dichotomous. The ROC curve deals with medical tests that give continuous measurements and cannot be used for qualitative characteristics.

Thresholds that minimize the sum of false positives and false negatives can also be obtained by a procedure called **discriminant analysis**. This procedure is particularly useful when the number of possible categories is three or more, say cirrhosis, hepatitis, and malignancy of liver. For discriminating between two competing diagnoses, two approaches are available as discussed next. The first approach based on the sensitivity–specificity ROC curve is more popular but less valid, and the second based on **predictivities** is a new and more valid approach.

### *Sensitivity–Specificity Based ROC Curve*

Is T4 better or TSH better in discriminating between hyperthyroid and euthyroid cases? Comparison of the performance of two quantitative tests can be obtained by the area under the ROC curve. See the topic ***C*-statistic** that measures this area. Historically, the name ROC comes from signal detection developed during World War II. For details of ROC curve, see Sackett et al. [1]. A brief is given as follows.

Consider the example of many full-term births in a hospital requiring induction of labor that succeeds in most cases but fails in a few. In case the induction fails, a Cesarean is done for delivery. This involves pain, time, and money and also requires mental preparedness. It would be nice for the woman and the family as well as the attending obstetrician if they are able to anticipate a Cesarean delivery on the basis of the patient characteristics. The traditional method for this is to compute the Bishop score based on dilatation, effacement, consistency, and position. Other parameters that influence the success of induction of labor are maternal age, parity, BMI, and amniotic fluid index. Suppose a study was carried out in $n = 166$ cases with prelabor rupture of membrane to find if the duration since rupture can help in predicting the Cesarean delivery. Although the study was prospective, sensitivity and specificity were calculated for different durations of rupture. There were 36 distinct durations. The values obtained for each minimum duration are shown in Table R.6.

**TABLE R.6**
**Sensitivity and (1 – Specificity) for Cesarean Delivery at Different Duration of Rupture of Membrane**

| Duration (h) Greater Than or Equal to | Sensitivity | 1 – Specificity |
|---|---|---|
| 0.00 | 1.000 | 1.000 |
| 0.63 | 1.000 | 0.976 |
| 0.88 | 1.000 | 0.969 |

**FIGURE R.5** ROC curve of duration since rupture of membrane for Cesarean delivery.

The ROC curve obtained by plot at different cutoffs is shown in Figure R.5. The diagonal is the line of equality. A statistical software package found that the area under the curve (AUC) is $C = 0.898$ with its standard error (SE) = 0.029, and 95% CI from 0.841 to 0.956. With $C = 0.898$ out of a possible 1.0, it seems from this ROC that duration since rupture of membrane itself is a good indicator to anticipate Cesarean delivery. The best cutoff that maximizes (sensitivity + specificity) is 9.75 h. At this duration, the sensitivity is 0.74 and the specificity is 0.90 (1 – specificity = 0.10).

Although not shown in this example, the Bishop score was not found to be as good an indicator of an impending Cesarean as was duration since rupture in this example. Otherwise also, the Bishop score is subjective and nonreproducible because of higher interobserver and intraobserver variability. Our example illustrates how ROC can be effectively used for medical decisions. The example is illustrative only and should not be construed to mean that duration since rupture can be solely used to anticipate Cesarean. For this, studies in different locales are needed.

The ROC curve is useful in

- Evaluating the discriminatory ability of a test to correctly pick up known diseased and nondiseased subjects
- Comparing efficacy of two or more medical tests for assessing the same disease
- Comparing two or more observers measuring the same test (interobserver variability)
- Finding the optimal cutoff point of a quantitative test to least misclassify the diseased and nondiseased subjects.

The first of these—discriminatory ability—is assessed by sensitivity–specificity at different cutoffs as already explained, and the overall performance is measured by the area under the ROC curve. Efficacy of two or more medical tests is also compared by the AUC—better test will have a higher area. The same is used to compare two or more observers. The details of the last, namely, the optimal cutoff point, are given next.

### *Methods to Find the "Optimal" Threshold Point*

The ROC curve can help to identify a threshold that gives the highest sum of sensitivity and specificity in situations where these two are available for a large number of values. In our example, the values are on a continuous scale, but ROC can also be obtained when they are in spaced categories. The number of such categories must be at least five for the ROC curve to be adequate. In our sample, there are 36 categories.

Three criteria are used to find the optimal threshold point from the ROC curve. These are known as points on the curve closest to (0, 1), the **Youden index**, and the minimize cost criterion, respectively. The first two methods give equal weight to sensitivity and specificity and impose no ethical cost and no prevalence constraints. The third criterion considers cost, mainly the financial cost, for correct and false diagnosis, cost of discomfort to person caused by treatment, and cost of further investigation when needed. This method is rarely used in medical literature because it is difficult to estimate the respective costs and prevalence is often difficult to assess. The other two are described next.

If $s_n$ and $s_p$ denote sensitivity and specificity, respectively, the **Euclidean distance** between the point (0, 1) and any point on the ROC curve is $d = \sqrt{[(1 - S_N)^2 + (1 - S_P)^2][(1 - S_N)^2 + (1 - S_P)^2]}$. To obtain the optimal cutoff point to discriminate the disease with nondisease subject, calculate this distance for each observed cutoff point and locate the point where the distance is minimum. Most of the ROC analysis software packages calculate the sensitivity and specificity at all the observed cutoff points, allowing you to do this exercise.

The second, the Youden index [2], maximizes the vertical distance from line of equality to the point $(x, y)$. The main aim of the Youden index is to maximize the difference between true positive rate ($s_n$) and false positive rate ($1 - s_p$), and a little algebra yields $J = \max(s_n + s_p)$. This is discussed as a separate topic.

These procedures for finding the optimal threshold are applicable when both sensitivity and specificity are equally important. If they are not, expert judgment may be required to find an appropriate cutoff depending upon whether sensitivity or specificity is more important.

For details of the area under the ROC curve and how this is used for inference, see the topic ***C*-statistic**. A word of caution is in order. Nothing is impossible, but it is extremely unlikely in health and medicine that you get area under ROC = 1. But the question has tremendous significance. Sometimes the sample values are such that they give you an area nearly equal to 1. This is more common with small samples where it is most likely a case of overfitting. If you get an area nearly equal to 1 in large samples, be assured that the evidence is firmly for an excellent test.

### *Predictivity-Based ROC Curve*

The threshold based on the conventional ROC would be valid across the population since sensitivity–specificity is not affected by prevalence of the disease. However, the diagnostic efficiency is obtained by the predictivities and not by the sensitivity–specificity, and predictivities are affected by the prevalence of the disease. Thus, the ROC curve between positive predictivity and (1 – negative predictivity) may be more useful in a local setup as it takes prevalence into account and uses the right kind of indicators.

When predictivities are not known, the relationship between predictivities and sensitivity–specificity and prevalence can be used to estimate these (see **predictivities**). These can be used to find the criterion that is best to confirm the diagnosis (i.e., maximally increase the positive predictivity) and to exclude the disease (i.e., maximally increase the negative predictivity). Consider the following example of creatine phosphokinase (CPK) in myocardial infarction (MI) to understand how this is done.

Figure R.6 is drawn for thresholds 350, 250, and 150 U/L of CPK level for detecting MI assuming that (sensitivity, specificity)

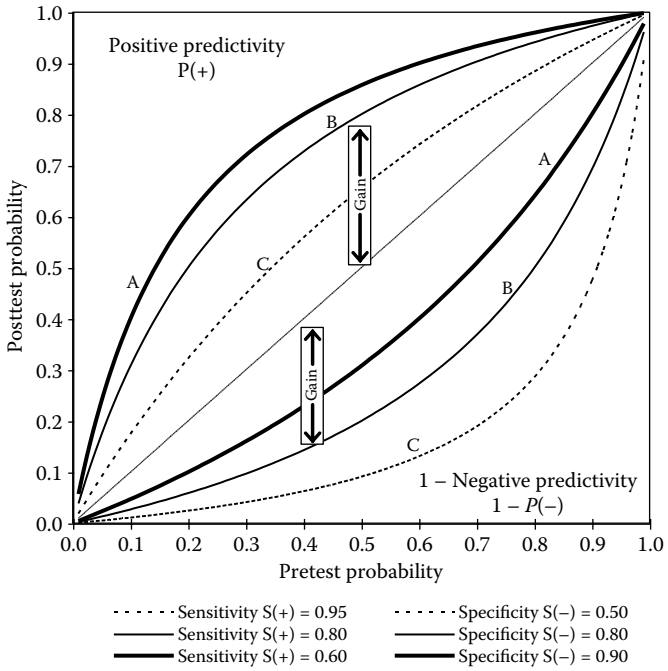

**FIGURE R.6** Illustration of the relationship between pretest and posttest probability of presence of disease (positive predictivity) and absence of disease (negative predictivity).

for these thresholds, respectively, are (0.60, 0.90), (0.80, 0.80), and (0.95, 0.50). Shown are positive predictivity on the upper left side of the diagonal and (1 – negative predictivity) on the lower right side of the diagonal for different prevalences (pretest probability). Thus, this is a predictivity counterpart of the ROC curve. The curves are marked as A, B, and C for the three pairs of sensitivity–specificity levels, respectively, corresponding to the three CPK levels under consideration. When sensitivity and specificity are equal, the curves are symmetrical as illustrated by curve B in this figure. Depending on the pretest probability for the patient in hand, which could be either the known prevalence of infarction in these types of cases or the **personal probability** on the basis of history and signs and symptoms, and the CPK level present, you can immediately obtain the posttest probability (or predictivity) of the presence of infarction with such curves.

If the chance of infarction in a patient with specific signs and symptoms is 60% (pretest probability 0.60) and the CPK level is found to be 150 U/L, then curve C applies and the posttest probability of MI can be read as 0.70. This is a gain of merely 10% over pretest probability. If the CPK level is 350 U/L, then curve A applies and the posttest probability is 90%—a handsome gain of 30% over the pretest probability for the presence of the disease. These gains can be utilized to find a threshold CPK level that is best in the sense of highest gain over a particular pretest probability. Now, note the following.

All the discussion of the sensitivity–specificity and predictivities assumes that these can be exactly obtained. In practice, these will be based on the study of a sample and are subject to sampling error. Similar variation is also expected in the prevalence rate, and this too will be generally based on a sample. Thus, caution should always be exercised in interpretation of the predictivities. Even when a pretest probability is based on the clinician's belief concerning the presence of disease after taking the history and examination into consideration, it would most likely vary from clinician to clinician. Thus, the values of sensitivity–specificity and predictivities serve only as guidelines and do not have much utility in an absolute sense. The ultimate decision, as always, rests with the attending clinician and with whether to give credence to such indicators.

## record linkage, *see also* medical records

Where you have two or more records on any given patient for the same or disparate disease, record linkage is a method of assembling the information contained therein such that the same individual is counted only once and the record is comprehensive. This also helps in removing duplicates and for confirming one source with another. Knies et al. [1] provide a good example of record linkage for community-level surveys.

When unique identifiers are present, the linkage is immediate and causes no further challenge. This is called exact matching. Records of the patients for laboratory investigations, radiological examinations, clinics, and wards are linked with this identifier. If this comes up automatically through computer databases, as in most countries around the world, the linkage is easy. In a setup where unique identifiers are entered manually, the probability of wrong punch is not ruled out.

The process of record linkage becomes challenging in setups where there are no such unique identifiers. This can happen when trying to link birth and death registration records with hospital records or with census records, or while linking one hospital record with health center records. In such cases, vital characteristics of the persons are matched. For example, the name in one record may be Mark JH and in another record as Jay H Mark, and there might be two or more persons with the same name even when the parents' names are matched. Information such as dates of hospitalization and diagnosis are checked with the corresponding information in the other record, besides age and sex. Such matching may have a chance of error and is called statistical matching. In this case, the first step is to frame the rules regarding the characteristics to be exactly matched so as to minimize the chance of mislinkage and the characteristics for which flexibility is allowed. The linkage is done in the second step.

## records (medical), *see* medical records

## reestimation of sample size

This is encountered in **adaptive designs** of clinical trials. Suppose after due consideration of available knowledge, you plan a trial on 1000 subjects in each arm with 1 year follow-up. After 2 months into the trial, you find from **interim appraisal** that your anticipations at the planning stage were incorrect and the trial will give you confirmatory results about efficacy (or lack of it) in just 6 months

(or that you need to extend it to 16 months to get the adequate number with the desired end point); or only 700 subjects would suffice (or 1500 would be needed); or that doses you are trying are too high (or too low) and you need to have a middling dose; or that a concomitant treatment is needed; or that a particular subgroup such as males of age 70+ years needs to be excluded. Sometimes even the baseline information on the enrolled subjects may indicate that modifications in the design are needed. Such questions specially occur in a **group sequential design**.

Among various adaptations just listed, the statistically most relevant is the reestimation of the sample size on the basis of the actual **effect size** found at interim stages. Reestimation requires intricate statistical inputs as this is done to preserve the planned **level of significance** and the statistical **power** for detecting a specified effect. Such adaptation does not cause much of ethical problems; rather it seems to enhance ethics by keeping provision to stop the trial early in case convincing evidence of efficacy or of futility appears. Although the general perception is that sample size reestimation can increase or not increase but can never decrease (except in the case of stopping for futility), there is no statistical justification for regulators to consider this. If a trial is inappropriately curtailed and consequently fails to get a significant result, the loss is of the trialist and not of the regulatory authorities. Thus, the authorities may be unconcerned about reduction in sample size—their concern is that the trial remains fairly powered and the **Type I error** remains under control. Reduced sample size is more of a concern for ethics committees who may worry about wastage of efforts and unnecessary exposure to the patients if the reduced size does not produce convincing results.

McClure et al. [1] give an example of how all this works in practice. The authors point out that sample size estimation at the time of planning is often based on educated guess of the parameter values, and that these may in fact prove to be overestimates or underestimates. For example, after the study is started, the published data may indicate that the recurrent stroke rates might be lower than initially planned for the study. Failure to account for this could result in an underpowered study. The researchers may perform a sample size reestimation and evaluate different scenarios based on the reestimated overall event rate, including increasing the sample size and increasing the follow-up time, and determine their impact on both the Type I error and the power to detect the initially planned treatment difference. They illustrated that by increasing the sample size from 2500 to 3000 and by following the patients for 1 year after the end of recruitment, they would be able to maintain the planned Type I error rate and also increase the power of the study.

As another example, consider a trial planned on 330 subjects in each group, where this sample size is based on the efficacy of 70% and the power 80% to detect an effect (difference in efficacy) of 10%. After conducting the trial on 200 subjects in each group, suppose you find that the efficacy is just 40%. If that were so, the power with a sample size 330 would be only 73% for detecting a difference of 10% in efficacy. If the power 80% is to be retained, the sample size must be increased. The answer to "how much increase" comes from sample size reestimation. Important features of this procedure are given next for quantitative outcome with a **Gaussian** (normal) **distribution**.

Let the number of subjects already assessed at interim appraisal stage be $n_1$ in each group. Obtain the sample means ($\bar{y}_1$, $\bar{y}_2$) and the sample standard deviations (SDs) ($s_1$, $s_2$) for two groups in the trial. Since they would be generally required to have a common SD, a pooled estimate of $\sigma^2$ is $s_p^2 = \left(s_1^2 + s_2^2\right)/2$. The difference that this sample would be able to detect is $t_{(2n_1-2)}\sqrt{2s_p^2/n_1}$. If the difference you planned to detect is more than this, the sample size $n_1$ is already adequate, and there is no need to go any further. If not, additional subjects are included such that the final sample size $n$ per groups is at least as much as $t^2_{(2n_1-2)}\left(2s_p^2/d^2\right)$, where $d$ is the minimum medically relevant difference that you propose to detect [1]. This will ensure the power originally planned and the probability of Type I error not exceeding prefixed $\alpha$. This procedure requires that the trial is unblinded. If blinding is important, this exercise is done by a third group such as the **Data Safety and Monitoring Board** (DSMB). Gould and Shih [2] have developed a procedure that obviates the need to break the codes.

Bowden and Mander [3] have provided an example of a trial comparing medical treatment of knee osteoarthritis with surgery to relieve the pain. There were doubts about the effect size likely to be seen in the RCT context. Thus, a trial with interim analysis was planned. They followed a different and more complex procedure of sample size reestimation, but the interim analysis after 50 patients in each arm was revised to include 140 per arm—an addition of 90 patients per arm to meet the power requirement and to keep the Type I error within the specified threshold.

We have presented an overly simplified version of the complex topic. For further details of sample size reestimation, see Shih [4].

## reference category

A reference category is one that is used as the baseline for comparison with other categories. In a case–control study, the control group is the reference against which the performance of the case group is studied. It is generally the normative category. The concept of reference category is commonly used in **logistic regression**. When logistic coefficients are available, the corresponding **odds ratio (OR)** relative to a reference can be immediately computed. It is this property of the logistic regression that has made this method so popular. The category coded as $x = 0$ serves as the reference, and $e^b$ is the ratio of odds for category $x = 1$ relative to the reference category where $b$ is the logistic coefficient. For example, if $b = 1.3$ for a positive family history in case of breast cancer, OR = $e^{1.3} = 3.67$. This means that the odds of breast cancer in those with a positive family history are 3.67 times the odds in those without a positive family history.

For real nominal categories, suitable **contrasts** of interest or **indicator variables** define reference category. These contrasts are generally defined in terms of the difference of one group from one or more of the others. If the objective is to examine the relationship of 5-year survival with site of malignancy, you can have one particular site, say lung, as the reference category and compare this with oral, prostate, esophagus, etc. This can be done either by forming contrasts such as (lung—oral), (lung—prostate), etc., or by coding. In the case of coding, the computer package may have to be

told that these are categorical; else use the indicator variables. If you consider it more appropriate, you can have "prostate cancer" as the reference category. In this case, all other sites will be compared with this cancer. This requires coding accordingly with the help of indicator variables. The advantage with these kinds of coding is that each category will have its own logistic coefficient, and the coefficient for one category can differ from that of another category. Thus, differential effects of the categories on the response, if present relative to the reference category, will emerge. Since other categories are compared with the reference, the conclusions are more reliable when the number of subjects in the reference category is reasonably larger relative to the other categories.

In some situations, such as categories of subjects with no disease, disease 1, disease 2, etc., it is obvious that the category with no disease will be the reference. But there are situations where the reference category is not obvious as in the cancer example in the preceding paragraph. While comparing males with females, any sex can serve as the reference. Similarly, for studying risk of disease in a different blood group, any blood group can serve as the reference for comparison. In the case of marital status categorized as never married, currently married, divorced/separated, or widowed, you may have to make a judicious choice.

Statistically it does not matter what the reference category is. The results are going to be the same. It is just that the proper choice of reference category makes it easier to interpret the results. When this is important, do not leave that to the "default" category of the software package. Some packages use the highest category (the one that is stated last in your data or with the highest code in case of ordinal categories) as the default reference, whereas others use the lowest. When you are leaving it to the software package, just be more careful in interpreting the results.

## registration of trials

The conventional medium for publication of clinical trial results is a peer-reviewed journal. Such publications have many merits, but they also suffer from restricted access, fixed format, and limited space. Thus, many trials, particularly those with negative findings, do not find much favor with the editors, and such trials remain obscure. Also, trials that are partially reported because of limited space can accentuate bias. It is widely recognized that researchers have an ethical obligation to make the full results of human research public, whether or not the results of the study are positive.

Several innovations have evolved to meet this need. The World Health Organization (WHO) has led an international effort to promote registration of clinical trials at the time of initiation. International Committee of Medical Journal Editors (ICMJE) has issued its own registration requirements [1]. These requirements include submission of the complete protocol that would make it obligatory not just to publish but also not to miss out any inconvenient findings. This may also enhance the quality of the trial, because the protocol has to follow a standard format, and any deviation from the protocol would have to be explained. Selective reporting and suppression of unfavorable findings can be easily detected. This also requires public sharing of the data (except confidential and proprietary information) soon after publication of the results. The data can be posted on the individual websites for public viewing.

Besides WHO and ICMJE, different countries have agencies for registering a trial. In the United States, the National Institutes of Health has International Standard Randomized Controlled Trial Number (ISRCTN) with nearly 200,000 registered trials as of 2015, half of them outside the United States. The National Health Service of the United Kingdom has Clinical Research Collaboration (UKCRC). They provide support for high-quality, efficient, effective, and sustainable clinical trials research in the United Kingdom. Indian Council of Medical Research also has a registry, and there is a Brazilian Clinical Trials Registry.

ICMJE registry is for the publication of trial results in regular journals, but Wager [2] has argued that peer review has a poor record in detecting incorrect or fabricated data: the interpretation could be subjective, and claims can be unfounded. Wager made a passionate plea for open access as advocated by the Public Library of Science (PLoS). If the results are freely accessible on publicly funded websites, the cost and delays can be reduced. Journals can publish reviews and critiques of those results, and can also provide interpretation for different audiences such as researchers, clinicians, and patients. The journals may also relax its norms and not preclude articles based on web-posted results if a researcher chooses to do so.

BioMed Central publishes a large number of open-access journals. Among these is the *Journal of Negative Results in BioMedicine*. This is in realization of the need of professionals to know about negative trials as much as for positive trials.

## regression coefficients, *see also* regression models (basics of)

Regression coefficients are the constants through which the relationship between a quantitative variable $y$ and a set of regressors ($x_1$, $x_2$,…, $x_K$) is expressed. These are best understood in a linear regression where the equation is $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_K x_K + \varepsilon$. In this equation, ($\beta_1$, $\beta_2$,…, $\beta_K$) are the regression coefficients. This can be extended to include $\beta_0$ also, which is an intercept. The sample estimates of these regression coefficients are denoted by $b_0$, $b_1$, $b_2$,…, $b_K$, respectively, and are generally obtained by the **least squares method**. This method finds those values of $b$'s that minimize the sum of square of deviations of the observed values from the regression equation. Mathematical derivation of these estimates requires matrices and their inversion, requiring the level of mathematics we are avoiding in this book. However, this is easy to explain when there is only one regressor. For this, see the topic **simple linear regression**. Also see the topic **logistic coefficients**, which also are regression coefficients albeit in logistic regression.

### *Interpretation of Regression Coefficients*

Coefficients in the case of regression for quantitative variables have a very simple interpretation. In the regression equation

$$\hat{y} = b_0 + b_1 x_1 + b_2 x_2 + \ldots + b_K x_K,$$

if $x_2$, for example, increases by unity, then $\hat{y}$ increases by $b_2$ when the other $x$'s remain the same. Thus, $b_k$ for any $k$ is the independent contribution of one unit of $x_k$ when the other $x$'s remain constant. (This in a way also explains why $x$'s should not be strongly correlated among themselves, called **multicollinearity**. If they are, it is difficult to imagine that only one varies without any change in the others.) Thus, these coefficients are "adjusted" for other $x$'s in the model. When a simple regression is obtained between $y$ and any one $x_k$ excluding the other $x$'s, the regression coefficient $b_k$ obtained is called unadjusted. The adjusted $b_k$ can be more than the unadjusted $b_k$, less than the unadjusted, or may not change, depending on how other $x$'s affect $y$.

Each regression coefficient measures the *average* contribution of the corresponding variable. The actual contribution in a subject can vary. This could be partly due to deviation from average and partly due to the influence of factors not included in the model. The attempt is to manage variations and consequent uncertainties by using statistical methods so that a valid conclusion can still be drawn. A **confidence interval (CI) for the regression coefficient** can be used for this purpose.

If the data are log-transformed, the interpretation of regression coefficients can dramatically change. See the topic **logarithmic scale/transformation** for details.

### *Statistical Significance of the Regression Coefficients*

When all specified regressors are forced into the model, then some of these may not be statistically significant and can be dropped without significantly affecting the efficiency of the model. In other words, some regression coefficients could be nearly zero. The test of $H_0$ that a particular regression coefficient is zero or not is done by using the **Student *t*-test** under some conditions such as Gaussianity, independence, and homoscedasticity. This is obtained as $t = b/\text{SE}(b)$, where SE($b$) is the standard error of $b$ and same as mentioned for its CI. Most software packages directly give $P$-values for each regression coefficient. Statistical significance is a reasonable assurance that the regression coefficient is not zero and that the corresponding regressor is indeed making some contribution in determining the value of the dependent variable.

A computer output for regression would generally also provide the $P$-value for the intercept $b_0$. But this needs to be interpreted with added caution. This $P$-value corresponds to $H_0$: Intercept = 0. This is plausible only when $y$ is expected to be zero for $x = 0$. This is not plausible, for example, when regression is between age and weight. Birth weight is the weight at age = 0 but is not expected to be zero. A zero intercept will not be of any interest except in a few special cases such as regression through origin.

### *Standardized Regression Coefficient*

A regression coefficient is called standardized when the corresponding regressor is **standardized**. This implies that in place of regressor $x_k$ in the regression equation, $x_k^* = \dfrac{x_k - \bar{x}_k}{s_k}$ is used. This standardized variable has mean 0 and variance 1 in the sample. The values of $\bar{x}_k$ and $s_k$ can be easily computed from the sample values; else the software can be asked to use standardized values in the regression. If $x_k$ is body mass index (BMI) and you have a total of $n$ subjects, $\bar{x}_k$ is the mean BMI of these $n$ subjects and $s_k$ is the standard deviation (SD). When the regressors are standardized, the dependent variable should also be standardized before running the regression. This will make the *regression through origin* with $b_0 = 0$.

Standardization removes the unit of measurement. If birth weight is measured in kilograms and if the ordinary regression coefficient, now called the metric regression coefficient, is 1.7, this would become 0.0017 when birth weight is measured in grams. There is no need to make this transformation when standardized values are used. But the interpretation of standardized regression coefficients is in terms of SD units. The second advantage of standardized regression coefficients is that they are comparable across the regressors. If one regressor is BMI and the other is calorie intake per day, it would be legitimate to conclude about which one is contributing more by comparing their standardized coefficients. This now is possible because the standardized coefficients are independent of units of measurement of the variables. Whereas this comparison would be statistically correct, the actual assessment of which regressors are more important than others would depend on their biological context. More important ones not only would have statistical significance but also would be those that are easy or less expensive to elicit and contextually relevant. The other problem with standardization is that this uses sample mean and sample SD, which themselves could be subject to large sampling fluctuation, particularly when the sample size is small. Also, mean and SD may not be valid in case the distribution is highly skewed. Quite often in a regression setup, the values of the regressors are deliberately chosen. Thus, the spacing could be quite arbitrary. This would affect the SD and correspondingly the standardized regression coefficient. The comparison of two standardized regression coefficients for assessing which one is contributing more could be jeopardized in case of arbitrary spacing of $x$'s.

Standardized regression coefficients can be obtained directly without standardizing the regressors and the dependent. It can be shown that

$$\text{standardized regression coefficient: } b_k^* = b_k * \frac{s_k}{s_y},$$

where $b_k$ is the ordinary (metric) regression coefficient, $s_k$ is the SD of $x_k$, and $s_y$ is the SD of the dependent $y$. When there is only one regressor (simple linear regression), the standardized regression coefficient is the same as the (Pearsonian) correlation coefficient.

Besides their usefulness in interpreting the importance of the regressors in explaining or predicting an outcome, regression coefficients are also sometimes utilized in developing scoring. A common and acceptable method of assigning scores to individual characteristics is based on the regression coefficients that are estimated using a multiple regression method when the outcome is quantitative. The method of assigning scores proportional to the regression coefficients is valid only when the values of the predictive factors are standardized to mean 0 and variance 1 before the regression is run. The regression coefficients, without this standardization, are not comparable and are severely affected by the unit of measurement. The method of assigning scores for qualitative dependent can be similarly based on the logistic coefficients as done for developing APACHE score.

## regression diagnostics, *see* regression fit (adequacy of), regression requirements (validation of)

## regression fit (adequacy of), *see also* regression models (basics of)

When performing regression analysis, there are a number of procedures and tools that can be used to test that the regression is as it should be: together, these are termed **regression diagnostics**. These diagnostics aim at two levels. First, check that all the requirements for fitting a regression model are adequately satisfied, and second, that the model obtained is indeed adequate or not. This section

discusses the second point. For the first, see the topic **regression requirements (validation of)**.

The most common criterion for judging adequacy of a regression fit is the proportion of total variance explained by the regression. This is named as squares of the **multiple correlation coefficient** ($R^2$) for linear regression and **coefficient of determination** ($\eta^2$) for other regressions. See these topics for details. The higher the variance a regression is able to explain, the better the regression becomes. Generally a model with $R^2$ less than 0.60 is considered not adequate, $R^2$ in the range (0.60–0.69) is considered reasonable to pursue, $R^2$ in the range (0.70–0.79) is considered as desirable, $R^2$ in the range (0.80–0.89) is considered good, and $R^2 \geq 0.90$ is excellent. Rarely ever $R^2$ will become as high as 0.90 in medical applications because of high variability among individuals. Statistical significance of $R^2$ is tested by the ***F*-test**.

The second criterion for adequacy of a regression model is its biological relevance. It should include all the characteristics as regressors that are considered important contributors to the outcome as per the current knowledge, although it may include others also that are statistically significant—biologically relevant or not in the hope that the relevance may emerge in course of time. More important is that the regression process must start with all relevant variables and nothing important is left out. For details, see the topic **regressors (choice of)**.

Not all observations involved in fitting a regression model contribute equally to the result. *Leverage* is the name given to the influence of each observation on the fitted values. While checking the validity of a model, the aim is to examine any or all observations with a high leverage. To check the effect of any such observation, refit the model without that observation and calculate what is called the *Cook distance*, which is a measure of the change that would occur in the estimated parameters in the model of interest if a particular observation were omitted. The larger the Cook distance, the more important the observation.

Further diagnostics, similar to Cook distance, are named *DFBETA and DFFIT*. DFBETA shows how much each coefficient changes in standard deviation units when an observation is excluded. The influence of any observation on the estimated mean response is measured by DFFIT. This is the number of standard deviations the *estimated mean value* moves if each observation, in turn, is excluded. Note that these are individual values and not for variables. Generally, apparent outliers are subjected to this analysis, and this can be done with the help of an appropriate software package. For variables, statistical significance as obtained by the Student *t*-test is used. For further details of DFBETA and DFFIT, see Montgomery and Peck [1].

The most popular criterion for assessing the adequacy of a regression model is the plot of the residuals of the regression. These deserve a topic of their own: refer to the topic **residuals**. If the fit is good, the residuals would be random with small variance and no outliers. Cook and Weisberg [2] have described such graphic methods for assessing the adequacy of regression models.

2. Cook RD, Weisberg S. Graphic for assessing the adequacy of regression models. *J Amer Stat Assoc* 1997;92(438):490–9. http://www.jstor.org/stable/2965698

## regression fitting (general method of), *see also* regression models (basics of)

Before the method of fitting a regression, consider the basic requirements. To obtain a regression equation (this is also called fitting a regression), the data required are the values of dependent $y$ corresponding to different values of the regressor $x$'s. For one set of values of $x$'s, one or many values of $y$ can be observed. For example, in a regression of body surface area (BSA) on age in children, you may have three children of the same age: 7 years. This is the value of $x$. Their BSAs are likely to be different. These are the values of $y$. In this case, for one $x = 7$, there are three values of $y$, one corresponding to each child. But $y$ should be available for several distinct values (at least four for the regression to be meaningful) of $x$. The values of the $x$ variables can be *deliberately* chosen to serve the purpose since they are considered fixed in a regression model.

The total number of individuals, as usual, is denoted by $n$. The number of regressors, $K$, should preferably be considerably less than the number of subjects $n$ (i.e., $K \ll n$), and the same $K$ regressors must be available for each subject in any analysis. The exact method of fitting varies according to whether $y$ is qualitative or quantitative, but the basic steps are common. For qualitative $y$, the dependent actually is the proportion of subjects with the specific quality. This gives rise to **logistic regression** and is discussed as a separate topic in this book. For quantitative $y$, generally ordinary **least squares** regression is obtained. Common steps for fitting for both ordinary and logistic regressions are as follows.

Step 1. Identify the dependent variable of interest. It should ideally be an outcome or response of the regressors. In the case of risk of lung cancer and smoking, smoking does not depend on the risk, but risk depends on smoking. Thus, risk is $y$ and smoking is $x$. In some cases, the direction of dependence may not be clear. Between cholesterol level and obesity, there could be a debate regarding which is a precursor of the other. Abnormal histology of the liver can precede cholecystitis or can follow cholecystitis. Both are admissible. In such cases, either could be investigated for its dependence on the other. Regression in these cases is just an expression of relationship and not of dependence.

Step 2. Recognize the nature of the dependent variable—that it is whether quantitative or qualitative. If quantitative, check whether it is likely to have a **Gaussian** (normal) **distribution** or a **Poisson** or any other distribution. If it is qualitative, check whether it is dichotomous or polytomous, and if polytomous whether it is ordinal or nominal. For details of these terms, see the topic **scales of measurement (statistical)**. These considerations will determine that ordinary quantitative regression is required or logistic, Poisson, or any other, and whether or not any transformation of the dependent is needed. Generally, most continuous dependents such as creatinine level and glucose level will follow a Gaussian distribution as such or after necessary transformation, small counts such as the number of family members with positive history follow a Poisson distribution, and dichotomous variables a binomial distribution.

Step 3. Identify the set of regressor variables. The number of regressors must be substantially less than the proposed sample size. The regressor set ideally should consist of all those that are known or suspected to influence the response $y$. It may not always be feasible to study all possible variables, and some selection may be necessary. Choose those that influence more than the others and those that are directly related in place of those that cause indirect influence. These should preferably be unrelated to one another, at least not intimately related. If they

are intimately related, **multicollinearity** is said to exist and can adversely affect the reliability of the regression. Regression equation will make more sense when only one of the highly correlated variables is retained. See the topic **regressors (choice of)** for further details.

Step 4. Decide the general form of relationship that you want to investigate, i.e., decide whether you want to restrict to linear regression, curvilinear regression, or a nonlinear form of regression. See the topic **regressions (types of)** for details of various types of regressions. The best guide for selecting the right type is the **scatter diagram**, particularly where there is only one regressor, and both $y$ and $x$ are quantitative. If there are many regressors, then many plots would be required: one corresponding to each regressor. Also decide if any **interaction** term is to be included. The basic function of regression analysis is to provide the best estimate of the regression coefficients once the form of regression, the dependent, and the regressors are specified. However, several forms can be explored, and the best can be objectively identified. Remember though that all regressions are compromises, and they never depict the data exactly.

Steps 1, 2, 3, and 4 together grossly specify what is called the **regression model**.

Step 5. Estimate the **regression coefficients**. This is done in such a manner that the fitted line or the curve passes closest to the points in the scatter plot. The mathematical method generally employed to obtain such regression coefficients is called the **maximum likelihood method**. This method finds those values of the regression coefficients that make our observed sample most likely to happen. The other method commonly used in regression is called the **least squares method**. For this reason, the whole method of regression with quantitative dependent is sometimes referred to as ordinary least squares. This finds a regression that is closest (least sum of the squared distances) to the points in the scatter diagram. Both these methods tend to produce an equation that *regresses* toward the mean of $y$ across different values of $x$ (see the topic **regression to the mean**). These two methods in many practical situations lead to the same estimates particularly when $y$ follows a Gaussian distribution for each set of $x$'s. Many software packages are available to perform the calculations required to estimate the regression coefficients. A feature of estimation of the regression coefficients is that some residuals are positive and others negative such that their sum is always zero. See the topic **residuals**. When the estimates of the regression coefficients are obtained, the regression model can be fully specified in view of steps 1 to 4.

Step 6. Test the goodness of fit of the obtained regression model. The method for this test depends on whether $y$ is quantitative or qualitative. See the topic **regression fit (adequacy of)**.

Step 7. The overall regression model may or may not be a good fit, but it is also important that individual regressors are tested separately for their significance. The method for testing this is also different for qualitative $y$ than for quantitative $y$. The regressors found statistically significant are considered to contribute to the relationship and are retained in the model. The "not significant" ones can be dropped without substantially affecting the utility of the model. Such deletions help to enhance the simplicity of the model, called parsimony.

Step 8. Calculate **residuals** and check for validity of requirements of the regression model. Residuals are the differences between the fitted value of $y$ and its observed value. The validity requirements are stronger for quantitative $y$ than for qualitative y. One of them is **homoscedasticity**, i.e., uniform variance of $y$ for different values of the regressors. A transformation such as the logarithm, square, and square root may be sometimes needed to meet this requirement. The other way to overcome this is to modify the method of estimation from least squares to *weighted least squares*. Also for testing or for computing confidence interval (CI), the residuals must follow nearly a Gaussian pattern in the case of the usual quantitative data. If the residuals are skewed, other distributions such as gamma, Poisson, or negative binomial are tried. These methods are intricate and not discussed in this book. A scatter plot of residuals versus each $x$ is often helpful in assessing the validity of requirements and in suggesting improvements to the model.

Sometimes a relation exists, but the regression fails to detect it. The success depends mostly on the adequate specification of the model in steps 1–4 and the sample size. Thus, failure to find a relationship through regression does not necessarily mean that no relationship exists.

One of the important functions of regression is to provide an estimate or to predict the value of $y$ for a given set of $x$'s. There is a fine distinction between an estimated value and a predicted value. The former term is generally used for the *mean* of $y$ for a group of individuals with a specific value of $(x_1, x_2,\ldots, x_K)$, and the latter is used for the value of $y$ for a single individual. The former has less variance than the latter, although both have the same value. Because the estimated and predicted values are the same, these terms are interchangeably used in this text.

Besides several topics in this book related to regression, a large number of books are available just on regression. Consult any of those in case you want more details. One among them is by Harrell [1].

1. Harrell F. *Regression Modeling Strategies: With Applications to Linear Models, Logistic and Ordinal Regression, and Survival Analysis*, Second Edition. Springer, 2015.

## regression models (basics of), *see also* regression fitting (general method of)

Regression models are the ones that depict relationship between two or more variables. Relationships are inherent in medicine and health, and it is common to investigate them in quest of new understanding. Eosinophil count normally decreases from birth to adulthood, and the risk of lung cancer increases with the amount and duration of smoking. Total leukocyte count (TLC) and hemoglobin (Hb) levels decrease up to the age of 6–8 years and show some increase thereafter in healthy subjects. Height velocity is at its peak during adolescence. Blood pressure (BP) levels have a positive relationship with the waist–hip ratio (WHR), and the incidence of dental caries in children depends negatively on the socioeconomic grade of their family. Such relationships are everyday occurrences in the practice of medicine and health, so much so that they are sometimes taken for granted. There are two primary purposes of studying such relationships: (i) to be able to predict, with some degree of precision, the value of one with the help of the others; and (ii) to help understand

the underlying mechanisms in such a relationship, particularly by studying the effect of alteration in the value of one variable when other conditions do not change. The latter can provide useful clues about what determines the outcome and how much influence each variable has.

It is known that height and weight are correlated with age in children, but visual acuity is independent of age in this group. Hb level, serum ferritin, and mean corpuscular volume are related to one another, but each is unrelated to WHR. Risk of breast cancer may be related to dietary constituents but unrelated to Hb level. But the relationship varies from person to person, and presence or absence of relationships is not absolute. Some relationships show up sometimes but vanish at other times. Variation and uncertainties play a prominent role in the presence or absence of such relationships. Some individuals or groups defy the nature and strength of relationships from the one seen in other subjects. Thus, care is needed in their use and interpretation. As always, the attempt is to identify the trend and separate it out from fluctuations. Relationship is just another term for such a trend.

What do we statistically mean by relationship? Consider the example of cholesterol level affected by obesity and hypertension. Cholesterol level is a continuous variable in this case. The degree of obesity can be measured on a continuous scale by body mass index (BMI), but it can also be divided into four groups, namely, thin, normal, overweight, and obese. Then the quantification of BMI is lost, although the gradient remains. That cholesterol is affected (or not affected) by obesity is a perfect conclusion in this case, but relation in statistical sense is the *nature or form of relationship.* Thus, this is an expression of quantitative change in one variable per unit change in the other. In the cholesterol level/obesity example, a relationship would be able to indicate how much increase in cholesterol level is expected when BMI increases from, say, 25 to 26, or from overweight to obese category. Such a form of relationship is called **regression** when the outcome is stochastic, i.e., varies from person to person. An equation such as BMI = weight/height$^2$ is not a regression equation. BMI does depend on weight and height, but it is not stochastic; it is not subject to any variation for given weight and height. Similarly, the equation for aortic valve area (AVA) in square centimeters, AVA = π*(LVOT/2)$^2$*SVTI/MVTI, where LVOT is the left ventricular outflow tract diameter (cm), SVTI is the subvascular velocity time integral (cm), and MVTI is the maximum velocity time integral across the valve (cm), is mathematical and not statistical since the dependent is not subject to any variation. The term regression is applicable only when the dependent variable is stochastic, i.e., it depends on chance.

In general, a regression model is expressed as

$$\hat{y} = f(x_1, x_2, \ldots, x_K),$$

where

$\hat{y}$ is the predicted value of the outcome or response of interest, called dependent

$f$ is some function that specifies the actual form

$x_1$, $x_2$,..., $x_K$ are the variables that may predict the variable $y$, called independents.

See the topic **dependent and independent variables** for various names and forms of these variables. Regression, in fact, is a representation of the actual relationship in the "population," but a reasonable sample helps us to get an estimate. The difference between the regression-predicted value of $y$ and the observed value of $y$ is called **residual** and is denoted by $e$, i.e., $e = (y - \hat{y})$. For the methods of this section, each value of $y$ must be independent of other values of $y$. For example, they cannot be the same measurement belonging to different sites of the same body. $K \geq 2$ variables on the right side of the regression equation make it a *multivariable* setup, although not a *multivariate* setup. As explained next, this allows us to study the "net" effect of each and joint effect of two or more independent variables on the dependent. While such a multivariable setup seems like the only feasible method to assess joint effect, net effect of each individual variable can be studied by stratified analysis also. If BMI and sex are suspected to affect cholesterol level, you can stratify by sex and study the effect of BMI separately for males and females. If BMI is in 4 categories, you need a total of 8 categories of subjects for a stratified study. If hypertension is also added as a factor and is in 3 categories (e.g., normotension, borderline, and clear hypertension), you need data in a total of 24 categories. This multiplies fast as more factors are added. On the top of this, stratified analysis requires adequate sample size in each such category. Also stratified analysis is not feasible if any of these factors is on continuous scale unless it is categorized. Multivariable setup obviates these problems.

As explained later, such a relationship in health and medicine is never exact, and the right-hand side of the regression equation provides only an estimated or predicted value of $y$. For this reason, this is denoted by $\hat{y}$. In the example just cited, cholesterol level can be denoted by $y$ and obesity and hypertension status by $x_1$ and $x_2$, respectively. In general, there can be many $x$ variables. The interest actually may be in change in $y$ for change in one particular $x_k$, but other $x$'s that may influence $y$ are also kept in the regression so that the adjusted effect or independent effect of $x_k$ can be studied. Other $x$'s are called **concomitant** or **confounding** variables. For example, in a study on change in triglyceride levels with age in children, the possible concomitant variables are BMI, fat intake, insulin level, physical activity, etc. In some situations, the interest may be in the independent effect of each of these $x$'s instead of any particular $x_k$.

Conceptually, regression requires observation of several values of $y$ for each value of $x$. For example, for regression of diastolic BP ($y$) on age ($x$), you should have, say, 10 individuals of age 20 years, 15 of age 21 years, 6 of age 25 years, 12 of age 28 years, etc. These should be random samples from the population of subjects of different ages. Essentially, *mean* diastolic BP for each age is used to obtain the regression.

Regression seeks a trend in *means* of $y$ at different values of $x$. This is illustrated for linear regression in Figure R.7, where the distribution of $y$ for each $x$ is Gaussian. There are only four values of $x$ in this figure, but generally there are many. Regression is the best fit to the means. This may not pass through all the means even when population means are considered and can definitely happen in the case of sample means. For regression of diastolic BP on age, supposing the average diastolic BP in a sample of males of age 30 years is 79.5 mmHg, in males of age 40 years is 82.7, in males of age 50 years is 85.2, etc., then the *trend* is DiasBP = 71.0 + 0.3(age).

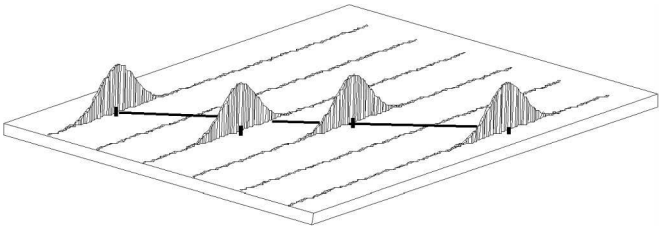

**FIGURE R.7** Conceptual framework of distribution of $y$ for each $x$ in a linear regression setup.

The level expected from the trend could differ from the observed means. The second component of residuals arises from the difference of the trend from the observed means.

There are several types of regression: linear, curvilinear, or nonlinear, depending upon the shape of its graph as explained under the topic **regression (types of)**. It could be quantitative (ordinary least squares), **logistic**, **Cox**, **Poisson**, or any other type depending upon the nature of the dependent variable. If the number of independent variable is just one, it is called simple, and in case of more than one independent variable, it is called multiple. See the topics **simple linear regression** and **multiple linear regression**, both of which are restricted to linear models. When the dependent is more than one for simultaneous consideration, it is called **multivariate regression**.

Irrespective of the type of regression, all regressions are only an expression of the nature of a statistical relationship as revealed by a set of data. They merely indicate how the dependent variable generally behaves when the independent variables change in value. This relationship is not necessarily causal and could be entirely incidental.

## regression requirements (validation of), *see also* logistic regression (requirements for)

So long as there is a measurement ($y$), called dependent, that is suspected to be determined or associated with another set of measurements ($x$'s), called independents or the regressors, and the interest is in studying their relationship, regression is always the model that can be used. There is no further underlying requirement. The question of requirement arises when you want to know whether this is an adequate model or not, practically useful or not, serves the purpose or not, etc. The whole exercise of fitting a regression can be a waste of effort and can even mislead unless its underlying requirements are satisfied. These requirements are different for different types of data and different types of regression, but all these may ultimately come down to the sample size, choice of the regression model, and the choice of the regressors besides Gaussian pattern, independence, and homoscedasticity of the dependent variable. All these together come under the generic of **regression diagnostics**, although this also contains methods to check that the regression is adequately fit or not.

Assuming that the sample of subjects is representative of the target population and is preferably randomly chosen, the first requirement is a large-enough sample size so that the results are valid and reliable. A rule of thumb floating around is that there must be at least 10 observations per regressor; if there are 5 regressors, $n$ must be at least 50. This rule seems more valid for **logistic regression** with an additional constraint that it is the limiting size—applicable to the rarest combination of the regressors. For quantitative regression, where the regressors are also quantitative, this requirement is not as strict as it is for logistic. Our experience suggests that as the number of regressors increases, the sample size requirement progressively declines. For 10 regressors, instead of a minimum of $n = 100$, perhaps a sample size of 80 would provide fairly reliable estimates of the regression coefficients. However, if the interest is in statistical power to detect a certain correlation, the sample size requirement can be higher. As always for sample size, the larger is better.

The choice of regression model depends mostly on the type of the dependent variable. A separate section on the topic **regression (types of)** provides details of what type of regression can be used in which situation. For example, there are conditions where curvilinear or nonlinear is more adequate than linear, where multiple is more adequate than simple, and where logistic, Cox, Poisson, or other regressions are more adequate than ordinary least squares.

Choice of **regressors** is also discussed separately. This has focus on the issues such as **multicollinearity** and the number of regressors, particularly in view of size of sample on one hand and parsimony of the model on the other.

### *Gaussian Pattern, Independence, and Homoscedasticity*

Whereas the method of **least squares** for fitting a quantitative regression is nonparametric and does not require any specific pattern of $y$ values, it works well only when there are no outliers. Real requirements come when trying to obtain confidence intervals (CIs) and for testing statistical significance. These procedures ordinarily require that the residuals follow a Gaussian distribution. They also require that the values of $y$ are independent of one another (except when **generalized estimating equations** are used), and the distribution of $y$ for various sets of values of $x$'s has the same variance, called **homoscedasticity**.

Independence of residuals can be violated in a case such as a time series where the value of $y$ depends serially on its value on the previous occasion. Such **autocorrelation** can occur because the time effect by itself may not be able to take care of other factors that may be simultaneously changing, such as population size and technological development. The effect of these changes spills into the residuals and causes autocorrelation. In this case, the residual plot may track snakily or follow some other pattern. The **Durbin–Watson test** is used to detect any such correlation.

**Homoscedasticity** can be checked by a scatter plot of residuals for different values of $x$. A random pattern is an indication of uniformity of variance. If the spread of residuals is found to follow a discernible pattern, a **transformation** such as the logarithm, inverse, square, or square root may help. Calculation for regression coefficients and for their significance will have to be done all over again after such a transformation.

Gaussian pattern is a requirement for finding the CIs and the test of hypotheses on the regression coefficients. This requirement is actually for the values of $y$ for each set of the values of $x$'s but is best examined for residuals because then there is no need to consider values at different values of $x$'s and all residuals can be combined. Residuals must exhibit a random pattern. As discussed under the topic **residuals**, any special or identifiable pattern in residuals can either be in the variability or in the values themselves or in both. Also there might be identifiable outliers that need to be closely examined, and excluded if found to be erroneous values. Groups of apparent outliers indicate that an important covariate is missing from the regression model. No observation should be dropped unless there is good nonstatistical evidence that the observations should be excluded. Note that if you delete valid data with large residuals, this will artificially improve the model fit, leading to a false impression of the precision of the parameter estimates.

Let us reemphasize that Gaussian pattern, independence, and homoscedasticity are requirements for a valid test of statistical significance but not for estimating the regression coefficients. These estimates can still be obtained by the method of least squares and interpreted in the usual way. But the coefficients so obtained lack credibility if the requirements are violated. For example, they may not be unbiased or may have inflated variance that makes them less reliable. Also, the practical utility of the model is greatly diminished if one is not able to test its statistical significance, and this can happen if the requirements are violated.

An example where all the common requirements of a regression model are violated arises when studying coronary artery

calcification (CAC). The amount of CAC helps in predicting future risk of coronary artery disease (CAD) morbidity and mortality. The distribution of CAC would contain a high relative frequency of zeroes and would be highly skewed. Even logarithmic transformation [ln(CAC + 1)] does not help. (To get an interpretable logarithm, 1 is added, since log of zero is $-\infty$.) Also, the variance of the quantity of CAC increases with age. If it is measured at multiple locations in the same subject, the independence is also lost. This will continue to be so for residuals too. In a situation like this, a complex model, namely, the generalized estimating equations, may be appropriate.

With some experience, you can reasonably judge the validity of these requirements by examining the process of generation of the data and by looking at the patterns in the data. Transformation, if needed, can be incorporated into the model itself. For further details, see Montgomery and Peck [1].

## regression splines, *see* spline regression

## regression to the mean

This phenomenon was first noted by Galton [1] in 1886 when he observed that *each peculiarity in man is shared by his kinsmen, but on the average to a less degree*. With regard to height, for example, tall parents will tend to produce tall offspring, but these, on average, will be relatively shorter than their parents. Similarly, short-statured parents will have children who are relatively taller. The term is now in general usage for the phenomenon that a variable that has an extreme value on its first measurement will tend to be closer to the center of the distribution in a subsequent measurement. For example, in a screening program for hypertension, persons with high blood pressure (BP) are asked to return for a second BP measurement. On the average, the second measure taken will be lesser than the first. This also explains why the term "regression" is used, which literally means "going back."

Regression to the mean can result in reduced BP in those who have a high level even without treatment. This may seem like people with higher BP benefitting more than those with lower BP. Thus, the difference between pre- and post-treatment values cannot be taken on its face value. This highlights a limitation of **before–after studies**. In place of difference, if the data are analyzed by using baseline values as a covariate, the effect of regression to the mean would ameliorate to a great extent.

Wilcox et al. [2] have reported regression to the mean phenomenon for birth weight, and Kario et al. [3] for BP. This can happen in any situation where repeat measurements are taken, but is not necessary to happen. The hypothesis behind this phenomenon is that nature tries to settle down to its normal course when upheavals occur. For details, see Morton and Torgerson [4].

It should be clear that regression to the mean is more pronounced with extreme values as they subsequently try to catch up with the mean. If a regimen produces excellent effect in one patient, be prepared to accept that it may not be so in another patient due to the regression to the mean effect. Given a chance, the same patient may also not replicate the effect. If the performance is consistently high, you are confident that the regimen is good. An initial high value and the subsequent moderation can be due to regression to the mean effect and not due to the treatment. This is a ubiquitous phenomenon and should always be considered as a possible cause of the observed change.

A statistical explanation is not far to seek. Bland and Altman [5,6] have explained it well. The slope in simple linear regression of $y$ on $x$ is computed as $\rho\frac{\sigma_y}{\sigma_x}$, where $\rho$ is the correlation coefficient between $y$ and $x$, and $\sigma_x$, $\sigma_y$ are the respective standard deviations (SDs). Thus, change of one SD in $x$ affects change of $\rho$*SD in $y$ on average. Since $\rho \le 1$, $y$ is closer to its mean than $x$ is. This would not be so when $\rho = 1$: an almost impossible value in a medical setup. They have given examples of comparison of two methods of measurement and of publication bias where regression to the mean can spoil the relationship. Also, see the article by Barnett et al. [7].

## regression trees, *see* classification and regression trees

## regressions (types of)

Among various types of ordinary least squares regressions are linear, curvilinear, nonlinear, and asymptotic, as well as simple and multiple. Among several other types are logistic, Poisson, and Cox regressions. There are several others as listed at the end of this section. This section provides an overview—specific types are discussed separately under the relevant topic.

### *Linear, Curvilinear, and Nonlinear Regressions*

Although most regressions used in practice are linear, the utility of curvilinear and nonlinear regressions in health and medicine has been increasingly realized. An understanding of the distinction between these types of regressions is important.

For $K$ regressors, the regression

$$\hat{y} = b_0 + b_1x_1 + b_2x_2 + \cdots + b_Kx_K.$$

is called linear since it is linear in the coefficients $b_1$, $b_2$, …, $b_K$. Geometrically, this equation defines a hyperplane in the $(K + 1)$-dimensional space and reduces to a line in two dimensions (length and breadth) when $K = 1$. When there is only one independent variable $x_1$, the regression equation is $\hat{y} = b_0 + b_1x_1$, which depicts a line. It is more convenient to write it as $\hat{y} = a + bx$. This

is the equation for **simple linear regression**. When the number of regressors is more than one, this is called **multiple linear regression**. See these topics for details.

The constants $b_1$, $b_2$,…, $b_K$ in the regression equation are called **regression coefficients**, and $b_0$ is called the **intercept**. These, in fact, are estimates of actual regression coefficients in the target population. The corresponding regression parameters in the population are denoted by $\beta_0$, $\beta_1$, $\beta_2$, …, $\beta_K$, respectively.

Curvilinear regressions are those where the regression coefficients are linear but the regressors are not. They may be square, log, reciprocal, or other types. Graphically, they show curves instead of line or plane. For further details, see the topic **curvilinear regression**. A good example of a curvilinear relationship is that between diastolic BP and age in female adults in a general urban population in India [3]. (The regression for males was linear.) The regression obtained for females is

$$\hat{y} = 58.18 + 1.668t - 0.0453t^2 + 0.000439t^3,$$

where $\hat{y}$ denotes estimated diastolic BP in mmHg and $t$ is age in years up to 60 years. The shape is as shown in Figure R.8.

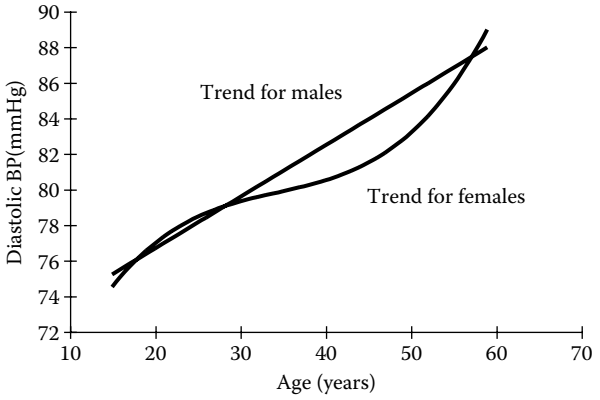

**FIGURE R.8** Diastolic BP in relation to age in adult males and females.

This is a curve but can be considered linear in $x_1 = t$, $x_2 = t^2$, and $x_3 = t^3$. Each power of $t$ can be regarded as a separate regressor. The regression thus is intrinsically linear. For this reason, such a regression is called curvilinear. *All polynomials are curvilinear.* The above equation is a polynomial of degree 3. The exponential growth curve $y = ae^{bx}$, seen in multiplication of organisms when not interrupted as in a laboratory (Figure R.9a), is apparently nonlinear but is intrinsically linear. In this case, $\ln(y) = \ln(a) + bx$, which takes the form $z = b_0 + bx$ where $z = \ln(y)$ and $b_0 = \ln(a)$. This is then a straight line but is between $\ln(y)$ and $x$. There are several other forms of the equation that are intrinsically linear. An example of another type of curvilinear relationship is that between increase in the Hb level in anemic women (say, less than 8 g/dL) and duration of iron supplementation (Figure R.9b). The initial increase is high but soon levels off. This can be represented by $y = a - be^{-cx}$, where $x$ is the duration of supplementation and $y$ is the Hb level. This is called **asymptotic regression** and is linear between $y$ and $z = e^{-cx}$.

Certain relationships are genuinely nonlinear in parameters and cannot be reduced to a linear form. A popular example is the relationship between height and weight in children represented by a growth chart. This possibly is so complex that it cannot be expressed by an equation and can be depicted only graphically. The other example is the equation

$$y = a/(1 + be^{ct}),$$

which represents a population growth model where $t$ is the time or the year (Figure R.9c). There are three parameters, $a$, $b$, and $c$, in this model. No transformation of variables $y$ and $t$ can reduce this equation to a linear form. Thus, this is a genuine nonlinear relation. The other nonlinear form is cyclic such as between estrogen levels in menstrual cycle (Figure R.9d). See the topic **nonlinear regression** for more details.

Despite all-round advancements, statistical software packages have still not given the intelligence to choose an appropriate form of regression. The user must specify the broad shape. The software finds only the best coefficients that would make the specified shape closest to the scatter. The shape of regression is decided by the following considerations.

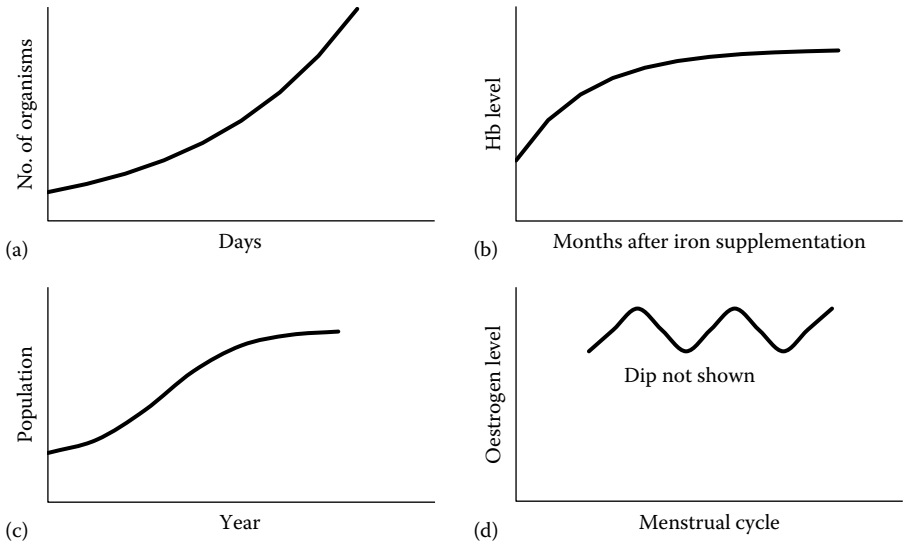

**FIGURE R.9** Some examples of curvilinear and nonlinear relationship: (a) multiplication of organisms over time (exponential curve); (b) rise in hemoglobin level after iron supplementation (asymptotic curve); (c) population growth curve; and (d) estrogen level in menstrual cycle (cyclic curve).

- Start from the simple linear regression with the most prominent factor as the only regressor. Simple linear is easy to understand and easy to explain. Check if (i) the value of the **multiple correlation coefficient** $R^2$ is reasonably high, (ii) the regression is close to the scatter, (iii) the residuals are random with small variance, and (iv) the relationship is biologically explainable. If satisfied on all these three counts, you are done. These three remain cardinal indicators for judging the adequacy of any regression.
- If simple linear regression is inadequate, examine the scatter closely for any specific pattern. It could be parabolic, cyclical, exponential, or any other. Such patterns can be fitted by using terms such as square, cube, reciprocal, and logarithm of the regressor variable. For cyclical factors such as estrogen level in women of reproductive age, try the sine function. If needed, approach a statistician to identify the form of regression for investigation.
- If the outcome measurement looks appreciably affected by two or more factors, consider multiple linear regression. Include as regressors only those factors that can really affect the outcome and are relatively independent of each other (no **multicollinearity**). If there are many candidates, use the **stepwise method** to select a few significant ones. Do not forget to consider interaction—for this, use the product (multiplication) of the variables that you think can interact.
- If multiple linear regression also does not give satisfactory results in terms of the four cardinal indicators listed earlier, try multiple nonlinear regression. But this can become too complex to explain, and the parsimony is lost. Weigh the cost–benefit of this exercise. Sometimes it is worth spending time and resources on investigating a complex relationship. Perhaps many relationships are complex, and many researchers probably waste resources on exploring simple relationships where in fact the relationship is complex.
- If that also fails, conclude that either the choice of regressors was inappropriate or not enough information is available about the factors responsible for that outcome. In this situation, the first step is to do basic research and find factors that could be rightfully conjectured as explanatory of the outcome.

Note also that choosing a form of regression implies that you know enough regarding which form is appropriate. Quite often the mechanics of how predictors affect the outcome are not known. In this situation, various forms are tried in the hope that one of these would fit the data, and then a biological explanation is sought for that kind of relationship. If the likely form of relationship as indicated by biological processes is known or can be conjectured, try to obtain a regression of this form. Either way, epistemic uncertainties can be prominent because both are based on the existing knowledge—and the existing knowledge can be inadequate and does not end the uncertainties. No matter what form of regression is chosen, part of variation will always remain unexplained. Good researchers tighten the control on this unexplained part so that medical decisions are more valid and reliable.

### *Logistic, Poisson, and Cox Regression*

The terms linear, curvilinear, and nonlinear regression generally apply to the setup where the dependent is quantitative, mostly continuous. What if the dependent is qualitative? In a medical setup, clinicians are often interested to know whether or not a set of regressors can predict presence of disease, or that a critical patient is going to survive or has benefitted from a treatment, etc. For such dichotomous outcomes, the regression of choice is **logistic**. This can be extended to polytomous (nominal or ordinal) outcomes. For details, see the topic **logistic models/regression (basics of)**.

There could be another type of dependent that counts events of interest—the number of patients waiting for kidney transplant, the size of sibship, the number of episodes of diarrhea last month in a child, etc. These counts are quantitative but are rarely large in magnitude. For such dependents, the appropriate model is **Poisson regression**. This can also be used for rates per unit of time such as deaths per year by accidents in a city and incidence of a disease in a segment of a population. For fitting a Poisson regression, the method of **generalized linear regression** can be used with a log-link. See the topic **link functions**.

Another type of regression popularly used in medical setups is the **Cox regression**. This is used when the hazard ratio of occurrence of an event is to be modeled to depend on a host of regressors. Hazard is a concept intimately related with time—thus, this method is used where durations are studied.

The regression types we have mentioned are for univariate dependent. In some situations, the interest is in multivariate dependent such as simultaneous consideration of various lung functions. In this situation, a **multivariate regression** is obtained. This is just multivariate analog of the corresponding univariate regression but requires heavy calculations and careful interpretation of the computer output. See that topic for details.

### *Other Types of Regressions*

One can think of other types of regressions depending upon the peculiar characteristics of the dependent variable. Examples are **ridge regression**, **quantile regression**, and **spline regression**, although these are not common in medical setup. In addition, we also have **harmonic regression**, **hierarchical regression**, and **meta-regression**, all of which are separately discussed.

## regressors (choice of), *see also* stepwise methods, best subset method of choosing predictors

Regressors are the variables that are included in a regression model to study their effect on the outcome. If the interest is in finding the effect of age and sex on the systolic level of blood pressure (BP), age and sex are the regressors. In general, one can think of a large number of factors that can affect any outcome of interest, but all of them can be rarely included in a regression. Adequacy of the regression and its practical utility mostly depend on proper choice of the regressors.

Among several considerations, choice of regressors depends on the purpose of running the regression. One purpose could be to examine how the regressors affect the outcome, called explanatory regression. In this regression, the explanation you get from one set of variables may be different from what you get from another set of variables. Such differing explanations may not be biologically plausible. In this setup, the choice of variables is crucial and requires deep thinking so that the effect of regressors has medical meaning. The second purpose could be prediction wherein any set of variables that predicts close to the observed values is good. This set of variables may or may not have much biological meaning: this does not matter for prediction. Two different sets of regressors can be equally good in the prediction of the outcome, and any can be chosen for this purpose.

The next step is to decide how many regressors should be included and which ones. Generally all those that are suspected to affect the outcome are included, but the size of the sample can place a severe restriction on how many regressors can be included. In ordinary least squares setup with quantitative dependent, the number of variables should be substantially less than the sample size $n$, but in logistic regression, a ratio of 1:10 is advocated between the limiting sample size and the number of regressors. *Limiting sample size* is the least number of subjects in cross-classification of the regressor values. Our experience suggests that this is too conservative, and progressively less $n$ is required as the number of regressors increases.

Theoretically, it is possible to specify a large number of regressors and ask the computer program to identify those that contribute significantly in statistical sense. **Stepwise methods** are used for this purpose. A more prudent method is to examine the biological plausibility of each and select those that can really affect the outcome. This is like not worrying about the size or shape of the stones for producing fire by rubbing them but worrying about their dryness. The key is relevance for the generalization to be valid. Remember in this context that separation of relevant from irrelevant factors is the beginning of knowledge. Include interaction terms where appropriate by considering the product of the regressors as a new variable. This product would be as good a regressor as any other. The difficulty with this approach is that the present knowledge about regression may be inadequate—many others could be important but not fully known yet. Nonavailability of data on some relevant regressors may be another limitation.

The other statistical method for selecting the right variable in a regression model is to check the statistical significance of each individual regressor by running a simple regression. Those not significant can be excluded without much loss. However, there are examples when a variable by itself is ineffective but becomes important when another variable with synergy is present. Another method is to consider the square of the **multiple correlation coefficient** ($R^2$). You can compare one model with $K_1$ regressors with another model with $K_2$ regressors by using **adjusted $R^2$**. This can also help in choosing the right regressors.

The methods just described tend to automatically exclude variables that have high **multicollinearity** with other regressors. Including too many regressors can cause multicollinearity that considerably reduces the efficiency of the regressions. If systolic BP is among the regressors for, say, serum glucose level, then inclusion of diastolic BP among the regressors may not serve much purpose. This is because systolic and diastolic levels are highly correlated. If body fat can be calculated from skinfold at triceps and thigh, there is no use in keeping all three as regressors; keeping body fat as a regressor is enough. An association or correlation exceeding 0.8 on a scale of 0–1 is considered enough to exclude the variable, particularly when the form of relationship to be examined is linear.

## rejection region, *see* acceptance and rejection regions

## relative efficiency of estimators

A combination of sample observations is considered an *estimator* as long as you use a notation and do not plug in the values. When the values are substituted, it becomes an estimate. Mean $\bar{x}$ is an estimator of population mean μ, but the average hemoglobin level 12 g/dL is an estimate. The concept of efficiency is for the estimator and not for the estimate. An estimator is considered statistically more efficient compared with another estimator of the same parameter if it has a smaller standard error (SE), because it provides more precise information about the **parameter**. Relative efficiency is the ratio of the sampling variances (square of SE) of the two estimators of the same parameter. Generally, it is obtained in comparison with the most efficient estimator. The most efficient estimator is the one that has minimum variance among all possible estimators. For example, statisticians found long ago that sample mean is the most efficient estimator of the central value in a Gaussian distribution. In comparison, sample median has variance $\pi/2$ times as large as the sample mean. Thus, the relative efficiency of the sample median is $2/\pi$ or 64% for Gaussian distribution. For another distribution, such as double exponential (two-sided exponential), the median is twice as efficient as the mean.

It is customary to talk about the **asymptotic relative efficiency** (ARE) of an estimator instead of just efficiency. This is the relative efficiency when $n$ is infinity—practically meaning a large sample and can be obtained for any statistical procedure. The ARE is an indicator of how good a procedure is relative to another when the sample size is sufficiently large. This is generally obtained for **tests of hypothesis** rather than for the estimators. You may be aware that statistical tests tend to provide "significant" result as the sample size increases even if the effect size is small. Even a minor effect can become statistically significant when the sample size is sufficiently large. Thus, in the case of tests of hypothesis, relative efficiency is the ratio of sample sizes required to reject the null by the two methods under comparison. For example, it is established that the ARE of the Wilcoxon–Mann–Whitney signed rank test is 95.5% compared with the one-sample Student $t$-test when the distribution is Gaussian; $n = 955$ will give you the result with the same reliability by the Student $t$-test as a signed rank test will give with $n = 1000$ from a Gaussian distribution. This, however, does not tell you the full story. The signed rank test is mostly used for small samples, and for these, the Student $t$-test will perform much better if the underlying distribution is Gaussian. Many other nonparametric tests do not have such high ARE and thus are advocated only when the sample size is small and the underlying distribution of values is far from Gaussian.

## relative potency, *see also* bioassays

Potency is a measure of the targeted change due to a regimen—the higher the potency, the lower the requirement of dose of the regimen, and relative potency is the change brought about relative to a standard regimen. This is more relevant when the regimens are two preparations that are identical but differ in their concentration. The cardinal method for estimating the relative potency is **bioassay**, which helps to characterize and compare the potency of a variety of regimens.

When **dose–response** curves for the test and the standard are parallel as required for **parallel–line assays**, relative potency is generally estimated by the ratio of $ED_{50}$ of a well-characterized standard and $ED_{50}$ of the test preparation. That is, when parallelism holds,

$$\text{relative potency: } \rho = \frac{ED_{50} \text{ of standard}}{ED_{50} \text{ of test}}.$$

Xu et al. [1] used this method to conclude that the potency of hyperbaric ropivacaine is 0.67 relative to that of isobaric ropivacaine, in a subarachnoid block for knee arthroscopy—thus, a higher dose of hyperbaric is required for the same anesthetic effect. In place of $ED_{50}$, $ED_{20}$ or any other defined magnitude of response can be used where parallelism holds. If not parallel, the ratio $ED_{20}$ can give very different results. Parallelism must be validated before relative potency is calculated in this manner. When parallelism is violated, the method based

on multiple-point estimates over the range of responses from $ED_{20}$ and $ED_{80}$ can be used as proposed by Villeneuve et al. [2].

$ED_{50}$ can be replaced by the mean dose in most cases, maybe after log or any other suitable transformation. If this is accepted, an alternative in terms of dose–response relation can be explained as follows. In case of parallel–line arrays, the dose–response equations are

$$y_s = \alpha_s + \beta x_s \text{ for the standard preparation}$$

$$y_s = \alpha_t + \beta x_t \text{ for the test preparation}$$

In this case, the intercepts differ but the slopes are the same, and

$$\text{relative potency: } \rho = \frac{\alpha_t - \alpha_s}{\beta}, \text{ which is estimated as}$$

$$R = (\bar{x}_s - \bar{x}_t) - \frac{(\bar{y}_s - \bar{y}_t)}{b}.$$

For quantal (yes/no type) of responses, logit transformation is used, and this changes to $y_t = \text{logit}(p_t)$ and $y_s = \text{logit}(p_s)$, $p_t$ and $p_s$ being the proportion response (Figure R.10a).

Now consider **slope–ratio assays** where the response lines have the same intercept but different slopes. In this case, the basic equations are

$$y_s = \alpha + \beta_s x_s \text{ and } y_t = \alpha + \beta_t x_t.$$

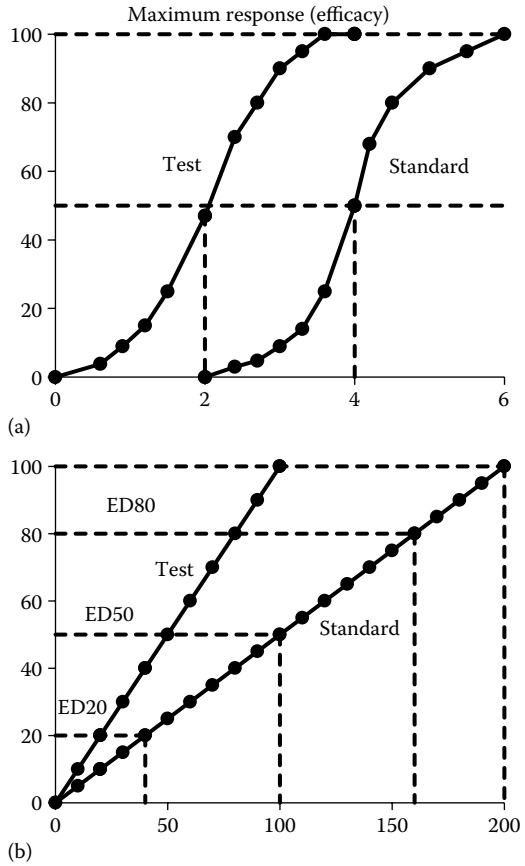

**FIGURE R.10** Relative potency in (a) parallel–line and (b) slope–ratio assays. (Redrawn from Villeneuve DL et al., *Env Toxicol Chem* 2000:19(11):2835–43. http://www.usask.ca/toxicology/jgiesy/pdf/publications/JA-253.pdf.)

In this case, the relative potency $\rho = \beta_t/\beta_s$, and the sample estimate is $R = b_t/b_s$, where $b_t$ and $b_s$ are the estimated respective regression coefficients on the basis of the actual data (Figure R.10b).

Consider an example of digestibility of egg and rice protein where digestibility score measures how much protein is really absorbed in the body. Both are given in doses of rice and egg with 0, 5, 10, 15, and 20 g of protein to three persons each, with all other diets standardized. This means that 15 persons receive egg protein and another 15 receive rice protein. Let the estimated regression equations be $y_t = 5 + 1.0x_t$ for rice (test) and $y_s = 5 + 0.5x_s$ for egg (standard) protein. This gives relative potency of rice protein = 1.0/0.5 = 2.0 relative to egg protein for digestibility. Thus, rice protein is twice as "potent" with regard to digestibility score as egg protein in this example.

Confidence interval for relative potency, being a ratio, can be obtained by the **Fieller theorem**. The methods we have discussed are valid mostly for Gaussian distributions. If the response distribution is far from Gaussian and transformation does not help, nonparametric approach similar to the one proposed by Sen [3] can be adopted.

## relative risk (RR)

Relative risk (RR) is the ratio of the risk of developing an outcome such as disease ($D$) in those with an antecedent factor ($A$) compared with those without this factor. This is also called the **risk ratio**. Risk can be measured by incidence at any defined point in time. In terms of probabilities,

$$\text{RR} = \frac{P(D+/A+)}{P(D+/A-)},$$

where $D$ is for disease and $A$ for antecedent. The + sign is for presence and the – sign for absence. Antecedents of interest can be the exposure to a risk factor.

The concept of relative risk obviously requires a **prospective study** that gives rise to the data as in Table R.7, where $\pi$'s are the group probabilities in the population. The dot in the subscript indicates the total for that particular subscript. In terms of these notations, $\text{RR} = \pi_{11}/\pi_{12}$ subject to the condition that $\pi_{11} + \pi_{21} = 1$ and $\pi_{12} + \pi_{22} = 1$. It measures the degree of association of outcome with the antecedent factor. If the incidence of lung cancer among heavy smokers for 10 years is 3% and among nonsmokers 0.5%, then RR = 6, i.e., heavy smokers have six times as much risk of developing lung cancer as nonsmokers.

The numbers $a$, $b$, $c$, and $d$ in Table R.7 are for the number of subjects observed in the sample. The value of RR in the target population can be estimated from a sample of subjects as follows:

$$\text{Estimate of RR}: \widehat{RR} = \frac{a/(a+c)}{b/(b+d)} = \frac{p_1}{p_2},$$

**TABLE R.7**
**Structure of a Study for Relative Risk (RR): Independent Samples**

| | Antecedent | | |
|---|---|---|---|
| **Outcome** | **Present** | **Absent** | **Total** |
| Present | $a(\pi_{11})$ | $b(\pi_{12})$ | $\boldsymbol{O_1.(\pi_1.)}$ |
| Absent | $c(\pi_{21})$ | $d(\pi_{22})$ | $\boldsymbol{O_2.(\pi_2.)}$ |
| **Total** | $\boldsymbol{n_1(1)}$ | $\boldsymbol{n_2(1)}$ | |

None of the cell frequencies should be very small, say less than five, so that the estimates are not unstable. If any cell frequency is zero or very small, say less than 1, then a modified estimate of RR is

$$\widehat{RR}_{\text{mod}} = \frac{(a+0.5)/(a+c)}{(b+0.5)/(b+d)}.$$

This modification is just a ploy to be able to compute RR but does not make it stable. These and several other expressions in this topic are estimates, but we ignore the hat (^) sign for simplicity. Even in the literature, an indication that these, in fact, are estimates is rare.

Consider 120 women of parity ≤ 2 and 120 women of higher parity who are subsequently assessed for anemia. The study design is **prospective** instead of cross-sectional. Parity in this case is the antecedent and anemia is the outcome. If the incidences of anemia in the two groups are 23% and 40%, then $a = 28$ and $b = 48$ since the sample size is 120 each. These give an estimate of

$$\text{RR} = \frac{28/120}{48/120} = 0.58.$$

Thus, the risk of anemia in the lower parity women is nearly half of that in the higher parity women.

The following comments are helpful in clarifying certain issues regarding RR:

- RR = 1 implies independence, i.e., the risk in exposed subjects is the same as in nonexposed subjects. It might seem paradoxical that correlation = 1 means perfect relationship, but RR = 1 means no relationship; however, that is how RR is calculated. RR > 1 means a higher risk in the exposed subjects, and RR < 1 means a lower risk. RR < 1 can be interpreted as a protective effect in place of risk as in our parity–anemia example. RR cannot be negative but can be 100 or more. RR alone is rarely enough to draw a valid conclusion about a cause–effect type of relationship unless other possible explanations are ruled out.
- An RR does not tell what the actual risks were. For example, the same RR can be obtained as 27/9, 4.5/1.5, 0.045/0.015, etc. Actual risks are entirely different in these cases, but RR = 3 in all of them. Risk may decrease over time without an alteration in the relative risk. This will happen when the risk in the comparison group also declines in the same proportion as in the test group.
- Context can be important for the interpretation of an RR. If you find that diabetes doubles the risk of stroke, you would be careful without worrying about baseline. If the risk of vehicular death in regular conditions is 1/10,000 and in bad weather conditions 2/10,000, you may still take it lightly despite double risk.
- Assessment of an RR is considered important to discuss the consequences with the patient and in preparing a management strategy. Remember, however, that one great limitation of an RR is that the relative risk can be a high value if the risk in the unexposed group is low, giving a fallacious impression of a very high risk. If the risk in the unexposed group is only 2% and in the exposed group 70%, the RR is 35. On the other hand, if the risk in the unexposed group is high, say 60%, the RR cannot exceed 100/60 = 1.67. It cannot exceed 2 if risk in unexposed is 0.5 or more. Thus, the RR heavily depends on the risk in the unexposed group. In view of this limitation, interpretation of the RR requires caution.
- For the RR to be a valid measure, it is necessary that the two groups under comparison are identical except for the presence of risk factor in one and its absence in the other. Thus, the design of the study that ensures this equivalence is important.
- A value of the RR between 1 and 2 may look small but can have tremendous public health importance if exposure is widespread. For example, in some countries, more than one half of the adult population use tobacco (smoke + smokeless). An RR of 1.20 of premature death in these adults is just 20% increase in chance of early death, but this can translate into thousands of additional early deaths due to the use of tobacco in a population.
- **The confidence interval for an RR** can be easily obtained for large samples as explained separately.

### *Test of Hypothesis on RR*

The null hypothesis is mostly RR = 1 that says that the risk is the same in the two groups under comparison. This null can be tested for large samples by the usual chi-square test. We illustrate this with the help of the data in Table R.8 on maternal age and wheezing lower tract illness (LRI) during the first year of life of 500 boys [1].

For the data in Table R.8, $\text{RR} = \dfrac{48/165}{65/335} = 1.68$. This means that higher maternal age increases the risk by 68%. For testing its statistical significance, the expected frequencies under $H_0$ can be calculated as usual, and chi-square can be calculated as follows:

$$\chi^2 = \frac{(48-37.29)^2}{37.29} + \frac{(117-127.71)^2}{127.71} + \frac{(65-75.71)^2}{75.71} + \frac{(270-259.29)^2}{259.29} = 5.93.$$

A statistical software package gives $P = 0.015$. Since this is less than the usual 0.05, the null hypothesis is rejected, and it is concluded that RR ≠ 1.

Note that chi-square is a two-tailed test and so the conclusion too is two-sided. If there is a priori reason to ensure that RR would be more than 1, then $H_1$: RR > 1. For such one-sided alternative,

**TABLE R.8**
**Maternal Age and LRI in Infant Boys**

| | LRI | | |
|---|---|---|---|
| **Maternal Age (Years)** | **Yes** | **No** | **Total** |
| <26 | 48 | 117 | **165** |
| ≥26 | 65 | 270 | **335** |

**TABLE R.9**
**Matched Pairs with Dichotomous Antecedent and Dichotomous Outcome: Prospective Study**

| | Partner 1: Antecedent Not Present (Not Exposed or Control) | | |
|---|---|---|---|
| **Partner-2: Antecedent Present (Exposed or Experiment)** | **Positive Outcome (Disease+)** | **Negative Outcome (Disease–)** | **Total** |
| Positive outcome (disease+) | a | b | ***a + b*** |
| Negative outcome (disease–) | c | d | ***c + d*** |
| **Total** | ***a + c*** | ***b + d*** | ***n = a + b + c + d*** |

it may be prudent to use the formula $z = \frac{\ln RR}{SE(\ln RR)}$ and refer it to the Gaussian distribution to get the one-sided *P*-value. For a large sample, $SE(\ln RR) = \sqrt{\frac{1}{a} - \frac{1}{n} + \frac{1}{b} - \frac{1}{n}}$. For these data, this is $\sqrt{\frac{1}{48} - \frac{1}{165} + \frac{1}{65} - \frac{1}{335}} = 0.1648$, and $z = \frac{0.4055}{0.1648} = 2.46$. From Gaussian distribution, $P(z \geq 2.46) = 0.0069$. This *P*-value is not only less than 0.05 but also less than 0.01. The relative risk can be said to be *highly* significantly more than RR = 1. There is only an exceedingly small chance that RR = 1 will give frequencies as extreme as observed in this sample.

### *RR in Matched Pairs*

A general situation for matched pairs with regard to antecedent and outcome in a prospective study is shown in Table R.9.

In this case, the RR is estimated as follows:

$$\text{Relative risk (matched pairs): } RR_M = \frac{a+b}{a+c},$$

where the notations are the same as in Table R.9. The meaning of *a*, *b*, *c*, *d* is different here than in Table R.8 (in independent samples). The numerator of this equation is the number of subjects developing the disease among those exposed, and the denominator is the number of subjects developing the disease among those nonexposed. The exact expression for the SE of $RR_M$ is complex, but it is known that the odds ratio for matched pairs, $OR_M$, approaches $RR_M$ for rare outcomes. Thus, the same CI and test criterion can be used for $RR_M$ as for $OR_M$ in most practical situations. For $OR_M$, see the topic odds ratio.

## reliability, *see also* repeatability and reproducibility

Reliability is the property of giving the same result on repeated measurement in identical conditions. For true reliability, the values must vary considerably from subject to subject, although the repeat values for each subject should be nearly the same as before. This property generates confidence as you know that the result would not be any different if the measurement is taken again. Besides measurements, in a medical setup, the question of reliability arises in a large number of situations such as instrumental reliability, reliability of conclusions, and statistical reliability of estimates. A brief of each of these reliabilities is given in this section, but first realize that the variation in a repeated measure can be due to one or more of the following reasons:

- Chance or unsystematic events.
- Systematic inconsistency.
- Actual change in the underlying event being measured.
- Measurement reliability is not just the property of an instrument. It also depends on the conditions (busy day at the clinic, stress, new application) in which measurement is done. Factors due to subjects (e.g., patient fatigue, mood) and factors due to ability of the observer/rater/interviewer to elicit correct response from the respondent also affect the repeated measurements.
- Instrument reliability, i.e., the research instrument or measurement approach (e.g., poorly worded questions, quirk in mechanical device).
- Data processing reliability, i.e., manner in which data are handled (e.g., miscoding).
- Lack of clarity of instructions, i.e., amenable to varying interpretation by different observers.
- Besides fatigue, variations can also arise due to boredom, memory lapse, carelessness, lack of motivation, lack of concentration, etc.

Colloquially, reliability is sometimes equated with success. If a system fails often, we say that it is unreliable. If the response is 30% consistently across groups of patients, it is consistent but is still perceived unreliable as only a few respond. Sometimes, it is related to a time period such as considering a regimen reliable if it is able to get response within, say, a week, and unreliable if it is not able to do so. Our concern in this section is with statistical reliability, which is consistency in varying conditions.

### *Reliability of Measurements*

Measurement is a process by which the dimension of an object or event is either quantified or classified. Numeric assignment is done for dimensions that signify magnitude or the quantity, whereas the classification is done for qualitative attributes. Reliability of a measurement is the degree to which consistent values are obtained in repeated applications in identical conditions. Conceptually, this is distinct from other reliabilities such as instrument reliability since measurement reliability is the inherent property of a measurement and refers to the consistency when the instrument is fully reliable.

For example, weight of a person is a reliable measurement compared with a pain score that can quickly change depending upon the instability exhibited by the person.

Statistical reliability of measurements was initially defined as the ratio of true variance to the observed variance and is the quantification of the consistency of values across replications. True variance may never be known so that the reliability of measurements is assessed in terms of agreement of values taken at two or more occasions. The extent of agreement is measured by **intraclass correlation** if the measurements are quantitative and by **Cohen kappa** if they are qualitative. An intraclass correlation exceeding 0.90 can be considered excellent, that between 0.80 and 0.89 good, and that between 0.70 and 0.79 tolerable. Values less than 0.70 are suspect for reliability, although they might be good in other contexts. For Cohen kappa, the thresholds are milder: <0.3 is considered unreliable, 0.3–0.5 tolerable, and higher values progressively good. These measures are valid if the errors in measurements are independent of their quantitative level. If higher errors are anticipated for larger values, the errors may have to be converted to, for example, percentages.

Sometimes reliability of measurements is confused with **inter-rater reliability**. This occurs because errors in measurement are considered to have arisen due to differential skills of the observers used for repeated measurements, and not because of inherent variations in the measurement.

### *Reliability of Instruments/Devices*

Reliability of an instrument or device is the stability of the response with repeated use of the instrument in identical conditions. A clinician uses various tools during the course of practice such as signs–symptoms syndrome, physical measurements, laboratory and radiological investigations, and intervention in the form of medical treatment or surgery. Besides his or her own skills in optimally using what is available, the efficiency of a clinician also depends on the **validity** and reliability of the tools he or she uses. Unlike validity, the concept of reliability is not related to any gold standard. For example, we know that a clinical thermometer is a reliable tool for measuring body temperature since it behaves the same way under a variety of conditions. Reliability of an instrument is its ability to be consistent across varying conditions in the sense of providing the same results when used by different observers or in different setups. The performance of a reliable tool is not affected much by the external environment in which the tool is used. This kind of reliability across repeated measurements can be studied by agreement assessment such as by the **Bland–Altman method** or by computing the **intraclass correlation coefficient**.

An instrument such as a questionnaire can have multiple items. Reliability may suffer if the wordings are not precise and instructions are not explicit so that there is room for subjective interpretation either by the assessor or by the assesse, or by both. How does one assess the reliability of such an instrument? It has two components: (i) internal consistency and (ii) stability across repeated use. The first concerns the consistency of responses across various items in the same test. A popular measure of internal consistency of a multi-item instrument is **Cronbach alpha**, which assesses congruence of items with one another: whether or not they amiably hang out together. All the items should be tapping different aspects of the same attribute and not different attributes. In effect, the items of a scale should be moderately correlated with each other. Also, each item should correlate well with the total score. This is what Cronbach alpha broadly assesses. Another method is **split-half consistency**, which measures agreement between two random halves of the instrument. The next is repeatability that essentially involves administering the test twice to the same subjects—thus also known as **test–retest reliability**. It can be calculated for an instrument that does not provide any learning to the respondent, and the second-time responses are not affected by the first-time responses. The scores or the measurements obtained on the two occasions are checked for agreement. This can be checked itemwise in case of multi-item instrument (such as a questionnaire), but generally the total score is compared.

The choice of items included in a multi-item tool makes or mars the reliability. You may have to examine various criteria for determining which items to keep and which to discard. Eliminate any items that are ambiguous or do not make sense to the respondent. Generally speaking, an item should have a correlation of more than 0.20 with the total score; if it is lower, that item should be discarded. Also, the reading level or the understanding required to respond should not be too high. For this, it is advisable to **pretest** the tool on a group of people comparable to those who will actually be the ultimate targets, checking that they do, in fact, understand each item.

Another type of instrument commonly used in medical assessment is a scoring system. This is similar in nature as a questionnaire and can provide varying results in repeated use when the wordings, the sequence, and the method of eliciting response are not standardized. The reliability of a scoring system is also assessed the same way as of a multi-item instrument discussed in the preceding paragraphs.

Consider an example on nutritional rickets. Severity of this disease can be assessed by the degree of metaphyseal fraying and cupping, and the proportion of the growth plate affected, based on radiographs of wrists and knees. Thacher et al. [1] evaluated the utility and reliability of a 10-point scoring system that progresses in half-point increments from 0 (normal) to 10 points (most severe). They found that the interobserver correlation of the score was 0.84 or greater for all observer pairs they used, and the intraobserver correlation was 0.89 or greater for each observer. Thus, there is a fair amount of consistency. The authors conclude that this score should be useful to objectively assess the severity of rickets. This illustrates how reliability measurement can be useful.

### *Reliability of Estimates*

A major statistical exercise in many medical studies is to estimate the effect size of an intervention and to estimate incidence, prevalence, etc., of a condition. The question of estimation arises because the entire population is almost never studied and a sample is used for inference. All samples are notorious for providing varying estimates from sample to sample. Thus, it is necessary to assess the reliability of the estimates.

Reliability of estimates is evaluated by their **standard error (SE)**. See this topic for details if you are not familiar with it. These SEs almost invariably depend on two things: (i) the intrinsic variation from subject to subject and (ii) the sample size. For example, $SE(\bar{x}) = \sigma^2/n$, which indicates that the higher the sample size, the greater the reliability. This sounds intuitive also: an estimate based on a sample size of 100 would not vary as much from an estimate based on another sample of this sample size as an estimate based on a sample of size 10 would.

In the case of multiple linear regression, the reliability of the regression can be measured by the **multiple correlation** coefficient ($R$). Most researchers present results of such regression in terms of $R^2$. Generally speaking, the higher the $R^2$, the greater the reliability. But high $R^2$ for a small sample size is not really helpful because standard errors are still high and the reliability of the estimates is low. A high $R^2$ can also occur in the case of **multicollinearity**, where many individual regression coefficients are not statistically significant.

In the context of senile dementia, van Belle et al. [2] argue that the concept of the reliability can also be applied to the change over time. The reliability of the estimates of change is shown to depend primarily upon the *length* of time of observation, not the *number* of observations made. The authors introduce the concept of signal-to-noise ratio to compare reliabilities in change scores.

### *Reliability of Conclusions*

Reliability of statistical conclusions mostly depends on the sample size, given that the data are correct and analyzed properly. Sometimes, as in a case–control study, a large number of controls when easily available and more cooperative are included, which helps to increase the reliability of the results. A study by Kornitzer et al. [3] on the effect of serum selenium level on cancer mortality is an example in which this strategy was adopted, and three controls were included for each case. Consistent results in repeat studies, where feasible, also increase the confidence level.

Nonresponse in clinical trials and many other studies requiring follow-up has an adverse impact on the results: the ultimate sample size available to draw conclusions reduces, which affects the reliability of the results. This deficiency can be remedied by increasing the sample size corresponding to the anticipated nonresponse. However, this does not remedy the bias in case the nonresponse is selective by those who are critically sick, or have more robust health, etc.

### *Reliability versus Agreement*

The reliability is consistency, whereas the agreement is similarity of values. Apparently, there seems hardly any difference. However, Kottner and Streiner [4] make reference to a study by Costa-Santos et al. [5] to provide a valuable example about the difficulties in comparing and interpreting reliability and agreement coefficients arising from the same measurement situation. According to them, much of the confusion around reliability and agreement estimation is caused by conceptual ambiguities. In case of agreement, the absolute degree of measurement error is of interest. If all values are high but agree, the agreement would be high. On the other hand, reliability would be low if all values are high (and consequently have high variance) since reliability also considers interindividual variability that agreement does not. A clear distinction between the conceptual meanings of agreement and reliability is necessary to select appropriate statistical approaches and adequate interpretation.

Streiner and Norman [6] have discussed some of these issues in more detail.

## repeatability and reproducibility, *see also* reliability

According to Peng [1], repeatability and reproducibility are the two foundational characteristics of a successful scientific research enterprise. In common parlance, repeatability and reproducibility are interchangeably used, but these have slight technical difference in statistical context. Repeatability of a study is the property that it will produce a result consistent with the original when another study is conducted in the same conditions. This is also called **replicability**: the keyword being "consistency." The result of the second study may not be exactly the same but would be consistent. This slight leeway is allowed since the subjects could be different, and there might be other subtle unrecognizable differences that could cause minor variations despite essential similarity. Reproducibility is the ability to get the same result when the same set of data is analyzed again with the same or another method. This can be assessed only when the raw data are accessible. If the data analysis is poor, the results will not reproduce, which will indicate lack of expertise or poor judgment of what method should be used and how. Thus, reproducibility is more statistical in nature than repeatability. This also points to some false positive and false negative results arising due to inadequate analysis, although false results can also be due to several other reasons such as poor quality of data, poor design, and inadequate definitions.

Whereas repeatability is regularly assessed by conducting similar studies in varying setups, assessment of reproducibility has not been easy. A major bottleneck in this is the nonavailability of raw data for reanalysis. Many journals now encourage researchers to store the data at publicly available websites, and some provide facility to warehouse the data at their own website; however, there is a considerable reluctance by the researchers to share the data that can be unscrupulously used for other analyses and conclusions. According to Peng [1], the answer is to build trust, and this would come from the credibility of the researchers as established by evidence of their skills and expertise.

## repeated measures ANOVA

**Repeated measures** are those that are taken at different fixed points in time for each subject. Repeated measurements could be heavily correlated—thus, they require special methods. Repeated measures analysis of variance (ANOVA) is used to analyze data arising from repeated measures where the outcome is continuous and is studied in different groups of subjects. The objective in this analysis is to find whether or not the average values differ among groups.

Medical studies are commonly conducted for investigating changes over time in one or more outcome variables. Firstly, consider the simplest case of two measurements per subject, that is, there is only one group of subjects and they are measured on two occasions only. For example, in a clinical trial, this could be before and after treatment. The analysis of such data is straightforward—you would use a paired ***t*-test** (or the nonparametric equivalent if the requirements of the paired *t*-test are not met). However, in the case of more than one group, there are other options, discussed below,

for analysis of repeated measures data when there is just one repetition [1].

- Ignore the baseline measurements and simply compare the final measurements with the usual tests used for non-repeated data, i.e., **one-way ANOVA**. To take account of other covariates affecting the outcome, general linear regression could be used. Obviously, this takes no account of the baseline measurements and is a feasible option (although not necessarily recommended) if there is no reason to believe that the groups differed at baseline, such as in a study where subjects are randomly assigned to groups.
- Calculate the change for each subject at each time point and compare the average change across groups using the same methods as just described. Unfortunately, this method tends to overcompensate for any baseline differences.
- Use the method of **analysis of covariance (ANCOVA)**. This compares the final values across groups while also taking account of the baseline values. Essentially, it is done by carrying out a multiple regression, putting in the final values as the dependent variable and the baseline values, as well as the variable used to define the groups, as the independent variables. If applicable, other covariates can also be taken into account by adding them into such multiple regression.

Now consider several repetitions. The temptation may be to compare subjects at each time point separately, perhaps with a series of unpaired *t*-tests. We will come to the setup with several groups in a short while, but first consider only one group of $n$ subjects, each measured at the same $T$ time points, such as measuring hemoglobin (Hb) level at monthly intervals in $n = 60$ pregnant women. If the measurements are done from the third month to the ninth month, then there are $T = 7$ measurements per woman. In this special case, one can think of analyzing the data by two-way ANOVA considering each subject as one factor with 60 levels and time points as the second factor with 7 levels, provided that the validity conditions hold. The null hypothesis of interest in this case would be equality of means at seven time points. This will have one observation per cell, and the interaction such as the fast rise in Hb in one woman and the slow rise in the other cannot be studied—only the average at seven time points can be compared. This analysis will also ignore the trends over time, if any, since ANOVA considers all levels (in this case, time points) nominal and not metric. This analysis will also ignore that some women have a low level to begin with whereas others have a high level. Thus, this analysis has severe limitations.

Suppose these women are divided by their parity as 0, 1, 2, and 3+. This makes it a real repeated measures ANOVA setup. If there are 30 women of each parity, there will be a total of 120 women and each will be measured seven times at monthly intervals. The objective now is to compare the mean Hb level across parity groups and not across time points. Two-way ANOVA is adequate for this kind of repeated measures design subject to the condition that the difference $(x_t - x_{t'})$ has the same population variance for every pair of occasions: the subscript $t$ is for the time point. This is achieved when all $x_t$'s have the same variance, and the covariances between all pairs of $x_t$ and $x_{t'}$ are equal (see **sphericity**). Small differences do not matter if $n$ is large, but the differences could be very large in some situations. Measurements close in time may be more highly correlated than those widely separated in time. Heart rates (HRs) 1 and 5 min after anesthesia could be highly correlated, and HRs after 1 and 30 min poorly correlated. Thus, the covariances will not be uniform, and the condition for using repeated measures ANOVA will be violated. In this case, use the **Huynh–Feldt correction** if the **Mauchly test** for sphericity is significant.

Another alternative is to consider repeated observations on each subject in multivariate setup and do **multivariate analysis of variance (MANOVA)**. This works well for balanced design with large $n$ and does not require sphericity of repeated values, but the software may produce a complex-looking output. This output generally mentions several tests, but **Wilks lambda** is preferred in most cases as this could be exact under regular conditions such as multivariate Gaussian distribution. Although MANOVA is a preferred method for equal $n$, if you find MANOVA output difficult to decipher, do univariate repeated measures ANOVA as stated earlier. Both these analyses test equal means response at different time points and across groups, but not time trends. You can test gross differences in time trends by including the time*groups interaction term, but that really does not test any specific time trend such as linear, quadratic, or any other polynomial form. Special commands can be given in most standard software packages for testing the presence of such a trend. If this interaction is significant, conclude that the average time trend in at least one group is different from the trend in other groups.

Complexities seem to never end with repeated measures. What happens if the design is unbalanced (unequal $n$'s in different groups) and covariance matrices across groups are also unequal? For this situation, the **Welch test** is recommended in place of $F$. This is similar to the Welch test for the two-sample situation. But the $n$ in the smallest group should preferably be at least $3*(T - 1)$ for testing main effects and at least $5*(T - 1)$ for testing interaction, where $T$ is the number of time points for repeated measures. Also consider the following.

- In case the groups are randomly selected from a large population, use **mixed effects** ANOVA.
- **Multilevel modeling** is another possible approach for analyzing repeated measures data. This requires considerable statistical expertise and a good statistical package.
- All this is for a metric, preferably, continuous outcome. If the outcome is binary, the data can be analyzed by repeated measures **logistic regression** using logit **link** in **generalized linear models**.

## Sphericity and Huynh–Feldt Correction

Equality of covariances together with equality of variances within a matrix is known as *compound symmetry*. A slightly relaxed condition is that the differences between all pairs of times are independent (covariance = 0) and have same variances. This is called **sphericity** and is the actual required condition for repeated measures ANOVA. This is tested by the **Mauchly test**.

The Mauchly test for sphericity works well for Gaussian data and reasonably well for minor departures from Gaussianity, but not when departures are gross and the dataset is small. When sphericity is violated, too many hypotheses are falsely rejected. When in doubt, the safe bet is to use **Huynh–Feldt correction** to df's. This correction can be used directly without worrying about Mauchly test results, and is explained separately. Many statistical packages provide results with Huynh–Feldt correction and also the corresponding $P$-value. The value of $F$ remains the same, but the correction factor reduces both the df's of $F$ by a factor called epsilon. You may find other types of epsilon also in your software output, but the Huynh–Feldt epsilon is widely accepted. In a rare case, this correction factor can exceed one, in which case no correction to df is done.

Besides sphericity, which is for variances–covariances among values at different points of time within each group, you also need

to worry about homogeneity of covariance matrices across groups when groups are two or more. For this, the **Box *M* test** is used. This also requires Gaussian distribution of the data.

For further details of repeated measures ANOVA, see Verma [1]. In case the data have many zeroes, special methods such as the one discussed by Berk and Lachenbruch [2] can be used.

## repeated measures studies

In many medical situations, as in the case of administering an anesthetic agent, it is necessary to monitor a subject by repeatedly observing vital signs such as heart rate and blood pressure at specified intervals. The basic feature of repeated measures is longitudinal follow-up, although it can be short as in the case of trials on anesthetic agents or can last for years as for quality of life after surgical interventions. The purpose is to measure the change with respect to the previous values, to assess the trend, and sometimes to identify the time point when the changes are significant. This is valid only if there is no natural or man-made change in values over time, that is, when any change can be assigned purely to the intervention. Guard against subjects showing improvement because of self-regulating mechanism in the body without intervention because that may contaminate the effect of intervention. Beware of fatigue setting in so that readings at later instances are taken with the same earnestness as in the earlier phase. Also, there should not be any **Hawthorne effect**. Analysis of such repeated measures requires special methods because these are not independent. Subsequent values depend on previous values, and this violates the validity of most statistical methods such as **analysis of variance (ANOVA)**. Special methods such as **repeated measures ANOVA** are used for this setup. The follow-up in repeated measures design is done at predefined intervals for each subject. If the time points are different for different subjects, it is called a **longitudinal study** instead of a repeated measures study.

As an example, consider a carcinogenic marker measured just before administration of a carcinogen in mice and after 1, 2, 5, and 10 days. This can also be done separately for the control group that receives the placebo. The changes are noted in the experimental and the control groups. In case of anesthetic agents, repeated measures help to study the short-term outcome separately from that emerging in the long term and the trend can be studied. **Bioequivalence** studies necessarily use a repeated measures design, because only then can the **pharmacokinetics** and the course of disease can be studied.

A repeated measures study may have two or more groups such as different dose groups or subjects with different forms of a disease. Each subject in each group can be measured at several time points to study the trend of quantitative outcome such as various enzyme levels. The objective in this case is to find if the average time trend in one group is the same as in the other groups. This is the same as assessing absence of the interaction group*time. For studying such interaction, $n$ in each group must be sufficiently large so that it has power to detect this kind of interaction.

Repeated measures have the potential to provide unnecessary satisfaction because of apparently having a large volume of data. If blood pressure of 10 subjects is measured hourly 12 times during day time for diurnal variation for a week, you will have a total of 840 data points for systolic and 840 for diastolic level. This can mislead you to believe that a large sample of values is available. Actually, there are only $n = 10$ subjects. Reliability of conclusions will not be high in this case despite a large number of data points because of small sample size.

## replicability, *see* repeatability and reproducibility

## replication

Replication is repeating the study. It is through replication that considerable confidence is added when the same results are obtained. Replication by another worker in a different setting helps to confirm that the results were not dependent on local conditions that were unsuspectingly assisting or hindering the outcome. Such replication also provides evidence for the robustness of the results. Sometimes the investigator himself wants to replicate the experiment to be on firm footing, particularly when the response varies widely from subject to subject. The variability across subjects remains unaltered, but replication reduces variability in experimental results; when the results between replicates are similar, their reliability naturally increases.

Replication also fulfills an important statistical requirement. It helps quantify the **random error** in the experimental results. It is also an effective instrument in reducing the effect of this error. Random errors occur due to imprecision of the process—in methods, measurements, etc., such as in staining, magnification, rotation, counting, and timing; and in the environment such as room temperature, humidity, or minor variation in chemicals, reagents. They also occur due to the varying care adopted by different observers. Killeen [1] explores the concepts in more detail. Macdonald [2] published a rejoinder to Killeen, discussing replication probabilities. For more details, see these references.

## reproducibility, *see* repeatability and reproducibility

## reproduction rates (net and gross), *see* fertility indicators

## reproductive number (of a disease)

The basic reproductive number of a disease is the average number of people to whom an affected person is able to spread this disease during its life course. The concept applies to communicable diseases, particularly infectious diseases. If an infected person is able to infect at least one person on average during the entire period of infectivity, then the infection will sustain or increase. In countries where hepatitis B infection is on the rise, this rate is more than one. The 2014 Ebola virus disease had this number between 1.71 and 2.02 in different countries of West Africa [1] causing the spread in epidemic proportions. If the reproductive number is less than one for any disease, expect that the infection will die down or stabilize at a low level. This underscores the need to control transmissibility of an infectious disease in order to reduce it to incidence. Dietz [2] gives a survey of various methods of estimation of the reproductive number. One particular method is as follows.

The definition implies that the reproductive number depends on the duration of infectivity, the infectiousness of the organism, and the number of susceptible persons that come in contact with the index case. This is calculated as follows:

$$\text{reproductive number: } R_0 = C^*P^*D,$$

where

$C$ = the average number of contacts an index case has with the susceptibles during the infective period.
$P$ = probability of transmission per contact per unit of time: this is the transmissibility.
$D$ = duration that the index case remains infectious.

Transmissibility depends on the infectiousness of the disease, susceptibility of the contacts, and the *herd immunity*. For example, it is surmised that diphtheria transmission throttles if effective vaccine coverage is 85% or higher. This is the herd immunity as this limits the scope of spread of infection. The gross reproductive number of this disease is estimated as 6–7, that is, an infective case of diphtheria can infect 6–7 persons if enough susceptibles come into contact. The reproductive number of a disease varies from population to population mostly due to the variation in the number of contacts and transmissibility. Diphtheria is not able to spread in most parts of the world because children are immunized and there are not enough susceptibles, which makes the basic reproductive number of this disease quite low.

The gross reproductive number assumes that all contacts are susceptible. In practice, some contacts may be immune either because of previous infection or because of immunization. If one third of contacts are immune, the effective reproductive number of diphtheria would be nearly 4.7 in place of 7. It can be used to estimate the heard immunity required to stop the spread of infection, shown as follows:

$$\text{required herd immunity} = 1 - \frac{1}{R_0},$$

where $R_0$ is the reproductive number. For diphtheria, for example, if $R_0 = 7$, required herd immunity is $(1 - 1/7) \times 100 = 86\%$. If the reproductive number for any disease is just 2, the herd immunity required is only 50%. Immunization plans can be drawn accordingly. This calculation assumes that all the vaccinations are fully effective and the coverage is fairly spread out so that it does not leave out pockets of susceptibles.

Holtgrave [3] provided an interesting projection for human immunodeficiency virus (HIV) infections in the United States that shows that the transmission rate of the disease in the country has substantially decreased. So, is elimination of HIV infection feasible in the foreseeable future? The author demonstrated that if the HIV transmission rate were reduced by 50%, then the reproductive number of HIV infection would drop below unity. Experts have asserted that the HIV transmission rate can be halved by 2020, if not earlier, provided that sufficient investment is made toward achieving this goal. This should lead to eventual elimination of HIV infection in the United States.

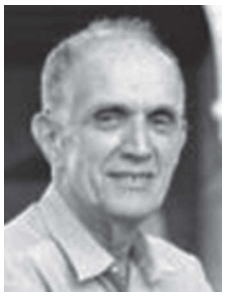
## resampling

Under this method, subsamples from an existing sample are drawn that help to draw statistical conclusions and also help to check if the results replicate on such subsamples. Thus, this method assesses the reproducibility or **reliability** of the results besides helping to tackle difficult setups where lack of standard conditions hampers valid conclusions. Two popular methods of resampling are **bootstrapping** and **jackknifing**. The following is a brief and introductory account; see Good [1] for details.

### *Bootstrapping*

You probably know that bootstrap is the loop at the back of a boot that is used to pull the boot on. In science, the term bootstrap is used for an algorithm with initial instructions such that subsequent steps are automatically implemented. In statistics, bootstrap is generating thousands of samples from the available sample. If you have a sample of size $n$, another sample of size $n$ can be drawn with replacement. This means that the sampled value is noted and replaced back as a candidate to be resampled. Theoretically, the same value can repeatedly appear in a bootstrap sample.

The actual procedure of bootstrap is something like this. If you have a sample of size $n = 18$, select one at random from this sample. Replace this value back so that you again have 18 values. Select another from these 18, which is the second value in the generated pseudo-sample. Since the sampling is with replacement, the same value can be selected again. Do this 18 times and you have a *pseudo-sample* of size 18. In a rare case, the same value can occur 18 times in one pseudo-sample. The process can be repeated to build thousands of pseudo-samples from one sample. These will be called bootstrap samples and can be drawn easily with computer-generated random numbers through an automated procedure. These samples build a proxy universe for valid inferences. However, the inferences will be valid only for the population represented by the initial sample. For this reason, it is advised that the initial sample is a genuine random sample from the target population. The method was first proposed by Bradley Efron in 1979 [2] as a variation of jackknife resampling.



Bradley Efron

Each of the bootstrap samples can give the mean, median, quartile, standard deviation, or whatever **statistic** is required. You will have thousands of these values, one corresponding to each pseudo-sample, and can generate a pseudo-distribution of sample median, sample quartile, etc. This distribution can be used, for example, to find a range such that 2.5% medians are less than the lower limit of this range and 2.5% are more than the upper limit of this range that

will provide 95% *bootstrap* confidence interval for median. This can be done for any parameter of interest of any population. The method is particularly useful where the conventional methods are not applicable due to unknown distributions.

Note how the available data are used to tell more about the data through resampling. No extra help is needed—thus the name bootstrap. But also note that bootstrapping of a bad sample (not representative) cannot yield valid results. In this case, bootstrap may give you a false sense of security.

To understand the actual usage of this method in statistics, consider the following. It is well known that the statistic ±1.96SE as a 95% confidence interval (CI) comes from the **Gaussian distribution**. This can be used for the CI for mean from a non-Gaussian distribution also when *n* is large because then the **central limit theorem** comes to the rescue, but cannot be ordinarily used for estimating nonadditive parameters of interest such as median (e.g., $\mathbf{ED_{50}}$) and **quartile**. The method of bootstrap was originally devised to find the CI for such parameters. The proxy universe generated by bootstrap samples is used for finding the CI as stated in a previous paragraph by basically generating 1000 bootstrap samples. This method is **nonparametric** and can be used to estimate the parameter of any distribution of the data.

The bootstrap procedure is also used for assessing **robustness** of results. This involves taking several samples from the same group that was actually studied and examining if the results replicate. This is different from what is just described. For robustness, the same size is generally preferred so that the varying *n* does not cause problems, but you can have a bootstrap subsample of, say, 150 each time without replacement when you actually have a sample of size 200. Although such resampling can be done many times, generally three or four subsamples of this type would be enough to assess robustness.

### *Jackknife Resampling*

Originally, the jackknife is sampling $(n - 1)$ values without replacement from the available *n* sample values that would construct *n* samples of size $(n - 1)$ after deleting one at a time. The first jackknife subsample would comprise all the values except the first, the second subsample will have all the values except the second, etc. In other words, one value is left out each time in turn, and *n* subsamples are created from just one sample. If a large sample is available, two or more values can be dropped each time. For dropping two at a time, the procedure would be as follows. If you have a sample of $n = 212$ subjects, drop numbers 1 and 2 and recalculate the result on the basis of numbers 3–212. Then drop numbers 2 and 3 and recalculate the result based on numbers 1 and 4–212, and so on. Generally, all possible subsamples are considered, and these subsamples can be used for inference regarding the parameters of interest. For example, the mean or average of these *n* subsamples would have better reliability than the mean of just one original sample.

The term jackknife signifies a ready simple tool that can be folded and opened, and can be used in a variety of situations. The technique was first proposed by Quenouille [3] in 1956 as a tool to estimate bias, although he did not use the term jackknife.

The method is primarily used to detect outliers that have major effect on the results. It is evident that jackknifing is very effective in detecting outliers. If, for example, the mean of the fifth subsample that has dropped the fifth value is very different from the other means, you know that this fifth value is an outlier. The method can be used for assessing robustness also. For robustness, there is no need to study all possible samples—possibly three or four subsamples are enough. If the results replicate in repeated subsamples, there is evidence that they are robust. The method works well for summaries that use all the values, such as mean and variance, but can fail for median, which does not use tail values. For further details of the method, see Shao and Tu [4].

The only difference between bootstrap and jackknife is that, in the latter, one or more values are serially dropped at a time and the results recalculated. Thus, in jackknife resampling, the subsamples are not necessarily random. This method can be used even when the sample is relatively small such as 10 or 15.

The following example illustrates another use of jackknife resampling for deriving various validity measures of a new method of classification of breast cancer cases. Breast Imaging Reporting and Data System (BI-RADS) is a conventional method of mammographic interpretation. Buchbinder et al. [5] used a computer-aided classification (CAC) that automatically extracted lesion-characterizing quantitative features from digitized mammograms. This classification was evolved on the basis of 646 pathologically proved cases (323 malignant). The jackknife method (100 or more subsamples by a computer) was used to calculate that the sensitivity of CAC is 94%, specificity is 78%, positive predictivity is 81%, and the area under the ROC curve is 0.90.

Resampling methods can be used for a variety of purposes and obviate the need to depend on Gaussian distribution. Many enthusiasts believe that there would be a paradigm shift, and statistical methods would be primarily based on resampling instead of the conventional methods. These methods show promise today as much as they did 25 years ago but have not been able to make much headway so far.

## research

Research is either discovery of new facts, enunciation of new principles, or fresh interpretation of the known facts or principles. It is an attempt to reveal to the world something that either was never thought of or was in the domain of conjectures—at best being looked at with suspicion. It is a systematic investigation to develop or contribute to generalizable knowledge. Research is a step in relentless search for the truth—it is an organized and systematic approach to finding answers to questions or to refute the existing knowledge. The basic function of research is to answer the why and how of a phenomenon, but searching answer to what, when, how much, etc., is also part of research endeavors. All these questions have relevance to any discipline, but medicine seems to have special appetite for such enquiries. The goal of medical research is to improve health, and the purpose is to learn how systems in the human body work, why we get sick, and how to get back to health and stay fit. It is the logical process to better understand the etiology, pathophysiology, diagnosis, therapy, and prognosis of health aberrations. Research is the very foundation of improved medical care. It can also provide evidence for policies and decisions on health development.

Although research brings dividends in terms of satisfaction, eminence, and funding, does it really benefit the medical science?

According to Chalmers et al. [1], of more than 25,000 reports published in six leading basic sciences journals between 1974 and 1983, just 100 included confident claims of new discoveries, mere 5 resulted in licenses by 2003, and only 1 intervention is being widely used. Thus, it looks as though the focus is lost somewhere along the process. Poor methodology aggravates the research wastage, and this could well be a reason for such dismal performance.

Perhaps we need to focus on patient outcome in terms of not just physical improvement but also meeting their mental and social expectations, and the perception of the doctors and other health care providers. This may require indulgence in soft data as opposed to the present emphasis on hard data, in realization that inaccurate measurement of the real outcome of interest can be more beneficial than accurate measurement of unimportant, perhaps superficial, outcomes.

Whereas outcomes or the results of research endeavors are important by themselves, the process of research determines the credibility. The planning should be based on critical appraisal of the available evidence in the context of the methodology adopted to create that evidence. The deficiencies should be objectively evaluated and remedial actions taken. While interpreting the results, it is important to distinguish the quality of evidence between an aggregation of small-scale studies and a single large-scale study with immaculate methodology.

## research synthesis, *see also* systematic reviews, meta-analysis

Synthesis is the process of combining and reconciling varied and sometimes conflicting evidence. Although statistical *analysis* is acknowledged as an essential step in empirical research, the importance of *synthesis* is sometimes overlooked. Research synthesis is a global term that includes **systematic reviews** and **meta-analyses**.

The findings of an investigation do not often match with those of another similar investigation. Diabetes, smoking habits, and blood pressure levels were found to be significant factors of mortality in Italy in one study, but not in other studies in the same country [1]. Prevalence of hypertension in India was found to range widely from 0.36% to 30.92% in a general population of adults [2]. Sometimes the results are at odds with one another. These anomalies occur for a variety of reasons such as genuine population differences; sampling fluctuation; disparate definitions, methodology, and instruments; and differences in the statistical methods used. A major scientific activity is to synthesize these varying results and arrive at a consensus. The discussion part of most articles published in medical journals tries to do such a synthesis, but this can be biased toward the finding of the study and prone to subjective judgments. The objective of most review articles is basically to present a holistic view after reconciling the varying results in different studies. In addition, techniques such as meta-analysis seek to combine evidence from different studies. These synthesis methods are primarily statistical in nature and are important components of medical research endeavors.

Varying results by different workers put a question mark on what conclusion one should draw. The effect of lack of uniformity is a waste of intellectual efforts. Synthesis helps to retrieve at least part of the disparate and conflicting results by analyzing in specifics that seem to have caused such results. Another related term is integration that takes us a step further in science by accumulation and refinement of information.

Research synthesis is like putting together stones of different sizes and shapes for constructing a fairly smooth wall. This is difficult but doable by filling up gaps with knowledge that sticks like cement. According to Barnett-Page and Thomas [3], this may require (i) cross-disciplinary approach to build a solid framework of evidence; (ii) different synthesis methods depending on the type of data; (iii) innovative thinking for filling up the gap and, more importantly, for identifying the gaps; (iv) critical thinking to be able to decide what to include and what to exclude; and (v) skills in putting together disparate pieces of information in a manner that commands trust and is considered credible. Thus, synthesis requires rigorous skills of distilling and combining the ideas.

For further details of research synthesis, see Cooper et al. [4].

## residuals, *see also* regression models (basics of)

All **models** are simplified version of the actual process—thus, there would always be some difference between the values obtained from the model and the actual observations. This difference is called error in the context of the population and residuals in the context of the sample. The models are built in a manner that these residuals are minimal without sacrificing the simplicity. The **least squares method** is a case in point that minimizes the sum of squares of residuals in regression models.

In the case of **multiple linear regression**, the model is

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_K x_K + \varepsilon,$$

where the $x$'s are the regressors and $y$ is the dependent. The term $\varepsilon$ is the part that remains unexplained. This notation is for the population and is called error. The corresponding sample analogue for the model is $y = b_0 + b_1 x_1 + b_2 x_2 + \ldots + b_K x_K + e$, where the $b$'s are the estimates of β's and now $e$ is called the residual.

Consider the simple regression model given by BSA = 1321 + 0.3433(Wt in g) for children where BSA is the body surface area. If this equation holds, it tells what BSA to expect in children of different weights. With this model, the estimated BSA of a child of 20 kg is 8187 $cm^2$. The actual values would most likely differ from these predicted values. If the actual BSA of a child of 20 kg is found to be 8093 $cm^2$, then the difference from the expected is –94 $cm^2$. If another child of 20 kg has BSA 8214 $cm^2$, then the difference is +27 $cm^2$. The residual for the first child in this example is –94 $cm^2$, and for the second child it is +27 $cm^2$. In general, for the subjects giving rise to the regression, some residuals will always be positive and some negative in such a manner that their sum, and hence mean, is always zero.

The magnitude of residuals is crucial in judging the adequacy of a model. If the model is a good fit to the data, the residuals will be

mostly small. Because their mean is zero, small residuals amount to a small standard error (SE). Conversely, a small SE of residuals is an indication that the model obtained is a good fit to the data. If not, examine if addition of more relevant regressors can reduce the SE. Examples of unusual residual plots are given in Figure R.11c and d, where the residuals have a U-shape in one of the figures indicating that the model is inadequate and incorporation of the $x^2$ term might help. In the second figure, the residuals are almost equally divided on either side of zero, but the variability increases as $x$ increases. This is called *fanning* and indicates lack of **homoscedasticity**. A log or square root transformation of $y$ may help in achieving uniformity of variance over $x$ in this case. Thus, the residual plot can provide important clues for improving the model.

Ordinary quantitative regression methods require that the residuals follow a Gaussian pattern. This is especially important for obtaining confidence intervals on various parameters and for test of hypothesis on them. If the residuals are indeed random, most will be around zero and progressively less and less with larger values in absolute sense. Thus, they will follow a Gaussian pattern. If not, the usual practice is to try transformation depending upon the shape of the plots as explained in the preceding paragraph.

Consider a study on relationship between cholesterol level and body mass index in morbidly obese people (BMI ≥ 40 kg/m$^2$). In such subjects, the cholesterol level does not increase with BMI as found for non-obese people; rather it somewhat decreases, and the slope in **simple linear regression** is negative. Figure R.11c shows the plot of residual versus $x$ when such a regression analysis of cholesterol level ($y$) on BMI ($x$) was run, and Figure R.11d shows the plot versus $y$ values. The first plot shows that the residuals are almost equally and randomly (no discernible pattern) divided across the zero line, and they are concentrated more around the zero line with a few points far away, confirming that the residual distribution is not far from Gaussian and no residual seems to be an outlier. The scatter of the plot does not really differ much with increasing $x$, confirming homoscedasticity. Large values of residuals indicate that the BMI itself is not enough to explain the cholesterol level in these subjects—other regressors are needed for the regression to be an adequate representation of the data. In case of multiple regression, similar plots can be done versus each regressor, and conclusions as just illustrated can be drawn.

The residuals versus $y$ values give a neat straight line (Figure R.11d) with increasing residuals as $y$ increases. This shows that the model overpredicts for low values of cholesterol level and underpredicts for high values, and indicates a room for improvement either by incorporating new regressors or by including powers of $x$. Transformation of $y$ can also help. There is no outlier in our sample, but this kind of plot is helpful in detecting outliers as well when present.

It is customary to examine the plot of residuals versus the predicted $y$. In case of adequate fit, this plot is also expected to randomly hover around the zero line just as it does versus $x$ in Figure R.11a. In case there is a discernible pattern, there is a scope for improving the model.

Perhaps it is more informative if the residuals are Studentized, which is obtained by dividing each by the SE since the mean is already zero. Under the Gaussian conditions, 95% of these residuals should lie between –2 and +2.

## residual sum of squares, *see* error sum of squares

## response rate

Statistically, this is the proportion of subjects who really responded to a question or a therapy. This generally does not have a time component but is still called a rate. The following example illustrates that the response rate could be anomalous in some situations.

Consider a clinical trial on a new therapeutic regimen that is expected to improve the response rate in patients with

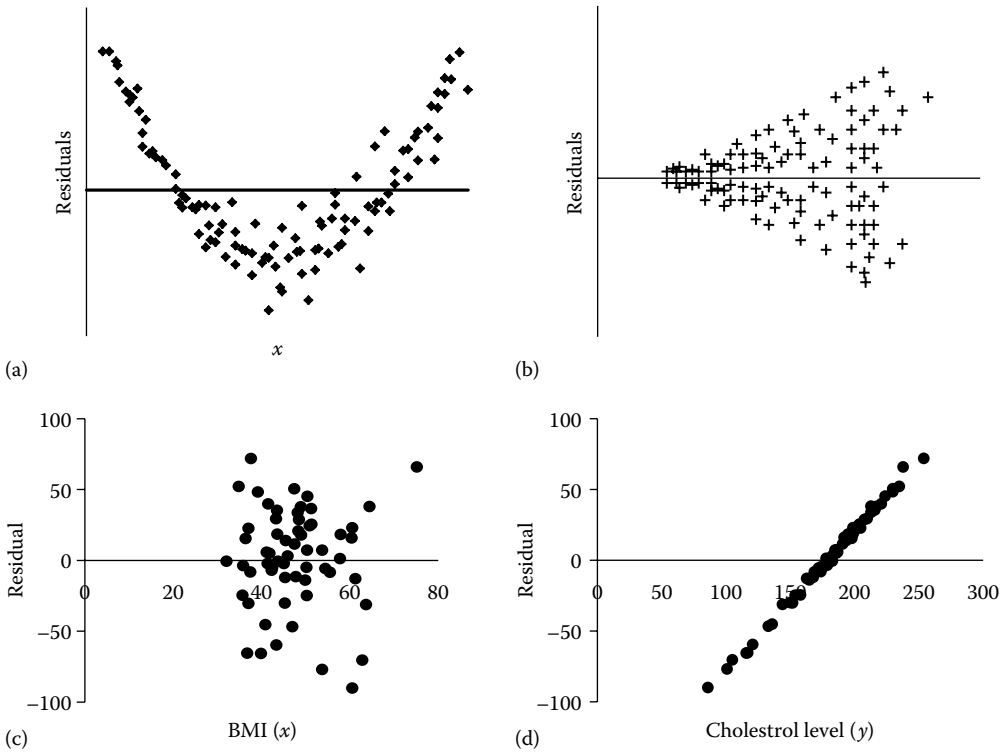

**FIGURE R.11** Residual plots: (a) U-shaped; (b) fanning: (c) versus $x$; and (d) versus $y$.

hyperthyroidism within a stipulated period. A total of 40 cases with varying grades of disease were put on trial, and an equal number receiving the existing therapy were used as controls. The allocation of subjects into treatment and control groups was randomized. The data in Table R.10 were obtained when the response of subjects was subsequently divided according to the severity of their condition.

The response rate in the treatment group was 80.0% and in the control group 62.5%. This difference is statistically significant ($P < 0.05$). When the subjects were divided according to the severity of the disease, it turned out that the therapy has a differential effect in mild than in severe cases. Randomization did not match the control group with the treatment group for severity of the disease in the subjects. When mild and severe cases from the control group were compared with those of the treatment group, respectively, the new treatment was found to be of no significant value.

This example illustrates that response rates as arrived at in a study or as reported in a publication cannot be taken granted on face value. Beside the case mix as in our example, there could be other problems. Penwarden [1] gives an example of online surveys where this problem is particularly acute. Such surveys are common but are notorious for low response rate, and the response can be severely biased. Even a rate of 25% in online surveys is amazing. Telephone surveys generally yield just about 10% response. Compare this with a rate of 90% that people can easily achieve with captive population who are asked to respond to a questionnaire as part of their duty such as nurses in a hospital. The response rate also depends on how useful the survey is perceived by the respondents. If they think that this is going to help them, they will respond in large proportion. If a survey is based on three or four questions, perhaps almost everybody will respond. Larger questionnaires tend to distract the respondents and may yield unreliable information, particularly toward the end of the questionnaire. Even in face-to-face interviews, fatigue sets in with the interviewer as well if it is long, and the survey loses quality.

The response rate also depends on how the questions are framed. A similar question when put in an interesting manner may yield a response, even a correct response, compared with a badly worded question. Rapport established by the interviewer with the respondent could be a key parameter determining the response rate as well as the quality of responses. It helps to have an interviewer from the same milieu as the respondent, speaking the same dialect, perhaps of the same intelligence.

Now let us talk a bit about responses to medical regimens. This has a different meaning since this response implies that the patient has shown perceptible improvement. It is in this sense that the term response is used in Table R.10. This kind of response rate is generally believed to vary either because of difference in the potency of the intervention or because of severity of disease. But there might be other factors as well that tend to be ignored such as nursing care, family support, inner motivation to fight the disease, etc. Thus, one should apply sufficient caution in interpreting the response rate of an intervention.

**TABLE R.10**
**Response Rate in Mild and Severe Hyperthyroid Cases**

| Group | Number of Subjects | Number Responded | Response Rate (%) |
|---|---|---|---|
| I. Treatment group | 40 | 32 | 80.0 |
| Mild | 30 | 26 | 86.7 |
| Severe | 10 | 6 | 60.0 |
| II. Control group | 40 | 25 | 62.5 |
| Mild | 8 | 7 | 87.5 |
| Severe | 32 | 18 | 56.2 |

## response surface

Consider regression of the birth weight of full-term healthy babies on the weight of the father and mother. Suppose the regression equation obtained on the basis of a random sample is

$$\text{BW} = 2.65 + 0.008\ (\text{MW}) + 0.004\ (\text{FW});$$
$$55 \le \text{MW} < 80;\ 60 \le \text{FW} < 90,$$

where BW is birth weight, MW is mother's weight, and FW is father's weight. All weights are in kilograms. Since there are two regressors in this equation, graphically a plane is obtained in place of a line. This is the response surface of this equation as shown in Figure M.8 in the topic **multiple linear regression**. This is just about the most simple response surface. The response in this equation is considered to be linearly affected by the weight of the father and mother. In practice, there will be many factors that will affect the response; it will not be linear and could be quite complex.

Response surface methodology is a step further. It does not restrict to depicting to response surface but extends to designs that optimize the response for different levels of the factors. This requires investigations into how the response varies as the values of the factors are changed, and also requires picking up a combination of factors that optimizes the response. The factor values in this case must be manipulative, that is, they are not something like age and sex, which are not in our control, but are something like types of treatment, dose levels, route of administration, and intake schedule. All these are within our control, and we can find which combinations of these factors really minimize, say, duration of hospitalization. The response surface in this case is some function of the levels of factors, say $f(x_1, x_2, \ldots, x_K)$, and may look like a regression model. The difference is that in case of regression, best-fitting response surface is obtained for given values of $(x_1, x_2, \ldots, x_K)$, whereas here the regressor values are altered to optimize the response.

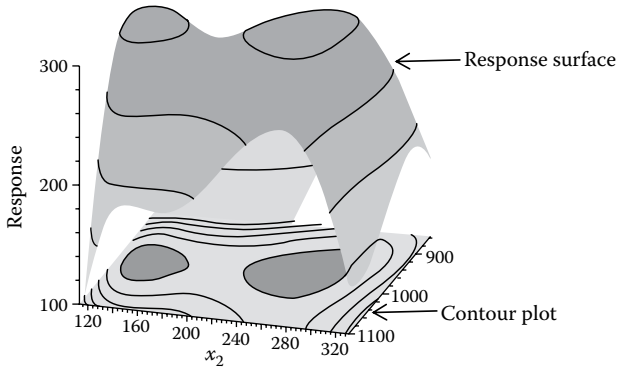

**FIGURE R.12** Three-dimensional response surface and the corresponding contour plot. (From Alvarez LF. Response surface methodology, in: *Approximation Model Building for Design Optimization Using the Response Surface Methodology and Genetic Programming* (PhD Thesis). University of Bradford, U.K., 2000. http://www.brad.ac.uk/staff/vtoropov/burgeon/thesis_luis/chapter3.pdf.)

Response surface methodology involves obtaining contour curves between levels of two factors, say between $x_k$ and $x_{k*}$, keeping all other factors fixed. The kind of contour you can obtain and the corresponding response surface are shown in Figure R.12 for variables $x_1$ and $x_2$.

Ref. [2] is a useful resource for understanding the response surface methodology.

## retrospective studies

Retrospective studies are those that investigate antecedent–outcome relationship by going from known outcome to the unknown antecedents. A format for examining gestational age in relation to maternal anemia is that births with different gestation periods are chosen and anemia status of the mothers during the antenatal period is retrieved from records. The first assessment in this format is the outcome, and the antecedents are subsequently assessed for each type of known outcome. Note the temporal difference between this and a **prospective study** (Figure R.13).

Investigation in the case of retrospective studies is in the reverse direction—from outcome to the antecedent. This may seem unnatural but is generally considered more efficient. Note the quickness with which a study in this format can be carried out. There is no need to wait for the outcome to develop or not develop. The outcome is already known, and the information on antecedent is obtained either from records or inquiry. The cases, and in most studies controls, are assembled, and information regarding their past exposure to risk factors is collected. The cases can arise or can be recruited in the future such as cases of breast cancer coming to a clinic, yet the study is technically retrospective so long as it investigates antecedents for a known outcome.

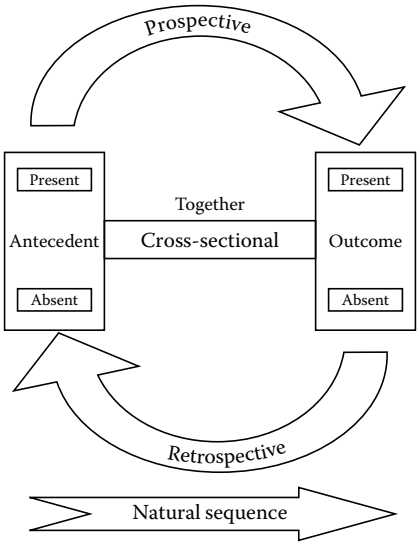

**FIGURE R.13** Schematic representation of prospective, retrospective, and cross-sectional studies.

Only subjects for whom the outcome is already known can be studied with a retrospective design. The outcome is the factor in this format, and the antecedent, which is elicited in retrospective studies, is the response. In prospective studies, on the other hand, antecedent is the factor, and outcome is the response since that is what is elicited.

Many studies do not proceed from the outcome to the antecedent, yet are termed as retrospective in the medical literature. This usage indicates the time frame and not the etiological sequence. For example, Hilska et al. [1] in 2001 reported an analysis of 150 patients with primary proximal colon cancer in Finland who were operated upon during 1981–1990. But the outcome measure was a 5-year survival rate. The study still is from the antecedent (colon cancer) to the outcome (survival). It is a prospective study going by the terminology we use, and could be called a retrospective cohort, but not technically a retrospective study.

A retrospective study can also be conducted in the current time frame in special situations. Women with preeclampsia can be assessed for their present nutrition level and parity as risk factors in the hope that the level of such risk factors was the same before the occurrence of preeclampsia and contributed to the condition. The direction of investigation in this study is also from the outcome to the antecedent—and thus is technically retrospective.

Sampling of subjects in a retrospective study is based on the outcome; thus, the first step is to identify and define the outcome of interest. This could be negative such as disease or death, or positive such as relief or a specified minimum reduction in cholesterol level. The criteria for diagnosis of a disease and its severity must be fully specified. For example, in cancer cases, the stage of disease and, of course, the affected site must be specified. Depending on the amount of information available, it is sometimes useful to keep a separate track of the definite from suspected cases. Obtaining information on possible risk factors that could have given rise to this outcome is the next step. The most common approach for eliciting such history is interviewing the respondent. Because of the **recall lapse** and the intentional misreporting, it is better to depend on records if they are relatively complete.

Most retrospective studies are in the **case–control** format where one group is with disease and the other is without disease. The frequencies of antecedent in these two groups are compared, and the analysis is mostly by **logistic regression** where the **odds ratio** (OR) of each antecedent is obtained. However, some retrospective studies are done without controls. Obtaining history of cancer cervix patients regarding infections, diet, and use of oral contraceptives is retrospective but not case–control if noncancer subjects are not part of the study.

Retrospective studies have many inverse properties to prospective studies. A retrospective study can be accomplished with a relatively small number of subjects in less time and resources. It is efficient for rare outcomes because it can begin with a sufficient number of cases. It can simultaneously evaluate many causal hypotheses and is efficient also in the evaluation of interaction between different risk factors. A case–control study also allows easy control of confounders. All such advantages accrue mostly because a large number of affected cases are generally available in this format.

On the downside, recall lapse is common in a case–control study that can bias the results. Differentials such as the ability of cases to recall events easily than controls can cause additional bias. It can also be biased because only those who already have had the required outcome can be included. Many severe cases may have already died and cannot be a part of this type of study. A case–control format will not be able to establish the sequence of events.

**TABLE R.11**
**General Performance Comparison of Prospective, Retrospective, and Cross-Sectional Designs**

| Criteria | Prospective | Retrospective | Cross-Sectional |
|---|---|---|---|
| Cost and time | High | Low | Low |
| Number of subjects required | Large | Small | Large |
| Suitability for rare exposures | Good | Poor | Poor |
| Suitability for rare outcomes | Poor | Good | Poor |
| Spectrum of etiologic factors that can be investigated | Small | Large | Large |
| Spectrum of outcome factors that can be investigated | Large | Small | Large |
| Recall lapse and other biases | Not likely | Very likely | Not likely |
| Completeness of information | High | Low | Full, but only cross-sectional |
| Dropouts | More | Less | None |
| Changes in the characteristics of the subjects over time | More likely | Less likely | None |
| Assessment of temporal relationship | Good | Difficult | Not possible |
| Suitability for assessment of sensitivity and specificity | No | Yes | Yes, if the sample is representative |
| Suitability for assessment of predictivities | Yes | No | Yes, if the sample is representative |
| Evaluation and control of confounders | Poor | Good | Fair |
| Assessment of risk | Direct by relative risk | Indirect by odds ratio | Approximate by prevalence rate ratio |
| Assessment of cause–effect relationship | Good | Fair | Poor |

Table R.11 is a useful summary comparing the performance of prospective, retrospective, and cross-sectional designs with regard to their performance.

### *Sampling in Retrospective Studies*

Since a retrospective study is based on cases with disease to begin with, the sample size must be adequate that can represent the entire spectrum of subjects and can provide reliable results suitable for generalization. Cases included should ideally be representative of all persons with the specified outcome, but many case–control studies are carried out on a nonrandom sample. Random selection is especially important for **descriptive studies** but probably not so important for **analytical studies** including retrospective studies. Experience suggests that the relationship between antecedent and outcome can be adequately assessed despite a nonrandom sample in many situations as long as the bias is under check, the basic requirement for which is the baseline equivalence of the cases and controls.

At the same time, these studies also involve estimating a parameter such as OR, finding a confidence interval (CI), and testing a hypothesis. These statistical procedures do require a random sample of the subjects. Indeed, a random sample should be taken whenever feasible. In addition, many of these statistical methods require a large sample.

### *Nested Case–Control Studies*

An extension of retrospective studies is **nested case–control studies**. In this setup, a cohort of subjects is followed up, and cases (and controls) are chosen from this cohort. See the example below for a nested case–control study that uses stratified sampling to assess the effect of serum selenium levels on cancer mortality.

The serum selenium level is widely suspected to affect cancer mortality, although the results across studies are not coherent. Belgium has a system to follow up each patient till death. From this "cohort," a stratified (by sex: male and female) random sample of 201 cancer deaths of age 25–74 years out of a total of 343 during a 10-year period was studied by Kornitzer et al. [2] for their selenium level as well as some other factors. Three controls were also selected from the cohort for each case, and these were matched for age and gender. Thus, a total of 603 controls were also studied. The serum selenium level was found to be a significant predictor of cancer mortality in males but not in females.

Also note that the investigations proceeded from outcome (cancer death) to an antecedent (serum selenium level), and thus the study is retrospective in nature. Since controls were also investigated, it is a case–control study. It is nested because follow-up of each person is routinely done in Belgium, and cases and controls were chosen from this follow-up. Controls were easily available, and choosing three controls per case helped to increase the reliability of results without the corresponding increase in cost.

On the flip side of this study is the sample of 201 cancer deaths out of 343 and the claim that it is a random sample. Such 60% sample is not a norm: one can legitimately wonder why nearly all 343 could not be included in the study. Had all these been investigated, it would still be a sample in the sense that they occurred in a 10-year period that would naturally exclude past and future deaths.

## reverse causation

We all grew up thinking that cause precedes the outcome. But it is possible that the time frame of cause and effect might be reversed of what is generally thought of. In some cases, the effect, although not causation, seems to precede the cause, although that might be temporary. Also called retrocausation or backward causation, reverse causation refers to a situation where apparently the outcome precedes the exposure against the conventional relationship from antecedent to outcome. This may look strange but is not an altogether

unlikely situation. For example, the studies might indicate that obese people are more depressed as though obesity contributes to depression. Actually, depression might change dietary preferences and can cause obesity. This is the reverse causation. A study by Marquis et al. [1] reported that increased breastfeeding did not cause stunting of children in a shanty town in Lima, but stunted children generally were increasingly breastfed.

Flegal et al. [2] discussed the phenomenon of reverse causation in the context of effect of illness-related weight loss on the relation between body weight and mortality. A low weight can cause illness rather than the usual paradigm of illness causing low weight. This is an example where it may be difficult to establish what caused what, and reverse causation might be operative. For a good discussion on causality, see Pearl [3].

No clear approaches are yet available for studying reverse causation. Flanders and Augestad [4] suggest that the analysis should be balanced with **sensitivity analysis** and **simulations**. Lawlor et al. [5] used the Cox proportional hazards model for studying reverse causality between weight and mortality.

## reviews, *see* systematic reviews

## ridge regression, *see also* regression models (basics of)

This is a method of fitting a regression to minimize the effect of **multicollinearity** on the estimates when it exists among the regressors.

Any regression method, when widely used, is looked at very critically and the inadequacies noted. Thus, several modifications have been suggested for the regression to meet specific requirements. Among those used sometimes in health and medicine is the ridge regression. Consider predicting body fat with the help of skinfold thickness at the triceps, mid-arm, and thigh. These three are highly correlated, and the regression coefficients are likely to have an increased variance because of such multicollinearity among the regressors. The regression model loses its sheen and its utility is compromised because of such instability of the estimates. This can also happen when the sample size is too small for the number of regressors. Ridge regression is one of the modifications that can remedy this problem to a great extent. Instead of using the method of least squares, a method called ridge is used that produces slightly biased estimates of the regression parameters but substantially reduces the standard errors (SEs). Some statistical software packages provide an option to run this kind of regression. A brief is as follows, but see Montgomery and Peck [1] for more details.

As a safety against blown-up estimates (that can happen due to multicollinearity or due to a large number of regressors relative to the sample size $n$), ridge regression puts a constraint that $\Sigma b_k^2 < C$, where $b_k$'s are the estimated regression coefficients and $C$ is some predefined constant, known as the ridge parameter. This estimation is done after the regressors are standardized, and there is no need of any intercept. This constraint implies that the least squares method that we generally use for estimating a regression coefficient is penalized if the sum of squares of regression coefficients becomes too big. The net result is that the estimates of the regression coefficient reduce in magnitude, but the cost is that they are no longer unbiased. That is, the usual property of the estimates of regression coefficients reaching the corresponding population regression coefficients in the long run does not hold. This is the price paid to get more reliable estimates in such situations.

de Vlaming and Groenen [2] discussed the use of ridge regression for prediction in quantitative genetics using single-nucleotides polymorphism data, which have a high number of variables and high multicollinearity. They also discussed how **LASSO**-type methods can be helpful in running a ridge regression.

## risk difference, *see* attributable risk

## risk factors

These are those factors that directly or indirectly affect the outcome of interest. In the context of diseases, a risk factor can be defined as a "measurable characteristic that is associated with increased disease frequency and that is a significant independent predictor of an increased risk of presenting with the disease" [1]. In common parlance, the term *risk* connotes an adverse outcome, but this term in statistics is used even for favorable factors. Thus, the effect of risk factors on the outcome can be negative or positive. The Framingham Heart Study is generally attributed to have used this term for the first time [2], although the underlying concept has been widely applied earlier.

Risk factors are distinguished from a cause. The cause of typhoid is *Salmonella typhi*, and the cause of thyroidism is iodine deficiency. Cause is easily identifiable for most infective diseases, but that is not so for most chronic diseases. In chronic diseases, "causes" are usually multifactorial; thus, the concept of risk factor was born, which works in probability senses—some people are affected and some not—that also when other conducive factors are present. When risk factors are under control, the disease incidence is lower. For example, the risk factors of cardiovascular disease are hypertension, obesity, sedentary habits, and imprudent diet. They increase the risk but do not cause cardiovascular disease.

The concept of risk factors is applicable only to the **analytical studies** and not to the **descriptive studies**. These factors should be identified before data are collected by using previous results, clinical insight, and thorough understanding of the disease process. One easy method of identifying relevant risk factors for a study is to draw up a list of all factors that could possibly influence the outcome of interest based on your own knowledge, wisdom of seniors, or a review of the literature, and choose the more relevant ones that would be studied as risk factors or antecedents for their role in the outcome in the context of the study.

As the knowledge expands, the list of risk factors for various health outcomes increases, and they are now increasingly identified with more emphasis on their exact quantitative contribution. This quantification helps in their **ranking and selection**, thereby helping to devise more rational strategies for control of diseases. The most common statistical methods used to study the risk factors are **logistic regression** for qualitative outcome (yes/no or (mild/moderate/severe/critical), ordinary **regression** for quantitative outcome, and **Cox regression** for hazards. When properly analyzed and correctly interpreted, these regressions will quantify the contribution of each risk factor to the outcome, both in the presence of other risk factors and in their absence. Remember that some risk factors produce synergistic effect when other favorable conditions are present—thus, the interpretation requires care. For a discussion on mediator, independent, overlapping, and proxy factors, see the article by Kraemer et al. [3].

An important issue often forgotten while interpreting the effect of risk factors is that our knowledge is limited, and that all studies are done as per the existing knowledge. There may be important risk factors about which we do not know yet. Thus, the implication of findings remains truncated. Terms such as *net effect* of a risk factor, for example, in case of multivariable logistic regression, are inappropriate since the regression is based only on the known risk factors, and the effect of unknown factors continues to haunt the results. In addition, many risk factors still are in the hypothetical instead of the real domain as they are just suspected and not proven.

Besides logistic regression, among other statistical methods available to identify important risk factors is **sensitivity analysis**. For example, risk of coronary disease can be modeled to depend upon the presence or absence of diabetes, hypertension, and dyslipidemia. This model might be able to correctly predict 10-year risk in 62% of the cases. However, addition of smoking and obesity may increase this to 70%. This addition of 8% is substantial. Thus, predictivity of coronary disease is *sensitive* to the choice of risk factors. The first model is based on three risk factors and the second on five risk factors. Had the contribution of smoking and obesity been only 2% or 3%, the conclusion would be that prediction of coronary disease is insensitive to smoking and obesity when diabetes, hypertension, and dyslipidemia are known. This kind of argument can be used to establish robustness of the results on risk factors.

Risk factor finding can be tricky sometimes as illustrated by the following example provided by Yusuf et al. [4]. More than 80% of the global burden of cardiovascular disease occurs in low-income and middle-income countries, but knowledge of the importance of risk factors is largely derived from developed countries. Therefore, the effect of such factors on risk of coronary heart disease in most regions of the world is unknown. To delineate these, the authors established a standardized case–control study of acute myocardial infarction in 52 countries, representing every inhabited continent. They managed to enroll 15,152 cases and 14,820 controls. They found that smoking, history of hypertension or diabetes, waist/hip ratio, abnormal lipids, smoking, hypertension, diabetes, abdominal obesity, psychosocial factors, consumption of fruits, vegetables, and alcohol, and regular physical activity accounted for most of the risk of myocardial infarction worldwide in both sexes and at all ages in all regions. Their research suggested that approaches to prevention can be based on similar principles worldwide and have the potential to prevent most premature cases of myocardial infarction anywhere in the world.

## risk ratio, *see* relative risk

## robustness

Robustness in modeling implies consistency, sustainability, and stability of results in less than ideal conditions. For statistical procedures, it connotes certain resilience to deviations from their underlying requirements. Robustness also refers to insensitivity of the overall conclusion to various limitations of data, limited knowledge, and varying analytical approaches. By showing endurance of results to withstand the pressure of minor variations in their validity underlying conditions, robustness establishes wider applicability of the results.

The results that risk of coronary disease is higher in persons with higher blood pressure and risk of lung cancer is higher in persons smoking heavily are robust. The presence or absence of other factors does not affect these results much, and this is seen in all population segments. On the other hand, the conclusion that urinary sodium excretion is dependent on salt intake is not robust since it is so easily affected by metabolism, creatinine excretion, and body mass index. The result that the risk of lung cancer increases by 3% by smoking 100 additional cigarettes-years is also not robust. This chance can easily be 2% or 5% depending on the person's nutrition, exposure to kitchen smoke, etc.

Models, by definition, are relatively simple statements of complex processes. They are man-made manifestations of nature. By their very nature, models are imperfect representations of the real world and, at best, are only approximations of the actual situation. Statistical models are no different as they too often work only in very specific situations, and slight variation in the conditions can produce weird results. In any case, they are supposed to work in the long term and may fail in individual cases. Thus, it is important that robustness of statistical models is established before they are put to use.

Good researchers exhibit robustness of their results to rule out challenges from critics. The evaluation could be done for the set of underlying conditions as a whole but is generally done for its components such as robustness to choice of variables, to instrumentation, and to the methodology. Individual conditions are altered, in turn, to examine if the broad conclusion still remains the same. If you are using a published result for your practice, examine if the result is sufficiently robust to the altered conditions under which you intend to apply it. This also is a way to minimize the impact of uncertainties. **Sensitivity analysis** is one of the many methods to assess robustness, where it is assessed by varying the conditions such as excluding or including some risk factors, altering their validity conditions, changing the basic structure, etc. The other method is **resampling** where subsamples are analyzed to examine if the results replicate.

Many statistical studies of robustness examine the behavior of the estimates with and without outliers in the data. They are sometimes

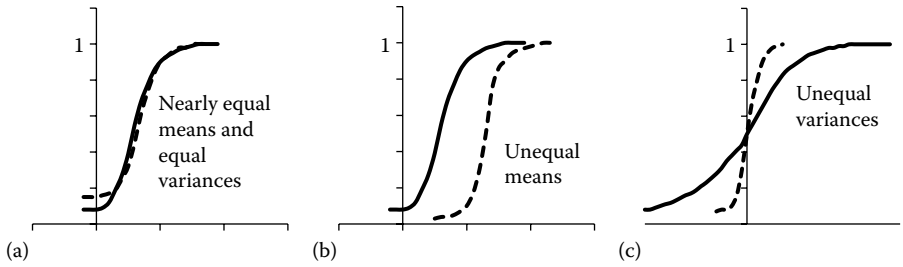

**FIGURE R.14** Plot of cumulative distribution functions in two groups when (a) the distributions are nearly equal, (b) the distributions have unequal means, and (c) the distributions have unequal variances.

extended to examine the effect of serial dependence, skew distribution, varying variance, etc. For example, the Student *t*-test is considered robust to departure from its validity conditions. In a slight variation, the term robust model is used in medicine also for experimental unit such as whether mouse is a robust model to study advanced diabetic kidney disease, and whether cardiomyocytes is a robust preclinical model for assessing atrial selective pharmacology. Our concern in this section was not with medical but with statistical robustness, as may be evident from our discussion.

## ROC curve, *see* receiver operating characteristic (ROC) curve

## $R^2$, *see* multiple correlation

## runs test for equality of distributions

Runs test is used for two purposes and the test takes a different form for these two cases. First is runs test for randomness as discussed under the topic **randomness (statistical tests for)**, and the second is for testing equality of two distributions as discussed next. This also is very similar to the test for randomness.

Run is a sequence of similar values such as increasing or decreasing order, or similar response in case of qualitative data. Consider a sample of size $n_1$ from group 1 ($x$'s) and of size $n_2$ from group 2 ($y$'s). If $n_1 = 4$ and $n_2 = 5$, the following is one of the possibilities when arranged in increasing order:

$$\underline{x\,x}\;\underline{y\,y\,y}\;\underline{x}\;\underline{y\,y}\;\underline{x}$$

This configuration has five runs based on the group to which they belong as indicated by the underlines. If the distribution of values in these groups does not differ much (Figure R.14a), the values in these groups, when arranged in, say, increasing order, would thoroughly mix and the number of runs would steeply rise. As shown for groups with unequal means in Figure R.14b, and with unequal variances in Figure R.14c, you can imagine that the number of runs would be much smaller in these situations. Thus, if the number of runs is smaller than expected, the null hypothesis of equality of the two distribution can be rejected. This is a nonparametric method and can be used in a variety of situations.

This test uses the following argument. Let the number of obtained runs in our sample be denoted by $R$. The

$$P(R \text{ runs}) = \frac{\text{number of ways of getting } R \text{ runs}}{\text{total number of ways of arranging } x\text{s and } y\text{s}}.$$

The denominator is always $(n_1 + n_2)!/(n_1! + n_2!)$. If $n_1 = 4$ and $n_2 = 5$, this is 11!/(4!*5!) = 13,860. This multiplies fast. The numerator depends on whether $R$ is even or odd, and requires knowledge of permutations and combinations. The test is easy for large samples since, in this case,

$$\text{mean of the runs, } \bar{R} = \frac{2n_2n_2}{n_1+n_2} + 1, \text{ and the SE,}$$

$$s_R = \sqrt{\frac{2n_1n_2(2n_1n_2 - n_1 - n_2)}{(n_1+n_2)^2(n_1+n_2-1)}}.$$

For a large sample, Student $t = \dfrac{R - \bar{R}}{s_R}$ with df = $(n_1 + n_2 - 1)$. Reject the null of equality of two distributions if the calculated value of $t$ is less than the critical value at the predetermined $\alpha$ level of significance. Since Student $t$ also approaches Gaussian $z$ for large samples, this is sometimes stated in terms of ***z*-test**.

# S

## sample

A sample is that fraction of the **population** that is actually studied. In almost all situations, the statistical population of interest is big, and we rarely have resources to study all the subjects. Even if the resources are unlimited, we can only study existing cases—the future cases and many of the past cases cannot be studied. And the irony is that the conclusions from the empirical studies are drawn, and we think they would be applicable to future cases. Thus, the sample remains an integral part of medical research framework.

Two questions primarily arise while studying a sample: (i) whether the sample is an adequate representation of the population it is supposed to represent and (ii) whether it is large enough to ensure adequate reliability of the conclusions. A large number of random and nonrandom methods are available to address the former question as discussed under the topic **sampling techniques**, and the **sample size** is a big separate topic in itself to address the latter. We are not repeating those arguments here.

## sample design, *see* sampling techniques (overall)

## sample size determination (general principles)

Sample size, $n$, is just about the first thing that comes to mind when planning an investigation. Indeed, it is among the most important considerations that determine the utility of a study. A good researcher would always provide sample size calculation for his/her study and would give full justification of the values used as inputs to these calculations. This exercise is done in advance (before conducting the study) and stated in the study **protocol** not just for record but also to plan the resources, for setting the time frame, etc., accordingly, and all this is stated again at the time of reporting of results. Charles et al. [1], in a statistical review of 215 published reports of randomized controlled trials, found that 5% did not report calculation for sample size, and 43% did not include full details.

Statistically, the larger the sample, the better the **reliability** of the results. This comes from the fact that the **standard error (SE)** of estimates has $n$ or its function in the denominator, and the inverse of the SE measures the reliability of the estimate. A smaller SE results in a narrow width of the confidence interval (CI)—this increased precision provides more confidence in the results and better statistical power to detect any specified effect. Yet, the sample size should not be too large as this could mean a waste of resources. If a study of only 200 subjects can give a reliable answer, why spend resources to study 250? An unduly large sample is unethical in experiments because it means that some subjects are unnecessarily exposed to an intervention whose utility is in doubt. A small sample, on the other hand, may not give evidence one way or the other, and the study may fail to achieve its objectives. Thus, this also is a waste of resources.

Administratively, a large sample is hard to execute as it tends to become a burden on the investigator in most situations (Figure S.1), and small samples are not useless altogether as they are valid for a pilot, exploratory, or feasibility study, including phase I trials.

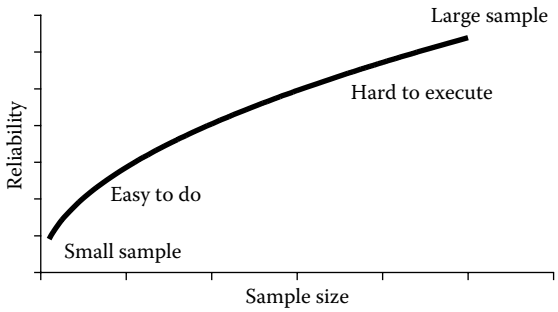

**FIGURE S.1** Reliability of a study and difficulty in its execution with increasing sample size.

When honestly done, small sample studies do allow us to move forward from knowing less. A small sample can be adequate if the anticipated effect size is large. In most other situations, small samples fail to provide a definite conclusion.

A statistician is sometimes expected to be able to suggest an adequate sample size immediately on being told of the title and the objectives of a study. This is like expecting a physician to prescribe a treatment regimen for pain in the abdomen without going into the details. A physician would need some more information such as the duration and intensity of pain, exact location, palpability or tenderness, any accompanying complaint, sometimes an x-ray image, etc. Similarly, the question about sample size can be answered only after some deliberation on the variability of the observations, precision required, confidence desired, etc. These general principles are explained in this section. Most biostatistics books do not emphasize the common structure behind sample size calculations, although many give details of sample size determination in specific setups. The general procedure for determining the sample size is different for estimation as compared to that for testing of hypothesis as follows.

### *Sample Size Required in Estimation Setup*

Estimation of a parameter such as mean and proportion is generally the primary objective of **descriptive studies**. A descriptive study could be a case series, but that is rarely based on a random sample. This leaves **sample survey** as the only relevant format of descriptive studies for calculation of sample size in estimation setup. But estimation is done in **analytical studies** as well, where parameters such as difference in efficacies and odds ratio are estimated. The following are the details of the concerns that need to be addressed to arrive at a sample size for estimating a population parameter. These details focus on mean and proportion, but the same sort of arguments applies to the other parameters. These may look like commonsense considerations in determining the sample size for estimation.

1. The first consideration for the calculation of sample size is the primary *variable of interest*. In antecedent–outcome setup, the sample size will be based on the outcome

variables. If blood pressure, body mass index, blood glucose, and cholesterol level are measured as outcomes in a study on noncommunicable diseases, the sample size can be based on any of them, and different variables will give different answers. You may like to calculate for all of them and choose the maximum as the required sample size. Generally, though, sample size calculation is done for a specific target variable of primary interest. It is helpful to specify this in any case so that the focus of the study is clear.

2. The second point of consideration is the nature of the primary variable: whether it is discrete or continuous, what its statistical distribution is, and whether the distribution can be approximated by Gaussian (normal) for large samples. Almost all formulas for determining sample size are valid under **Gaussian conditions**.
3. The next is the **parameter** of interest—whether it is mean, proportion, difference, odds ratio, correlation coefficient, or what. Sample size formula will depend on the choice of such parameter.
4. What is the **variability** between subjects in the population? Cholesterol levels tend to differ widely even among healthy subjects. Thus, a small sample of, say, seven subjects would not be adequate to reveal the full spectrum of cholesterol levels present in the target population. That is, another sample of seven subjects can yield an entirely different picture. Body temperature, on the other hand, is relatively stable in healthy subjects, and a small sample can be adequate. If the material to be sampled is as homogeneous as blood in the body, even one drop may be enough to reveal nearly the full picture in a person. The sample size requirement increases as the variance increases. In the case of sample proportion $p$, the variance depends on the value of the population proportion $\pi$. Thus, the question becomes, what proportion of subjects are expected to possess the characteristic under investigation? In relative sense, a large sample is required if $\pi$ or $(1 - \pi)$ is small.
5. What is the minimum degree of **precision** required? A pharmaceutical company may be interested to know very precisely the percentage of those with tuberculosis who are becoming drug resistant. This can help the company to assess the exact market for a new antitubercular drug. On the other hand, in surveys on opinions, attitudes, and behaviors, an error in the estimate to the extent of as much as 10% or sometimes even higher may be tolerable. The sample size should evidently be larger when greater precision is required.
6. What *least confidence* in the estimate would be tolerable? No empirical conclusion is 100% dependable, but the investigator may wish to be sufficiently confident that the conclusion will be replicated in repeated samples. There is always a chance of it being false. The chance of reaching a wrong conclusion can be kept low, generally less than 5%, by including a reasonably large number of subjects in the sample. In some cases, such a large sample may not be feasible because of constraints of time and resources, and a larger error may have to be tolerated. If a chance of as much as 10% or 20% of being wrong can indeed be tolerated, as in the case of some opinion surveys, then a small sample may be adequate.
7. Are there *any subgroups of interest?* If conclusions are to be drawn for various subgroups, as in stratified sampling in some cases, then each subgroup needs to be adequately represented. The sample size quickly multiplies and can become an enormous number if cross-classifications of a number of factors are under consideration. For only two factors, viz., age at menarche as <12 and ≥12 years, and age at first live birth as <25 and ≥25 years, the four cross-classifications are (i) menarche at <12 years and first live birth at <25 years, (ii) menarche at <12 years and first live birth at ≥25 years, (iii) menarche at ≥12 years and first live birth at <25 years, and (iv) menarche at ≥12 years and first live birth at ≥25 years. If there are four factors and all are dichotomized, the number of cross-classifications is $2^4 = 16$. Results would be reliable if each of these classifications has an adequate number of subjects.
8. How much, if any, **nonresponse** is expected? Although nonresponse raises questions about the validity of the survey because of bias it introduces, it also reduces the effective number of subjects that can be utilized to draw conclusions. Thus, a larger sample is planned if it is feared that many subjects may not be available, may not cooperate, or may have to be dropped because of development of, say, undesirable side effects. If the subjects are healthy and an invasive procedure is involved, even as small as a pinprick, the attrition could be large.
9. What **sampling technique** is to be used? For example, cluster sampling may require double the size or even larger relative to simple random sampling (SRS) because of the clustering effect. Different procedures have different limitations. Procedures such as stratified and two-stage can require smaller samples to achieve the same precision if the units can be rationally divided into homogeneous groups. This may be difficult to achieve when sufficient information is not available or when the subjects are widely scattered. Then the sample size could increase and will depend on the **design effect**.
10. Although ignored in most practical situations, the sample size also depends on the sampling distribution of the summary measure under study. This section assumes Gaussian (normal) distribution, which is likely at least for mean and proportion when the sample size is large.
11. Sample size also depends on the number of variables to be *simultaneously* considered. Because of complexity, this book discusses only one variable at one time setup for calculation of sample size.
12. Sample size also depends on the design of your study. Designs such as matching and repeated measures require different approach from that in independent samples.

In summary, a bigger sample is required for estimation if

i. Interindividual variability is higher or expected prevalence is low.
ii. More confidence or higher precision is required in the result.
iii. There are subgroups for whom results are to be applied.
iv. Higher nonresponse is expected.
v. Sampling method is other than simple random (in most situations).

Let the population parameter under estimation be denoted by $\tau$ and its sample estimate by $t$. Let $\delta$ be the difference between the two, i.e., $\delta = |\tau - t|$. Suppose the investigator requires that this difference does not exceed a specified limit $L$ in at least $100(1 - \alpha)\%$

of repeated samples. The quantity $L$ is called precision and is the half-width of the CI. The quantity $(1 - \alpha)$ is the confidence level. If a Gaussian form of distribution can be assumed for the sample estimate $t$, which, in fact, could be so in most cases when the sample size is large, it can be shown that

$$L = z_{1-\alpha/2}*\text{SE}(t),$$

where the coefficient $z_{1-\alpha/2}$ is taken from the standard Gaussian distribution such that the probability between $-z_{1-\alpha/2}$ and $+z_{1-\alpha/2}$ is $(1 - \alpha)$. The exact value of $z_{1-\alpha/2}$ for $\alpha = 0.05$ is 1.96; for $\alpha = 0.10$, $z_{1-\alpha/2} = 1.645$; and for $\alpha = 0.01$, $z_{1-\alpha/2} = 2.58$. Thus, for confidence level 90%, $L = 1.645*\text{SE}(t)$; for 95%, $L = 1.96*\text{SE}(t)$; and for 99%, $L = 2.58*\text{SE}(t)$.

This equation is basic for the calculation of sample size in an estimation setup. Let us call this the general equation. In this equation, SE($t$) would almost invariably have $n$ in the denominator, which could then be worked out when other values are known. But a difficulty is that SE($t$) would also contain an unknown parameter such as $\sigma$, which is to be replaced by its estimate. Where would you get this estimate before the survey is conducted? This is obtained either from a previous study or from a pilot study. SE($t$) also depends on the sampling method proposed to be followed. The sample size so obtained may have to be inflated to adjust for expected nonresponse. If estimates for various subgroups are required, then this calculation is done separately for each subgroup.

If there are many parameters under estimation, two approaches are available. The first is to calculate the sample size for the most important parameter if that can be identified. The second is to calculate the size for all the parameters and use the one that is the largest. The latter would give better-than-required precision of some estimates, but each estimate will have *at least* the specified precision. The following example may clarify the procedure to be followed in some cases.

A sample survey is planned to estimate the average level of fasting blood glucose in surviving and apparently healthy females of age 60 years and above of a particular ethnic group. It is desired that the estimate should be within 1.2 mg/dL of the population mean with probability 0.95. A previous study revealed an estimate of standard deviation (SD) = 6.3 mg/dL. How big a sample is required if an SRS is to be followed?

In this case, $L = 1.2$. For SRS, $\text{SE}(\bar{x}) = \sigma/\sqrt{n}$. If we replace $\sigma$ by its estimate $s = 6.3$, then our general equation gives $1.2 = 1.96 \times 6.3/\sqrt{n}$, or $n = 105.9$. This is always approximated upward, in this case to $n = 106$. (A purist would legitimately argue that the Student $t$ value should be used in place of $z_{1-\alpha/2}$ since $\sigma$ is being replaced by $s$, but it does not matter much since we are restricting this discussion to large samples.)

If greater precision (lower $L$) is required, say $L = 0.4$, then $n = (1.96 \times 6.3/0.4)^2 = 953$. Note how rapidly the sample size increases when the required precision is enhanced. If the confidence level $(1 - \alpha)$ is raised to 0.99, then, for $L = 1.2$, $1.2 = 2.58 \times 6.3/\sqrt{n}$ and $n = 184$. If the subject-to-subject variability in the population is smaller, say $s = 2.4$ only, then for $L = 1.2$ and $\alpha = 0.05$, $n$ is 16.

A bigger sample is required whenever (i) greater precision is needed, (ii) more confidence is necessitated, or (iii) the variability in the population is large. The quantity that affects it most is the precision you desire of the estimate. For double the precision (i.e., half $L$), the sample size required becomes four times.

If separate estimates for two age groups such as 60–69 and 70+ years are required, and if SD and other values are the same for each age group in our example, the same sample size is required for subjects of 60–69 years and for those of 70+ years. The total sample size doubles.

For proportions and $(1 - \alpha) = 0.95$, the general equation becomes $L = 1.96*\text{SE}(p)$. If the objective is to estimate the proportion of apparently healthy subjects who can be suspected as diabetic on screening using the cutoff 120 mg/dL of fasting blood glucose level and if it is desired that the estimate should not differ by more than one-fifth of the proportion of $\pi$ in the population, then $L = \pi/5$. This is the relative precision that can be expressed as 20% of $\pi$ or $0.20\pi$. Since $\text{SE}(p) = \sqrt{\pi(1-\pi)/n}$, we need a value of $\pi$ for the sample size calculation. If it is anticipated to be between 0.02 and 0.03, both limits can be used to calculate the sample size. For $\alpha = 0.05$, our general equation gives $0.02/5 = 1.96\sqrt{0.02 \times 0.98/n}$ for $\pi = 0.02$, and $0.03/5 = 1.96\sqrt{0.03 \times 0.97/n}$ for $\pi = 0.03$. The former gives $n = 4706$ and the latter $n = 3106$. The bigger of the two is statistically safer. Thus, a sample of size nearly 4700 is required.

Sometimes it is desirable to do reverse calculations. If resources permit a specific $n$, the general equation can be used to find the precision corresponding to that $n$. For example, if not more than 30 subjects can be studied due to resource limitations in our example on fasting blood glucose level, and if the values of the SE and the level of confidence remain the same, then $L = 1.96 \times 6.3/\sqrt{30} = 2.3$ mg/dL. Thus, the estimate of mean fasting blood glucose level can be more than 2.3 mg/dL away from its true value in the population 5% of the time. If this error is acceptable, go ahead with a sample of size 30. If this is too high, reconsider the idea of carrying out the study on only 30 subjects, as a larger sample may be required.

The level of confidence can also be calculated corresponding to a given size of sample and fixed $L$. For $n = 30$ and $L = 1.2$, we get $1.2 = z_{1-\alpha/2} \times 6.3/\sqrt{30}$, or, $z_{1-\alpha/2} = 1.04$. From the Gaussian distribution, get $\alpha/2 = 0.1492$. Thus, $\alpha = 0.30$ and the confidence level is only 70%. When $n$ is 30, there is only 70% chance that the estimated mean would be less than 1.2 mg/dL away from the actual mean in the population. This chance may be too low to proceed with a study on such a small sample.

As mentioned earlier, the sample size formulas follow a similar general pattern but differ in detail in different situations. We are devoting separate sections in this book on the sample size determination in different setups.

### *Sample Size for Testing a Hypothesis with Specified Power*

The primary aim of analytical studies is to investigate antecedent–outcome relationship. Although other setups are possible, the most common is to find whether two groups are different or not with respect to an antecedent factor in the case of retrospective studies, and with respect to an outcome in the case of prospective studies. Statistically, this leads to testing of hypothesis setup.

The method for determining sample size in the testing-of-hypothesis setup depends on the actual criterion used for testing. Various criteria are discussed under different topics in this volume. At this stage, it may be stated that the sample size calculation requires the following information in most situations encountered in practice. These are mostly the same as in the estimation setup, but there are some changes.

1–4. Same as in the estimation setup.

5a. How much minimum *difference* ($\delta$) between the actual value of the parameter and its value under the null hypothesis is **medically important**? This is the test of hypothesis counterpart of "degree of precision" in the estimation setup. A medically important difference is specified under the alternative hypothesis $H_1$. A small difference is difficult to detect, and a large sample would be required for a

small difference to be statistically significant. If the minimum difference to be detected were large, a small sample would be adequate. This difference is determined on clinical considerations and not on statistical considerations. Do not confuse it with actual effect size, which could be more or could be less than the minimum medically important effect.

5b. What is the statistical **power** required? This is the probability of detecting a specified difference when present and calling it statistically significant. The notation for this is $(1 - \beta)$. Power depends on the magnitude of the difference specified in (5a) above. If the power is to be 99% for the specified difference, obviously a bigger sample is required than for power of 80%. Power and $n$ have a direct relationship for any fixed level of significance.

6a. What **level of significance** is required? In the testing-of-hypothesis setup, the complement of confidence level is the level of significance $\alpha$. On the analogy stated for CI, a large sample is required if $\alpha$ is to be kept small. If a large $\alpha$ can be tolerated, a relatively small sample would be enough.

6b. Is the test a **one-tailed test or a two-tailed test**? A one-tailed test with $\alpha = 0.05$ is equivalent to a two-tailed test with $\alpha = 0.10$ in most situations. A high $\alpha$-level in a two-tailed setup is a relatively small $\alpha$-level in a one-tailed setup. This is true for ***P*-values** also. Thus, one-tailed testing requires a smaller sample size compared to what a two-tailed setup requires. If $n = 300$ gives $P = 0.03$ in a two-tailed test, the same $n$ would generally give $P = 0.015$ in a one-tailed test. For one-tailed $P = 0.03$, the required $n$ would be smaller than for a two-tailed $P = 0.03$.

7–12. Same as in the estimation setup.

In the case of large $n$, when Gaussian conditions prevail, these considerations lead to an equation of the following type in most situations for a two-sided test for detecting a difference of at least $\delta$ between the values under the null and alternative hypotheses (if present) with at least $100(1 - \beta)\%$ power:

$$z_{1-\alpha/2} * \mathrm{SE}_0 + z_{1-\beta} * SE_1 < \delta,$$

where $\mathrm{SE}_0$ and $\mathrm{SE}_1$ are the standard errors of the estimate of this parameter under the null and alternative hypotheses, respectively. If these two SEs are the same (this would be so when the variances in the two groups are the same and the sample sizes also are the same), the relation can be approximated as $(z_{1-\alpha/2} + z_{1-\beta}) * \mathrm{SE} < \delta$, or in variance terms, as $(z_{1-\alpha/2} + z_{1-\beta})^2 * \mathrm{Var(estimate)} < \delta^2$. The sample size $n$ would occur in the expression of the SE. This can be solved to obtain $n$ when everything else is specified. This takes a different form in different setups; see the topic **sample sizes for statistical analyses**, for example. A detailed and unified account of sample size calculations is given by Hanley and Moodie [2].

### *Some Comments*

It is ironic that sample size calculations require the value of the SD of the observations even before the sample is studied. As advised, this may be anticipated from a value reported in a previous study or from the estimation arrived at from a **pilot study**. There would be variations that are best resolved by discussion with a biostatistician. Sometimes it may involve guesswork, and the sample size so calculated will be approximate. To be safe, it is better to inflate this $n$ slightly to compensate for possible error in the estimate of the SD. When SD from previous studies is not available and the range is available instead, a conservative guess for SD for calculation of sample size is range/4, particularly if the underlying distribution is nearly Gaussian. For proportion $\pi$, a conservative estimate is 0.5 that will give a higher sample size than any other value of $\pi$.

The other, possibly more valid, option is to calculate sample size for a range of values of parameters whose values are uncertain, and choose the one that looks feasible without compromising the scientific requirement of the study. This is easy these days as repeated sample size calculations can be done with many readily available online calculators.

For sampling methods other than SRS, the SEs of those sampling methods should be used for these calculations. This, for example, in a two-stage sample, can raise questions on balancing the number of primary units for first-stage sampling and the number of subjects to be selected at the second stage. The calculations can become complex, and the information required for computing the size can also become difficult to manage. Besides the sampling method, remember that whatever sample size you come up with after calculations would need upward revision for uncertainty in the values used in the calculations, nonresponse, number of subgroups, design of the study, etc. If the nonresponse is anticipated to be completely at random in $100*p\%$ of subjects, the adjusted sample size is $n/(1 - p)$. For example, if the calculation reveals that $n = 200$ and the expected nonresponse is 15%, the required $n$ is $20/(1 - 0.15) = 236$. After 15% nonresponse, the final sample would be 200.

The formulas and procedures generally available for determining the sample size are valid for large samples where Gaussian approximation is valid. With advances in computer technology, it is now possible to use exact methods for small samples. However, these methods are still sketchy and available for a restricted class of situations. For example, Rahme and Joseph [3] worked out exact methods for determining the sample size for binary outcomes, Royston [4] published tables of sample sizes for pair-matched case–control studies, and Hilton and Mehta [5] devised an algorithm for ordered categorical data for small samples.

An additional consideration not accounted for in the usual formulas is the number of concomitant variables or covariates that are proposed to be studied together. The higher this number, the bigger the requirement of the sample size. The sample size quickly multiplies and can become an enormous number if cross-classifications of a number of factors are under consideration as already illustrated. Results would be reliable only if each of these classifications has an adequate number of subjects. No clear guidelines are available about the sample size that would be adequate to take care of, say, five risk factors as opposed to two risk factors, but a rule of thumb is that each cross-classification should have a sample of at least 30 subjects. This is applicable when the disease prevalence is large, say ≥20%. A size of at least 30 implies for four cross-classified binary factors that there must be at least a total of $16 \times 30 = 480$ subjects, evenly distributed to the 16 categories. All these comments are summarized in Table S.1.

The sample size many times depends on the resources and time available for a project. For a master's thesis, only 1 year is generally available with practically no funding. Thus, the sample size would be small regardless of what the formulas say. Our advice in such situations is to choose a topic for which an adequate number of subjects are available within 1 year, and restrict to the investigations that are feasible. Perhaps the master's thesis should not be done on rare diseases. Else, be clear that it would be a pilot study in nature whose results would not have much reliability but can provide important clues to plan a major study.

**TABLE S.1**
**Requirement of Larger Sample**

| Requirement | Sample Size |
|---|---|
| Smaller Type I error | Larger |
| Smaller Type II error (higher statistical power) | Larger |
| Smaller difference to be detected | Larger |
| Higher inter-individual variability or smaller proportion | Larger |
| Higher anticipated nonresponse | Larger |
| Higher number of subgroups | Larger |
| Higher number of variables to be considered together | Larger |

Even for big studies, resources and time constraints sometimes dictate the sample size. Vickers [6] gives this interesting example: A colleague points out that the drug under trial is safe and inexpensive, and could be advocated if it is able to reduce average pain score by even half a point. A recent paper showed an SD = 2 for the change, for which the formula gives $n$ = 774. Fund limitation may not allow one to do such a big trial. What if SD = 1.5? The sample size reduces to 380, but it is still high. Lower the bar and aim at detecting pain score reduction by 0.75 instead of half a point. Now $n$ = 170, which is doable. If this is chosen, the size of the study is dictating the research objective, whereas in reality research objective should dictate the sample size. In practice, this can happen and is accepted.

In situations where a large sample is not feasible, a small-scale study is better than no study at all with two precautions. First, a study based on a smaller-than-desired sample is pilot in nature that may not give conclusive results. Second, a separate class of statistical procedures such as nonparametric and permutation tests are sometimes used to analyze data based on small samples. These methods require extensive calculations—much more than the usual methods—and separate software packages are used for this purpose. Generally, only very large difference would turn out to be statistically significant in case of small samples, except for experiments on animals because of highly standardized conditions in the laboratories.

### *Nomograms and Tables of Sample Size*

Many medical researchers find sample size formulas difficult to adopt. Most statistical software packages incorporate tools to calculate sample size based on one's requirement. Two other alternatives are available, although they may not be readily available. One is **nomogram**—a graph containing lines and curves, and needs only a ruler to read the sample size that would meet the specifications. Altman [7] gave a nomogram for the size of SRS for comparing two groups, and Kumar and Indrayan [8] developed one such nomogram for reading the sample size required in cluster sampling (see the topic **nomogram**). Neter and Wasserman [9] gave nomograms for sample sizes for analysis of variance situations where three or more groups are compared for means. If you are weary of the formulas and the relevant software is not available, try to locate a nomogram for your situation. Nomogram is especially helpful to find sample sizes for several scenarios and to choose the scenario that is considered most suitable for the problem in hand. It can be easily used and reused, and can be carried in your pocket when going to field areas if necessary.

The second alternative is a table of sample sizes. Some authors have worked out sample sizes for various situations and tabulated them such as what Lwanga and Lemeshow [10] did for commonly occurring simple situations. The sample size required for specified values can be directly read from such tables. An interpolation may be required when the desired exact specification is not present in the table.

### *Rules of Thumb*

Sometimes approximate calculations are done for simplicity. For example, for power of 80%, $1 - \beta = 0.80$ and $z_{1-\beta} = 0.84$, and for $\alpha = 0.05$, and two-sided hypothesis, $z_{1-\alpha/2} = 1.96$. Thus, the formula for detecting a mean difference of $\delta$ in the two groups, under the usual regularity conditions, becomes

$$n = \frac{(1.96 + 0.84)^2 * \sigma^2}{\delta^2} \approx 8 \frac{\sigma^2}{\delta^2}.$$

For power = 90%, this becomes $\approx 11\sigma^2/\delta^2$. These are easy to remember and can be used for 80% or 90% power and two-sided level of significance 0.05 without being too far off. These values of power and the level of significance seem to occur commonly in medical research studies. Just take the ratio of variance to the minimum difference to be detected and multiply by 8 to get the sample size per group [11].

In addition, there are rules of thumb. They lack scientific basis and many scientists dislike them. When no baseline information for computation of sample size is available and the constraints do not permit pilot study either, the following rules of thumb can be used.

A large-sized medical trial should include nearly 300 subjects in *each* group, a midsized trial nearly 100 in each group, and a small-sized trial at least 30 in each group. The last can be used for master's theses where time and resources are limited. A bigger study is multicentric with these numbers in each center. Same norms can be used for a retrospective or case–control study. However, in the case of a prospective study, the number to be followed up should be such that at least 30 persons are finally available with the outcome of interest in *each group*. This applies to field trials also. In this case, an extremely large group may be needed to yield an outcome such as hepatitis B infection in at least 30 subjects after administration of a protective vaccine. To calculate exact numbers, use the exact formulas. A study of these formulas would indicate that a laboratory experiment on animals could be done on a smaller number because of fairly standard and controlled conditions in a laboratory that minimize variations.

For a descriptive study that seeks to find normal levels in healthy subjects, the rule of thumb is to include at least 200 subjects in each group for which norms are required, although in this case the exact number can also be calculated using an appropriate formula. For pathological levels in patients, the group size could be smaller. Depending upon the targeted reliability of the results, exact sample size requirement can be calculated. However, all these may have to be modified because of feasibility considerations when resources and time are limited. Such limitations obviously compromise the reliability.

## sample size for odds ratio and relative risk, *see also* sample sizes for study formats, sample sizes for statistical analysis methods, sample sizes for simple situations (mean, proportion, and differences)

Odds ratio (OR) in case–control studies and relative risk (RR) in prospective studies are among the most common parameters studied in medical context. In view of their special importance, we devote this full section to the sample size determination for estimating and testing of hypotheses of OR and RR.

You may want to review the topic **sample size determination (general principles)** for an overview of the basics of sample size determination. The procedure and the requirements for estimation (**confidence intervals**) are different from those for **testing of hypotheses**. If the objective is estimation, then it is necessary to specify the confidence level ($1 - \alpha$) and the precision desired on either side of RR or OR. This is generally specified as a proportion of RR or OR. The anticipated RR or OR or the anticipated probability of disease (or of exposure) in the respective groups should also be specified. If the objective is to test a hypothesis, then the specification of the relative precision is not required, and the **significance level** is required in place of the confidence level. Specification of the statistical power ($1 - \beta$) is needed for a testing-of-hypothesis setup, and for this, the difference to be detected must also be specified.

While $\alpha$ and $\beta$ are mostly determined externally, it is important to select suitable values for effect size for these calculations. For this, review the literature fully and locate a study in a similar setting so that the estimates are plausible for your study. The choice of the minimal effect size to be detected should be reasonable and suitable such that it is practically meaningful, and conducting the study is feasible. The factors time, cost, and recruitment of subjects should all be considered together with the power and minimal difference. Also consider the statistical procedure to be used—for example, a different procedure may be needed if a logistic regression is planned rather than a simple $2 \times 2$ table analysis. In addition, consider the ethical and financial cost also for finalizing the sample size.

The formulas are given in Table S.2 for large-scale studies as they are based on **Gaussian conditions**. They require the anticipated probabilities in the two groups under comparison. If only one of these probabilities can be reasonably anticipated, the anticipated value of RR (or of OR) would be needed. In that case, the other probability can be calculated by using the definition of RR or of OR. The notation now is $\pi_1$ and $\pi_0$ for disease probability in the exposed and unexposed groups, respectively, and $\pi_1'$ and $\pi_0'$ for exposure probabilities in the case and control groups, respectively. In terms of these probabilities, RR = $\pi_1/\pi_0$ and OR = $\dfrac{\pi_1'/(1-\pi_1')}{\pi_0'/(1-\pi_0')}$.

An astute reader would note that formula (b) in Table S.2 for test of hypothesis on RR uses $\overline{\pi} = (\pi_1 + \pi_0)/2$, but such an average is not used in formula (d) for OR. Instead, only $\pi_0'$, which is the exposure rate among the controls, is used. Quite often, this rate is reliably known in the case–control setup, and there is no need to use the average. If you are not fully confident about $\pi_0'$, the first part in formula (d) should be $\sqrt{2\pi(1-\pi)}$ just as in formula (b).

The formulas in Table S.2 are restricted to the following: (i) two independent samples (not matched pairs), (ii) a large $n$ so that the Gaussian pattern is applicable, and (iii) for OR, a small proportion of the subjects have disease. Relative precision $\varepsilon$ is on either side of RR or OR, and the alternative hypothesis is RR $\neq 1$ or OR $\neq 1$. Both these inferences are two-sided. For the one-sided alternative, replace $z_{1-\alpha/2}$ by $z_{1-\alpha}$. The formulas for matched pairs are mentioned later in this section. The following examples illustrate the calculations.

Consider a clinical trial in which a new regimen is compared with an existing regimen for their role in control of nausea while treating depression. The objective is to estimate the RR of nausea in depression cases. The anticipated values are as follows:

Proportion with nausea in the patients on new regimen $\pi_1 = 0.40$
Proportion with nausea in the patients on existing regimen $\pi_0 = 0.50$
Relative precision desired, $\varepsilon = 0.10$ (i.e., estimated RR should be within 10% of its actual value)
Confidence level 95%, i.e., $\alpha = 0.05$

Thus, $z_{1-\alpha/2} = 1.96$, and, from formula (a) in Table S.2,

$$n = \frac{(1.96)^2}{[\ln(1-0.10)]^2}\left[\frac{1-0.40}{0.40} + \frac{1-0.50}{0.50}\right] = 865$$

with upward approximation.

This is the number of subjects required for each of the regimens. If the relative precision is relaxed to $\varepsilon = 0.20$, then $n = 193$. The sample size requirement declines steeply when the precision requirement is relaxed.

As another example, consider the plan of a case–control study of people with beta-thalassemia major to evaluate their thyroid status. This is a rare disease. Thyroid status is divided into only normal and abnormal categories but under very stringent criteria. The objective is to assess whether there is any association between thyroid status and beta-thalassemia. Thus, this is a testing-of-hypothesis setup. Suppose the anticipated values are as follows:

Proportion with abnormal thyroid among cases, $\pi_1' = 0.25$
Proportion with abnormal thyroid among controls, $\pi_0' = 0.10$
[Thus, anticipated OR is (0.25/0.75)/(0.10/0.90) = 3.]

S

**TABLE S.2**
**Sample Size Required for Two-Sided Inference on Relative Risk (RR) and Odds Ratio (OR)**

| Problem | Formula for Computing $n$ (Large $n$) per Group | Explanation of the Notations |
|---|---|---|
| | **Relative Risk** | |
| (a) Estimating RR | $\frac{z^2_{1-\alpha/2}}{[\ln(1-\varepsilon)]^2}\left[\frac{1-\pi_1}{\pi_1}+\frac{1-\pi_0}{\pi_0}\right]$ | $\pi_1, \pi_0$ = anticipated probability of disease among the exposed and nonexposed subjects, respectively<br>$\varepsilon$ = relative precision in terms of proportion of RR |
| (b) Hypothesis testing for RR = 1<br>Equal exposed and unexposed groups | Or, $\frac{1}{(\pi_0-\pi_1)^2}\left[z_{1-\alpha/2}\sqrt{2\bar{\pi}(1-\bar{\pi})}+z_{1-\beta}\sqrt{\pi_1(1-\pi_1)+\pi_0(1-\pi_0)}\right]^2$<br>$\frac{\left[z_{1-\alpha/2}\sqrt{2\bar{\pi}(1-\bar{\pi})}+z_{1-\beta}\sqrt{\pi_0(1+r)-\pi_0^2(1+r^2)}\right]^2}{[\pi_0(1-r)]^2}$ | $\bar{\pi}=(\pi_1+\pi_0)/2$<br>$\pi_1, \pi_0$ as above<br>Medically relevant least RR is $r=\pi_1/\pi_0$ |
| | **Odds Ratio (Rare Disease)** | |
| (c) Estimating OR | $\frac{z^2_{1-\alpha/2}}{[\ln(1-\varepsilon)]^2}\left[\frac{1}{\pi_1'(1-\pi_1')}+\frac{1}{\pi_1'(1-\pi_0')}\right]$ | $\pi_1'$ = anticipated probability of exposure among the cases<br>$\pi_0'$ = anticipated probability of exposure among the controls<br>$\varepsilon$ = relative precision in terms of proportion of OR |
| (d) Hypothesis testing for OR = 1<br>–One control per case | $\frac{1}{(\pi_1'-\pi_0')^2}\left[z_{1-\alpha/2}\sqrt{2\pi_0'(1-\pi_0')}+z_{1-\beta}\sqrt{\pi_1'(1-\pi_1')+\pi_0'(1-\pi_0')}\right]^2$ | $\pi_1', \pi_0'$ as above<br>Medically relevant least OR is $[\pi_1'/(1-\pi_1')]/[\pi_0'/(1-\pi_0')]$ |
| –C controls per case | $\frac{1}{(\pi_1'-\pi_0')^2}\left[z_{1-\alpha/2}\sqrt{\left(1+\frac{1}{C}\right)\pi'(1-\pi')}+z_{1-\beta}\sqrt{\pi_1'(1-\pi_1')+\pi_0'(1-\pi_0')}\right]^2$ | $\pi'=\frac{\pi_1'+C\pi_0'}{C+1}$; $\pi_1', \pi_0'$ as above |

*Note:* Two independent samples; same $n$ for each group.
$\alpha$ is the significance level and $(1-\beta)$ is the statistical power; $z_a$ is such that $P(Z \geq z_a) = a$. For $\alpha = 0.05$, $z_{\alpha/2} = 1.96$; for $\beta = 0.05$, $z_\beta = 1.645$; for $\beta = 0.10$, $z_\beta = 1.28$; for $\beta = 0.20$, $z_\beta = 0.84$.

With significance level $\alpha = 0.05$ and power $(1-\beta) = 0.80$, $z_{1-\alpha/2} = 1.96$ and $z_{1-\beta} = 0.84$, and we get from formula (d) in Table S.2 that

$$n = \frac{1}{(0.25-0.10)^2} \times \left(1.96\sqrt{2\times 0.10\times 0.90}+0.84\sqrt{0.25\times .0.75+0.10\times 0.90}\right)^2 = \frac{1}{0.0225}(0.8316+0.4425)^2 = 73$$

with upward approximation.

Thus, only 73 cases and 73 controls are required for this study. The second formula in (d) in Table S.2 for $C$ controls per case can be approximated as

$$n \approx \frac{(1+1/C)\bar{\pi}(1-\bar{\pi})(z_{1-\alpha}+z_{1-\beta})^2}{\delta^2}.$$

For $C = 1$, this becomes $n \approx \frac{2\bar{\pi}(1-\bar{\pi})(z_{1-\alpha/2}+z_{1-\beta})^2}{\delta^2}$.

With $z_{1-\alpha/2} = 1.96$ for 5% level of significance for a two-tailed test and $z_{1-\beta} = 0.84$ for $C = 1$, the formula can be further approximated as

$$n \approx 8\bar{\pi}(1-\bar{\pi})/\delta^2 \text{ for power} = 80\%$$

and

$$n \approx 11\bar{\pi}(1-\bar{\pi})/\delta^2 \text{ for power} = 90\%.$$

These are simple to remember.

If OR is specified in place of $\pi_1$, the exposure rate in the case group can be obtained as $\pi_1 = \frac{\pi_0(OR)}{1+\pi_0(OR-1)}$. For example, for $\pi_0 = 0.30$ and OR = 3, $\pi_1 = (3\times 0.30)/[1+0.30(3-1)] = 0.5625$. Going further, these values give $\bar{\pi}$ = ½(0.30 + 0.5625) = 0.43125, and for $\alpha = 0.05$, power = 0.90, and from formula (d) of Table S.2,

$$n = \frac{\left[1.96\sqrt{2\times 0.43125\times 0.56875}+1.28\sqrt{0.30\times 0.70+0.5625\times 0.4375}\right]^2}{(0.30-0.5625)^2} = 73.$$

With an approximate formula, for $\delta = 0.5625 - 0.30 = 0.2625$, this becomes $n = (2\times 0.43125\times 0.56875)(1.96+1.28)^2/(0.2625)^2 = 75$, and further an approximate formula for 90% power gives $n = (21\times 0.43125\times 0.56875)/(0.2625)^2 = 75$, which is not much different from 73 arrived at earlier from a more exact formula.

Consider a study on maternal anemia in low birth weight infants versus in normal weight infants. Suppose the anticipated prevalence of maternal anemia in normal birth weight group is 5% ($\pi_0 = 0.05$) and in low birth weight group is OR = 3.0. This is the "exposure" of interest in this example. How big a sample size is required to get a width of 1.5 of 95% CI for OR? A width of CI is the double of $\delta$,

i.e., $\delta = 1.5/2 = 0.75$. With these values, we get $\pi_1 = (0.05 \times 3.0)/[1 + 0.05(3.0 - 1)] = 0.136$, and formula (c) in Table S.2 gives, for $\varepsilon = 0.5$,

$$n = \left(\frac{1.96}{\ln(1-0.5)}\right)^2 \left(\frac{1}{0.136\times 0.864} + \frac{1}{0.05\times 0.95}\right) = 236.38.$$

Thus, 237 cases and similar number of controls are required for this study in a one control per case setup.

For one-to-one **matched** (pair-matched) studies, the sample size is obtained in terms of the number of discordant pairs. This is because only the discordant pairs contribute to the decision in such studies. According to Schlesselman [1], the number of discordant pairs required to detect minimum OR of $\lambda$ with a probability (power) of $(1 - \beta)$ and level of significance $\alpha$ is

$$m = \frac{\left[\frac{1}{2} z_{1-\alpha/2} + z_{1-\beta}\sqrt{\pi(1-\pi)}\right]^2}{(\pi - 1/2)^2},$$

where $\pi = \frac{\lambda}{1+\lambda}$ (under the null, $\lambda = 1$ and thus $\pi = ½$). One strategy to achieve this number could be to go on recruiting subjects until you get these many discordant pairs. This is not a good strategy since no effective planning can be made. To plan, see if you can have some estimate of the proportion of pairs with discordance. If this is $p$, the total number of pairs required is $n = m/p$. Otherwise, an approximation that requires independence of the exposure in the cases and controls is $p \approx \pi_0(1 - \pi_1) + \pi_1(1 - \pi_0)$ [1]. For example, to detect an OR = 2 (this gives $\pi = 1/3$ for $\lambda = 2$) with a power of 90% and two-tailed significance level 5%, the number of discordant pairs required is $m = [1.96/2 + 1.28 \times \sqrt{(⅓ \times ⅔)}]^2/(⅓ - ½)^2 = 91$. If control group exposure $\pi_0 = 0.30$ and OR = 2.0, $\pi_1 = (0.30 \times 2.0)/[1 + 0.30(2.0 - 1)] = 0.4615$, and $p \approx 0.30 \times 0.5385 + 0.4615 \times 0.70 = 0.4846$, assuming independence. These values give $n = 91/0.4846 = 188$. Thus, a total of 188 pairs are required in this study. When the exposure in the case group is not independent of the control group, adjustment suggested by Fleiss and Levin [2] can be used.

## sample size for simple situations (mean, proportion, and differences), *see also* sample sizes for study formats, sample sizes for statistical analysis methods, sample sizes for odds ratio and relative risk

The sample size formulas for simple situations are given in Table S.3 for estimation and in Table S.4 for testing of hypothesis. These are for mean, proportion, and their difference in two populations, and do not include formulas for ratios such as odds ratio and relative risk (for OR and RR, see **sample size for odds ratio and relative risk**). These formulas are based on the procedure explained under the topic **sample size determination (general principles)**. The notations are also explained in the tables, and the formulas are valid only for situations in which Gaussian approximation is applicable. The parameter values such as $\pi$ and $\sigma$ that appear in these formulas have to be replaced by their anticipated values that could be either those previously reported, based on a pilot study, or just educated

**TABLE S.3**
**Sample Size Calculation for Simple Estimations (Valid for Large *n* Only)***

| Problem | Formula for Computing *n* | Description of the Notations |
|---|---|---|
| (a) Population proportion with specified absolute precision | $\frac{z^2_{1-\alpha/2}\pi(1-\pi)}{L^2}$ | $\pi$ = Anticipated value of the proportion in the population<br>$L$ = Absolute precision required on either side of the proportion |
| (b) Population proportion with specified relative precision | $\frac{z^2_{1-\alpha/2}\pi(1-\pi)}{(\varepsilon\pi)^2}$ | $\pi$ = Anticipated value of the proportion in the population<br>$\varepsilon$ = Relative precision in terms of fraction |
| (c) Population mean with specified precision | $\frac{z^2_{1-\alpha/2}\sigma^2}{L^2}$ | $\sigma$ = Population SD (can be estimated from a pilot study)<br>$L$ = Specified precision of the estimate on either side of the mean |
| (d) Difference between two population proportions with specified absolute precision—equal $n$ in the two groups | $\frac{z^2_{1-\alpha/2}[\pi_1(1-\pi_1)+\pi_2(1-\pi_2)]}{L^2}$ | $\pi_1$, $\pi_2$ = Anticipated proportions in the two populations<br>$L$ = Absolute precision required on either side of the difference in proportions |
| (e) Difference between means of two populations with specified precision—equal $n$ in the two groups | $\frac{z^2_{1-\alpha/2}\left(\sigma_1^2+\sigma_2^2\right)}{L^2}$ | $\sigma_1$, $\sigma_2$ = Population SD of the two populations (can be estimated from a pilot study)<br>$L$ = Specified precision of the estimated difference on either side of the mean difference |

| (d) For difference between two population means—equal *n* in the two groups | $\frac{(\sigma_1 z_{1-\alpha/2}+\sigma_2 z_{1-\beta})^2}{\delta^2}$ | $\sigma_1$, $\sigma_2$ = Population SD of the two populations (can be estimated from a pilot study)<br>They will be equal in most situations<br>$\delta$ = Minimum medically important difference between means under $H_1$ that is proposed to be detected |
| (e) For independence in matched pairs | $\frac{\left[z_{1-\alpha/2}\sqrt{\pi_{10}+\pi_{01}}+z_{1-\beta}\sqrt{\pi_{10}+\pi_{01}-(\pi_{10}-\pi_{01})^2}\right]^2}{\delta^2}$ | $H_0$: $\pi_{10} = \pi_{01}$<br>$\pi_{10}$ and $\pi_{01}$ are the discordant probabilities<br>$\delta = \pi_{10} - \pi_{01}$ is the difference proposed to be detected |

*Note:* $\alpha$ is the level of significance and $(1 - \beta)$ is the statistical power; $z_{1-\alpha}$ is such that $P(Z \le z_{1-\alpha}) = 1 - \alpha$.
For $\alpha = 0.05$, $z_{1-\alpha/2} = 1.96$, and $z_{1-\alpha} = 1.645$. For power = 0.90, $z_{1-\beta} = 1.28$; for power = 0.80, $z_{1-\beta} = 0.84$. For other values, consult Gaussian distribution. If the alternative hypothesis is one-sided, replace $z_{1-\alpha/2}$ by $z_{1-\alpha}$.
*Large *n* is needed so that the distribution of *p* can be approximated by Gaussian form, and so that the distribution of sample mean is Gaussian if the distribution of values is not Gaussian.

guesses, as always done in sample size calculation. All formulas assume simple random sampling and a univariate setup.

In many medical situations, the standard deviations (SDs) in the two groups under comparison are equal, that is, $\sigma_1 = \sigma_2$. If the SD in one group is very different from the SD in the other group, sample sizes are optimal if $n_1/n_2 = \sigma_1/\sigma_2$. This helps in minimizing the standard error (SE) of difference in means. For the sample size for estimating proportions with specified precision, if educated guess of $\pi$ is not available, use $\pi = 0.5$, which will give the maximum *n*. The following example illustrates the calculation.

To plan a study on the difference in the prevalence of filariasis in agricultural and nonagricultural workers in an endemic area, a pilot study was carried out with 30 workers of each type. The prevalences, respectively, were 33% and 20%. What sample size is needed if the difference is to be estimated within 3 percentage points with 90% confidence?

This problem is for difference between proportions and would require formula (d) of Table S.3. The calculation requires anticipation that the proportions in the population would be nearly the same as those in the pilot study. Thus, $\pi_1 = 0.33$ and $\pi_2 = 0.20$. Confidence $100(1 - \alpha) = 90\%$ or $\alpha = 0.10$. Since $L = 0.03$, from formula (d) in Table S.3, we get

$$n = \frac{z_{0.05}^2(0.33\times 0.67 + 0.20\times 0.80)}{(0.03)^2}$$
$$= \frac{(1.645)^2 \times (0.3811)}{(0.03)^2}$$
$$= 1146.$$

Thus, a sample of nearly 1150 is required in each group of workers.

The previous example was on estimation. Now consider an example on testing of hypothesis. Suppose a decline of at least 10 mg/dL in triglyceride level (TGL) after a therapy is considered clinically important. It is proposed that a group of nonvegetarian obese and nonobese subjects will be kept on vegetarian diet to see if their TGL declines by this clinically important magnitude. The SD of their TGL is anticipated to be 15.7 and 12.5 mg/dL, respectively. The researcher wishes to detect a 10 mg/dL difference with probability 0.80. What sample size should be chosen if the level of significance is 0.10?

In this case, $\delta = 10$ mg/dL, $\sigma_1 = 15.7$, and $\sigma_2 = 12.5$ (all are estimates, though). The interest is only in decline, so $H_1$ is one sided. (In this case, a rise cannot be ruled out, but keep that aside for this example.) Now, $\alpha = 0.10$ and $(1 - \beta) = 0.80$ give $z_{1-\alpha} = 1.28$ and $z_{1-\beta} = 0.84$. With these values, formula (d) in Table S.4 gives

$$n = \frac{(15.7\times 1.28 + 12.25\times 0.84)^2}{10^2}$$
$$= (20.8 + 10.5)^2/100$$
$$= 10 \text{ when approximated upward.}$$

A sample of 10 obese and 10 nonobese subjects is enough for this study. A relatively small sample is required because the difference to be detected, 10 mg/dL, is quite large. If this is 5 mg/dL, then this gives $n = 40$ in each group. Conversely, if resources permit $n = 100$, then, for $\delta = 5$,

$$100 = \frac{\left(15.7 \times 1.28 + 12.5 \times z_{1-\beta}\right)^2}{5^2},$$

or

$$50 = 20.8 + 12.5 \times z_{1-\beta},$$

or $z_{1-\beta} = 2.384$ and the Gaussian distribution gives $(1 - \beta) = 0.9914$. Thus, a size of $n = 100$ will have a probability of more than 99% of detecting a difference of 5 mg/dL if present.

In case of **sensitivity and specificity**, which are also proportions, obtain the sample size as usual for proportions and divide by the prevalence rate of disease for sensitivity and by (1 – prevalence) for specificity. For more details, see the topic **sample sizes for statistical analyses**.

## sample sizes for statistical analysis methods, *see also* sample sizes for odds ratio and relative risk, sample sizes for simple situations (mean, proportion, and differences), sample sizes for study formats

For basic information on sample size determination, see the topic **sample size determination (general principles)**. This is a prerequisite to fully understand the current section. In this section, we present methods for determining sample size for different statistical analysis setups, namely, ANOVA, associations, correlations, hazard ratios and survival analysis, regressions (logistic and ordinary quantitative regression), and sensitivity–specificity.

### *Sample Size for One-Way ANOVA*

**Analysis of variance (ANOVA)** method is basically used to compare means of three or more groups. Because of multiple groups in this setup, the sample size determination is not as straightforward as in the case of two groups. Although planning of sample size in this setup can be approached in terms of controlling the width of desired confidence intervals (for estimation), we restrict our discussion in this section to **power** approach for testing of hypotheses as this is the dominant reason for using ANOVA. Also, for simplicity, we restrict to **one-way ANOVA** that incidentally also illustrates the kind of issues that arise in this context.

Let us consider that all factor levels are equally important and the sample sizes accordingly are also planned to be equal. If the major interest is in pairwise comparisons of factor level means, it is known that equal sample sizes maximize the power of these comparisons for a fixed combined sample size. Equal sizes are also helpful in ignoring slight departure from **homoscedasticity**. However, we do not deny that unequal sample sizes may be appropriate in some situations such as for comparing the effect of several different doses with that of a control—a situation where a larger sample in the control group is of definite help. Only that our presentation becomes simple if we restrict to the equal sample size situation, and could be understood well by medical professionals.

As always, for determining the sample size for testing of hypothesis situation, you need to specify (i) the significance level, generally fixed at 0.05; (ii) the minimum **medically important effect** as difference between group means that you would want to detect; and (iii) the **power** with which this difference is to be detected if present. Other considerations listed under the topic **sample size determination (general principles)** will continue to have a role as described therein.

Suppose there are a total of $K$ groups in one-way ANOVA setup, and the total number of pairwise comparisons is $K(K - 1)/2$. It is not necessary that all pairwise groups are of our interest—let $H$ of them be of our interest. The significance level for calculation of sample size may be taken as $\alpha/H$ as per the **Bonferroni procedure**, where $H$ is the number of comparisons. Then the sample size required in each group under **Gaussian conditions** for a two-tailed test is

$$n = \frac{(\sigma^2)(z_{1-\alpha/(2H)} + z_{1-\beta})^2}{\delta^2},$$

where the $z$-value comes from the Gaussian distribution corresponding to the prefixed level of significance $\alpha$, $(1 - \beta)$ is the prefixed power to be able to detect a difference of $\delta$ in the means, and $\sigma^2$ is the anticipated common variance that can be estimated by the **mean square error** (MSE) in ANOVA in any earlier study. This is valid when (i) the effects are fixed and not random; (ii) the null hypothesis is that means in all groups are equal and the alternative hypothesis is that at least one mean is different; (iii) all the underlying requirements of ANOVA are fulfilled such as independence of values, homoscedasticity, and Gaussian conditions; and (iv) each subject in each group is either randomly selected or randomly allocated to the groups. Statisticians may advise suitable adjustments in case of other sampling such as stratified or cluster is adopted, and in case the Gaussian conditions do not hold. The effect size for this formula is in terms of mean difference, which is the most straight way of specifying the effect size to be detected in this setup. If the effect size is specified in some other manner such as in terms of the ratio of between and within variance, the formula will change accordingly. Many software and online packages are available that calculate sample size when the effect size is specified in some other manner.

A major problem in adopting this formula, as in all sample size formulas, is obtaining the values of the $\sigma$'s on one hand, and determining the maximum clinically unimportant (or minimum medically important) difference $\delta$ on the other. For the former, the usual practice is to use values reported in earlier studies carried out in similar setups, or to conduct a pilot study and use the results if nothing is available in the literature. To be safe, it is better to inflate this $n$ slightly to compensate for possible error in the guessed value of $\sigma$. The other, possibly more valid, option is to calculate sample size for a range of values of parameters whose values are uncertain, and choose the one that looks feasible without compromising the scientific requirement of the study. This is easy these days as repeated sample size calculations can be done with many readily available online calculators.

For the clinically important difference $\delta$, you need to garner your experience, brainstorm with your colleagues, and consult literature to come up with either a maximum effect that can be considered clinically unimportant or a minimum effect that is clinically important to convince others to change their practice and use your results.

In some rare situations, the alternative hypothesis is not that at least one mean unequal but is that they follow a specified order. This is sometimes termed as *constrained hypothesis*, and the sample size for such alternatives is discussed by Vanbrabant et al. [1]; they have also provided tables of sample sizes for different powers and different alternatives.

### *Sample Size for Associations*

Association between binary attributes in two independent samples is assessed by calculating chi-square: by calculating the odds ratio in a case–control setup, by calculating the relative risk in a prospective setup, and by calculating either in a cross-sectional setup when the

**TABLE S.5**
**Probabilities in a Matched Pairs Setup**

| First Partner of the Pair | Second Partner of the Pair: Positive | Second Partner of the Pair: Negative | Total |
|---|---|---|---|
| Positive | $\pi_{11}$ | $\pi_{10}$ | $\boldsymbol{\pi_{1\cdot}}$ |
| Negative | $\pi_{01}$ | $\pi_{00}$ | $\boldsymbol{\pi_{0\cdot}}$ |
| **Total** | $\boldsymbol{\pi_{\cdot 1}}$ | $\boldsymbol{\pi_{\cdot 0}}$ | **1** |

sample drawn is random. For these, the method given under the topic **sample sizes for odds ratio and relative risk** may be used. For a paired binary setup (e.g., matched case–controls, crossover trials) where the **McNemar test** is used, the number of pairs required is

$$n = \left( \frac{z_{1-\alpha/2}\sqrt{\pi_{10}+\pi_{01}} + z_{1-\beta}\sqrt{\left(\pi_{10}+\pi_{01}\right) - \left(\pi_{10}-\pi_{01}\right)^2}}{\pi_{10}-\pi_{01}} \right),$$

where $\pi$'s are the anticipated probabilities as given in Table S.5 and the null hypothesis under test is $H_0$: $\pi_{10} = \pi_{01}$ (i.e., the probability of discordance of both the types is the same) with two-sided alternative $H_1$: $\pi_{10} \neq \pi_{01}$.

### *Sample Size for Correlations*

Correlation is obtained for two quantitative measurements linked in some manner such as they belong to the same subjects (e.g., correlation between systolic and diastolic blood pressure measured for 75 subjects), to the same time point (e.g., between neonatal and maternal mortality rates in a country from 1985 to 2015), to the same area (e.g., between incidence of cancer and incidence of heart disease in 30 cities), etc. The property that **Fisher *z* transformation** ($z = \frac{1}{2} \ln[(1 + r)/(1 - r)]$) of the product–moment **correlation coefficient** $r$ follows a nearly Gaussian (normal) distribution for large samples can be used to calculate sample size. For significance level $\alpha$ and power $(1 - \beta)$ to detect a correlation of at least $\rho$ with power $(1 - \beta)$, this is given by

$$n = \frac{\left(z_{1-\alpha/2} + z_{1-\beta}\right)^2}{c^2} + 3,$$

where $c$ is the Fisher $z$ transformation of the minimum correlation $\rho$ to be detected. (We are using notation $c$ instead of $z$ to avoid confusion with Gaussian probabilities $z_{1-\alpha/2}$ and $z_{1-\beta}$.) This sample size has a high chance to detect the specified correlation if present. However, the correlation coefficient, just as most other estimates, is unstable for a small sample size, and Schönbrodt and Perugini [2] found by Monte Carlo simulations that it stabilizes when the sample size is nearly 250. You can guess from this how big the sample size requirement can be in some situations.

For comparison of two correlations, the required sample size is given by

$$n = \frac{\left(z_{1-\alpha/2} + z_{1-\beta}\right)^2}{\left(c_0 - c_1\right)^2} + 3,$$

where $c_0$ and $c_1$ are the Fisher $z$ transformation of the anticipated correlations $\rho_0$ and $\rho_1$ in the two groups, which means that the minimum difference in correlations to be detected is $\rho_1 - \rho_0$. Practically all the parameter values are replaced by the corresponding sample values.

For obtaining the confidence interval on the correlation coefficient with specified precision, Moinester and Gottfried [3] have provided a procedure and a table of sample sizes.

### *Sample Size for Hazards Ratios and Survival Analysis*

**Hazard ratio** (HR) is the ratio of hazard of occurrence of an event at a particular point in time in the two groups under comparison. Since HR = 1 implies the same hazard in the two groups, the statistical significance is tested against HR = 1 (this is the same as ln(HR) = 0). The required sample size for detecting a particular hazard ratio $\theta$ when present with power $(1 - \beta)$ is obtained in this case by the number of events in place of the total sample. This is given by

$$\text{number of events} : d = \left( \frac{(\theta+1) * \left(z_{1-\alpha/2} + z_{1-\beta}\right)}{\theta - 1} \right)^2,$$

where $\theta$ = minimum hazard ratio to be detected if present, and the level of significance is $\alpha$. For detecting hazard ratio $\theta = 1.5$ with 90% power at 5% two-sided level of significance, this gives $d = 263$. If the event under study is death, you need as big a sample as to have at least 263 deaths. This may turn out to be an enormous number; for example, if 10% are anticipated deaths, a sample of 2630 subjects is needed.

An approximate but simplified and more popular version is

$$d = \frac{4\left(z_{1-\alpha/2} + z_{1-\beta}\right)^2}{[\ln \theta]^2}.$$

With this formula, to detect HR = 1.5 with power 90% at a two-sided significance level of $\alpha = 0.05$,

$$d = \frac{4(1.96 + 1.282)^2}{[\ln(1.5)]^2} = 256,$$

which is slightly different from the more exact $d = 263$ arrived at earlier. According to this formula, the number of events required to detect different HRs with power 80% and 90% is as given in Table S.6.

Table S.6 shows that the sample size requirement decreases as the HR to detect increases. Thus, one of the ways to reduce the requirement of sample size is to increase the follow-up time that will raise the HR, but this strategy will work when the follow-up is not expensive relative to a study on a larger sample.

**TABLE S.6**
**Number of Events Required for Detecting Specified HR and Power**

| HR | Power: 80% | Power: 90% |
|---|---|---|
| 1.5 | 191 | 256 |
| 2.0 | 66 | 88 |
| 2.5 | 38 | 50 |
| 3.0 | 26 | 35 |

For comparing hazards in two populations,

$$n = \frac{1}{p_A p_B \pi}\left(\frac{z_{1-\alpha/2} + z_{1-\beta}}{\ln\theta_1 - \ln\theta_0}\right)^2,$$

where $p_A$ and $p_B$ are the proportions of sample size allotted to the two groups ($p_A + p_B = 1$), $\pi$ is the anticipated overall probability of the event occurring within the study period, and $\theta_1$ and $\theta_0$ are the anticipated HRs in the case group and the control group, respectively. If samples from both the groups are equal, $p_A = ½$ and $p_B = ½$, then

$$n = \frac{4}{\pi}\left(\frac{z_{1-\alpha/2} + z_{1-\beta}}{\ln\theta_1 - \ln\theta_0}\right)^2.$$

The $\pi$ in the denominator takes care of the prevalence, and thus the sample size is total $n$ and not the number of events.

In addition to hazards, two other kinds of similar analyses are done in survival studies. The first is simple comparison of survival rate in two groups at a fixed point in time when there are no censored values. This could be like a 5-year survival rate in cancer patients. The sample size for this can be calculated by the usual formula for comparing proportions as given under the topic **sample size for simple situations**. The second is comparing the whole survival pattern by log-rank test where the null hypothesis is $S_1(t) = S_2(t)$ for all $t$, where $t$ is for time point and $S_k(t)$ is the probability of survival in the $k$th group till time $t$. This is the same as $H_1(t) = H_2(t)$ for all $t$, where $H$ is for hazard rate, or the hazard ratio $\theta = H_1(t)/H_2(t) = 1$, or $\ln\theta = 0$. This situation is the same as just discussed and the sample size formula is also the same, which is in terms of the number of events. For survival analyses, the number of events such as deaths and recoveries is important, and the sample size depends on the anticipated rate of occurrence of such events.

In case of a **Cox regression**, where the effect of regressors on the outcome is studied, Schoenfeld [4] showed that the sample size requirement remains the same whether or not an account is taken of such regressors.

### *Sample Size for Logistic and Ordinary Linear Regressions*

Very few biostatistics textbooks deal with sample size considerations for estimation and tests of hypothesis for a regression coefficient (slope) in a simple or multiple ordinary or logistic regression. **Logistic regression** case is even more complicated owing to nonlinearity nature of the logistic function. The formulas are available for relatively simple cases, and they are mostly approximate and valid for large samples only.

In a simple logistic regression model, if the covariate $x$ is continuous with a Gaussian distribution, the sample size formula for detecting the logistic coefficient $\beta_0$ as given by Hsieh et al. [5] is

$$n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2}{\pi(1-\pi)\beta_0^2},$$

where $\pi$ is the anticipated event rate at the mean of $x$. When the covariate $x$ is binary, this becomes

$$n = \frac{\pi(1-\pi)(z_{1-\alpha/2} + z_{1-\beta})^2}{B(1-B)(\pi_1 - \pi_2)},$$

where $B$ is the proportion of the population with $x = 1$, $\pi_1$ is the event rate at $x = 0$, $\pi_2$ is the event rate at $x = 1$, and $\pi$ is the overall event rate. Suppose in an underdeveloped country, the incidence of low birth weight births is 15%, i.e., $B = 0.15$. As many as 60% mothers of low birth weight babies have anemia, i.e., $\pi_1 = 0.60$. The health administration decides that a program of iron supplementation for pregnant women can be launched if it is able to bring this down to 40% or less. Thus, $\pi_2 = 0.40$. How big a sample should be chosen to check that this decline is detected with power 0.90 and significance level 0.025 (one-sided since supplementation program cannot increase the anemia level)? The average prevalence of anemia in this case is $\pi = (0.60 + 0.40)/2 = 0.50$. Substituting these values in the formula just mentioned gives

$$n = \frac{0.5(1-0.5)(1.96+1.28^2}{0.15(1-0.15)(0.60-0.40)} = 103.$$

A field trial with a sample of 103 pregnant women would give a convincing evidence that the supplement is able to bring down the anemia level to 40% or less in this population.

For case–control studies with continuous $x$, Lubin et al. [6] derived the following for $C$ controls per case:

$$n = \frac{C+1}{C} * \frac{\left[z_{1-\alpha}\sigma_x + z_{1-\beta}\sqrt{\frac{C\sigma_1^2 + \sigma_0^2}{C+1}}\right]^2}{\delta^2}.$$

The total sample size is $Cn + n$; $\sigma_1^2$ and $\sigma_0^2$ are the variances of the variable $x$ in the case and control groups, respectively; and $\sigma_x^2$ is the variance under the null hypothesis. For equal samples, just plug in $C = 1$.

For an ordinary simple linear regression, when both $x$ and $y$ are standardized (mean 0 and variance 1 by subtracting mean and dividing by the standard deviation), the hypothesis $\beta = 0$ is the same as the correlation coefficient $\rho = 0$; thus, the sample size requirement is the same, and the formula stated earlier for correlation coefficient is valid for simple linear regression too.

For multiple regression (logistic or ordinary), multiply these sample sizes by the **variance inflation factor** (VIF) = $1/(1 - \eta^2)$, where $\eta$ is the **coefficient of determination**. This can be replaced with the **multiple correlation** coefficient $R$ or its equivalent for linear regression. Same VIF applies to both the setups [5]. As always with sample size formulas, the parameter values are replaced by the anticipated values as estimated from previous studies.

### *Sample Sizes for Sensitivity and Specificity*

**Sensitivity and specificity** measure inherent validity of a diagnostic test against a gold standard. An adequate sample size is necessary to precisely estimate the validity of a diagnostic test and to test statistical significance. For their estimation with specified precision, the formulas are the same as for proportions but have to be adjusted for prevalence of the disease. The formulas when both diagnostic test and gold standard have dichotomous categories are as follows:

$$\text{For estimating sensitivity, } n = \frac{z_{1-\alpha/2}^2 * S_N(1-S_N)}{L^2 * \text{Prevalence}},$$

$$\text{and for estimating specificity, } n = \frac{z_{1-\alpha/2}^2 * S_P(1-S_P)}{L^2 * (1-\text{Prevalence})},$$

where

$S_N$ = anticipated sensitivity
$S_P$ = anticipated specificity
$1 - \alpha$ is the confidence level
$L$ = absolute precision desired on either side (half-width of the confidence interval) of sensitivity or specificity

If the prevalence of disease you are investigating is 12%, divide the usual sample size by 0.12 to obtain the sample size for estimating sensitivity, and divide by 0.88 to obtain the sample size for estimating specificity. This almost ensures that the requisite number of disease positives and negatives, respectively, are available in the sample.

Malhotra and Indrayan [7] have devised a simple nomogram that yields a statistically valid sample size for anticipated sensitivity or specificity. This nomogram could be easily used to determine the sample size for estimating the sensitivity or specificity of a diagnostic test with required precision and 95% confidence level. A nomogram instantly provides the required number of subjects by just moving the ruler and can be repeatedly used without redoing the calculations; it can also be applied for reverse calculations to find the confidence level corresponding to the available sample size, but it is not applicable for testing of the hypothesis setup.

## sample sizes for study formats, *see also* sample sizes for odds ratio and relative risk, sample sizes for simple situations (mean, proportion, and differences), sample sizes for statistical analysis methods

Whereas sample size is primarily determined on reliability and power considerations as discussed under the topic **sample size determination (general principles)**, the study formats also play a role in providing it a context, and modifications in some situations can be made as needed. This section is devoted to the relevant features of various formats such as case–control studies, clinical trials, cross-sectional studies, surveys, medical experiments, and prospective studies, as applicable to sample size determination. Some essential aspects of sampling methods used in each setup are also included.

### *Sample Size for Case–Control Studies*

Although random sampling is not essential for analytical studies such as case–control, it too involves confidence interval estimation and tests of hypotheses on parameters such as odds ratio (OR) and prevalence rate of various antecedents. Thus, a reasonable sample size is required for these studies also. A **nested case–control study** may involve stratification, and each stratum must have an adequate number of subjects for any reliable conclusion. Control group is a necessary ingredient in case–control setup, and controls are sometimes oversamples (such as 1:2 ratio) in situations where they are easy to obtain and elicit.

Whereas broad methods of determining sample size in case–control studies remain the same, some new issues may come up. For example, in a case–control study on risk factors for breast cancer, the interest could be in age at menarche, age at first live birth, total duration of breast-feeding of all children put together, and the number of first-order blood relatives that have positive history. Cancer prevalence would be different in various categories of different variables. If there are many variables such as in this example, which one should be used for determining the sample size? If the focus is on only one of them, say, age at menarche, and others are just concomitants to remove their confounding effect, use the cancer prevalence rate in different categories of this variable only. If two or more variables have nearly the same importance, calculate the sample size for each of them separately and take the largest. Since there are two groups, case and control in this setup, OR may be a more appropriate parameter of interest. In any case, mean, proportion, OR, etc., and their standard errors, as required for calculation of sample size, would have to be mostly based on a previous study in a similar setting, and the precision in case of estimation, or the medically relevant least difference and power in case of testing of hypothesis, must be specified.

For one control per case, the sample size formula remains the same as for the OR (see Table S.2 in **sample size for odds ratio and relative risk**), where relevant proportions in case–control studies are the proportion of subjects found to have the antecedent of interest (exposure) in the cases and the controls, respectively. The formula for $C$ controls per case is also given at the same place. For continuous exposure where logistic regression is used, Lubin et al. [1] derived the following formula for sample size.

For $C$ controls per case (exposure a continuous variable):

$$n = \frac{C+1}{C} * \frac{\left[ z_{1-\alpha}\sigma_x + z_{1-\beta}\sqrt{\frac{C\sigma_1^2 + \sigma_0^2}{C+1}} \right]^2}{\delta^2},$$

where $\sigma_1^2$ and $\sigma_0^2$ are the variances of the exposure variable $x$ in the case and control groups, respectively, and $\sigma_x^2$ is the variance under the null. The total sample size in this case is $Cn + n$. For one control per case, just plug in $C = 1$ and get the sample size.

### *Sample Size for Clinical Trials*

Sample size is just about the first thing that comes to mind when planning a clinical trial, and it is also among the most important considerations that determine its utility. Since trials are conducted

on human subjects, they require extreme care in all aspects of execution including choosing a sample size. Ethical requirements of clinical trials are fairly well strict and allow neither a larger sample than required because it could mean unnecessary exposure to an unproven treatment, nor a smaller sample as that also could be unnecessary exposure as the results are not likely to be conclusive. In the latter case, a promising regimen that could have provided relief to many patients is missed and subjects needlessly exposed to a trial that was not properly planned. Besides risk of exposure, clinical trials are expensive; thus, they need to be conducted with precision, and a proper sample size has added importance.

In view of more importance of right sample size for clinical trials, let us reiterate that a large *n* could mean a waste of resources—if a study of only 200 subjects can give a reliable answer, why spend resources to study 250? A small sample, on the other hand, may not give evidence one way or the other, and the trial may fail to achieve its objectives. Thus, this also is a waste of resources. An unduly large sample is unethical in trials because it means that some subjects are unnecessarily exposed to an intervention whose utility is in doubt. An unduly small sample, too, is unethical because then the subjects are unnecessarily subjected to a trial of an unproven intervention that is not going to yield a result one way or the other. Having said that, the number of subjects should be reasonably large in each group so that the full clinical spectrum is represented and a trend, if present, can clearly emerge; also the reliability of the results is ensured. It should have adequate statistical **power** to not miss a minimum medically relevant difference when present.

Failure of many **randomized controlled trials** (RCTs) in detecting a medically relevant difference because of insufficient **power** is a matter of concern for medical community. During the 1970s, Freiman et al. [2] observed after studying 71 negative RCTs on new therapeutic procedures that the sample size was too small in most of them for power of 90% to detect a 25% improvement in outcome. In nearly three-fourths of these trials, the sample was inadequate to detect a 50% improvement. In other words, even if there is a 50% improvement in efficacy of the new treatment compared with the old, the trial results were still statistically not significant. It would have most likely become significant had there been a bigger trial. A quarter of a century later, Dimick et al. [3] reported the same for surgical trials. These once again underscore the need to be careful about the size of a trial—the number of subjects must be adequate to inspire confidence that a medically relevant difference would not go undetected.

In addition, a small sample has a high likelihood of being not fully representative and thus of producing biased results. Statistical methods have an in-built provision to take care of the larger sampling errors in small samples, but they are not equipped to take care of the lack-of-representativeness bias that is more likely to creep in small samples.

Sample size becomes especially critical for rare outcomes. With thorough aseptic conditions now maintained in operation theaters, chance of infection is negligible in routine surgeries such as for hernia. However, antibiotics are still given in some settings, albeit for a short duration. If a trial on the effect of antibiotics is done on 100 cases in a test group and another 100 controls, the trial is doomed from the start since no group may develop infection, or just one or two infections may occur in one group. This cannot lead to any reliable conclusion. All of this needs to be taken into account when calculating the sample size in this sort of scenario.

**Logistic regression** can be the key statistical method for analyzing of an RCT. There is a greater need to correctly perform the sample size calculation for this setup. In a logistic regression with *K* independents, conservatives generally advocate that at least 10**K* subjects should be observed for the rarest outcome in the analysis. If $K = 4$, and mortality is the outcome of interest, there must be at least 40 deaths in your sample according to this rule. If mortality is 8%, the total sample must be 500. However, this looks too strict for many situations as the experience suggests that the results are fairly reliable if no category has frequency less than 5.

The primary aim of most clinical trials is testing of hypothesis and not obtaining a confidence interval for the effect size. Thus, the sample size also is mostly calculated to achieve a prespecified power to detect a prespecified effect at a prespecified level of significance (see the topic **sample size determination [general principles]**). For two groups such as test and control, and a two-sided test for quantitative outcome, the sample size in each group is given by the formula provided in Table S.4 in **sample sizes for simple situations (mean, proportion, and differences)**.

Many clinical trials focus on more than one outcome. In this situation, the sample size is either calculated on the basis of the most important outcome if that can be identified, or calculated for all the outcomes and maximum taken. However, in case of multiple outcomes, the chance of false statistical significance increases. If the standard deviations (SDs) of the two groups are very different, it is advisable to choose the samples such that $n_0/n_1 = \sigma_0/\sigma_1$, where $n_0$ is the sample size in the control group and $n_1$ in the treatment group and so are the σ's. If there are more than one active treatment and all the treatments are to be compared with control, the power is maximized by a larger sample of control subjects.

If the response is binary in place of quantitative such as adequate relief/no adequate relief and survived/died, the formula based on proportions is the same as given in Table S.4 in **sample sizes for simple situations (mean, proportion, and differences)**. The formula for means of continuous responses is also given in the same table. For **equivalence trials**, the formulas are slightly modified as follows. For quantitative outcome with Gaussian conditions, if the equivalence margin is from $-\Delta$ to $+\Delta$,

$$n = \frac{(\sigma_0 z_{1-\alpha/2} + \sigma_1 z_{1-\beta/2})^2}{(\Delta - \delta)^2},$$

where δ is the expected difference in means, generally set as $\delta = 0$. For proportions, this becomes

$$n = \frac{\left[z_{1-\alpha/2}\sqrt{2\bar{\pi}(1-\bar{\pi})} + z_{1-\beta/2}\sqrt{\pi_1(1-\pi_1)+\pi_0(1-\pi_0)}\right]^2}{(\Delta - \delta)^2},$$

where $\delta = \pi_1 - \pi_0$. Note how the denominator changes in case of equivalence trials, and β becomes β/2 because **two one-sided tests (TOSTs)** are used for this setup. For details, see Lin [4]. If the outcome is duration, the formulas mentioned for survival analysis would apply.

### *Sample Size for Cross-Sectional Studies*

The term *cross-sectional studies* is used for those observational studies that elicit information on the antecedent and the outcome together on a sample of subjects, which is generally but not always randomly drawn from the target population. In contrast, note that in the case of prospective studies, the samples of the exposed and nonexposed are chosen separately, and in the case of retrospective studies, samples are chosen from the diseased and nondiseased subjects.

This kind of preclassification is not done for cross-sectional studies, although the purpose remains to investigate the relationship between the antecedents and the outcomes.

Validity of conclusions regarding the association of two or more factors depends on their proper representation in the sample in proportion of their presence in the target population. Random sampling serves as a great facilitator to achieve such representation. Assessment of other parameters such as sensitivity–specificity and predictivities also is adversely affected if these proportions are biased in any manner. Thus, random sampling is especially important for cross-sectional studies.

Sample size determination in cross-sectional studies does not pose any additional issues, and all the formulas mentioned in Table S.2 under the topic **sample size for odds ratio and relative risk** can be used depending on whether the objective is to test the hypothesis on OR or on relative risk (RR). All these sample sizes are valid for simple random sampling; suitable adjustments may be needed if the sampling method is different.

### *Sample Size for Descriptive Studies and Surveys*

The primary objective in **descriptive studies** and surveys is not investigating associations but finding the best estimates of the prevalence of the conditions of interest in different segments of a population. Investigation of association lends them to analytical framework, and the study is no longer strictly descriptive. Associations might be investigated in descriptive studies on post-hoc basis to gather additional information for future studies, but the planning, including sample size calculation, is done for estimation. Thus, the procedure and the formulas for determining the sample size for estimations apply, and the desired precision of the estimates is specified in this case in place of the medically important effect and the power needed for calculation of sample size for testing of hypothesis setup. Random sampling is doubly important in descriptive studies so that a sample representing different cross sections of the population is obtained.

Sample size for estimating the parameters such as mean and proportion depends primarily on variance of the estimate and the precision required. This may be intuitively appealing to those who have quantitative thinking—a larger sample is required for smaller margin of error. Depending upon the parameter of interest, any of the formulas given in Table S.3 in **sample sizes for simple situations (mean, proportion, and differences)** can be used to calculate sample size.

A sample size calculation for estimating a proportion requires some explanation. This could be the proportion of subjects of a particular type or a chance of occurrence of a particular event. Two kinds of formulas are available for this parameter: one uses absolute precision, and the other relative precision. When absolute precision is used, the sample size is maximum for anticipated $\pi = 0.50$, where $\pi$ is the proportion in the target population. Absolute precision is specified, for example, as ±5% or ±0.05, which for $\pi = 0.50$ implies that the sample providing an estimate between 0.45 and 0.55 is acceptable. If $\pi = 0.06$, precision ±0.05 gives a range of 0.01–0.11. Relative to such a small value of $\pi$, this range is too large. If prevalence of tuberculosis in a particular population is 6% and the sample estimate is anywhere between 1% and 11%, practically nothing is achieved. Such low precision can be a result of a small sample. Thus, precision for a proportion should be stated in terms of a relative value such as 10% of $\pi$. Ten percent of $\pi = 0.50$ is 0.05 and that of $\pi = 0.06$ is 0.006. A much larger sample size is required for such precision when the anticipated is $\pi$ small.

### *Sample Size for Medical Experiments*

Experiments on animals such as mice are done on small numbers per group, yet they provide reliable results. One might wonder why the statistical formulas do not apply to this setup. There are two reasons: (i) experimental animals are much more homogenous such as those that are of the same strain (Sprague–Dawley, Wistar, Donru, etc.)—thus inter-individual variability is small, and (ii) laboratory conditions are fairly well standardized, and the factors that can influence the results are under good control. Thus, any difference found between groups can be legitimately ascribed to the treatment. For this reason, experiments on five to six mice per group are norm than exception. This cannot be said about clinical trials or observational studies. When data from experiments are analyzed, if the data do not follow a Gaussian pattern, exact or nonparametric methods may have to be used because of a small sample per group.

Laboratory experiments on animals do not raise much concern about sampling methods because the experimental animals of one particular species are generally chosen for this purpose, and they can be easily considered as representative of their "population." However, whenever factors such as age, gender, and weight can affect findings, either the animals should be stratified for independent experiment on each stratum, or only one particular stratum of animals should be investigated. For example, to study the effect of middle turbination resection on facial growth of rabbits, the animals must be of the same age. For telomerase activity, which is implicated in all immortalization and carcinogenesis, age and gender of rats are important because they affect the level of this activity. Also, in this case, the strain of rats can affect the findings. Thus, separate experiments should be done in samples of rats of different strains.

Experiments on biological material such as blood specimens, vaginal swabs, and antigens are also common. If each specimen is identified and linked with a known person, the situation is back to sampling of individuals. For these, the same methods as described for humans should be followed. For experiments on anonymous unlinked biological specimen, think about the possible sources of bias that can inhibit generalization to a larger group. The specimen must represent the full spectrum of material in the target population. Whenever a large number of specimens are available, a random sample should be chosen, although this is rarely done in practice. Because an experiment necessarily involves an intervention, baseline equivalence of the test and control group is generally considered sufficient for validity of the results with a rider that the results are valid under laboratory conditions. Randomness of sampling in such situations has a limited role. Instead, **random allocation** is required.

### *Sample Size for Prospective Studies*

Prospective studies are those observational analytical studies that explore subjects with and without antecedent for developing an outcome of interest with the objective of finding how, if at all, the incidence (risk) of the outcome is affected by the presence or absence of the antecedent. The statistical parameter of interest in most such studies is the **relative risk** of developing the outcome in those with antecedent compared with those without the antecedent. It is easier to talk about the exposed and the nonexposed, and disease and no disease, in place of the antecedent and the outcome. We will come to repeated measures later in this section; for the time being, let the interest be in incidence of the disease at the end of a specified period of follow-up.

For simplicity, which incidentally is also the most common setup, consider a dichotomous disease with present and absent categories. The RR in this case is simply $\pi_1/\pi_0$, where $\pi_1$ is the incidence of

disease in exposed and $\pi_0$ is the incidence among nonexposed. Any such ratio is relatively easy to handle when a logarithm is taken since then $\ln(RR) = \ln \pi_1 - \ln \pi_0$, which has a linear from. Thus, **central limit theorem** can be applied for large $n$, and the Gaussian (normal) distribution can be used for calculation of the sample size. With this background, you may feel comfortable using the formulas given for sample size for the OR and RR. As always, these would require a preliminary guess of the incidences from previous studies, specification of the required precision for estimation, and specification of the medically important RR and associated power for calculation of sample size.

For an example, consider a prospective study of workers in the United States who file claims for work-related musculoskeletal disorders reported by Turner et al. [6]. The primary outcome of interest was duration of work disability in 1 year after filing the claim. The purpose was to develop statistical models that could predict the duration of chronic work disability after the initial suffering from the disorder. The required sample size was calculated as 1800 workers for low back injuries and 1200 for workers with carpal tunnel syndrome (CTS). Values of statistical power used for these calculations were 0.96 for low back and 0.85 for CTS, and the significance level chosen was $\alpha = 0.05$ (two-tailed) for both. The example illustrates that the sample size could be quite large for prospective studies when power and significance level are considered. The concept of power is related to the minimum medically relevant difference, but the abstract of this article does not mention this difference. A large sample size was feasible in this case because the study is mostly based on administrative database and follow-up interviews were conducted over telephone.

For comparison of two groups with respect to the mean of the quantitative outcome, the required sample size in prospective studies is

$$n = \left( \frac{z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_1}{\mu_1 - \mu_0} \right)^2 \text{ for one-tailed test}$$

(replace $\alpha$ by $\alpha/2$ for two-tailed test),

where $\alpha$ is the level of significance, $(1 - \beta)$ is the statistical power, $\sigma_0$ and $\sigma_1$ are the respective SDs in the groups under comparison, and the minimum difference to be detected is $\delta = \mu_1 - \mu_0$. If the minimum detectable difference is to be obtained for specific $n$, this is given by

$$\delta = \mu_1 - \mu_0 = \frac{z_{1-\alpha}\sigma_0 + z_{1-\beta}\sigma_1}{\sqrt{n}}.$$

For estimating the incidence rate with $100*(1 - \alpha)\%$ confidence in one group,

$$n = \frac{z^2_{1-\alpha/2}}{\varepsilon^2},$$

where $\varepsilon$ = the required relative precision as a fraction of the anticipated incidence. For testing of hypothesis of equality of incidences in the two groups,

$$n = \frac{\left(z_{1-\alpha/2}\pi_0 + z_{1-\beta}\pi_1\right)^2}{(\pi_0 - \pi_1)^2},$$

where $\pi_0$ = incidence rate (in terms of proportion) under the null hypothesis, and $\pi_a$ = incidence rate in terms of proportion under the alternative hypothesis (the minimum difference to be detected is $\pi_0 - \pi_1$).

In many prospective studies, the follow-up period is not uniform and the incidence per unit of time is calculated after working out person-time (person-years, person-weeks, etc.). This is valid only when the risk of disease at, say, the 15th week is the same as that at the 2nd week of follow-up. Let the subjects either have a common date of entry into the study and are followed up until they develop the outcome or censored, or let them be included in the study in order of their arrival but followed up only until a specified duration. When this is done, the sample size formula for testing the significance of difference in risks (called **attributable risk**) at $\alpha$-level of significance, according to Lwanga and Lemeshow [7], is

$$n = \frac{\left(z_{1-\alpha/2}\sqrt{2f(\bar{\pi})} + z_{1-\beta}\sqrt{f(\pi_0) + f(\pi_1)}\right)^2}{(\pi_0 - \pi_1)^2},$$

where $\pi_1$ and $\pi_0$ are the incidences per unit time in the two groups in the sense that $\pi_1 - \pi_0$ is the minimum medically important difference to be detected with power $(1 - \beta)$; $\bar{\pi} = (\pi_1 + \pi_0)/2$; $f(\pi) = \pi^3 T/(\pi T - 1 + e^{-\pi T})$ if the duration of the study is fixed as $T$ (censored observations) (for $f(\bar{\pi})$, $f(\pi_1)$, and $f(\pi_0)$, replace $\pi$ by $\bar{\pi}$, $\pi_1$, and $\pi_0$, respectively, in these expressions); and $f(\pi) = \pi^2$ if $T$ is not fixed.

**Repeated measures study** requires consideration of the correlation among repeated measures while planning the sample size. If the average difference over time in continuous measure is relevant for calculation of sample size, Hedeker et al. [8] give the following formula for quantitative outcomes:

$$n = \left[ \frac{(z_{1-\alpha} + z_{1-\beta})\sigma}{\delta} \right]^2 * \frac{\left[1 + (K-1)\rho\right]}{K},$$

where $K$ is the number of time points for which repeated measures were taken, $\rho$ is the correlation coefficient between values obtained by repeated measurement (assumed the same for all time points and equal in both the groups), $\sigma^2$ is the variance of the response values (also assumed the same for all time points), and $\delta$ is the time-average difference proposed to be detected. This says that the requirement of sample size will increase as $\rho$ increases when positive, as is likely the case in practically all situations of repeated measures. For example, if $K = 5$ time points, $\sigma = 80$, $\rho = 0.5$, $\alpha = 0.05$, power = 0.90 to detect $\delta = 20$ point average difference, the required sample size is $n = 101$ per group.

For dichotomous outcomes, the formula under the usual notations becomes

$$n = \left[ \frac{z_{1-\alpha/2}\sqrt{2\bar{\pi}(1-\bar{\pi})} + z_{1-\beta}\sqrt{\pi_1(1-\pi_1) + \pi_0(1-\pi_0)}}{\pi_0 - \pi_1} \right]^2 * \frac{\left[1 + (K-1)\rho\right]}{K}.$$

## sample size reestimation, *see* reestimation of sample size

## sample surveys

The term *sample surveys* is generally used for large-scale **descriptive studies** to estimate the prevalence of certain specified conditions, although it is loosely used for many other types of studies as well. Demographic and Health Surveys [1], periodically carried out in many developing countries to get a snapshot of health and fertility in the country at a specified point in time, and Global Adult Tobacco Surveys [2] for assessing tobacco use in various segments of population in different countries are examples of such surveys. Periodic National Health and Nutrition Examination Surveys in the United States [3] are important source of information on the health status of the population. This also is a sample survey. Associations or correlations and even a cause–effect relationship may come out of such surveys as a by-product, but they are not among the objectives of the surveys. Surveys generally produce results applicable to one specific area, one specific time, etc., as opposed to the results of the experimental studies that tend to transcend time and space. When the surveys are periodic, as in the examples just cited, they provide information on trend also. Prevalence in different segments of population can be statistically compared to find which group has higher prevalence. Reference level of medical parameters such as of cardiac functions in healthy subjects is also obtained by sample surveys, and similarly sample surveys can also be conducted in diseased subjects to find what and how much aberrations in health occur in different segments of population.

Since the objective is estimating the parameters in a survey, the sampling methods that can provide a representative sample become especially important. Most large-scale surveys do not use **simple random sampling** because that can provide scattered subjects; instead use a **multistage sampling** with appropriate stratification to ensure that no important section of the population is left out. Many large-scale surveys use **cluster sampling** so that many subjects are available at one place that can drastically reduce the cost of the survey, and make it easier to administer the survey. Some sections of a population that are not substantial in number but are crucial, such as people of old age, may have to be overrepresented in survey sampling so that reliable estimates can be generated for such segments also. Elaborate calculations of sample size are made for the surveys that can provide precise information on target parameters, keeping the sampling methodology in mind and the corresponding **design effect**. Estimation methods too are adjusted to provide unbiased estimates with the desired precision. **Standard errors** of the estimates are a necessary accompaniment of such estimation that provide an assessment of the reliability of the estimates, and sometimes confidence intervals are worked out to get a range of not implausible values.

Descriptive studies conducted at a local level such as on patients visiting a clinic or a set of clinics are also called a survey as long as the focus is on prevalence and averages rather than associations and cause–effect. Profile of cases arriving, say, for kidney stones, is technically a survey.

Among many examples of sample surveys in health and medicine, a recent one is that conducted by Chen et al. [4] in Wuhan (China) for comparing the number of men who have sex with men among rural-to-urban migrants. Kenny et al. [5] reported a population-based survey on maternal and child health service utilization in Liberia.

## SAMPL guidelines

SAMPL stands for "Statistical Analyses and Methods in the Published Literature," guidelines prepared by Lang and Altman [1] to address the issue of errors in reporting of statistical analyses in published literature in health and medicine. This issue has been raked up for a long time by a large number of workers; many have suggested remedies, but SAMPL guidelines put them together. They specify what exactly should be reported with different analyses such as hypothesis testing, association analyses, correlation analyses, regression analyses, analyses of variance and analyses of covariance, etc., besides of course for preliminary and primary analyses. The basic emphasis is on describing statistical methods with sufficient details to enable a knowledgeable reader with access to the original data to verify the reported results.

The guidelines are still in the making and require further improvement. For example, for preliminary analyses, the guidelines mention about collapsing data into categories but do not say that the reason for doing so should also be mentioned and the categories so formed must be justified with the implications of how different categorizations can lead to different results, or whether we should present analysis with and without categories. They also do not mention anything about missing data and outliers. Similarly for primary analyses, the guidelines require that the method for analysis should be fully described, but it does not say that a reference can also be given for the source

where this is described and only modification, if any, needs to be described. The guidelines require specification of the nonparametric tests used to analyze skewed data, but they do not say about recourse to central limit theorem for large samples when the data are marginally skewed. Perhaps it is not possible to include every bit of detail in such a guideline, but a beginning has been definitely made that can improve statistical reporting in medical journals.

Moher D, Altman DG, Schulz KF, Simera I, Wager E). Wiley, 2014. http://onlinelibrary.wiley.com/doi/10.1002/9781118715598.ch25/summary

## sampling (advantages and limitations)

The concept of sampling is neither new nor unfamiliar in everyday life. A cook examines a few grains of rice to find whether nearly all of them are properly cooked. In medicine, study of blood, urine, stool, and sputum samples and biopsy specimens is common.

The advantages and limitations of sampling are better appreciated when the meaning of the term *population* as used in statistics is clear. As explained under the topic **population (the concept of)**, this term has special meaning in statistics and can be understood as the target group from which sample subjects are chosen, or the larger group to which the findings would be extrapolated. In a descriptive study of acute respiratory infection (ARI) in a country, the target population could be all existing cases of ARI in that country, and for a cervical cancer control program, the target population could be all married women of age above 40 years. For studying risk factors of enlarged prostate, the population of interest could be all men of age 50 years and above in an area. Thus, statistical population depends on the context and the objective. Cost and logistic considerations seldom allow the study of all the subjects in a population, and sampling becomes a natural choice. Nevertheless, all subjects in the target population can also be investigated, in which case the study is called complete enumeration or **census**.

Even if all existing cases are surveyed, there is no guarantee that the results would apply to future cases. Thus, the concept of population in the context of medicine is more hypothetical than real. When all existing cases are indeed included, it still remains a sample considering that future cases are not included. Medical empiricism implies that the findings on the existing cases are used for future cases. Sampling is a prerequisite for this paradigm. However, if the objective is to find the prevalence of diabetes mellitus in the year 2008 among females of age 40 years and above residing in a particular city, complete enumeration is possible. Similarly, if a complete registry of cancer cases in a defined population is available, perhaps sampling is not needed for assessing the existing situation.

A futuristic perspective brings in the concept of **universe**. A universe could be larger than the target population that has implications for the result. Future cases are part of the universe but not of the population.

Although there are many advantages of sampling, sometimes there are also limitations, both of which are described next.

### *Advantages of Sampling*

The advantages of sampling can be listed as follows:

1. Sampling may be the only feasible method for collecting relevant data in some situations. Samples of blood, urine, semen, and biopsies are everyday examples in medicine. Complete enumeration is not feasible for such items.
2. Lower cost and less demand on personnel because of smaller coverage in samples relative to the total population.
3. Higher speed with which the results can be obtained.
4. Because of the relatively small number of subjects in the sample, more reliable information can often be collected by deploying better trained personnel, by adopting technologically more accurate methods, and by close supervision. This is a significant advantage but many times not realized.

### *Limitations of Sampling*

Despite these clear advantages, the results obtained from a sample cannot always be accepted. The following limitations may be noted:

1. Sampling necessarily entails an argument from the fraction to the whole. The validity of this argument depends on the representativeness of the sample. Not all samples are representative, although methods are available that make it likely to happen. But the choice of the method of sampling may be difficult in many situations as it is not always known what kind of sampling would give a truly representative sample to provide results applicable to the target population. At the same time, it is true that representativeness may be essential for descriptive studies where the objective is to generate valid and reliable estimates of prevalence; it is not necessary for an analytical study. As argued by Rothman et al. [1], representativeness by itself may not deliver valid scientific inference. The overall associations observed in the study sample may not apply to every subgroup. The overall effect is merely an average effect that has been weighted by the distribution of people across these subgroups. Thus, if there is a sample that is representative of the sex distribution in the source population, the results do not necessarily apply either to males or to females, but only to a hypothetical person of average sex. In addition, if the objective is to establish a relationship in a specified type of cases, as in most analytical studies including clinical trials, a representative sample is a secondary consideration.
2. When information is required for small segments containing a few individuals, sampling may fail to provide sufficiently precise information on them.
3. Sometimes a complete count is needed anyway, such as for a diagnosis and outcome profile of cases admitted to a hospital each year. In such cases, sampling is unnecessary.
4. Inclusion of some subjects in the sample and exclusion of others for a study may cause a feeling of discrimination among the subjects. Caution, some groundwork, and persuasion may be required.
5. All samples suffer from what is called **sampling fluctuations**, and we need to be on guard that the inference drawn is based on sound statistical considerations. This may require expertise that may not be easily available in some setups.

1. Rothman KJ, Gallacher JEJ, Hatch EE. Why representativeness should be avoided. *Int J Epidemiol* 2013;42 (4):1012–4. http://ije.oxfordjournals.org/content/42/4/1012.full?sid=1488b059-40cf-44d8-aef2-d2e67cf49f63

## sampling distribution of proportion *p* and mean $\bar{x}$

Samples by themselves are a great source of uncertainty. Yet sampling is considered a preferred strategy in most situations because of its overwhelming advantages enumerated in the topic **sampling (advantages and limitations)**. Statistical methods help in arriving at a conclusion regarding a population parameter based on just one sample. The basic tool used for this purpose is the sampling distribution. This is the distribution of the sample estimate seen in repeated samples as explained later in this section. Before discussing sampling distributions, understanding of some basic concepts is necessary.

### *Point Estimate*

Depending upon whether the variable is qualitative or quantitative, the basic parameter generally of interest is proportion (or probability) $\pi$ or mean $\mu$, respectively. In the case of anemia, the interest could be in either the proportion $\pi$ (or percentage) of subjects responding to iron–folic acid supplementation or the mean $\mu$ of rise in hemoglobin (Hb) or hematocrit (Hct) level. In a sample of 200 subjects, if the proportion responding is $p = 0.30$ (or 30%) or the mean rise in Hb level is $\bar{x} = 1.6$ g/dL after supplementation for 100 days, then it is generally expected that the entire target population would also show a similar picture, provided that the sample is adequately representative. The sample values $p$ and $\bar{x}$ are considered to be **point estimates** of $\pi$ and $\mu$, respectively. Such sample values are also called **statistics** where the usage is in the plural sense. When a large number of samples are actually available, the mean of $p$'s over such samples will approach $\pi$ and the mean of $x$'s will approach $\mu$. Much of the uncertainty generated by the **sampling error** can be satisfactorily resolved by studying the behavior of the statistics such as $p$ and $\bar{x}$ from sample to sample. Their intersample variability is measured by their respective standard errors.

### *Standard Error of* p *and* $\bar{x}$

As in the case of individuals, the variability in $p$ and $\bar{x}$ from sample to sample is measured in terms of their standard deviation (SD), but it is now called the standard error (SE). Thus, SE is the measure of variability of estimates from sample to sample. This special term helps to distinguish interindividual variability (measured by the SD) from intersample variability (measured by the SE). The SE of $p$ measures the variability in proportion $p$ from sample to sample, and the SE of $\bar{x}$ measures the variability in mean $\bar{x}$ from sample to sample. The larger the SE, the greater the variability and the lesser the confidence in the sample results. Thus, the inverse of SE is also a measure of reliability. You can intuitively realize that in the sample, some values are small and some are large so that the sample variance is relatively large. For sample mean though, large values average out with small values, and mean tends to be relatively stable across samples—more so as $n$ increases. Thus, SE is always less than SD.

The SE is calculated on the basis of all possible samples of particular size $n$ from the specified target population. However, these samples are not actually drawn. Statistical theory helps to obtain SE on the basis of just one sample, provided it is randomly drawn at least at one stage. This underscores the need to work with random samples. In the case of simple random sampling (SRS), the SEs are computed as follows:

$$\text{standard errors: } \mathrm{SE}(p) = \sqrt{\frac{\pi(1-\pi)}{n}}, \text{ and } \mathrm{SE}(\bar{x}) = \frac{\sigma}{\sqrt{n}}, \qquad \text{(S.1)}$$

where

$n$ is the size of the sample.
$\pi$ is the proportion in the population.
$\sigma$ is the SD of individual measurements in the population.

If measurements of all $N$ subjects in the entire target population are really available, the value of $\sigma$ is computed for all these values. In practice, though, the population parameters are seldom known and cannot be calculated (if they are known, there is no need of a sample). They are *estimated* from the corresponding values in the sample. Because the estimator of $\pi$ is the sample proportion $p$ and that of $\sigma$ is the sample SD $s$,

estimated standard errors:

$$\widehat{\mathrm{SE}}(p) = \sqrt{\frac{p(1-p)}{n}} \text{ and } \widehat{\mathrm{SE}}(\bar{x}) = \frac{s}{\sqrt{n}}, \qquad \text{(S.2)}$$

where $s$ now is computed with denominator $(n - 1)$, which helps to achieve a more accurate estimate in the long run (called **unbiased** in statistical parlance). The following comments in this context are useful:

1. SE($p$) is maximum when $\pi = 0.5$ and smaller when $\pi$ is either small or large. But its interpretation requires additional care. For $n = 100$ and $\pi = 0.05$, SE($p$) = $\sqrt{0.05 \times 0.95/100} = 0.022$, but for same $n$, $\pi = 0.25$, SE($p$) = $\sqrt{0.25 \times 0.75/100} = 0.043$. In absolute terms, the SE in the first case is nearly half of what it is in the second case. In relative terms, though, the first SE is 44% of $\pi$, while the second is only 17% of $\pi$. Thus, the first is higher in a relative sense. These are referred to as the **absolute precision** and **relative precision**, respectively, of $p$ and have serious repercussion on the confidence intervals.
2. Estimate of SE($p$) fails when $p = 0$ or $p = 1$ because then SE = 0. This case requires a separate consideration. The actual SE uses $\pi$, and $\pi = 0$ implies an impossible event. If you get $p = 0$, increase the sample size as much as to get at least one positive response, preferably more.
3. SE($\bar{x}$) is large when $\sigma$ is large. That is, if the individuals vary too much from one another, the sample means too will exhibit a large variation from sample to sample. Conversely, if the individual measurements are nearly alike or homogeneous, the sample mean in one sample will be nearly the same as in another sample.
4. Both SEs are inversely proportional to the square root of sample size $n$ and decrease as $n$ increases. This implies that two samples containing 100 subjects each from the same population would not differ as much with respect to $p$ or $\bar{x}$ as two samples containing only 20 subjects each would. Thus, a larger $n$ increases the confidence in the sample results. It is this feature that propels statisticians to suggest a larger sample. But this increase can be counterproductive if the cost becomes prohibitive. Thus, a balanced approach is needed.
5. Note that $p$ is the proportion of cases possessing a specific attribute in a group of subjects. For example, one may say that 11% ($p = 0.11$) in a sample of $n = 70$ normal births have a gestation period less than 265 days. In this case, SE($p$) = $\sqrt{(0.11 \times 0.89)/70} = 0.037$ or 3.7%. This result should be stated as "the percentage of births with gestation less than 265 days in a sample of 70 normal births is 11, with SE = 3.7%." This SE measures the expected variation in the percentage from one sample of size 70 to another sample of the same size from the same population.

6. In case of the mean, there is a special need to maintain the distinction between SE and SD. SE is for the aggregated picture obtained from the sample, and SD is for individual values. If the average duration of the gestation period in 30 normal births is 280 days with SD = 5 days, then SE is only $5/\sqrt{30} = 0.91$ days. It would be inappropriate to say that the average gestation period is 280 ± 0.91 days. The correct statement is that the average gestation period is 280 with SD = 5 days, that is, the mean should generally be accompanied by SD and not by SE. Also the usage of the ± sign should be discouraged for stating SD or SE since it gives the erroneous impression that adding and subtracting SD or SE gives the entire range of values.
7. Formulas for actual SEs are as given earlier in Equation S.1, but $\pi$ and $\sigma$ would be rarely known and it would be necessary to use the estimates. This would yield Equation S.2. The hat (^) sign indicates that these are estimates and not actual SEs. But this makes the notation very complex, and we ignore the hat sign and use Equation S.2 as though the equations are the actual SEs.

### *Sampling Distribution of* p *and* $\bar{x}$

As already mentioned, the values of proportion $p$ and mean $\bar{x}$ tend to vary from sample to sample. Just as individual measurements have their distribution pattern such as Gaussian, skewed, or J-shaped, the sample proportion and sample mean have a specific distribution pattern when many samples are available. This is called the sampling distribution. This distribution actually can be complex, depending on the form of the underlying distribution of the individual values, but it can be approximated by Gaussian (normal) under **Gaussian conditions** that basically require a large sample if the underlying distribution is not Gaussian. The mean of this distribution would be the same as of the original values, but the SD would be what we call the SE as explained earlier. If Gaussian conditions are not met, the sampling distribution of $p$ would be similar to a binomial distribution, but the distribution of $\bar{x}$ for small $n$ can be weird depending on the distribution of values in the parent population.

## sampling error/fluctuations

One sample from a population in all probability will be different from the second sample, as some or all individuals in the second sample may be new. Thus, the results obtained from one sample may not match with those from another sample. This variability is included in the sources of uncertainties and is called *sampling fluctuation*. If a sample of 300 healthy males of age 60–64 years from a population has an average systolic blood pressure (BP) of 142 mmHg, it is quite possible that another sample of 300 from the same population yields an average of 139 mmHg. But how likely is it that the average in a new sample will be as low as 128 mmHg or as high as 155 mmHg? The magnitude of this "error" depends primarily on three factors:

i. *The method of sampling*. The subjects should be selected in such a manner that a wide spectrum has adequate representation and repeated samples give nearly the same picture.
ii. *The size of the sample*. When the sample includes a large number of subjects, the picture obtained from one sample is not likely to be very different from that of another sample of the same size because both tend to be fair representatives of the population. This cannot be said for small samples.
iii. *Variability among the subjects in the population*. If the cholesterol level differs widely from person to person, then obviously the samples would reflect the same variability.

*Sampling error* is a term used for the difference between sample estimates and the actual value in the population. Thus, the difference $(\bar{x} - \mu)$ in the case of mean and the difference $(p - \pi)$ in the case of proportion are sampling errors. Hence, *sampling error actually is not an error*; it is just a variation arising due to sampling. Since the estimate varies from sample to sample, sampling error will also vary from sample to sample. As the sample size increases, the chance of a large sampling error decreases provided that the sample is randomly drawn. This error is endogenous to the investigation in contrast with nonsampling error that indeed is an error arising from inappropriate design, misreporting, misjudgment, incorrect recording, nonresponse, etc. The nonsampling error is exogenous in nature. The core of statistical methods deals with sampling fluctuations and sampling errors; but nonsampling errors are not ignored either and control of these also is attempted at each stage of investigation.

## sampling frame, *see* sampling terms

## sampling techniques (overall)

Sampling technique is the method to draw a sample from the target population. This is primarily divided into random and nonrandom methods. The topic **random sampling methods** provides an overview, and the individual methods such as **simple random**, **stratified random**, **systematic random**, **cluster random**, **multistage random**, and **probability proportional to size sampling** are discussed in this volume under the respective topics. This section presents an overview primarily to distinguish random from nonrandom methods of sampling.

A sample is called **random** when the inclusion or exclusion of a particular eligible subject depends on chance and cannot be predicted in advance. However, the chances are not necessarily equal for all subjects for inclusion in the sample. For this reason, it is sometimes prudent to call it a **probability sample**. The methods we just listed are all probability sampling methods.

Random selection should not be axiomatic but should be regarded as just a strategy to get a representative sample. If representativeness can be achieved by any other method, the same can be adopted; but experience suggests that nothing better than random is available. However, the larger the sample relative to the size of the population, the better the chance of it being representative—random or not.

There are situations where neither random nor representative sample is important. A sample of volunteers for phase I of a clinical trial is a nonrandom sample. Nonrandom samples inhibit generalizability but can still be useful in some situations as in phase I trial since the primary objective there is to find the tolerability of the regimen. This is one of the methods to draw what is called a convenient sample or a **purposive sample**. Such methods are collectively called **nonrandom sampling** methods.

As the name implies, **convenience sample** is the one that is drawn according to convenience. For example, whosoever is available and agrees to participate among those that you could contact

is convenience sampling. Volunteers are an everyday example of convenience sample. This kind of sampling is adopted particularly when a large number of people of the type actually required for the study are not available. Since this is not a random sample at any stage, it may be heavily biased. The findings from such a sample cannot be generalized to the population from where this sample is taken, yet the findings may turn out to be useful in some situations. McCann et al. [1] took a convenience sample of clinical staff to study their attitude toward the causes and management of aggression in acute old-age psychiatry inpatient units. Hwang et al. [2] took a convenience sample of ethnic minorities in South Korea for studying their utilization of complementary and alternative medicine. In both these cases, the convenience sample has not been a wastage of resources.

Another nonrandom method is **snowball sampling** that is used to spot obscure groups of people. Yet another is quota sampling where subjects are sequentially included without any random method to fill a prefixed quota. One can also conceptualize another method of sampling, which can be called **haphazard sampling**. This would be so when some subjects are selected by one or more random methods and others by one or more nonrandom methods, or when one stage is random and the second stage is nonrandom. This method does not follow any scheme.

## sampling terms

Sampling uses several special terms that must be clear to understand and adopt various sampling methods. Some of these are explained in this section.

### *Unit of Inquiry and Sampling Unit*

Different kinds of units are used in sampling. The **unit of inquiry** is the ultimate unit on which the information is obtained. A **sampling unit** is the one that is used for selection of the subjects. In a community survey on protein energy malnutrition, the sampling unit could be a family, but the unit of inquiry could be a child younger than 5 years. One sampling unit can have multiple units or may have no unit to inquire on. Sometimes the sampling is done in stages, such as selection of some hospitals in the first stage, then wards or departments within the selected hospitals in the second stage, and then patients in the selected wards in the third stage. The unit of inquiry could be a patient, but sampling units are multiple in this kind of sampling.

### *Sampling Frame*

The list of all sampling units in the target population is called the *sampling frame*. The units are chosen from this frame. The units must be mutually exclusive, and the frame should be an exhaustive list. If there is a study on hypertensives and diabetics, a person who has both cannot be listed twice. The list may separately include those who have both diseases, those who have only one of the two diseases, and those who have neither of these two diseases. Inclusion and exclusion criteria must be fully known to the sampler. Preparation of the frame requires precise definition of the unit as well as of the population. For example, if the unit is a case of sexually transmitted disease (STD), all the STDs should be specified. State whether a case of hepatitis B infection would be included or not. Also, state whether the cases would be those that have frank disease or cases with subclinical infection would also be included. The criteria of diagnosis of each should be stated, i.e., the diagnosis is based on clinical evidence alone or a laboratory confirmation is also required. In some situations, a map of the study area serves as the frame. In this case, geographical entities are selected instead of individuals or families. Units available in the selected areas constitute the sample.

The requirements of sampling frame are intense for **simple random sampling** since it would include all sampling units. In contrast to this, in **multistage sampling**, for example, sampling frame is required only for next-stage units within the selected previous-stage units. For example, for selecting districts within a state, frame of districts is needed; but once, say, 5 districts are selected where the next stage is census block, only the frame of blocks for the selected districts is needed. If the next stage is selection of families, the frame of families for only the selected blocks is needed. This obviates the need to prepare sampling frame of all the families in the state, which would be needed if the sampling of families is directly done by simple random sampling. This could be a huge convenience in some situations.

### *Sampling Fraction*

This is the proportion of subjects in the target population to be included in the sample. For example, you may decide to include 1 out of 5, which means 20% sample and the sampling fraction is 1/5. This fraction gives an idea to the reader how big is the sample relative to the size of the population, and can be important consideration in assessing the credibility of observational studies since high sampling fraction implies less **sampling error**. Medel-Herrero et al. [1] used sampling fraction to assess the reliability of one hospital statistics resource versus another one in Spain.

Sampling fraction has special application to **systematic sampling**, where one unit is randomly selected as per the sampling fraction and all others follow a systematic pattern in sequence using the same sampling fraction.

### *Sampling with and without Replacement*

Consider a finite population of size $N$ units. If one is selected by random or nonrandom method, the remaining available for sampling now is $N - 1$ units. In the next step, only $N - 2$ units remain. This is sampling without replacement. In case of sampling with replacement, the selected unit goes back to the population so that the size of the population remains the same $N$ for selection of the second and all subsequent units. Under this sampling, the same unit can be selected twice or many times since the unit is available again for selection. This allows infinite samples from a finite population. If $N = 500$ and the sample size is 20, select 20, replace them so that we again have 500 units to choose from, select another 20 (some of these could be the same units as in the first sample), and so on. Without replacement, you can select at most 500/20 = 25 samples, whereas with replacement, you can select as many as desired.

In a random sampling without replacement, the probability of selection of any particular unit is $1/N$ at the first selection but changes to $1/(N - 1)$ at the second selection for the unit not selected, then to $1/(N - 2)$, etc. These changing probabilities essentially mean that the independence is lost—the chance of selection of any particular unit at subsequent sampling is affected by what was selected

earlier. This can complicate the analysis. In case of sampling with replacement, what we get on the first step does not affect what we get on the second, and thus the independence is preserved. Most statistical methods require independence, although we realize that the same unit can rarely be allowed to be selected two or more times in the same sample. In case of a large population, the chance of the same unit being selected twice is anyway small and negligible.

When the population is very large, the probabilities for units selected subsequently without replacement are not much affected and the independence can be assumed. This is not so when the population size is small. Thus, samples chosen from a small population require exact analysis with relatively much more complex calculations. However, this is rarely required in practice. For example, in a simple random sampling, if one wishes to select 20 out of 500, the method such as that of 500 identical chits in a hat with numbers 1 to 500 and selecting 20 at the same time gives the same chance of selection to each unit even when the sampling is without replacement.

In methods such as **bootstrap**, where the sampling is with replacement, any number of samples can be drawn from the available sample. For example, if a sample of just 10 units is available, an infinite number of samples of, say, size 6, can be selected because of replacement. This is what gives strength to the bootstrap method.

## scales of measurement (statistical)

A scale is an instrument on which the characteristics are measured. It can be quantitatively calibrated in the usual sense or can be qualitative. Blood glucose level and urea clearance are measured in terms of quantities, whereas the blood group of a person is a quality recorded as either O, A, B, or AB. Age can be measured in days and hours but is often categorized in years as (0–4), (5–14), (15–49), etc. Disease severity and extent of malnutrition are quantities but are generally measured as none, mild, moderate, and serious. Site of malignancy is also a measurement in a statistical sense but is recorded as oral, lung, abdomen, breast, etc. Thus, there are a large variety of measurements. Statistical methods to study variation depend on the scale of measurements. These scales can be grouped in a variety of ways. A majority of them are described here.

### *Nominal Scale*

Not all measurements are necessarily in terms of quantities. Complaints and site of cancer are qualities but are still considered *measurement* in a statistical sense. The categories in such cases are only names, and the scale of such a measurement is called nominal. All space-related measurements such as the organ affected, site of lesion, and place of occurrence of disease are nominal, and so are attributes such as race and blood group. These names do not have any specific order. Thus, there is no notion of less than or more than in this kind of scale, and the only valid comparison is of equality or inequality. Gender is either male or female, and none is higher or more than the other. Diagnosis of liver disease as hepatitis, cirrhosis, or malignancy is nominal, and so is the nature of a handicap such as visual, speech, orthopedic, mental, etc. These variables are genuinely categorical, and the only way to associate numbers with them is by way of assigning a **code** to each category. Note, however, that codes for nominal categories are not metric scores—a category receiving code 4 is not twice the category receiving code 2. These codes cannot be treated as quantities and cannot be added, subtracted, multiplied, or divided. Codes are not the same as scores.

When the assessment of a characteristic is in terms of only two categories such as yes/no, present/absent, or favorable/unfavorable, these are called **dichotomous categories**. The corresponding variable is called a **binary**. Recording gender as male or female is the most glaring example of such a variable. If the number of categories is more than two, such as cirrhosis, hepatitis, and malignancy for liver disorders, these are called **polytomous categories**. Statistical methods are simpler for dichotomous than for polytomous categories. If a statistician advises you to collapse three or more categories into two for the sake of convenience during calculations, you should agree only if this does not reduce relevance and the operational value of the conclusion is not compromised. Clinical relevance should not be sacrificed for statistical expediency. Computers have largely obviated the need to compromise on this aspect.

Statistically, all measurements on the nominal scale are discrete **variables** since the number of categories is generally small, and the data are generally expressed in **contingency tables** and analyzed by **chi-square test**, particularly for large samples.

### *Metric Scale*

At the other end of the spectrum are characteristics that can be exactly measured in terms of a quantity. Duration of a disease, hemoglobin (Hb) level, heart rate, and parity are examples of such characteristics. These are said to be measured on a metric scale. Often these are recorded in categories such as years of age in (0–4), (5–14), (15–49), (50–69), and (70+) groups. Such categorization tends to ordinalize the metric scale and results in loss of information, yet it is preferred in some situations, as discussed in a short while.

There is a tendency in health and medicine to develop a **scoring system** for **soft data** such as the degree of severity of disease. This introduces a metric scale for soft data and definitely helps in achieving a better exactitude. Such scores are statistically satisfying but sometimes lose clinical relevance. If you are using a scoring system, ensure that it adequately represents varying grades of the observations. Assigning a number should not be at the cost of unjustified air of accuracy.

Sometimes a metric scale is divided further into interval and ratio scales. In an **interval scale**, there is no absolute zero, for example, body temperature. A temperature of 105°F cannot be interpreted as only 5% higher than 100°F. Similarly, it is incorrect to say that a person with an intelligence quotient (IQ) of 160 is twice as intelligent as a person with an IQ of 80. Differences matter but ratios are irrelevant in this kind of scale. This is so for many measurements in medicine that do not start from zero. Plasma glucose level, blood pressure, and heart rate are all examples of this kind of measurement. On the other hand, in a **ratio scale**, a zero point can be meaningfully

designated. It is correct to say that the duration of survival of 6 years is twice as much as 3 years, and parity 3 is thrice as much as parity 1. However, in this case also, their medical interpretation may not be based entirely on a proportional factor. The fine distinction between interval and ratio scales in most cases is not required for managing uncertainties through statistical methods.

The disadvantages of measurements on the metric scale are that, in many cases, such measurements are relatively more difficult, more time consuming, and more expensive. A large number of parameters may have to be considered together to say that the extent of burns is 78%, while it is easy to say on visual inspection alone that the burns are "extensive." However, such shortcuts invariably lack objectivity. Whenever feasible, prefer the metric scale to the ordinal scale. It is always wise to ensure that the metric measurements you are using are indeed valid and reliable.

Metric measurements can also be divided as continuous and discrete. For this, see the topic **variables** where these and other types of variables are described.

### *Ordinal Scale*

There are certain characteristics that should be measured in terms of quantity, but the nonavailability of a good instrument compels measurement in terms of what is called an ordinal scale. Disease severity when measured as none, mild, moderate, serious, or critical; likelihood of the presence of a particular disease when measured as ruled out, unlikely, doubtful, likely, or confirmed; and self-perception of health from very bad to very good on, say, a seven-point scale are examples of such characteristics. These are inherently metric, but an ordinal scale is more convenient in such measurements. The main reason for nonavailability of a metric scale is that many of these characteristics are multifactorial, for example, disease severity depends on signs and symptoms, measurements such as blood pressure and plasma glucose levels, and radiological assessment, etc., which makes assigning a single quantity extremely difficult.

Sometimes a device to measure a characteristic is easily available but is not adopted because such a level of accuracy is not needed. Smoking can be measured as the number of cigarettes smoked, but categories such as none, light, moderate, and heavy seem to serve the purpose sufficiently well in many clinical situations. Age can be measured in terms of years, but categorization into child, adult, and old may be adequate in some situations.

The basic advantage of using an ordinal scale rather than a metric scale is convenience in eliciting, recording, and reporting, and there is no need of any sophisticated device for measurement. Ordinal categories are often easier to comprehend than metric categories, although valuable and accurate information is lost in the process, and the analysis of data is rendered less efficient. Metric measurements are amenable to a host of mathematical manipulations that are not possible with ordinal measurements. Thus, prefer using hard measurements such as blood pressure level instead of grade of hypertension, and prostate volume instead of grade of enlargement. If the efforts required for hard measurements are enormous such as in measuring the size of the brain, or when no metric scale is available, use an ordinal scale. However, beware of anomalies in some ordinal categories. What is mild for one may be moderate for another, since these terms are rarely strictly defined.

Between nominal and ordinal, there might be measurements that are *semiordered*. Classification of malignancy as definitely absent, probably absent, uncertain, probably present, and definitely present is an example of a semiordered scale. These categories are partly nominal and partly ordinal.

**TABLE S.7**
**Comparative Features of Nominal, Ordinal, Interval, and Ratio Scales of Measurement**

| Type of Scale | Does It Measure Magnitude? | Is This Equally Spaced? | Does It Have Absolute Zero? |
|---|---|---|---|
| Nominal | No | No | No |
| Ordinal | Yes | No | No |
| Interval | Yes | Yes | No |
| Ratio | Yes | Yes | Yes |

Quite often, numerals are associated with ordinal categories such as 0 for none, 1 for mild, 2 for moderate, and 3 for serious. These numbers are then subjected to all sorts of algebraic calculations. Such calculations are valid only when the moderate degree is considered two times the mild degree, and the serious degree is considered three times the mild. These numerals also assume that the difference between mild and no disease is the same as that between serious and moderate disease. In practice, this may not be so, and sufficient caution is required in assigning numerals to ordinal categories and in drawing conclusions when based on calculations involving such numbers. Note that these numerals are not codes but are used as scores.

Main features of nominal, ordinal, and metric (interval and ratio) scales are summarized in Table S.7, which may give you a snapshot of their comparison.

### *Other Types of Scales of Measurement*

Several other types of scales are used in statistical data, and these are discussed elsewhere in this volume. Among these are **logarithmic scale** as opposed to the usual linear scale, **Likert scale**, and **Guttman scale**—the latter two are used for items in a questionnaire.

## scalogram analysis, *see* Guttman scale

## scatter diagrams

A scatter diagram aims to show the variation in the values of one variable in relation to another. Simple examples are blood pressure (BP) values in subjects of different ages and cholesterol levels in subjects with different body mass indexes. Different symbols can be used to distinguish between male and female subjects, or any such groups. Preferably both horizontal ($x$-axis) and vertical ($y$-axis) should be metric for a scatter diagram, but it is necessary for at least the $y$-axis to be metric ($x$-axis can be nominal or ordinal). If one variable is dependent on the other, the dependent variable is shown on the vertical axis. In Figure S.2a, the percent cholesterol esters is shown as dependent on total bilirubin in cases of cirrhosis, hepatitis, and common bile duct (CBD) obstruction. In the presence of regurgitation jaundice, the flow of bile into the duodenum may decrease, causing a reduction in the esterified form of cholesterol. Note an **outlier** in this figure. Scatter diagrams provide a great opportunity to spot such outliers.

When the scale on the $x$-axis is ordinal or nominal, the scatter takes the shape of stacking of symbols over one another as in Figure S.2b. Different symbols are used for different severities of jaundice in this diagram. Already it is difficult to untangle the points and identify the pattern for cirrhosis, hepatitis, and CBD obstruction

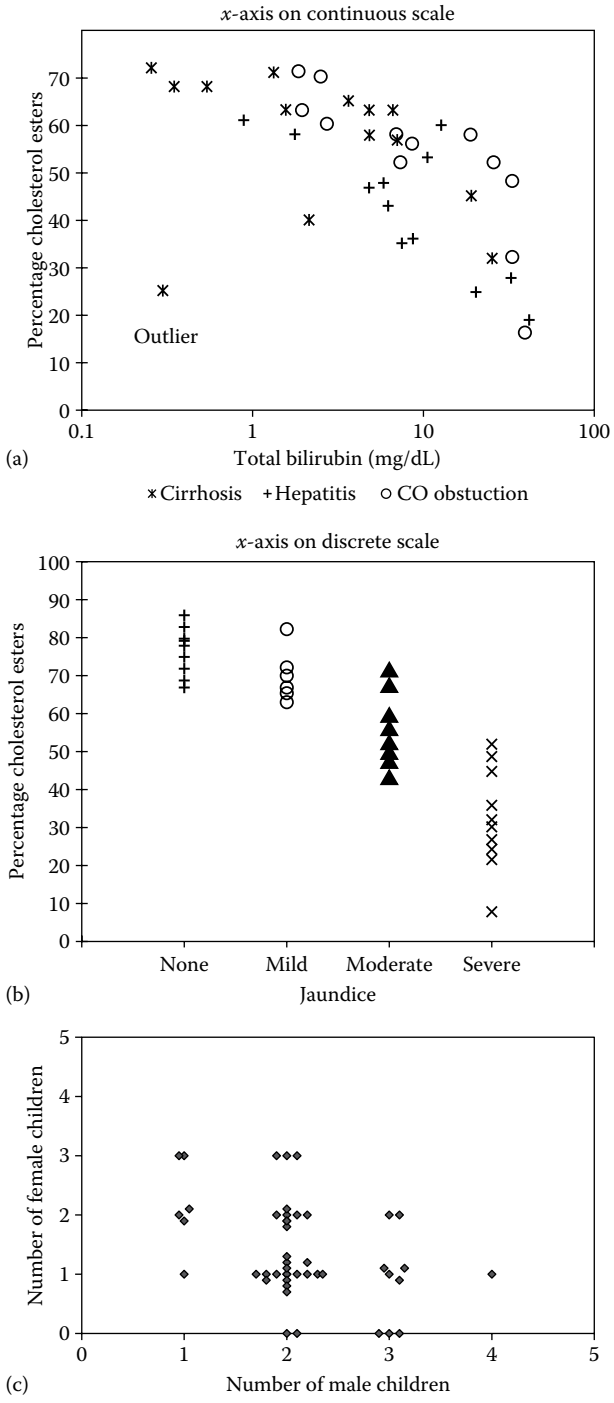

**FIGURE S.2** Three types of scatter diagram. (a) Dependence of percentage cholesterol esters on degree of jaundice measured by total bilirubin. (b) Percentage cholesterol esters in cirrhosis patients with different degrees of jaundice. (c) Use of jitter for overlapping points—male and female children at the time of sterilization in families preferring male children.

in Figure S.2a. The problem accentuates when measurements with different units are shown on the right and left axes (not shown). The next problem occurs due to too many points at one place in a scatter diagram that may look like a vague blob. For such overlapping points, try **jitter**, which is a minor perturbation for plotting purposes only, and use small size symbols. See Figure S.2c for an example.

## scoring systems (methods for developing), *see also* scoring systems for diagnosis and for gradation of severity

In our context, scoring systems give scores to various background characteristics of the people (age, sex, weight, occupation, etc.), signs–symptoms (pallor, spleen, pain, etc.), medical measurements (blood pressure, pulse rate, etc.), laboratory and radiological investigations (electrocardiogram [ECG], glucose level, chest radiograph, etc.), and other features, with the following objective: first to try to give them exactitude in terms of quantities, and second to combine them to provide a holistic picture. In some difficult-to-comprehend situations, such scoring systems can help address part of the problem arising from knowledge limitation (**epistemic uncertainties**) and can help to establish diagnosis and to grade the severity of the condition.

Developing a good scoring system has not been easy because of gaps in our knowledge to be exact and due to the need to have expertise for a realistic assessment. Yet many of them are available and used extensively. Developing a scoring system requires that the final status of the patients (either the diagnosis or the gradation of severity) is available with a widely acceptable set of criteria for at least some of them. Once the system is validated for its reliability and validity, it can be used on new cases.

Characteristics that have gradients are relatively easy to score than measurements on the nominal scale. If the gradient is already numeric such as pain on the visual analog scale, the score is immediately obtained for this variable; but the problem arises for ordinal factors that have gradients but no numeric scale is available. Examples are severity of disease, which is categorized as mild, moderate, serious, or critical, and degree of satisfaction categorized as completely dissatisfied to fully satisfied. Characteristics on the nominal scale such as presence or absence of signs and symptoms in any case defy quantitation at the individual level. The method of assigning numerics to ordinal and nominal characteristics should be such that it can reduce uncertainties and does not introduce additional questions regarding validity of the scoring system. A more general method based on **logistic regression** is discussed later in this section, but consider the following for the time being.

### *Method of Scoring for Graded Characteristics*

The simplest scoring for ordinal characteristic is linear, for example, 0 for no disease, 1 for mild disease, 2 for moderate disease, 3 for serious disease, and 4 for critical condition. As already mentioned, such a scoring assumes that the difference between mild and no disease is the same as that between critical and serious disease. It is legitimate to ask for such a scoring why scores 0, 3, 6, 9, and 12 are not more appropriate for severity of disease, which also are linear (3 added each time), or even why geometric scoring (twice of the previous) such as 0, 1, 2, 4, 8 is not better. Very few studies have been carried out to investigate various alternatives, and thus nothing can be stated with confidence. Nevertheless, the 0, 1, 2, 3, and 4 type of linear scoring remains the most widely used scores because of their simplicity. They go unnoticed. No explanation is generally required when such simple scores are used, while any other scores are expected to be accompanied by justification. However, it is better to investigate a set of patients with different severities to find how severe this disease is for them and assign a score accordingly. A more complex procedure to generate scores is illustrated in the following example. Similar innovative ways can be devised to develop a scoring system.

Functionality in multiple sclerosis patients has a gradient, and its metric measurement has always been a challenge. Various scales are used to assess functionality in the patients; among those relatively easy to perform are the 10 m timed walk (TMTW) and nine-hole peg test (NHPT) for the right and left hands. Vaney et al. [1] developed a short and graphic ability score (SaGAS) as (2 × TMTW + NHPTright + NHPTleft) after taking the logarithm of these timed values. The authors demonstrated good correlation of SaGAS with established tests such as Multiple Sclerosis Functional Composite, Expanded Disability Status Scale, and Rivermead Mobility Index. Features of SaGAS such as simplicity, intuitiveness, and nonphysician-based measurability were enumerated as advantages for its use in multiple sclerosis patients. The authors developed an easy-to-implement scoring system, and its good correlation with other more complex scoring methods is one way to demonstrate its validity. For a real assessment, comparison with a gold standard could be more convincing. Such a standard may not exist in this case; in most cases, the gold standard might be too cumbersome and expensive. Equivalence of the new scoring system with the gold standard when demonstrated would establish its real validity.

Consider measuring nursing workload in an intensive care unit (ICU) by a scoring system. Yamase [2] assessed this workload by 88 items relating to (i) the number of nurses required, (ii) muscular exertion, (iii) mental stress, (iv) skill, and (v) intensity. A three-round **Delphi** survey among 20 skilled ICU nurses assigned a consensus four-grade (0 to 3) score to each of the 73 items after excluding 15 items considered unnecessary. These scores were confirmed by surveying 118 nurses in other ICUs. The "comprehensive nursing intervention score" is the sum of all these individual item scores. The scoring system was confirmed as reflecting the true workload by applying it to the daily care of 107 patients. This example illustrates how a simple method can be used to develop a scoring system. Validation of the individual scores by another group of nurses and of the scoring system by using it in actual conditions tends to enhance the confidence in the scoring system.

### *Method of Scoring for Diagnosis*

Scoring for establishing diagnosis might help in situations where diagnosis or differential diagnosis is difficult and requires a lot of expertise that may not be immediately available. See the topic **scoring systems for diagnosis and for gradation of severity** for an example on the diagnosis of hypothyroidism that uses scores on clinical signs and symptoms. Here, the scoring helps to establish or rule out hypothyroidism in nearly half the cases. Thus, the need for further investigations is reduced to one-half. For another example, see Guo et al. [3] who provided a scoring system for the diagnosis of Hirschsprung's disease in neonates. Rosen et al. [4] proposed a smaller 5-item index as a diagnostic tool for erectile dysfunction compared with the larger 15-item scoring. Their index uses linear scores for each item.

Signs and symptoms are qualitative and play a significant role in establishing diagnosis. Converting such qualities to a numerical score has always been a challenge, and no widely acceptable method is available yet. The following examples and their discussion are based on the methods used by some workers who ventured into this area.

There are examples of assigning arbitrary scores. Obviously, they provide tentative results. A common and acceptable method of assigning scores to individual characteristics is based on the **regression coefficients** that are estimated using a multiple regression method when the outcome is quantitative. For qualitative outcomes, particularly those that are dichotomous, such as the presence or absence of a disease, **logistic regression** coefficients are used. The factors surmised to determine the outcome are antecedents whose coefficients in the logistic regression equations are significant. Since they can be interpreted as the log of odds ratio (OR), the larger the OR, the better the predictive utility of the factor. Thus, the score in proportion of the OR can be assigned to those factors that turn out to be significant predictors. The method is illustrated in the following example on unstable angina. This example also is more on the gradation of a disease than on diagnosis, although the outcome is dichotomous: either death or survival. For a more rigorous example, see **APACHE score**.

Unstable angina is a complex syndrome prognosticated by a host of factors such as age, hypertension, diabetes, hypercholesterolemia, smoking, previous myocardial infarction (MI), ST segment elevation in ECG, troponin test, etc. Piombo et al. [5] studied a large number of such factors in 473 patients and found four of them to be significant predictors in a multivariate logistic regression of in-hospital occurrence of refractory ischemia, acute MI, or death. These three together formed an unfavorable outcome. The ORs were 4.03, 2.29, 2.21, and 2.0 for ST segment deviation, age ≥ 70 years, previous coronary artery bypass grafting, and positive troponin test (T ≥ 0.1 mg/mL), respectively. The scores assigned were 4, 2, 2, and 2 corresponding to the respective ORs, and the highest possible score was 10. It was divided into three categories: 0 or 2 for low risk, 4 or 6 for intermediate risk, and 8 or 10 for high risk (scores 1, 3, 5, 7, and 9 are not possible in this scoring system). This scoring system was validated in another group of 242 patients that provided similar results. Nearly 63% of patients were assigned to the low-risk group, 31% to the intermediary-risk group, and 6% to the high-risk group. The predictive power of the scoring system assessed by the ***C*-statistic** (area under the **ROC curve**) was 0.72. The *C*-statistic is one of the important criteria that determine the validity of a scoring system.

This example on unstable angina was chosen not because it provides a valid scoring system but because it uses an appropriate method for selection of factors and for assigning them a proper score. There are many other examples of this type. Purasiri et al. [6] combined the results of clinical examination, mammogram, ultrasonograph, and fine needle aspiration cytology by assigning them weighted scores using stepwise logistic regression. This combined score performed better than any of the others individually in differentiating malignancy from benign lesions in suspected cases of breast cancer. In this study, the confirmed diagnosis was later available so that the "gold" was present. However, the authors used the term index and not score. Another example is the scoring system developed by Chiu et al. [7] for early detection of oral submucous fibrosis based on a self-administered questionnaire. This had a *C*-statistic of 0.90. Rassi et al. [8] also assigned scores proportional to the regression coefficients to the independent significant factors for death in Chagas disease. The *C*-statistic was 0.84 for this scoring system.

The method of assigning scores proportional to the regression coefficients is valid only when the values of the predictive factors are standardized to mean 0 and variance 1 before the regression is run. The regression coefficients without this standardization are not comparable and are severely affected by the unit of measurement. Since computation is not a limitation these days, regression equation itself can be used as the scoring system without any standardization.

Since a regression coefficient after standardization measures the contribution of the factor to the outcome, this method of scoring looks at least face valid as it assigns higher score to the factor that contributes more to the outcome. Also since the regression is able to identify the factors that are significant independent contributors and need to be included in the scoring system, this method has some desirable properties. However, it may fail to provide a valid scoring system in some situations as discussed next.

### *Validity and Reliability of a Scoring System*

Although qualities such as ease of understanding and ease of implementation can be cited, basic statistical qualities of scoring systems are **validity** and **reliability**. Of these two, validity is more important and difficult to assess too. If a scoring system were not valid, its good reliability would seldom be useful.

*Validity of scoring system.* How does one assess that a scoring system is providing the right result? First, it should look just about right (called face validity) and should correspond well to the knowledge of experts. If a scoring system surprises you and the experts, reconsider the elements that cause this surprise and make necessary modifications. But the most important assessment of validity is against a gold standard. The basic difficulty in assessing this is in identifying and implementing the gold standard against which the validity is checked. If the gold standard is easy to perform, there is no need for a scoring system. In the case of pregnancy-induced hypertension, Thurnau et al. [9] compared the scoring results with clinical manifestation. If clinical manifestation is to be considered the gold standard and if clinical assessment is relatively easy, nothing additional is gained by the scoring system. A scoring system is useful only when it really adds to the clinical picture or when it replaces a complicated procedure. The latter can happen when a final diagnosis is based on consensus of experts or when it emerges later in the course of disease. An explicit advantage is the objectivization the scores introduce, which clinical assessment may lack.

When the results from the gold standard are not available, the worth of a scoring system is assessed using alternatives. One is to see whether the scoring system gives results that are consistent with undisputable outcomes such as death. Rassi et al. [8] reported for their scoring system for predicting death in Chagas disease that patients with a low (0–6 points) score had 10% 10-year mortality rate, those with a medium (7–11 points) score had 44%, and those with a high (12–20 points) score had 84%. This provides an indirect evidence of validity of the scoring. Note in this case that the gold standard is death, and there is no way to assess it in advance except by prognostic factors summarized by the total score.

The second aspect of validity is establishing it in a different sample. This, in fact, testifies repeatability. If another sample of similar nature gives similar results, it is safe to conclude that the scoring system is not sample-specific and has at least some generalizability. In almost all examples discussed in this section, the validation sample is different from the development sample, and the results were shown to replicate adequately.

The third type of validation of a scoring system is its comparison with an established and more cumbersome system. This is to check if an easier version provides the same results. Both could be excellent or both could be poor, but that is not the issue in this kind of comparison. The comparison is not with a gold standard in this case. Such concurrent validity provides evidence that the easier version can replace the cumbersome procedure. Moreno and Morais [10] compared a 28-question simplified therapeutic intervention scoring system (TISS) with the standard 72-question TISS for nursing workload in ICUs and came up with the conclusion that the simplified version is just as good. Evans et al. [11] developed a scoring system for identifying mutation and found that it outperforms existing models.

*Reliability of a scoring system.* In addition to being valid, any medical assessment tool should also be reliable with respect to repeatability and reproducibility. Reliability may suffer if the wordings are not precise and instructions are not explicit, so that there is room for subjective interpretation either by the assessor or by the assessee or by both.

The reliability of a scoring system is assessed interobserver (also called an interrater) as well as intraobserver. For both these assessments, **intraclass correlation** is used. This correlation must be in excess of 0.90 for good reliability provided that there are no factual repetitions, and a value between 0.80 and 0.89 is considered acceptable. Any tool with intraclass correlation less than 0.80 is suspect and used with caution.

Another measure of reliability is the narrow width of the confidence interval (CI). This can be calculated for sensitivity, specificity, predictivities, and the area under the ROC curve for the derived scoring system as illustrated in the following example. If the width is sufficiently narrow, the system can be considered reliable.

Xu et al. [12] studied 129 patients with suspicion of prostate cancer who underwent transrectal sonography-guided repeat biopsies. They devised a scoring system based on the results of multivariate logistic regression. ROC analysis found that the best cutoff is 2.5 at which the area under the ROC curve was 0.816. Sensitivity was 76.5% and specificity 74.7% at this cutoff. Relatively low values of sensitivity–specificity and not particularly high area under the concentration curve show just about satisfactory validity of this scoring system but not high validity. CIs were not calculated; had they been, they would also show that the reliability also was not adequate.

## scoring systems for diagnosis and for gradation of severity, *see also* scoring systems (methods for developing)

Medical professionals can be statistically dichotomized as those preferring qualities and subjective assessments using clinical acumen, and those who prefer quantities that bring in exactitude. Some of those belonging to the latter group may like to quantify even signs and symptoms of a disease. How does one convert qualities into quantities at an individual level? The answer is through the scoring system, whereby signs and symptoms unique to a disease or more commonly seen are assigned a higher score and the others a low score. Thus, measurements on a nominal scale are ordinalized and finally converted to a metric scale. **APACHE** and **Apgar scores** are everyday examples of such conversions, although in Apgar, each sign gets an equal score. Pain on a visual analog scale measures pain intensity, but the McGill pain score comprises qualities like throbbing pain, shooting pain, and stabbing pain. Scoring systems also reduce a multivariate entity into a univariate quantity, thus increasing comprehension and utility. They also help in reducing some of the **epistemic uncertainties** that can arise from inadequate realization of how much weight is to be given to various pieces of information.

Realize that the scores are the quantitative values assigned to **ordinal data**. This increases the statistical power of the methods of analysis, if, and this is a big if, the scores truly reflect the "importance or medical significance" of the ordinal categories. In case the data are already quantitative and metric categories had to be formed for convenience, the midpoints of the intervals (called *midranks*) are a fairly good approximation of the category scores. If the categories were unequal such as age categorized into 0–1, 1–4, 5–14, etc., these scores would not be equally spaced. The temptation to give equally spaced scores such as 1, 2, 3, etc. (called *linear scores*) to such categories could provide misleading results. In the case of predictor variables, midranks and linear scores may not be able to capture the right importance. For example, the number of cigarettes smoked per day may be categorized as 0, 1–4, 5–9, 10–19, and 20+; however, their linear score as 0, 1, 2, 3, and 4, or midranks as 0, 2.5, 7, 14.5, and, say, 29, may not be able to capture the intensity of smoking for hurting the health, and therefore a more rational scoring may be needed. The same applies to scores 1, 2, 3, etc., assigned to mild, moderate, serious, etc., pertaining to the severity of diseases. However, the challenge is to ordinalize or assign quantities to signs and symptoms. As already mentioned, this is done by assigning a higher score to those that are more commonly seen or those that are specific to the disease.

Scoring systems are gradually gaining importance similar to the laboratory and radiological investigations. There was a time when these were considered below the dignity of a clinician, but now hardly any medical decision is taken without recourse to such investigations. A large number of scoring systems on various aspects are being developed: the list already runs into hundreds. These systems have found useful applications in gradation of severity of a disease as they consider several individual assessments together. Scoring systems have also been applied for establishing a diagnosis, particularly for differentiating one condition from another similar looking condition. Both types of scoring systems—for diagnosis and for severity of a disease—can add to the knowledge with which a medical condition is managed.

### *Scoring System for Diagnosis*

Attempts have been made periodically to quantify the field of medicine and developing scoring systems that can help in diagnosis. The following example on scoring for diagnosing thyroidism illustrates the procedure.

Hypothyroidism poses a challenge to physicians at the time of diagnosis. It is not easy to distinguish hyperthyroidism, euthyroidism, and hypothyroidism from each other based on clinical signs and symptoms. Assays for measuring $T_3$, $T_4$, and thyroid-stimulating hormone (TSH) levels help in reaching a diagnosis, but these tests are slightly expensive, and some hospitals in developing countries may not have the facility for such testing. Clinically clear cases of hyperthyroidism and hypothyroidism can be treated without taking into account laboratory results, and the tests are ordered only in doubtful cases. This can also reduce the load on laboratory services. A diagnostic index for hypothyroidism was devised by Billewicz et al. [1] taking into account the frequency of various symptoms and signs in this disease. They developed a scoring system excluding four features with zero score (Table S.8).

**TABLE S.8**
**Scoring System for Thyroidism**

| | Score | |
|---|---|---|
| **Signs and Symptoms** | **Present** | **Absent** |
| Physical tiredness | 0 | +2 |
| Slow cerebration | –3 | +2 |
| Diminished sweating | +6 | –2 |
| Dry skin | +3 | –6 |
| Cold intolerance | +4 | –5 |
| Dry hair | –2 | +2 |
| Weight increase | +1 | –1 |
| Constipation | +2 | –1 |
| Hoarseness of voice | +5 | –6 |
| Paresthesia | +5 | –4 |
| Deafness | +11 | 0 |
| Slow movements | +4 | –3 |
| Coarse skin | +7 | –7 |
| Cold skin | +3 | –2 |
| Periorbital puffiness | +4 | –6 |
| Pulse rate <75/min | +4 | –4 |
| Ankle jerk | +15 | –6 |
| **Total score** | **≤ –30** | **Euthyroid** |
| | **–29 to +24** | **Doubtful** |
| | **≥ +25** | **Hypothyroid** |

The scores are based on the logarithm of the ratio of frequency of presence and absence of symptoms in established hypothyroid and euthyroid cases. According to this scoring system, a clear diagnosis can be made based on signs and symptoms alone if the score is 25 or more (hypothyroid) or –30 or less (euthyroid). Laboratory assistance is required only when the total score is between –29 and +24. This can reduce the load on the laboratory by more than 50%. This scoring system was later simplified by Zulewski et al. [2]. Although this is a score, the authors liked to call it an *index*. Many such examples of mixed use of the terms exist in the literature.

Not many researchers look for a simple scoring system as illustrated in our example. Instead, a **logistic regression** equation is used as a scoring system (see **scoring system [methods for developing]**). Examples are a scoring system for repeat biopsies in suspected patients of prostate cancer [3] and for initial treatment failure in suppurative kidney infections [4]. These are some examples of various scoring systems available for diagnostic purposes; many others are available. Almost all such scoring systems are based on data from developed countries, which may not directly apply to the subjects in developing countries because of different nutritional and environmental factors. These scoring systems have to be appropriately modified before using them for patients in such countries.

Such systems should be used only when a valid diagnosis is difficult to establish or when the diagnosis depends upon physicians' preferences, their expertise, or results of laboratory or radiological investigations that lack credibility. Such inadequacies in the diagnostic process are more common than are otherwise apparent. A useful strategy is to use these scores as just additional adjunct to the clinical and laboratory evidence, and take a decision in a holistic manner.

### *Scoring for Gradation of Severity*

Prognostic assessment and the management of a patient depend to a large extent on the severity of the disease. There is considerable **epistemic uncertainty** about how to assess this severity. Different professionals use different methods. For uniformity and exactitude, at times, scoring is considered desirable.

The Glasgow Coma Scale [5] is used to grade coma patients by using a numeric scale for eye, motor, and verbal response. The **APACHE score** is used to assess severity in critically ill hospitalized adults [6]. Various variations of this score are available. The **Apgar score** is used to assess prognosis in a neonate. In case you are stuck with a problem of grading the severity of patients, see if a valid scoring system is available. If not, you may like to devise a scoring system yourself. One example of a scoring system for gradation of severity is as follows.

Chagas disease is an important health problem in Latin America, and cardiac involvement in this disease increases the severity and risk of death. Rassi et al. [7] developed a risk score based on the evaluation of 424 outpatients from a regional Brazilian cohort as given in Table S.9. The score is obtained as a sum of these points. They divided the score into three groups: low risk, 0–6 points; intermediate risk, 7–11 points; and high risk, 12–20 points. The risk pertains to the risk of death. The 10-year mortality rates for these three groups were 10%, 44%, and 84%, respectively. For an example of clinical risk-scoring algorithm to forecast scrub typhus severity, see Sriwongpan et al. [8].

As already stated, all scoring systems try to convert multiple measurements into a single unified but meaningful index. They transform multivariate data into a univariate score. Sometimes several scoring systems are available for the same condition, and it would be difficult to choose the right system. For example, severity in peritonitis cases can be assessed by APACHE score, Peritonitis Severity Score, Mannheim Peritonitis Index, Hacettepe Score, American Society of Anesthesiologists Score, etc. Choose a scoring system that looks more appropriate for your patients.

**TABLE S.9**
**Scoring System for Death in Chagas Disease**

| Risk Factor | Points |
|---|---|
| New York Heart Association Class III or IV | 5 |
| Evidence of cardiomegaly on radiography | 5 |
| Left ventricular systolic dysfunction on echocardiography | 3 |
| Nonsustained ventricular tachycardia on 24 h Holter monitoring | 3 |
| Low QRS voltage on electrocardiography | 2 |
| Male sex | 2 |

## screening trials, *see* clinical trials

## scree plot/test

Proposed by Cattel [1] in 1966, a scree plot is a depiction of cumulative contribution of the factors or principal components in a multivariate

data to the total variance. In **principal component analysis** (PCA) and **factor analysis**, the important components and the factors are identified by studying how much of the total variation they explain. Scree plot is used as a visual test to decide how many factors or principal components have substantial contribution, and these are then studied in detail. This is done by identifying natural breaks as revealed by sudden flattening in the plot. Sometimes the fall is gradual, and no clear answer to the number of appropriate factors is available; but in many situations, a scree plot has proved to be of substantial help. The name *scree* comes from the rubble that accumulates at the foot of a mountain as is evident from Figure S.3.

Suppose the percent contribution of the various factors in a factor analysis is as shown in Table S.10. The scree plot for this is shown in Figure S.3. Nearly 35% of the variance in this example can be considered uncovered as the contribution of the sixth factor itself is just 2%. There is no sudden leveling, and it is difficult to say how many factors would be sufficient in this case.

An alternative is to examine the numerical values of the percentage contribution of the factors. When this percentage suddenly falls or becomes less than any prespecified threshold, stop looking for other factors. This could be quite subjective. In Table S.10, the first two factors together are able to account for 47% variation, and the contribution of others looks minor. The unexplained part of variation is also depicted by this plot.

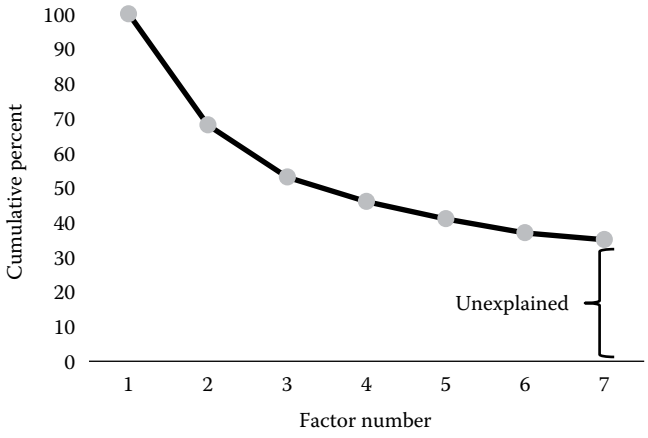

**FIGURE S.3** Scree plot for the data in Table S.10.

**TABLE S.10**
**Percent Contribution of Various Factors in a Factor Analysis**

| Factor | Percent Contribution | Cumulative Percent |
|---|---|---|
| 1 | 32 | 100 |
| 2 | 15 | 68 |
| 3 | 7 | 53 |
| 4 | 5 | 46 |
| 5 | 4 | 41 |
| 6 | 2 | 37 |
| 7+ | 35 | 35 |

## sensitivity and specificity

Tools such as laboratory tests are an integral part of modern medicine. Fine-needle aspiration cytology is done to detect breast cancer, Pap smear for cervical cancer, Western blot for human immunodeficiency virus infection, and chest x-ray for tuberculosis. Often, the sign–symptom syndrome functions as a *test* to form the basis for establishing a diagnosis. Generalized maculopapular rashes and fever with cough are considered indicative of measles, and prolonged acute chest pain indicates myocardial infarction (MI).

The tools used for evaluation and management of health and disease are seldom perfect. All tests are flawed to a degree. These produce correct results in many cases but fail, fully or partially, to perform well in some cases. Healthy individuals are occasionally classified wrongly as ill, sending false alarm, and some individuals who are really ill may not be detected, raising complacency. All such errors need to be controlled because there is a cost involved—cost of unnecessary treatment, cost of side effects, inconvenience, progression of disease, and even death of some patients. The ability of a tool or of a procedure to perform its assigned function correctly is called its **validity**.

A valid diagnostic test would correctly detect the presence as well as the absence of the disease. Some tests are more valid than others, although they may be more expensive. Rectal sonography is considered more efficacious than prostatic specific antigen values for detecting prostate cancer. Scintigraphy gives better results than electrocardiogram (ECG) for MI. However, **gold standards** that give perfect results all the time are rare, and most of them are expensive in time and effort. No medical test is valid in absolute sense. Errors in classification such as misdiagnosis and missed diagnosis occur no matter what test is used.

Malaria is characterized by high fever with chills and rigors, splenomegaly, and a positive blood smear. How valid is this set of criteria? Can it correctly identify all the cases of malaria, and can it correctly exclude all the nonmalarial cases? These two aspects are discussed next.

The ability of a test to give a positive result in true cases of a disease is called *sensitivity*. *Specificity* is the ability to give a negative result in cases where the disease is absent. Both are probabilities, though many times expressed in percentage terms by multiplying by 100. These are two components of validity of a test that measure its inherent goodness. Denote the presence of disease by *D*+ and absence by *D*–, and test positivity by *T*+ and test negativity by *T*–. Also let true positives be abbreviated as TP, false positives as FP, true negatives as TN, and false negatives as FN. The ability of a test to be positive when the disease is present is

$$\text{sensitivity } S(+): P(T+ \mid D+) = \frac{\text{TP}}{\text{TP} + \text{FN}}.$$

The ability of a test to give a negative result when the disease is absent is

$$\text{sensitivity } S(-): P(T- \mid D-) = \frac{\text{TN}}{\text{TN} + \text{FP}}.$$

These are best illustrated with the help of an example. Suppose ECG was performed on a total of 700 subjects with complaints of prolonged acute chest pain. Of these, 520 cases were earlier confirmed for the presence of MI and 180 for its absence. The results obtained are given in Table S.11.

Note the following for ECG as a test for the diagnosis of MI in this example:

TP = 416
FP = 9
TN = 171
FN = 104

It is known that 520 subjects had MI and the other 180 did not. Thus,

$$\text{sensitivity of ECG, } S(+) = \frac{416}{520} \times 100 = 80\%,$$

and

$$\text{sensitivity of ECG, } S(-) = \frac{171}{180} \times 100 = 95\%.$$

Thus, in this example, a negative ECG seems sufficiently specific in non-MI cases but not so sensitive in the cases with MI. Many cases of MI, in this example 20%, are missed by ECG, possibly because the required elevation in ST segment does not appear.

The following measures the combination of sensitivity and specificity, when both are equally important:

$$\text{inherent validity of a test} = (\text{TP} + \text{TN})/n,$$

where $n$ is the total number of subjects. In our example, the inherent validity of ECG is $(416 + 171)/700 \times 100 = 84\%$.

**TABLE S.11**
**Myocardial Infarction (MI) and ECG in Cases of Acute Chest Pain**

| | MI | | |
|---|---|---|---|
| **ECG** | **Present** | **Absent** | **Total** |
| Positive | 416 (TP) | 9 (FP) | **425** |
| Negative | 104 (FN) | 171 (TN) | **275** |
| **Total** | **520** | **180** | **700** |

### *Features of Sensitivity and Specificity*

A difficulty with the concepts of sensitivity and specificity is that they can be evaluated only when the presence or absence of the disease is known. If the disease status is already known, where is the need for a test? The concepts are still useful as shortly explained. The following points deserve attention:

1. The true diagnosis is evaluated on the basis of more refined methods, a gold standard, that may be far more difficult to adopt. Often, the real diagnosis emerges after the passage of time, for instance, on response to therapy or by autopsy. Many times, a surrogate is used as a gold standard such as histological evidence for cancer. If the gold itself is a bit shoddy, a good sensitivity or specificity may give a false sense of security.
2. The values of sensitivity and specificity can be changed by altering the criterion for positivity. In our MI example, if the creatine phosphokinase (CPK) level is also considered in addition to ECG, then some other values of sensitivity and specificity are obtained. The exact values will depend on what threshold of the CPK level is chosen to indicate MI. Different thresholds will give different values of sensitivity and specificity.
3. Generally speaking, an alteration in the criteria will either increase or decrease sensitivity but will affect the specificity in an opposite manner. That is, an increase in sensitivity is generally accompanied by a decrease in specificity, and vice versa.
4. It is assumed in these calculations that the disease and the test can be clearly classified as present/absent or negative/positive. In practice, you can have a category "may be" or "indeterminate" or "±." The calculations then become extremely complex and raise many additional issues that are outside the scope of the present book. Genuine cases with equivocal or uninterpretable test results can be excluded. In practice though, such results are seen to have some association with disease state, and the bias can creep in even when they are excluded.
5. As for almost any other criterion, values of sensitivity and specificity are valid for the type of cases actually used for calculation. If only mild cases are included, the values would not be valid for severe cases. For example, large or advanced tumors are easily picked up. You may like to include appropriate proportion of cases with different spectrum of disease to get more representative estimates of the sensitivity and the specificity. But the number in each category must be sufficient for estimates to be reliable.
6. Comorbidities may also affect the values. For example, NESTROFT (naked eye single tube red cell osmotic fragility test), used for screening thalassemia in children, shows good sensitivity in patients without any other hemoglobin disorder but also produces a positive result when other types of hemoglobinopathies are present.
7. The subjects without disease should be similar to those encountered in practice. They should be subjects with initial suspicion because otherwise the question of testing does not arise.
8. Another condition is that prior knowledge of presence or absence of disease should not affect the performance of the test. That is, the person interpreting the test should not consider the disease status. Better still if the person is kept blind to the disease status.

9. Guard against possible interobserver variation if more than one observer is used. This is particularly so when observer abilities are important in diagnosis such as for bone density assessment through magnetic resonance imaging by an experienced radiologist versus the one by a junior radiologist.
10. If a really rare (e.g., one in a million) disease is being studied, a positive result even with a good test is likely to be false on somebody in the remaining 999,999, and the calculation of sensitivity and specificity may be misleading.

Relation between sensitivity and specificity at different values of a quantitative test is studied by **receiver operating characteristic (ROC) curve**.

## sensitivity analysis, *see also* uncertainty analysis

The sensitivity analysis refers to the study of effect of changes in the basic premise such as individual and societal preferences or assumptions made at the time of model development. These assumptions are made to plug the knowledge gaps, which we call **epistemic uncertainties**. Thus, sensitivity analysis establishes or refutes robustness of the model. It is sometimes confused with **uncertainty analysis** and **confidence intervals**. The difference can be explained as follows.

In almost all practical situations, parameters of a statistical distribution of a medical measurement are not known and have to be estimated based on sample values. These sample estimates are point estimates and are subject to **sampling fluctuations**. This is measured by their standard error and reflected in the corresponding confidence interval (CI). This is the **aleatory** part of what is called the **parameter uncertainty**. In addition, there is epistemic uncertainty arising from our incomplete knowledge about the processes, which mostly remains guesswork and is determined by the experience of the experts, although some experts are able to postulate a whole distribution of parameter values that would incorporate both aleatory and epistemic parts. Including uncertainty to model parameters provides a range of prediction error that would be substantially wider than the statistical CIs. For studying the effect of parameter uncertainty on model outputs, consider both systematic increments as well as random perturbations.

Models, particularly statistical models, are not unique. Different sets of parameters may reasonably reproduce the same sample values. Thus, agreement between the model and the observed data does not imply that the model assumptions accurately describe the underlying process. Only that it is one of the plausible explanations and is empirically adequate. Thus, the model needs to be checked under varying conditions as stipulated under sensitivity analysis.

In contrast to this, uncertainty analysis is the process of measuring the impact on the result of changing the values of one or more key inputs about which there is uncertainty. Thus, this mostly arises due to the use of sample estimates. The inputs are varied over a reasonable range that can practically occur. In essence, sensitivity analysis is primarily for epistemic uncertainties, whereas uncertainty analysis is mostly for aleatory uncertainties.

For example, in the calculation of **disability adjusted life years (DALYs)** done initially by the World Health Organization, the assumption that death in young age is much more important than death in childhood or old age is a value choice and a suitable candidate to be examined by sensitivity analysis. In addition to such assumptions, variables used for developing a model also are basic to the model. These also depend on the choice of the investigator. A simple example of a model is systolic blood pressure studied to depend on age, sex, and body mass index in healthy subjects. Another choice could be age, sex, and socioeconomic status. These choices are deterministic rather than stochastic. More accurate measurement or scientifically sound methodology does not help alleviate this uncertainty. Sensitivity analysis varies these basic conditions and verifies that the broad conclusion still remains the same. Thus, this may be called an exercise in external **validation**.

The following example illustrates another aspect of sensitivity analysis. Risk of coronary disease can be modeled to depend upon the presence or absence of diabetes, hypertension, and dyslipidemia. This model might be able to correctly predict 10-year risk in 62% of the cases. However, addition of smoking and obesity can increase this to 70%. This addition of 8% is substantial. Thus, predictivity of coronary disease is *sensitive* to the choice of risk factors. The first model is based on three risk factors and the second on five factors. Had the contribution of smoking and obesity been only 2% or 3%, the conclusion would be that prediction of coronary disease is insensitive to smoking and obesity when diabetes, hypertension, and dyslipidemia are known. Then robustness of the smaller model would have established.

The sensitivity analysis investigates how the result is affected when the basic premise is altered. Unlike uncertainty analysis, this has nothing to do with the variation in the input values. Input factors themselves are changed. Sensitivity analysis deals with uncertainty in model structure, assumption, and specification. Thus, it pertains to uncertainty arising from what parameters are included and what are excluded.

The purpose of sensitivity analysis is to examine whether the key result continues to point to the same direction when the underlying structure is altered within a plausible range. The process involves identifying key outcome in the first place, and then the basic inputs that can affect this outcome. For example, in a clinical trial setup, the outcome could be mortality or the length of hospital stay. Both should generally lead to nearly the same conclusion. Thus, the outcome measure can also be changed to see if the results are still the same. Patients' inclusion and exclusion criteria can be relaxed, the method of assessment can be altered, and even the data analysis methods can be changed to see if this affects the final result. Intention-to-treat analysis can be tried in addition to the regular per protocol analysis that excludes the missing or distorted data. If the results do not materially change, the confidence in the results strengthens. The following example further illustrates this concept.

Estenssoro et al. [1] compared Argentinean patients on mechanical ventilation in intensive care unit (ICU) for more than 21 days ($n = 79$) with those with less ventilation ($n = 110$) for severity score, worst $PaO_2/FIO_2$ fraction, presence of shock on ICU admission day, length of stay in ICU, and length of stay in the hospital. Logistic regression identified shock on ICU admission day as the only significant predictor with an OR = 3.10. This analysis excluded patients who died early. It was not known that this result would or would not hold for patients dying early. To bridge this epistemic gap, the authors conducted a sensitivity analysis by including 130 patients who died early. Shock remained a powerful predictor that gives the conclusion that the only prognostic factor for prolonged mechanical ventilation is shock on ICU admission day irrespective of early or late death (or survival). Perhaps shock itself is a by-product of severity of illness and hypoxemia.

**FIGURE S.4** Illustration of sequential analysis.

## sequential analysis

This is the method of analysis of data generated by **sequential sampling**; that is, units or groups of units are selected one after the other, and the null hypothesis is tested every time on the basis of the accumulated data. The procedure stops either when the null is rejected or when a predetermined size of sample is reached. The procedure looks at medium- to long-term trend and may not be affected by a few outliers. Because of repeated testing of hypothesis, this procedure raises questions about controlling the **Type I error**. The method of sequential analysis, developed by Abraham Wald in 1945 [1], helps in this respect.

Sequential analysis tries to minimize the sample size for a fixed level of significance α and statistical power (1 – β). Wald worked out that the best approximation for the lower threshold is $a = \ln[\beta/(1-\alpha)]$, and that for the upper threshold is $b = \ln[\beta/(1-\alpha)]$. Incidentally, these give $\alpha = \frac{1-e^{a}}{e^{b}-e^{a}}$ and $\beta = \frac{e^{-b}-1}{e^{-b}-e^{-a}}$, just in case you already have thresholds $a$ and $b$, and want to see what will be the values of α and β for those thresholds.

The procedure is illustrated in Figure S.4 where the effect size obtained at each stage of sampling is plotted along with the upper and lower thresholds. Further sampling is stopped as soon as the effect size crosses any of these limits. In this figure, the effect size obtained after crossing the upper threshold is shown by the dotted line if the sampling continues.

For example, a clinician wishing to compare the effects of a regimen with a placebo may like to stop the trial if, at any stage, a convincing difference can be demonstrated on the basis of the available data. The procedure can also be used to find if the available data are adequate for a valid decision, as investigated by Egerup et al. [2] after a systematic review of randomized trials on the effect of intravenous immunoglobulins in women with recurrent miscarriages. They observed that insufficient information has been accrued so far for any convincing evidence in favor of the effect.

For further details of sequential analysis, see Lai [3] and Bakeman and Quera [4].

## sequential sampling

This kind of sampling is generally used for accepting or rejecting a lot on the basis of the number or percentage of "defectives" in the sample. One unit or a group of units is selected at a time from the lot, and the decision regarding rejecting or accepting it is made with reference to prespecified criteria based on the analysis of the accumulated values available at each stage; the sampling continues if no decision one way or the other can be taken. In most situations, a random sample is taken at each stage, although sequential sampling is more convenient when the units are coming in a queue such as patients in a hospital ward. Compare this with the usual procedure where a fixed sample is available and a decision regarding rejecting or accepting a lot is made with no third option. In case of sequential sampling, the third option to continue sampling is available. When one unit at a time is selected, this is called *unit-by-unit sequential sampling*, and when a group of units is selected each time, it is called *group sequential sampling*.

The advantage of sequential sampling is that a start can be made with a small sample, and a decision is made without wasting time and effort as soon as the adequate evidence accumulates one way or the other. In addition, in some situations, the researcher can do minor changes in subsequent sampling if needed to improve the research method and analysis. In most situations, this kind of sampling results in a smaller sample than the fixed sample approach. However, the big problem is the inconvenience of choosing a sample each time and undergoing a repetitive process that could be frustrating in some situations. The sample size in this case is a random variable as it is not fixed and depends on chance. Another problem is that the time elapsed between observations may alter the values due to natural changes or some unanticipated sudden changes. Since the sample size is not fixed, a proper planning of time schedule and resources required cannot be done. Despite such severe drawbacks, sequential sampling can still be recommended, where getting observations is very expensive, provided they can be quickly collected so that the elapsed period will not be able to make any difference in the values.

Consider a lot of testing kits, some of which can be defective; suppose that the lot would be accepted if not more than 1% are defective, that the lot would be rejected if more than 2% are defective, and that sampling would continue if the defective is between 1% and 2%. Statistically, the limits that give 95% assurance in large samples are $p_L - 1.645*\sqrt{(p_L q_L/n)}$ and $p_U + 1.645*\sqrt{(p_U q_U/n)}$, where $p_L$ and $p_U$ are the lower and upper limits, respectively, which are fixed in advance. These are $0.01 - 1.645 \times \sqrt{(0.01 \times 0.99/n)}$ and $0.02 + \sqrt{(0.02 \times 0.98/n)}$, which will change with $n$, and a plot of something like Figure S.5 will guide about acceptance, rejection, or continuation of sampling.

Sequential sampling has applications to the test of hypothesis setup also. However, in this case, the null hypothesis is never accepted, and the sampling continues until such time that we are able to reject the null or reach our predefined maximum sample. If the null cannot be rejected even with our maximum sample, the conclusion is that there is no sufficient evidence against the null. This method is sometimes used for **clinical trials** where the participants

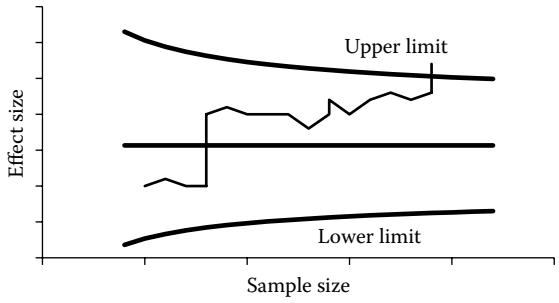

**FIGURE S.5** Decision in sequential sampling.

are sequentially added and the hypothesis regarding the effect of the regimen is tested. This is also used in **meta-analysis** where studies are sequentially added to the analysis to come to a firm conclusion. The difficulty in this procedure is that special methods are required to control the Type I error in view of repeated testing of hypothesis. For this purpose, the method of **sequential analysis** is used.

The term *sequential sampling* has been used in medical literature with varying meaning; there are not many examples of its use in the statistical sense we have presented in this section. Among some of the examples is that by Hirschfeld et al. [1], who used the sequential sampling approach to find a sample size that provides stable estimates of the odds ratios (ORs) in multiple logistic regression. For this, they added participants one by one to the dataset and computed ORs by running logistic regression every time. They had 10 regressors and found that all the ORs tend to stabilize at $n = 1000$ in their data.

## sex ratio

Sex ratio is conventionally the number of males per 100 females in a population or its segment. This innocuous-looking indicator has extensive implications, particularly for humans because humans tinker with the naturally determined ratio. Theoretically, the ratio should be 1:1 in a natural setting such as random mating and equal exposures, but it varies widely from area to area.

The sex ratio at birth in humans in the absence of any intervention has been observed 105 males per 100 females. This is widely observed across nations and considered "natural." The reason for higher male births is speculated to be the higher motility of X chromosomes that is relatively quicker to fertilize the female ovum compared with the Y chromosome, and is surmised to be the nature's response to higher mortality of males later in life due to greater exposure to environmental hazards. There are unfortunate human interventions that disturb the sex ratio at birth, primarily sex-selective abortions because of preference for sons and prejudices against females in some societies such as in India and China. According to an estimate, the ratio at birth in China in the 1990s was 120:100 and was nearly 110:100 in 2015 [1], and in India it was 110:100 in 2011 [2].

Despite the higher ratio for males at birth, this steeply declines in old age because of higher life expectancy of females almost everywhere in the world. The ratio declines to as much as 45:100 in old age people of Russia [1]. The overall sex ratio in the population is fairly even in most developed countries but is adverse to females in many developing countries. For example, in India, it was 106 males per 100 females in 2011.

Many people consider sex ratio as an important indicator of social health of a population, and an equal ratio is considered to indicate a good social health. Sex-selective abortions are decried not just because they skew the sex ratio but also because this practice jeopardizes the health of the women. Gender prejudices affect the health of the women in several other subtle ways.

Sex ratio is also used to describe the relative incidence of some diseases such as bladder cancer, which is more common in males, or possible skewed sex ratio in spontaneous abortions.

## Shapiro–Francia test

This is a modification of the **Shapiro–Wilk test** to find if a dataset has a non-Gaussian (non-normal) pattern. Gaussianity is required for many statistical tests such as the Student *t*-test, the analysis of variance *F*-test, and tests for regression coefficients, and these procedures cannot be used straightaway on non-Gaussian data. Although the Shapiro–Wilk test is considered the best omnibus test for this purpose, this test requires coefficients that are difficult to compute. The Shapiro–Francia test is relatively simple and has almost the same **power** as the Shapiro–Wilk test. This is given by

$$\text{Shapiro–Francia test: } W' = \frac{(\Sigma_i z_i x_{[i]})^2}{\Sigma z_i^2 \times \Sigma_i (x_i - \bar{x})^2}, \; i = 1, 2, \ldots, n,$$

where $x_{[i]}$ are the ordered values of $x$ ($x_{[1]}$ being the lowest), and $z_i$ is the ***Z*-score** of the $i$th **order statistics** [1]. *Z*-score is the expected standardized value if the distribution is Gaussian. *W*' can be shown as equal to the square of the Pearsonian correlation coefficient between $x_{[i]}$ and $z_i$, which measures the degree of linear relationship—thus *W*' indicates the straightness of the **normal probability plot**. Small values of *W*' are evidence of departure from Gaussianity, and the *P*-value can be obtained by using an appropriate statistical package. The test was developed by Shapiro and Francia in 1972 [2], and Royston [1] has provided a simple method to evaluate the Shapiro–Francia test. Although Royston [3] later also developed a pocket-calculator algorithm for this test with an application to medicine, the actual usage of this test is still rare, as simplification has lost relevance ever since all calculations are done by computer software packages. Nonetheless, deSouza et al. [4] used this test to check Gaussianity of urethral paravaginal fascial volume and of retropubic urethral length in females with urinary genuine stress incontinence, if you want to see its application.

## Shapiro–Wilk test

The Shapiro–Wilk test is considered the best test so far for testing non-Gaussian distribution of the data in hand and is quite commonly used. This was designed by Shapiro and Wilk in 1965 [1] and is calculated as follows:

$$\text{Shapiro–Wilk test: } W = \frac{\left(\Sigma_i a_i x_{[i]}\right)^2}{\Sigma(x_i - \bar{x})^2},$$

where $x_{[i]}$ are the ordered sample values from the lowest to the highest, and the $a_i$'s are constants generated from the means, variances, and covariances of the order statistics of a sample of size $n$ from a normal distribution. Small values of $W$ indicate that the distribution is non-Gaussian, and the $P$-value can be obtained by using an appropriate statistical package.

Royston [2] showed via Monte Carlo simulation that the transformed variable $y = (1 - W)^{\lambda}$, where $\lambda$ is determined by sample size $n$, is approximately Gaussian. He also gave a method of evaluating $W$ and its statistical significance for sample sizes between 3 and 2000. As almost any other statistical test, this test can be used to detect non-Gaussianity but not for confirming Gaussianity, although many researchers do not make any distinction between failure to detect non-Gaussianity and confirming Gaussianity. The Shapiro–Wilk test focuses on lack of symmetry, particularly around the mean, and is not much sensitive to differences toward the tails of the distributions. Tails may not be as important either because of extremely low frequencies.

Tiwari et al. [3] used this test for checking non-Gaussianity of fear assessment picture scale and modified facial affective scale in 60 children of age 6 to 8 years who were visiting a dental hospital in India and needed pulpectomy treatment. De Lima et al. [4] used this for testing non-Gaussianity of plasma concentrations of triglycerides, lactate, and glucose in adults in Brazil.

## significance (statistical)

Significant normally means something of consequence that affects our thoughts or practices. However, the term *statistical significance* is used in the context of **tests of hypotheses** where a statistical test is said to provide a significant result when the corresponding ***P*-value** is less than the predetermined threshold, called the **level of significance**. The procedure generally adopted to check statistical significance is to set up a null hypothesis and an alternative hypothesis, use a test criterion such as chi-square depending on the type of data, and calculate the $P$-value. This is the probability of the sample coming from the hypothesized distribution. If this $P$-value is less than the predetermined level of significance, the null hypothesis is rejected and the result is declared to have achieved statistical significance. It only indicates that the chances of the sample coming from the hypothesized null are too small—consequently, the null is not admissible and rejected. Generally, a threshold of 5% is used as the level of significance, meaning thereby that if the chance of sample values coming from a distribution with a parameter value as specified in the null hypothesis is less than 5%, the result is said to be statistically significant. It is customary to call a result highly significant when such a chance is less than 1%. Failure to get significance does not mean that the effect is not present—only that the amount of data available is not enough to show that statistically significant effect is present.

There is a considerable debate about the actual utility of the concept of statistical significance. See the topic **statistical tests versus confidence intervals** that emphasizes that a statistically significant result does not necessarily imply important or useful result. Note that failure to achieve significance such as of an independent predictor of risk in a multivariable model does not necessarily mean the variable has no clinical importance. Reasons a variable may fail to achieve such significance include insufficient sample size, correlation with some other variable in the model, etc., besides poor design or poor methodology. Many researchers unnecessarily get excited when they achieve statistical significance. Some even would resort to what is called **data dredging** to achieve significance. Statistical significance can always be legitimately achieved by increasing the sample size. For example, the difference of 1 mmHg in mean blood pressure of two groups would be statistically significant when the sample size is, say, 2000 in each group. Similarly, an exceedingly weak correlation coefficient of 0.1 may be statistically significant when the sample size is large. In most situations, statistical significance only says that some effect is present but does not say how much. For "how much," or to test "at least this much," a modification of the test is needed. Also, consider the statistical **power** of the test to be able to detect a specified minimum **medically important effect** when present.

The term *significance* has pervaded so much in empirical research that some journals have reserved it for statistical significance. Since the term *significance* is not the exclusive domain of statistics, and can be of various types, including one being the medical significance, we would suggest that significance based on $P$-values be specified as *statistical* significance. This helps to distinguish it from other types of significance.

One more caution: Statistical significance of a result can occur due to an honest sampling error in the sense that by chance you happen to have a sample that rejects the null hypothesis. When the level of significance is 5%, as is mostly the case, on average, 1 out of 20 results could be significant in error. This can particularly affect results when several statistical tests have been carried out for reaching to a holistic conclusion. Many researchers ignore this aspect of statistical significance. In addition, statistical significance can also occur in error due to incorrect data, faulty design, miscalculations, wrong method of analysis, etc.

Our advice is to consider statistical significance as just an aid to decision and not to use this as the sole criterion. Try to find a plausible biological reason for such significance, and use your common sense. If the results do not appeal to your conscience, there is a high chance that nonsampling error of the types just mentioned may have occurred. Believe in yourself more than the data, but report what you actually obtained—in some cases, a plausible reason is discovered at some time in the future.

## significance level, *see* level of significance, and also significance (statistical)

## significant digits

There is a tendency to overuse decimals in the reporting of results, creating a false sense of accuracy. Perhaps the higher number of decimals is considered to give a scientific look. The fact is that the final result should have only an appropriate number of decimal places, although for this a large number of decimal places should be used for intermediary calculations (a computer will automatically do that).

What is the appropriate number of decimals? A rule for percentages is to have only as many decimal places as are needed to retrieve the original number. As an extra precaution, one more decimal place can be used. For the percentage of subjects, this can be obtained by the following rules.

In percentages,

Maximum one decimal place if $n \leq 99$
Maximum two decimal places if $100 \leq n \leq 999$
Maximum three decimal places if $1000 \leq n \leq 9999$
And so on

It is sometimes desirable to use the same number of decimal places uniformly throughout a report even if $n$ varies from one section of the report to another. The number of decimal places in this case would depend on the highest $n$. If there are 260 subjects belonging to 80 families, the percentages for subjects as well as for families can go up to two decimal places each. In addition, there is a concept of significant digits. This is applicable particularly to the reporting of calculated values with an extremely large denominator. The leading zeroes are ignored while counting the significant digits. The value 0.00720 and the value 0.458 both have three significant digits and have the same accuracy. The values 3.06 and 0.069 have two significant digits each. This concept is particularly useful when the reported values are meant to be used for further calculations. Although we have advised that all reporting should have the same number of significant digits, many times varying digits due to leading zeroes can create the confusion in the minds of ordinary readers.

In expressing quantities other than percentages, such as mean and standard deviation (SD), the following rule is generally adequate: Report one decimal place more than in the original measurements from which mean and SD are calculated. For example, if hemoglobin level (in g/dL) is measured with one decimal place as 11.7, 13.8, etc., the mean and SD should be reported with two decimal places. The number of decimal places in a coefficient, such as in a regression equation, would depend on the numerical magnitude of the quantity with which it is multiplied. The coefficient 1.07 for birth weight in kilograms has the same accuracy as 0.00107 for birth weight in grams.

Sometimes original measurements are also made with excess accuracy. It would be a waste of resources to measure survival time in cancer patients in days and report it as 3.7534 years, or insulin level in a subject to two decimal places. A minute difference in such readings does not affect the validity of the measurement. The same sort of logic can be applied to percentages and means also. It does not matter whether the mean diastolic blood pressure level of a group is 86.73 or 86.54 mmHg. Both could be rounded off to 87 for medical interpretation. Thus, the decimal places in this case do not serve any useful purpose. Instead, they complicate the presentation and interpretation. However, they might be important for trend to show that one number is smaller than the other.

Many rates can be expressed as percentage, but for others, a different multiplier is used for convenience. For example, the death rate due to cervical cancer is stated as 8 per 100,000 women. This is the same as 0.00008 per woman or 0.008%. Siegrist [1], however, found that rates expressed as a frequency (8 per 100,000) are perceived differently than rates expressed as a probability (0.00008).

For rounding off, the following rule may be helpful: If the last digit to be rounded off is 5, make the previous digit even, i.e., 1.15 is rounded off as 1.2 and 3.45 as 3.4. Or, you can decide to stick to the odd digit in place of even digit. The idea is that 5 should go up half the time and down half the time because it is exactly midway. When the last digit is other than 5, rounding off is the nearest previous digit. But something like age in adults is conventionally reported in completed years, ignoring the digit after the decimal even if it is more than 5.

1. Siegrist M. Communicating low risk magnitudes: Incidence rates expressed as frequency versus rates expressed as probability. *Risk Analysis* 1997; 17:507–10. http://onlinelibrary.wiley.com/doi/10.1111/j.1539-6924.1997.tb00891.x/abstract

## sign test

This is a nonparametric test for checking that the **location** (generally the median) of a distribution matches with the one hypothesized, or whether the locations in paired observations are the same. Thus, this test does not talk about the mean, but any location, and median is the most commonly used location for this purpose. The only information required for this test is whether values are higher or lower than the hypothesized value, and the actual values are not needed. This is what makes it a nonparametric test, but this simplification is also responsible for rendering it less powerful compared with the tests that use actual values with known distributions. If quantities are to be considered, a **Student *t*-test** does a much better job under Gaussian conditions, and even if just ranks are available, a **Wilcoxon signed-ranks test** will be more powerful in detecting a difference if present than a sign test. Independence of observations is required for this test just as for most other tests.

A sign test is basically a small sample test since the Student *t*-test can be used taking advantage of the **central limit theorem** for large samples. This test counts the number of positive and negative signs, and uses a **binomial distribution** to find the *P*-value since the probability of positive and negative sign is known under the null

hypothesis. For example, if the null is for median, this probability is $\pi = ½$. If the null is for first quartile, $\pi = ¼$. In case of paired observations, the null is that the values are equally likely to be smaller or larger than the other, that is, $H_0$: $\pi = ½$ for median. If the paired values are $(x_i, y_i)$ $(i = 1, 2, \ldots, n)$, then count the number of pairs $s$ for which the difference $x_i - y_i > 0$ (positive) and find the probability of so many or more positives using a binomial distribution with $\pi = ½$ and given $n$. This will be the $P$-value for the right-tailed test. For the left-tailed test, find $P(S \le s)$, and for two-tailed, the $P$-value is twice the smaller tail value. The critical value can be approximated by $s = \frac{n+1}{2} + 0.98\sqrt{n}$ for small samples at 5% level of significance.

This can also be used to test if the median (or any other quantile) of a population is a particular value $\tilde{\mu}$. Consider an example of selenium intake measured for $n = 9$ male subjects of prostate cancer. Suppose these are (μg/day) 43, 62, 58, 32, 54, 50, 67, 47, and 51. Can the median be taken as 55 μg/day? This null hypothesis can be checked by a Student $t$-test assuming that the distribution is nearly Gaussian. A software package gives $t = 0.988$ and $P = 0.35$—thus, the null cannot be rejected. Now, for sign test, note that out of 9 subjects, 6 have intake less than this hypothesized value of 55 and 3 have more. If the null is true, we expect nearly half of the values greater than this and the other half less than this. From the binomial distribution with $n = 9$ and $\pi = 1/2$, $P(S \le 3) = 0.25$. For a two-tailed test, $P$-value = 2×0.25 = 0.50, and the null cannot be rejected by this method also; but the $P$-values are very different because the sign test is far too approximate in the sense that it does not consider actual values. The approximate critical value is $s = \frac{9+1}{2} + 0.98\sqrt{9} = 2.06$. Neither the number of positives nor the number of negatives is less than this critical value—thus the null cannot be rejected this way also.

Now consider the hypothesis that the third quartile is at least 60 μg/day. This gives $H_0$: $\pi = 0.75$. The number of observations less than or equal to 60 is 7 out of 9 in the same example. The binomial distribution for $n = 9$ and $\pi = 0.75$ gives $P(S \le 7) = 0.10$. This $P$-value also is not small and we concede the null.

## similarity (statistical measures of), *see* measures of dissimilarity and similarity

## simple linear regression, *see also* regression models (basics of), multiple linear regression

A regression is called simple linear when there is only one regressor and one dependent variable, both are quantitative, and the relationship can be graphically expressed by a line. The regression equation in this case is

$$\text{simple linear regression: } y = \alpha + \beta x + \varepsilon,$$

where α is the value of $y$ at $x = 0$, called **intercept**; β is the rate of change in the value of $y$ per unit change in the value of $x$, called **slope**; and ε is the remainder not accounted for by the regression, called error. Linear regression implies that the relationship under investigation is such that $y$ always changes by the same quantity β as $x$ increases from $x$ to $x + 1$, and that is almost always valid for the range of values of $x$ and $y$ under study, although slight extrapolation is allowed. For example, suppose the regression of systolic blood pressure (BP) in mmHg ($y$) on age in years ($x$) is SysBP = 110 + ½*Age that may be valid for healthy adults of age, say, from 20 to 80 years, and not applicable to children or persons of age above 80 years since the trend outside 20–80 years is not known. This regression implies that for each year of age, the systolic level of BP in healthy adults increases by ½ mmHg (or by 5 mmHg every 10 years), say, due to accumulation of atheromatous plaque, and this change is uniform between the age 20 and 80 years. If the rise in BP is faster in old age, the linear regression will not be adequate. If a healthy person of age 60 years has SysBP = 138 mmHg against the expected 140 mmHg as per this regression, the difference –2 mmHg is what we called error. This is not a mistake but a fluctuation around the line. This kind of ordinary regression requires that $x$ is considered fixed, and $y$ is the only **stochastic** variable. In our example, this would mean that there are, say, 4 adults of age 22 years, 7 of age 26 years, 1 of age 30 years, etc., and their systolic level is measured, so that the age is known and the BP is obtained. At each value of $x$, there may be one or more values of $y$; in fact, the theory requires that there is a whole distribution of the values of $y$ for each value of $x$. The value of $x$ is our choice, and the $y$ on the left side is the average for any fixed value of $x$.

Linear regression in most cases is a simplified version of the actual relationship, which is generally more complex and nonlinear. To reiterate, the linear version gives satisfactory results when the dependent and regressor variables have a straight relationship, i.e., where a unit change in the level of the regressor variable *over its entire range* in the target group is accompanied by nearly the same change in the level of the dependent variable. A straight line can then depict the trend over that range. In many situations, this does not hold. The relationship of total leukocyte count and hemoglobin (Hb) level with age in healthy subjects is nonlinear over the age range 0–20 years because these two decline up to age 6–8 years (physiological anemia) and then increase. In case the relationship is nonlinear, the linear regression would depict the linear part of the relationship.

### *Intercept and Slope*

Suppose $x_i$ is the age of the $i$th child in months and $y_i$ is his or her weight (in kg). A simple linear regression for children up to the age of 1 year could be $y_i = 3.4 + 1.1x_i$. This is shown in Figure S.6a. According to this regression equation, if $x_i = 0$, i.e., when age = 0 months, weight $y_i = 3.4$ kg. This is the intercept and, in this example, this can be interpreted as the average birth weight.

Graphically, the intercept is the distance from the origin to the point where the regression line intersects the $y$-axis (Figure S.6). The intercept has a biological meaning in our example, but in many situations, this is just imaginary. In the case of regression of weight on height in children, one cannot think of height = 0. In this case, the regression line would be extended to the $y$-axis to see the intercept. Algebraically, as mentioned earlier, just plug in $x = 0$ in the equation and get the value of the intercept when the regression is simple linear. If you have two or more independent variables (multiple regression), the value of all the $x$'s will be substituted as zero to get the value of the intercept. In case of sample values, this will give the estimate of the corresponding intercept in the population.

The slope is the gradient of the line. The higher the value of β, the steeper the slope, and its negative value implies that the slope is declining ($y$ decreasing with increasing $x$). In our example on weight of children, the value of β is 1.1 kg, which says that as age increases by 1 month, the weight increases on average by 1.1 kg. Since the regression has been obtained only for age 0–12 months, this statement is applicable to only this age group. Had the slope been 1.4,

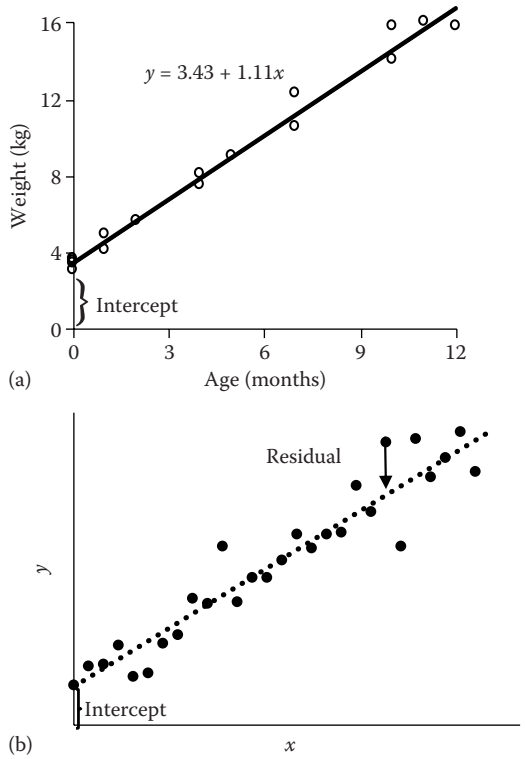

**FIGURE S.6** (a) Simple linear regression of weight on age of children less than 1 year. (b) Simple linear regression of $y$ on $x$ showing scatter plot, regression line, residual, and intercept.

the slope would be steeper, and if it were 0.9, the slope would be gradual. Also note that the interpretation of the slope depends on the units of measurement. In our example, age is in months and weight is in kilograms. If age is in weeks or in years, the value of the slope parameter will accordingly change.

### *Estimation*

The preceding discussion assumes as though the values of α and β are known. This will almost never be the case, and these parameters have to be estimated from the data obtained in a sample of subjects. A **least squares method** is generally used to estimate the values of α and β that finds those estimates that minimize the sum of square of differences between the expected and actual values. Some of these differences are positive and some negative, and the least squares method assures that the sum of these differences is always zero. Expected are those that are determined by the equation thus obtained. This method is nonparametric and does not require Gaussian (normal) distribution of any variable. When these estimates are substituted, the simple linear regression becomes

$$\text{estimated simple linear regression: } y = a + bx + e,$$

where $a$ and $b$ are the point estimates of α and β, respectively, and $e$ is now called the **residual** such that $\Sigma e = 0$. See Figure S.6b for the regression line, intercept, and residuals. For a given set of data, estimates $a$ and $b$ can be calculated as follows:

$$b = \frac{s_{xy}}{s_x^2} = \frac{\Sigma(x-\bar{x})(y-\bar{y})}{\Sigma(x-\bar{x})^2} \quad \text{and} \quad a = \bar{y} - b\bar{x}.$$

Thus, the estimate of the regression coefficient is the covariance between $x$ and $y$ divided by the variance of $x$. In terms of the correlation coefficient, this can be written as $b = rs_x/s_y$, where $s_x$ and $s_y$ are the sample standard deviations of $x$ and $y$, respectively, and $r$ is the correlation coefficient. The regression coefficient and the correlation coefficient have one-to-one correspondence in the sense that if one is negative, the other is also negative; but the correlation coefficient is bound between –1 and +1, while the regression coefficient is unbounded.

### *Confidence Intervals and Tests of Hypotheses for Simple Linear Regression*

So far, we have not used any Gaussian condition, but for finding the confidence intervals (CIs) and tests of hypotheses on the intercept and the slope, we need Gaussian (normal) distribution of the residuals. Since their sum is always zero, we say that $e \sim N(0, \sigma_e^2)$. The lesser the variance, the more reliable the estimates. The condition of Gaussianity can be relaxed for large $n$ because of the **central limit theorem**; otherwise, think of an appropriate transformation to convert the distribution to Gaussian. Independence of values is required anyway. Also, the variance of $y$ at different values of $x$ should be nearly the same, which is called **homoscedasticity**. When these conditions are met, it has been established that

$$b \sim N\left(\beta, \frac{\sigma_e^2}{\Sigma(x-\bar{x})^2}\right) \text{ and } a \sim N\left(\alpha, \sigma_e^2\left[\frac{1}{n} + \frac{\bar{x}^2}{\Sigma(x-\bar{x})^2}\right]\right).$$

Because of these properties, we can find the CI and test the hypothesis using a Student $t$-test after replacing $\sigma_e^2$ with its estimate given by $s_e^2 = \Sigma(y-\hat{y})^2/(n-2)$, where $\hat{y}$ is the regression-predicted value of $y$ given by $\hat{y} = a + bx$. This is popularly known as the mean square error (MSE). For details, see the topic **confidence interval (CI) for regression coefficient and intercept in simple linear regression**. A similar CI can also be obtained for the predicted mean and the predicted value of for any given $x$ within the admissible range. For this, see the topic **confidence interval (CI) for predicted *y* in simple linear regression**, where the standard errors (SEs) are also given. **Confidence band for the regression line** can also be obtained. It is helpful to note that the SEs of $a$ and $b$ have $\Sigma(x-\bar{x})^2$ in the denominator—thus, larger spacing of $x$'s would decrease the SE, and the estimates and conclusions would be more reliable. Wherever possible, widely different values of $x$ should be chosen—this can be done since the choice of $x$ values is with the researcher.

Under the Gaussian and other conditions just stated, statistical significance of the intercept and the slope can be tested by a Student $t$-test using the corresponding SE. This will have the form $t$ = (estimate – hypothesized value)/(SE of the estimate) and will have df = $(n-2)$. For illustration, consider the data in Table S.12 on duration of hospitalization of 10 patients in critical condition and their APACHE score at admission.

**TABLE S.12**
**Duration of Hospitalization and APACHE Score at Admission of Critically Ill Patients**

| Patient No: | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| APACHE Score ($x$) | 42 | 21 | 29 | 32 | 26 | 34 | 37 | 32 | 33 | 38 |
| Duration of Hospitalization (Days) ($y$) | 10 | 3 | 5 | 8 | 5 | 8 | 7 | 6 | 8 | 9 |

S

A software package gives the following for the data in Table S.12. These can be manually verified (there might be some minor variations due to rounding off):

$$\text{mean APACHE score } \bar{x} = 32.40, \text{ and}$$

$$\text{mean duration of hospitalization } \bar{y} = 6.90 \text{ days}$$

$$\Sigma(x - \bar{x})^2 = 330.00,\ \Sigma(y - \bar{y})^2 = 40.90,\ \Sigma(x - \bar{x})\,(y - \bar{y}) = 107.40$$

$$b = \frac{107.40}{330.00} - = 0.325, \text{ and } a = 6.90 - (0.325)\times 32.40 = -3.632$$

so that the regression equation is

$$\text{duration of hospitalization (days)} = -3.632 + 0.325^{*}\text{APACHE}.$$

This says that as the APACHE score increases by 1, the duration of hospital stay increases by 0.325 days on average (or nearly 1 day for every rise of nearly 3 in APACHE score) if the relation is really linear.

$$\text{MSE } s_e^2 = \Sigma(y - \hat{y})^2/(n - 2) = 0.749,$$

and this gives

$$SE^2(b) = 0.749/330.00 = 0.00227, \text{ and } SE^2(a) = 0.749\times[1/10 + (32.40)^2/330.00] = 2.547.$$

Thus, with Student $t$ at 8 df = 2.306,

$$95\%\text{ CI for the regression coefficient } \beta \text{ is } [0.325 \pm 2.306 \times \sqrt{(0.00227)}], \text{ or } (0.215, 0.435)$$

and 95% CI for the intercept $\alpha$ is $[-3.632 \pm 2.306 \times \sqrt{(2.547)}]$, or (–7.244, –0.020).

The SEs can also be used to test the hypotheses on $\alpha$ and $\beta$, although the former has very little relevance. Just for completeness, $t = 6.829$ ($P = 0.049$) for $H_0$: $\beta = 0$, and $t = -2.319$ ($P < 0.001$) for $H_0$: $\alpha = 0$. Both the nulls are individually rejected in this example.

## simple matching dichotomy coefficient, *see* association between dichotomous categories (degree of)

S

## simple random sampling

This is the basic method of selecting a sample of specified number of units from a given population. When the scheme is such that each unit of the population has the same chance of being included in the sample, it is called simple random sampling (SRS). A rigorous definition is that all possible samples of the same size have an equal chance of selection. It is customary in sampling to denote the size of the sample by $n$ and the size of the population by $N$. SRS is like picking $n$ slips from a lot containing $N$ lookalike slips numbered 1 through $N$. A more scientific method is to use random numbers, which can be very easily generated on a computer.

SRS seems easy but can turn out to be difficult to implement. A prerequisite is the availability of the **sampling frame**, preparation of which can be a very expensive exercise in many cases. If a study involves several hospitals, each hospital will have a list of its own patients, but a joint list of the patients in all participating hospitals may not be available at one place. In a domiciliary study, it may be difficult to prepare a list of families in an area. The next problem is that the randomly selected units can be physically very far apart residing in different areas, admitted to different hospitals, or being attended to in clinics in different locations. Note that such physical divergence may or may not add to the representativeness of the sample. There is no guarantee that SRS will adequately represent different segments of the target population. Being random, it is possible that the sample happens to include cases of serious or moderate severity but none of mild severity. Or all cases can be adults with no or very little representation of children. If adequate representation of such segments is required, the method of selection should be **stratified random sampling**.

Consider waist–hip ratio (WHR) and triglyceride (TG) data in a population of 100 male hypertensive subjects (Table S.13 on next page). This is the total population in this illustration. An SRS of size 16 may be the subject numbers 3, 18, 21, 31, 33, 45, 49, 53, 59, 62, 66, 71, 78, 79, 91, and 96 as marked by an asterisk in the table. For this sample, the mean ($\bar{x}$) TG level is 153.9 mg/dL, and the sample SD ($s$) is 15.8 mg/dL, whereas the population mean ($\mu$) for all the 100 subjects is 155.5 mg/dL and population SD ($\sigma$) is 17.4 mg/dL. The estimates from this sample are slightly lower than the values of the corresponding population parameters. This can happen with any sample, but in the long run, SRS provides **unbiased estimates**.

In this sample of 16 subjects, only 3 (nearly 19%) have WHR ≥ 1.10, whereas in the population, there are 48% in this category of WHR. Similarly, only 5 (31%) have TG ≥ 160 mg/dL against 43% in the population. There is no guarantee in the SRS that the sample will correctly represent the entire spectrum of subjects. Another sample may provide different values and different representation, called **sampling fluctuation**. However, as the sample size increases, the chances that the sample will be more representative of the features of population steeply increase, including the distribution, and the values of sample mean and SD become more representative. Theoretically, this is true for the average of the repeated samples also, although repeated samples are almost never actually taken. When sampling from a relatively small population, as in our example where $N = 100$, the estimates may require **finite population correction** as discussed under that topic.

## Simpson paradox

Simpson paradox occurs when the results obtained by the whole are different from what you get from the subgroups. This can happen when, for example, the case mix in the two groups is very different—one group has more serious cases and the other group has more mild cases. This imbalance in the subgroups tends to provide a distorted picture of the whole. In Figure S.7, pain score decreases with dose of the drug in both males and females, but when a combined scatter

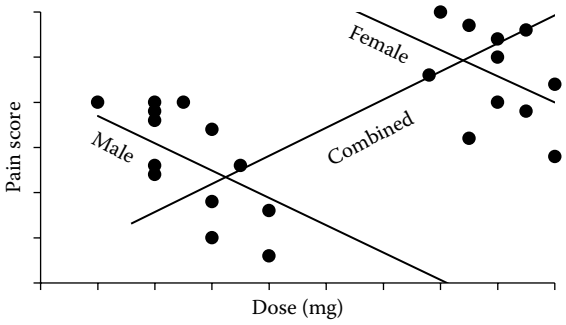

**FIGURE S.7** Relation of pain score with dose of a drug in male and female patients illustrating Simpson paradox.

**TABLE S.13**
**Serum Triglycerides (TG) in mg/dL and Waist–Hip Ratio (WHR) in a Population of 100 Male Hypertensive Subjects**

| Subject Number | WHR | TG | Subject Number | WHR | TG | Subject Number | WHR | TG |
|---|---|---|---|---|---|---|---|---|
| 1 | 1.21 | 152 | 35 | 1.17 | 151 | 68 | 0.93 | 148 |

*In the sample.

is considered, the conclusion would be that the pain score increases with the dose of the drug. This seems like an improbable thing to occur, but this paradox is occurring in this case because females have much higher pain score than males.

Edward Simpson was the first to formally address this phenomenon in 1951 [1], although the phenomenon was known earlier. This paradox has posed a dilemma of whether aggregated results or the disaggregated ones should be considered for action. Our example illustrates that the disaggregated results provide more correct assessment. In many situations, disaggregated data are not available, and the aggregated results are considered true, particularly when it is not known what stratifying characteristic should be used for disaggregation. The paradox also highlights why some statistical associations cannot be taken on face value.

Marang-van de Mheen and Shojania [2] have discussed this phenomenon in the context of standardized mortality ratios. **Standardization** with respect to the "culprit" characteristic of the two groups is the remedy in such situations. For further details of Simpson paradox, see Pearl [3].

## single linkage method of clustering

See **cluster analysis** for basic details of this kind of analysis. Single linkage is one of the several methods of hierarchical clustering. In hierarchical clustering, a measurement of dissimilarity such as **Euclidean distance** is used to classify the units into various groups using one of the several possible algorithms. Two units (or subjects) that are most similar (or least distant) are grouped together in the first step to form one group of two units. This group is now considered as one entity. Now the distance of this entity from other units is compared with the other distances between various pairs of units. Again, the closest are joined together. This hierarchical agglomerative process goes on in stages, reducing the number of entities by one each time. The process is continued until all units are clustered together as one big entity. See **hierarchical clustering** for the method to decide when to stop the agglomerative process so that natural clusters are obtained.

The primary problem in clustering is in computing the distance between two entities containing, say, $n_1$ and $n_2$ units, respectively. Several methods are available. The first is to consider all units in an entity centered on their average. Another method is to compute the distance of the units that are farthest in the two entities. A third method is to base it on the nearest units. There are several others. Single linkage is one such method.

In the single linkage method of clustering, the distance between two clustered entities is measured by the distance between the nearest located units of the entities. If one entity has 7 units with values denoted by $(x_1, x_2, \ldots, x_7)$ and the other has 4 units with values denoted by $(y_1, y_2, y_3, y_4)$, the first step would be to calculate the distance between $x_1$ and $y_1$, $x_1$ and $y_2$, …, $x_2$ and $y_1$, …, $x_7$ and $y_4$. The minimum of these 28 distances will be considered as the distance between these two entities (Figure S.8). If entity A contains $I$ units $(a_1, a_2, \ldots, a_I)$ and entity B contains $J$ units $(b_1, b_2, \ldots, b_J)$, then, under the single linkage method, the distance between these two entities is measured as $d_{AB} = \min_{ij}(dij)$, where $d_{ij}$ is the distance between the $i$th unit of the first entity and the $j$th unit of the second entity. This method can be easily extended to a multivariate setup.

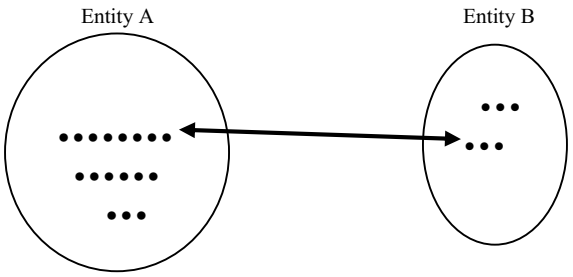

**FIGURE S.8** Single linkage distance between entity A and entity B.

A large distance indicates that the entities are really very different from each other and thus should not be clustered together. If this distance is small, the entities can be considered similar, and you can merge these two entities together to form a bigger entity.

This type of method seems more appropriate for clustering genomes as advised by DeLuca et al. [1] since the objective is to look for the closest similar genome, and for protein sequencing as mentioned by Petryszak et al. [2].

## six-sigma methodology

This methodology is used for **quality control** of products including medical products where quality issues are in any case paramount as they deal with life and death. Sigma (σ) is the notation for standard deviation (SD), and it is well known that three-sigma on either side of the mean in case of Gaussian (normal) distribution covers 99.7% of the probability and leaves out only 0.3% probability. Use it for errors and realize that these limits leave out only 0.3% chance of error as uncovered. Extend it to six-sigma on either side of the mean and that tolerates only 3.4 errors per a million opportunities. Notice how intolerant this is compared to the usual 95% confidence intervals defined by ±1.96SE that leaves out 5% chances of error.

In fact, only 4.5σ leaves out a chance of 3.4 errors per million opportunities, but an additional 1.5σ shift on either side (Figure S.9) is allowed as an abundant precaution for possible shift in the process in the future that can unknowingly happen due to subtle changes in the conditions under which a process operates.

Health care is a big industry, and quality issues cannot be sidelined. Medication errors, diagnostic errors, prognostic errors, etc., are quite common as we deal with a highly variable entity called human beings. Any manager in any industry can easily realize how difficult it is to achieve an error rate of less than 3.4 per million, more so in health care. A motivated team is required to identify areas of improvement and devise strategies to tackle them. Patient satisfaction surveys would be an integral part of this exercise. Statistically, this may require studies on cause and effect, and development of tree diagrams and flow charts, besides study of error distributions with its mean and variance, confidence intervals, and tests of significance. The process requires comprehensive and coordinated efforts from all the concerned departments such as administrators, managers, physicians, and technicians right from the stage when a product or a service is conceived. Six-sigma is generally implemented as a DMADV (define, measure, analyze, design, verify) process that can improve the system and can produce products and services with such high-quality levels.

Six-sigma is not just a statistical concept, and a caution is required when nonexperts use this methodology. For example, they may not realize the importance of a large sample size and instead may have unacceptably low numbers for monitoring that could jeopardize

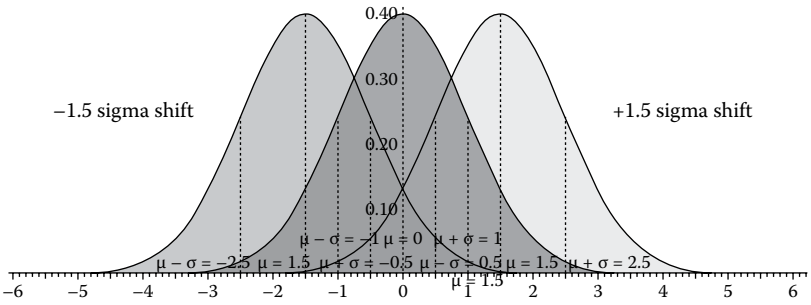

**FIGURE S.9** 4.5σ limits of a Gaussian distribution and 1.5σ shift on either side.

Gaussian application. In addition, errors such as ill-placed control limits (see **quality control**) and wrongly chosen factors can provide misleading results and may push some manager to consider six-sigma methodology as a nuisance. When properly used with well-meaning intentions, the methodology has enormous potential to improve various aspects of health care.

Six-sigma started with engineering products (Motorola in 1986) but has profound medical applications. Ortiz et al. [1] compared several six-sigma projects in health care industry in Colombia and reported that obstetric outpatients were the most suitable six-sigma project for improving care opportunities. Bedi et al. [2] used DMAIC (define, measure, analyze, improve and control) methodology of six-sigma strategy to assess the musculoskeletal disorders in India.

## skewness and the coefficient of skewness

Gaussian distribution pervades statistical thoughts so much that it is seen afflicted by ghost of Gauss. Although many quantitative medical measurements in healthy subjects do indeed follow a Gaussian pattern (Figure S.10a), not all do. Gaussian is a **symmetric distribution** with the left half being the exact replica of the right half. Many distributions do not have this feature. Figure S.10b shows the distribution of serum total homocysteine in healthy subjects in Norway [1]. This distribution has a longer tail on to the right because higher-than-mode levels are more common in healthy subjects. This is called a *right-skewed distribution*. The homocysteine level in any population is likely to follow the same pattern. Triglyceride levels in children are also found to be highly skewed to the right in Luxembourg [2]. On the other hand, the distribution of hemoglobin level is generally *left-skewed* (Figure 10.c) because lower values are commonly seen in healthy subjects.

The distribution of most medical measurements in healthy subjects is Gaussian and skewed in sick subjects. Examples of measurements with remarkable skewness among patients are tumor markers such as carcinoembryonic antigen (median in lung cancer 3.5 ng/mL but range 1–7580). In cancer particularly, the aberration increases in a multiplicative manner rather than additive such as becoming twice as much per unit of time. Logarithms transform multiplications to sums and tend to give the distribution a symmetric shape. Most right-skewed distributions can be converted to a Gaussian form by a suitable logarithmic or square-root transformation. For a left-skewed distribution, a reciprocal transformation can be examined; sometimes it works, sometimes not.

### *Checking Skewness—Simple But Approximate Methods*

Since most statistical methods are based on Gaussian distribution, this should be checked when in doubt. Sometimes the biological process underlying a medical measurement provides sufficient clue whether the distribution of a particular measurement is Gaussian or not as seen in the examples given in preceding paragraphs. In all other cases, a judgment must be made on the basis of the available data on a sample of subjects. In this situation, any of the following methods can be used for checking skewness in this situation. These methods work well for large $n$ but may fail for small $n$, and subjective judgment may be needed for small $n$.

If you are calculation oriented, just calculate the coefficient of skewness. Actual procedure for calculating this coefficient is complex as it requires the sum of the cubes of deviations from the mean, but a simple procedure is to calculate

$$\text{coefficient of skewness } I \approx \frac{\text{mean} - \text{mode}}{\text{SD}}.$$

This works reasonably well for unimodal (single-peak) distributions. A negative value of this coefficient indicates left skewness, and a positive value indicates right skewness. For a symmetric distribution, this coefficient is zero since then, in a unimodal distribution, mean = mode. A value <–1 or >+1 indicates highly skewed distribution.

In a Gaussian distribution—in fact in all symmetric unimodal distributions—mean, median, and mode are equal (Figure S.10a). In sample values, this could be approximately so. For other distributions, note the following:

Right-skewed distribution: mode < median < mean
Left-skewed distribution: mean < median < mode.

These are also shown in Figure S.10b and c. Incidentally, these words appear in a dictionary in the order seen for left-skewed distribution and reverse in the right-skewed distribution. Also the distance between the mean and median in a dictionary is small relative to the distance between median and mode as in these figures. The coefficient of skewness I is also based on such considerations. Thus, the first method to find that a distribution is symmetric or not is to calculate mean, median, and mode, and see if they follow any of the above-mentioned patterns. In samples, the difference between mean, median, and mode must be substantial for the distribution to be considered skewed.

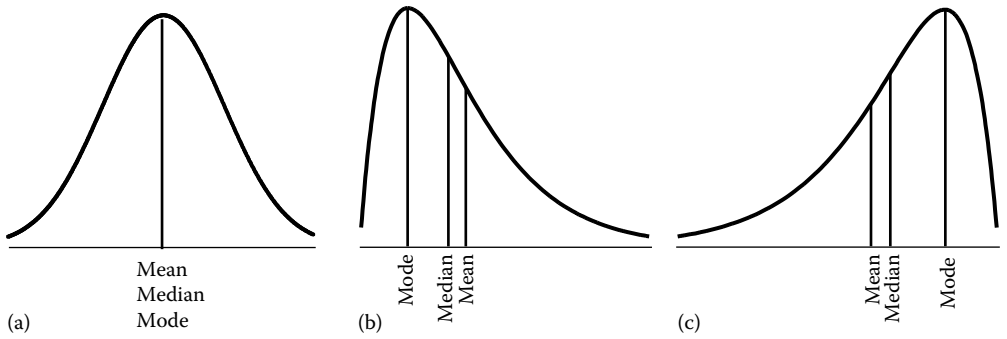

**FIGURE S.10** Location of mean, median, and mode in (a) symmetric; (b) right-skewed; and (c) left-skewed distributions.

If you are graph oriented, the most basic way to check Gaussianity is by **histogram**. Draw it for frequencies in different class intervals and see if it largely follows a bell shape or not. An alternative to histogram is **stem-and-leaf plot**. These are well known, and we are not giving any further details. A second approximate method is *quartile plot* of the type shown in Figure S.11a–c. For this, compute the first, second, and third **quartiles** $Q_1$, $Q_2$, and $Q_3$ and plot them on the Minimum to Maximum axis. If the distance between $Q_1$ and $Q_2$ is nearly the same as that between $Q_2$ and $Q_3$, it is safe to assume that the distribution is symmetric and possibly Gaussian. If the pattern is different as in Figure S.11b and c, the distribution is either left-skewed or right-skewed. If the sample size $n$ is really large, try this type of plot with **deciles** instead of quartiles.

You can see from Figure S.11b and c that $Q_3 - Q_2 > Q_2 - Q_1$ for positive skewness and $Q_3 - Q_2 < Q_2 - Q_1$ for negative skewness. Thus, another measure of skewness is

$$\text{coefficient of skewness II} = \frac{(Q_3 - Q_2) - (Q_2 - Q_1)}{(Q_3 - Q_2) + (Q_2 - Q_1)}.$$

An alternative to the quartile plot is the **box-and-whiskers plot** as presented in that topic. For symmetry, the boxes above and below median as well as the whiskers on both the sides should be nearly equal. A third graphic method is **ogive**, which is a plot of cumulative frequencies against the $x$-values. In a Gaussian distribution, this takes the shape of a **sigmoid**. If the shape is substantially different, take it as an indication of non-Gaussian shape.

Since most statistical methods work best for Gaussian distribution, there is a tendency to use transformation that can correct skewness in a skewed distribution. For positive skewness, logarithmic transformation is common. This rapidly shrinks large values to small values—thus the right tail of the distribution shifts toward the center, making it more symmetrical. The other popular transformation is square root ($x^{0.5}$), which also shrinks the right tail. Both of these are applicable to only positive values. In case all values are not positive, add slightly more than the highest negative so that none is zero or negative, and keep track of this while interpreting the results. For left skewness, square transformation ($x^2$) may work reasonably—square of 3 is 9 and square of 16 is 256—thus left tail and the negative skewness are reduced. It may be evident that the power of $x$ is less than 1 to correct right skewness and greater than 1 for left skewness. Procedures are available to find exactly which power of $x$ is best to minimize the skewness. For this, see the topic **power transformation**.

## slope (in regression), *see* simple linear regression

## slope–ratio assays, *see also* bioassays

Assays are experiments where we intentionally do something in different intensities to see what the effect is and compare it with the effect of a standard intervention (see **bioassays**). The effect

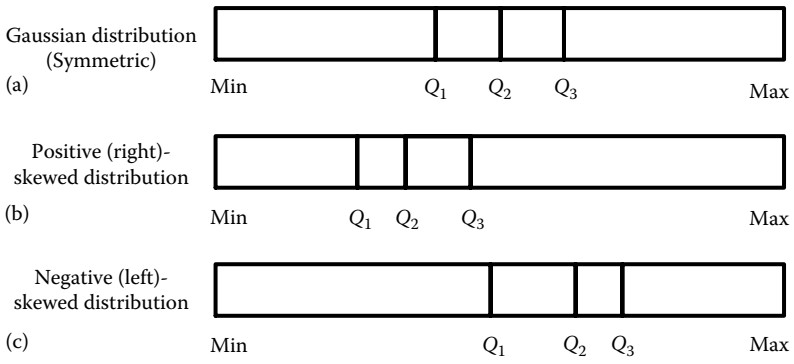

**FIGURE S.11** Pattern of quartiles in (a) symmetric (Gaussian); (b) right-skewed; and (c) left-skewed distributions.

of an intervention is technically called *response*, and the same intervention at different intensities is applied in the hope that as the intensity increases, the response will be higher. This particularly applies to poisons such as insecticides and pesticides, where larger dose results in higher response. In this case, the response is death, but in general, response could be any other outcome. This feature is seen in anesthetic agents, but the outcome of interest there is relief from pain. The primary objective of assays is to estimate the relative potency of the test intervention compared with the standard intervention for achieving a particular outcome. The assays that expect multiplicative response such as $2y$ at dose $2x$ but $4y$ at dose $3x$ are called slope–ratio assays. The basic setup in slope–ratio assays is that the response is the same for test and standard preparation at some baseline but increases (or decreases) at a faster rate for one preparation than the other as the dose increases. However, the trend in both should be linear for the slope–ratio assay to be valid. This is illustrated with the help of an example later in this section.

Death is called a quantal response (see **quantal assays**) as it occurs or does not occur, and there is nothing in between. In place of death, consider the time elapsed before death. If you give 2 mg of poison to rats, how much time does it take for a rat to die, and if you give 5 mg then how much time is taken? For the same dose, say 5 mg, some rats will take 4 h and some will take 5 h to die. Different rats will take different time, but the response is not death, instead is measured in quantitative terms in hours taken to die. When the comparison of such quantitative response is with a standard poison, this is called *quantitative assay.*

Slope–ratio assays are many times contrasted with parallel-line assays. In **parallel-line assays**, the plot of response versus dose falls in a straight line for both the test preparation and the standard preparation, and these lines are parallel to each other. This means that the difference in response remains constant as the dose escalates. In our example, the difference in time to death can be 4 h between test preparation and standard preparation at dose 2 mg, and the difference remains same 4 h at 3 mg, at 4 mg, etc. in the case of parallel-line assays. In place of actual dose $x$, one can have a transformation such as $x^{\lambda}$, called the *dose metameter.* Sometimes this kind of transformation is used to achieve a response that looks like that in parallel lines.

Quite often, the difference in response at different doses of standards and test preparation will not be constant. The difference in time to death could be 4 h at dose 2 mg but 6 h at dose 3 mg and 8 h at dose 4 mg. As the dose is increased by 1 mg, the difference increases by 2 h on average each time in this example and does not remain constant. This kind of response gives rise to slope–ratio assays.

For illustration, consider an experiment to find how the **bioavailability** (measured by area under the concentration curve) of drug B compares with the bioavailability of standard drug B in male adults.

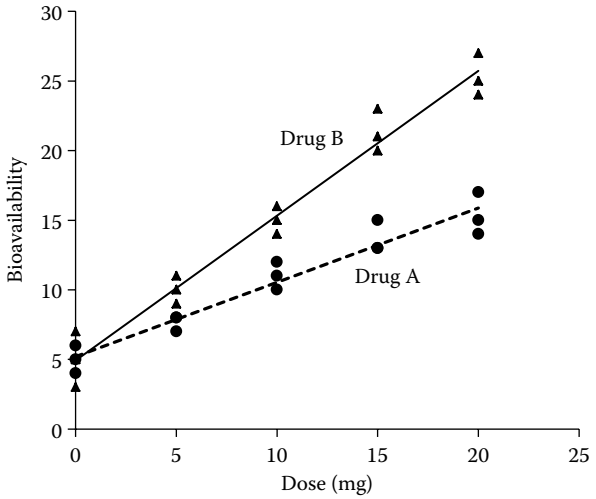

**FIGURE S.12** Regression plots for the data in Table S.14.

Both were given in doses of 0, 5, 10, 15, and 20 mg to three persons each; that is, a group of 30 male adults was randomly divided into two groups of 15 to receive drug A and drug B. The data obtained are shown in Table S.14.

If bioavailability is considered $y$ and dose is $x$, the linear regression of $y$ on $x$ is as shown in Figure S.12. Besides linearity, an important feature of regressions in this figure is that both the lines have the same intercept, but the slope for drug B is steeper than that for drug A. Let drug A be the standard and drug B the test preparation. The dose–response regression equations can be stated after ignoring the error term as

$$y_s = \alpha + \beta_s x_s \text{ for the standard preparation}$$

$$y_t = \alpha + \beta_t x_t \text{ for the test preparation,}$$

where $y_s$ is the response of standard preparation and $y_t$ of the test preparation. Different doses of standard and test preparations under trial are denoted by $x_s$ and $x_t$. $\alpha$ and $\beta_s$ and $\beta_t$ are the intercepts and slope of regression lines, respectively. Note that both have the same intercept—thus $\alpha_s = \alpha_t$, which is denoted by $\alpha$ in these equations. In the case of parallel-line assays, the intercepts are different and the slope is the same, but in the case of slope–ratio assays, the intercepts are the same and the slope differs. **Relative potency** in this case is the ratio of these slopes, that is,

$$\text{relative potency (slope–ratio assays) } \rho = \frac{\beta_t}{\beta_s},$$
$$\text{and its sample estimate is } R = \frac{b_t}{b_s},$$

S

**TABLE S.14**
**Bioavailability of Different Doses of Drug A and Drug B**

| | Receiving Drug A (Standard) | | | | | Receiving Drug B (Test) | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| **Person** | **Blank 0 mg** | **Dose 1 5 mg** | **Dose 2 10 mg** | **Dose 3 15 mg** | **Dose 4 20 mg** | **Blank 0 mg** | **Dose 1 5 mg** | **Dose 2 10 mg** | **Dose 3 15 mg** | **Dose 4 20 mg** |
| 1 | 5 | 8 | 10 | 13 | 14 | 7 | 11 | 16 | 23 | 25 |
| 2 | 6 | 8 | 12 | 15 | 17 | 3 | 9 | 15 | 20 | 24 |
| 3 | 4 | 7 | 11 | 13 | 15 | 5 | 10 | 14 | 21 | 27 |
| **Mean bioavailability** | **5.0** | **7.7** | **11.0** | **13.7** | **15.3** | **5.0** | **10.0** | **15.0** | **21.3** | **25.3** |

where $b_s$ and $b_t$ are the estimates of $\beta_s$ and $\beta_t$, respectively. These slopes are readily estimated with the conventional **regression** techniques.

A careful look at Figure S.12 reveals that the estimated regression equations are approximately $y_t = 5 + 1.0x_t$ for the test preparation, and $y_s = 5 + 0.5x_s$ for the standard preparation. This gives relative potency = 1.0/0.5 = 2.0. This is an approximation, but assume for the time being that this is correct. Then drug B is twice as potent with regard to bioavailability as drug A in this example. In other words, twice as much drug A is needed to get the same bioavailability as drug B. This example is extraordinarily simple in many ways as noted below:

1. In this example, the dose itself is being used in the regression and not its logarithm or any other transformation. Thus, the dose metameter is the dose itself. The same goes for response (bioavailability). In general, you may have to use a dose metameter and in some cases response metameter,first to achieve Gaussian distribution and second to get linear regression.
2. Doses are equispaced 0, 5, 10, 15, and 20 mg in this example. In actual experiments, this may not be so. Somebody may receive 12 mg, some 14 mg, some 17.5 mg, etc. This does not change the setup as the usual regression can be run even when the doses are not equally spaced.
3. Doses for the test and standard preparations are the same in this example, but, in general, they could be different.
4. Dose 0 mg is called the blank dose, and this factually is given to 6 persons in this example, whereas other doses are given to 3 persons each. A higher number of subjects for blank dose help to get a more reliable estimate of the intercept.
5. The number of doses under trial is the same for both the preparations in this example, yielding to what is called a *symmetric assay*. These are 4 doses for each plus one blank (although blank appears in both the groups). Thus, this is a 9-point assay. In general, the number of doses can differ; for example, standard can be tried for 3 dose levels and test for 5 dose levels. At least 3 doses of standard and 3 doses of test preparation are needed to validate linearity (see point 8), and a blank is needed to check for equality of the intercept (see point 7).
6. In this example, each dose has been given to 3 persons. In practice, one dose may be given to 4 persons, another dose to 7 persons, third dose to only 2 persons, etc., as these numbers can vary in an experiment. That also does not change the basic structure of the experiment, and the regressions can be obtained as usual. However, an equal number of subjects for each dose level minimize the requirement of the total number of subjects, and the computations are relatively simple. When the number of subjects are the same for each dose, this is called **balanced design**.
7. Figure S.12 shows for these data that the intercepts for the two regressions are the same. In practice, a statistical test based on analysis of variance (**ANOVA**) is conducted to check whether the intercepts are significanty different or not. Once they are found to be not different, then only the ratio of slope will provide the correct estimate of the relative potency.
8. In Figure S.12, the regressions are clearly linear. In practice, check that they are really linear, and deviation from linearity is not statistically significant. This test also is based on ANOVA and would be valid when the requirements of ANOVA are fulfilled.
9. Fiducial limits for relative potency, being a ratio, can be obtained by **Fieller theorem**.

For further details of slope–ratio assays, see Hewitt [1].

## Slutzky–Yule effect

Discovered by Eugen Slutzky [1] and Udny Yule [2] independently in 1920s, this is the correlation induced by a method such as **moving averages** in a **time series** of uncorrelated values as is apparent from the following example:

$$\text{moving average of order 3 at time } t\text{: } y_t = \frac{x_{t-1} + x_t + x_{t+1}}{3}.$$

The values in series $y$ created by moving averages would be correlated since $x_t$ would appear in $y_{t-1}$, $y_t$, and $y_{t+1}$, and even when the $x$-values are uncorrelated, **autocorrelation** of lag 1 could be 2/3 and 1/3 at lag 2 because of repeated appearance of the same values. If any particular value is large, all moving averages involving that value will be inflated. Generally, the inflation will be the greatest when that value is in the middle, and will progressively reduce on either side. The Slutzky–Yule effect is the spurious cyclical effect that autoregressive series can produce when there is none. In fact, it is because of such correlations that moving averages are able to provide a relatively smooth pattern.

Smoothing a time series by forming moving averages is a commonly deployed approach—thus, this effect is commonly seen in such cases. **ARMA and ARIMA models** of time series also tend to induce such correlations. Conversely, if a time series is exhibiting an oscillatory movement, examine if it is due to summation (or averaging) of values over time.

## small area estimation

Under this methodology, the results of a survey for a big population are sought to be used to generate estimates for small subareas, for which the sample size is inadequate to provide any reliable estimates, by using auxiliary information (such as from census or administrative records) already available for all units of the small area. Use of auxiliary information is basic to this method, and thus the method is also called the *synthetic estimation*. Small area can be a geographical area such as a county but can also be any specific group of interest such as a particular age–sex group. It is better understood as a domain, which is a more general term, and encompasses the spatial, demographic, disease, and such other groups. The method can be used when an increased sample size for each small area yields an unusually large sample that exceeds the resources

available for the survey, and the subareas have an inadequate sample for providing a reliable estimate.

As you can see, small area estimation is an indirect method of estimation as compared with a direct method that uses the collected data on the area. Its success depends on proper choice of the auxiliary variable since this method derives strength from this variable to simulate a large sample size. This auxiliary variable must be measured uniformly over the total area so that the information can be effectively used. If there is some nonresponse, this should be small and random, and not biased (selective). The link between the main variable of interest and the auxiliary variable is exploited to improve the reliability of the estimates, and this link should be clearly established and fully understood so that it can be properly used. If the auxiliary variable is not chosen properly, this may introduce bias into the estimates.

Small area estimation has a lot of relevance in assessing health status (such as disabilities) and health practices (such as drug use) at county or regional level that helps in developing adequate plans to meet the local needs. The National Center for Health Statistics in the United States pioneered the use of such synthetic estimation for developing state estimates of disability and other health characteristics from the National Health Interview Surveys. Sample sizes in most states were too small to provide reliable direct estimates for the states.

The method generally used for small area estimation is similar to what is used for **ratio estimators**. The link between the auxiliary variable and the variable of interest may be complex involving **hierarchical models** with **random effects**. Suppose $y_{ij}$ is the value of the study variable for the $i$th unit ($i = 1, 2, \ldots, n_j$) of the $j$th small area ($j = 1, 2, \ldots, J$), where $n_j$ is the number of population units in the $j$th area. Let the auxiliary variable be $x$ whose value $x_{ij}$ is available for each unit in the small area. The basic relationship between $x$ and $y$ is the link model in this case and can be expressed through a nested **regression model** as

$$y_{ij} = \beta x_{ij} + u_j + \varepsilon_{ij},$$

where $u_j$ is the area-specific random effect of area $j$, $\beta$ is the regression coefficient, and $\varepsilon_{ij}$ is the random error. For simplicity, we have taken only one auxiliary variable and are considering only the linear model, but there is no such restriction in small area estimation. As mentioned earlier, the validity of the estimation certainly depends on the suitable choice of the auxiliary variable and also on the suitable link model. In case needed, more auxiliary variables and curvilinear relationships can be included. This link model allows estimation of the parameters of $y$ (such as mean) for the small areas with relatively high precision. For details, see Rao [1].

## smoke-pipe distribution

This is the name proposed by Indrayan [1] for distribution of deaths by age in a developing country where infant mortality is high. Thus, this distribution has two modes—one around age 6 months (or even early) and the other around 75 years (Figure S.13). After the age of 80 years, the number of people remaining alive is small, and consequently, the number of deaths is also small, although the death rate in old age groups is extremely high (Table S.15). This feature gives it a shape of smoke pipe.

Since this shape is entirely different from Gaussian, it highlights the importance to be careful while dealing with age distributions of deaths in a population such as in building up of confidence intervals and testing of hypothesis. Statistical properties of smoke-pipe distribution are yet to be investigated.

1. Indrayan A. *Medical Biostatistics*, Third Edition. Chapman & Hall/CRC Press, 2012.

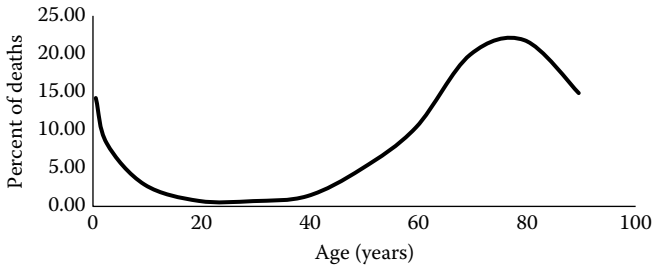

**FIGURE S.13** Smoke pipe distribution of deaths by age in a developing country.

**TABLE S.15**
**Distribution of Deaths by Age in a Developing Country**

| Age Group (Years) | Population ('000) | Age-Specific Death Rate (per 1000) | Number of Deaths | Number of Deaths per Year of Age | Percent of Deaths per Year of Age |
|---|---|---|---|---|---|
| 0–1 | 1.5 | 20 | 30 | 30 | 14.22 |
| 1–4 | 7.0 | 10 | 70 | 17.5 | 8.30 |
| 5–14 | 15.0 | 4 | 60 | 6 | 2.84 |
| 15–24 | 15.0 | 1 | 15 | 1.5 | 0.71 |
| 25–34 | 14.5 | 1 | 14.5 | 1.45 | 0.69 |
| 35–44 | 14.2 | 2 | 28.4 | 2.84 | 1.35 |
| 45–54 | 13.0 | 8 | 104 | 10.4 | 4.93 |
| 55–64 | 9.5 | 23 | 218.5 | 21.85 | 10.36 |
| 65–74 | 7.0 | 60 | 420 | 42 | 19.91 |
| 75–84 | 2.0 | 230 | 460 | 46 | 21.81 |
| 85–94 | 0.7 | 448 | 313.6 | 31.36 | 14.87 |

## smoking index, *see* Indrayan smoking index

## smoothing methods, *see also* spline regression, cubic splines

The term *smoothing* in statistics is used for extracting a trend from noisy data in such a way that important features of peaks and troughs remain preserved. Thus, this is similar to curve fitting by regression, but here, values adjacent to any point are given more weightage—low values adjacent to a high value are raised, and high values adjacent to low values are reduced so that they are aligned and produce a smooth trend. See Figure S.14 for an example. It is difficult to get this kind of trend by regression equation.

One example of such smoothing is in obtaining reference centile curves for growth parameters of children (see **growth charts**) where actual data at individual time points may show an irregular pattern, but curves are obtained after smoothing without losing the periods of slow growth and fast growth. Smoothing is done in this case in the realization that there is no reason for sudden jumps or falls in growth from age to age, and whatever changes occurring are gradual, particularly when the average for the entire "population" is considered. Similar reasons exist for other trends.

A large number of methods are available for smoothing, but all of them are intricate and require considerable expertise. An easy method is **moving averages** as generally used for time series data. The method generally used for centile curve smoothing is **cubic splines** as illustrated in that topic.

Another prominent use of smoothing is in spatial studies as done by Szonyi et al. [1] for incidence of Lyme disease in the United States. The objective here is identifying directional trends such as waning occurrence as we move from south to north. The same is the case with imaging as discussed by Patané [2] for different anatomical sites. The method they used is based on kernel smoothing and is different from what we have described.

Further details of smoothing methods have been provided by Simonoff [3].

**FIGURE S.14** Noisy data and smooth trend.

## snowball sampling

This is a nonrandom method of sampling that tries to reach an obscure and possibly closed group by forming a chain of eligible subjects. A popular example is drug users who rarely identify themselves as such a user, and are hard to locate, and similarly sex workers. If a researcher is able to somehow find one drug user, this one can reveal some others who are in his or her contact, and those in turn can reveal more of their contacts. For this reason, this is also referred to as *chain referral sampling*. Some would reveal their contacts; others would not. If each person is able to identify at least 3 more persons, the sample size could become 81 after 4 stages. This can help in finally recruiting a reasonably sized sample for an empirical study, although it is futile to expect a large sample by this method.

Despite being nonrandom, some idea of what is happening can be obtained by studying this kind of sample. Since this method is not based on probability sampling, statistical methods such as confidence intervals cannot be used. However, in **analytical studies** such as in experiments where the subjects are randomly divided, it should be possible to make a generalized statement regarding, say, feasibility of a regimen in such a group, similar to the exercise we do in phase I of a clinical trial.

Snowball sampling is relatively simple and cost-efficient, in some cases the only way out to reach people of the type one wishes to study, but can seldom provide a representative sample of the target population. Since the subjects identify others of their own type, a strong clustering effect may be present that can produce biased estimates. There is a possibility that after some links, the process becomes repetitive; that is, you start getting the same subjects again. Since this method is used for people who are mostly in illegal activities, special efforts may be needed to address their sensitivities and to get their cooperation to participate in the research.

## social classification

Social classification is an indicator of the social health of a person and is generally defined by his or her education, income, and occupation. These can be combined to devise a system of classification of people into various socioeconomic classes. There are many classifications available, but our preference is for the one devised by Indrayan [1] and given in Table S.16 because of its international applicability. In case of family, this applies to the head of the household, and the entire family is considered to belong to the same class.

Table S.16 suggests a scoring system for the three components, and a classification based on the aggregate score. The categories of schooling years and of occupation are absolute in this table and can probably be used anywhere in the world without alteration. But the income level in one country can seldom be compared with that in another country except possibly in terms of the **purchasing power parity**. But this is far too complex to calculate. Thus, a classification of income is on the basis of percentile, which will be specific to the area. There will always be 20% of the population below the 20th percentile and another 20% between the 20th and 40th percentiles, etc., which in fact are **quintiles**. Yet, the classification may be valid for comparing one subpopulation within a country to another subpopulation, and to some extent for an international comparison also. Such quintiles are generally available from the distribution of per capita income of the nation. If not available, it is relatively easy to assess that the person's income belongs to which quintile than exact income.

**TABLE S.16**
**Scoring for Social Classification**

| Score | Years of Schooling | Income[a] | Occupation |
|---|---|---|---|
| 0 | Nil (illiterate) | Below poverty line[b] | Unproductive or burden on society (e.g., begging), including unemployed |
| 1 | <5 | <20th percentile[c] | Unskilled labor |
| 2 | 5–10 | 20th–40th percentile | Skilled labor, artisan, small business, student, small farmer, soldier |
| 3 | 10–15 including vocational | 40th–60th percentile | Clerk, medium business, medium farmer, technician, salesperson |
| 4 | 15+ but nonprofessional nontechnical | 60th–80th percentile | Teacher, researcher, industrialist, big farmer, big business, government officer, manager |
| 5 | 15+ some of which is professional or technical | ≥80th percentile | Executive, doctor, attorney, consultant, engineer |

| Aggregate Score | Social Class |
|---|---|
| 0–3 | V |
| 4–6 | IV |
| 7–9 | III |
| 10–12 | II |
| 13–15 | I |

[a] In case of a family, calculate per capita income in the family.
[b] Income required to purchase low-cost balanced food to provide 2400 calories.
[c] Excludes those that are below poverty line.

A large number of common occupations are listed in Table S.16, but certainly not all. An indication of the score for other occupations not included in this table should be available from the pattern.

The minimum possible aggregate score is 0 and the maximum is 15. A classification is suggested in the bottom of Table S.16. The percentage of the population in different classes would give an indication of the social health of people. Many diseases and other health conditions have been observed to be associated with such social classification of the subjects. See **social health (indicators of)** for details.

For official classification followed in the United Kingdom, see the ONS document [2].

## social health (indicators of)

Social health is generally measured in terms of social status comprising education, income, and occupation. These, independently as well as in combination, are believed to have a deep impact on the well-being of the people. Education increases awareness and adds to the productivity of people. Income causes a sense of well-being by allowing access to a wider set of choices. Occupation helps to attain satisfaction of doing something worthwhile for society. These together are sometimes considered distal factors of health that affect proximal factors such as diet, smoking, and hygiene. The proximal factors affect physiological and pathophysiological processes that lead to disease and infirmity. Genetic factors and environmental factors such as pollution and water supply contribute to this process.

See **education indicators** for a large number of indicators used to measure education level in a community. We are not giving details here.

The most widely used measure of the level of income of a community is the per capita **gross domestic product (GDP)**, popularly called per capita income. Almost all countries compute this for the nation as a whole and usually for each of their states separately. Further subdivisions may not be easily available. Income per se in the national currencies is seldom comparable across countries because of differential purchasing power. A Singapore dollar cannot buy as much in Singapore as the Yuan equivalent can in China. For international comparison, the World Bank has worked out **purchasing power parity dollars**. Note, however, that income is mostly a family trait rather than an individual because children are not supposed to earn. If the average size of family is four, the average family income is four times the per capita income. When income data are not available, an indirect way to assess the economic status of a community is by the presence of amenities such as housing, telephones, televisions, computers, and automobiles per family or per 1000 population.

Ideally speaking, all jobs have dignity and deserve full respect. Practically, though, professionals such as attorneys, doctors, chartered accountants, and consultants are considered to enjoy better social health. Industrial laborers and coalmine workers do not generally enjoy the same status. Thus, there is an inbuilt hierarchy in occupation in most societies. Except for the percentage in different occupations, no worthy measure is available to measure occupational distribution.

Singh-Manoux et al. [1] compared three models for exploring the links between different measures of what they called adult socioeconomic position (SEP)—education, occupation, income—and psychosocial health. Their focus was predicting psychosocial health based on social position. Model I was a basic regression model with a measure of SEP as the predictor, and model II was a multiple regression model with all three measures of SEP considered as predictors. Model III treated education as a distal measure of SEP, and as an antecedent to the proximal measures of SEP in the prediction equations linking SEP to psychosocial health. The three models lead to completely different conclusions, but the authors preferred model III that showed education to have a stronger *indirect* effect on psychosocial health when compared to its direct effect. They concluded that proximal measures of social position might discriminate better as they portray the current and accumulated socioeconomic circumstances of the individual more accurately.

## Spearman–Brown formula

Spearman–Brown formula is used to reassess the **reliability** of a multi-item test or instrument when its length is increased or decreased, and the formula can also be inversely used to determine the length for fixed reliability. If the new test is $K$ times longer than the original, the reliability of the new test is given by

$$\text{Spearman–Brown formula: } \rho_K = \frac{K\rho_1}{1+(K-1)\rho_1},$$

where $\rho_K$ is the reliability of the new test, which is $K$ times as long as the original test, and $\rho_1$ is the reliability of the original test. For example, if the original test has reliability $\rho_1 = 0.62$, doubling ($K = 2$) the length of the test will give reliability $\rho_2 = 2 \times 0.62/[1 + (2 - 1) \times 0.62] = 0.77$. Inversely, for desired reliability $\rho_K$,

$$K = \frac{\rho_K(1-\rho_1)}{\rho_1(1-\rho_K)}.$$

If a test already has reliability of $\rho_1 = 0.75$ and it is proposed to be increased to $\rho_K = 0.85$, this gives $K = [0.85(1 - 0.75)/[0.75(1 - 0.85)] = 1.89$. If the original test had 10 items, the new test should have 19 items to increase its reliability from 0.75 to 0.85.

The formula was independently proposed by Charles Spearman [1] and William Brown [2] in 1910. It is applicable only when the new test has items of similar difficulty—they could be, for example, more indicators of the same trait—and is commonly used for psychometric evaluation of the test items in social research including health. Alves et al. [3] used this formula to determine the number of items in a linguistic adaptation of the Neonatal Intensive Care Units Family Needs Inventory in Portugal. Aadland and Ylvisåker [4] had an interesting application of the formula for determining the number of monitoring days to achieve an intraclass correlation coefficient of 0.80 for reliable measurement of sedentary time and physical activity in adults in Norway.

## specificity, *see* sensitivity and specificity

## sphericity, *see* Mauchly test for sphericity

## spline regression, *see also* cubic splines

Splines are projections of shaft that join another shaft through grooves or any other mechanism so that both can move together. In statistics, these are functions, mostly piecewise **polynomials**, which graphically fit into one another to provide a continuous though irregular shape. The joints are called *knots*, although these may not be visible in a finished graph. Polynomials are algebraic functions of any specified degree such as linear, quadratic, cubic, and quartic. When these are lines, the knots would be easily visible as the points joining lines with different slopes. Figure S.145a has five linear splines and four knots where these splines are tied. In **cubic splines**, for example, each one of the splines would be a cubic function that can give a shape of ∾ with no break, and they will smoothly join with one another on the knots (Figure S.15b). This figure is based on a different set of data and shows linear splines as well.

To understand splines further, consider two quadratic polynomials $y_1 = 3x^2$ and $y_2 = x^2 + 4x - 2$, the latter of which can also be written as $y_2 = 3x^2 - 2(x - 1)^2$. The reason that we want to give this alternative version of $y_2$ is to show that the two functions have the same value $3x^2$ at $x = 1$, and this is the knot where these two quadratic "splines" can be joined. We can say that $y$ is $3x^2$ for $x < 1$ and is $x^2 + 4x - 2$ for $x > 1$, both being the same at $x = 1$. Both polynomials are truncated. If functions do not have exactly the same value at any value of $x$, the closest value is searched and smoothing is applied so that they can be joined. This is done through an appropriate software package.

Spline regression is the process of joining many splines of the desired degree (linear, quadratic, cubic, etc.). This is used when you expect many different patterns of trends when the value of $x$ increases—the pattern for $x$ in the interval $(0–\theta_1)$ different from the pattern for $x$ in the interval $(\theta_1–\theta_2)$, and so on, for $x$ in the interval

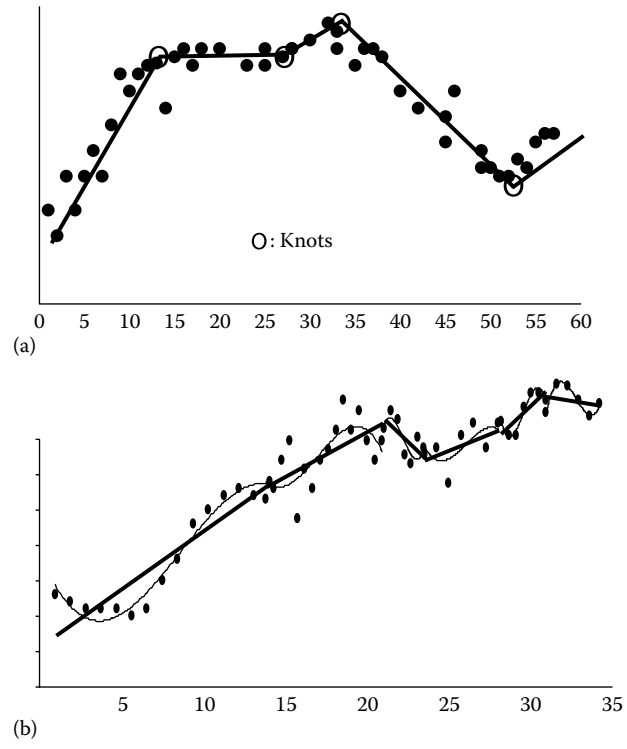

**FIGURE S.15** (a) Linear splines. (b) Cubic splines (snaky curve) imposed on linear splines.

($\theta_{K-1}$–$\theta_K$), where $\theta_k$'s are the $K$ knots. A common example is the construction of growth charts for children that may have phases of slow growth for some age intervals and of fast growth in some other intervals. In case of linear splines, this reduces to changing slopes up or down at some specific values of the regressor (Figure S.15a). A general spline regression takes the following form.

Regression equation for splines of degree $D$ with $K$ knots:

$$y = \beta_0 + \Sigma_d \beta_{1d} x^d + \Sigma_k \beta_{2k} (x - \theta_k)_+^D ;\ d = 1, 2, \ldots, D;\ k = 1, 2, \ldots, K$$

where the first part of the equation is the regular polynomial regression, and the second part is the one that is for knots and also for different polynomials for different splines, although each spline has the same degree $D$. The notation $(x - \theta_k)_+^D$ is for $[\max(0, x - \theta_k)]^D$ so that only values greater than or equal to $\theta_k$ are considered. The number of $\beta_{1d}$'s is $D$, the number of $\beta_{2k}$'s is $K$, the number of $\theta$'s is also $K$, and there is one $\beta_0$—the total of $(D + 2K + 1)$ parameters for estimation. The number of knots and their location mostly will not be known, and their choice is a challenge—a software package is used for this purpose also. Too few knots may not be able to detect all the points of slow and fast movements, and too many knots may show spurious features with unnecessarily wiggly regression. Obviously, reasonable estimation of so many parameters is possible only when the number of $x$ values is much larger so that overfitting is avoided. For this, the method of penalized least squares or **penalized likelihood** is used that can reduce the number of parameters for estimation by imposing penalty on the higher number of parameters. It is important to realize that this method allows flexibility since different types of polynomials can be fitted to different segments of $x$-values, thus removing the restriction of one regression equation to the entire range of $x$ as done in the usual regression. The challenge is also to ensure that the regressions in different segments exactly join at the knots with no jump or step. A good statistical software package and sufficient statistical expertise are required for fitting spline regression to the data.

Besides child growth curves, splines have been used in other setups also. For example, Zhang et al. [1] have studied the relationship between dose of smoking and difference in methylation intensity by cubic splines in older adults in Germany, and Ray et al. [2] demonstrated for subjects in a sleep clinic in the United States that spline regression method has the potential to improve sleep estimates using wrist actigraphy.

For further details of spline regression, see Marsh and Cormier [3].

## split-half consistency, *see also* consistency

Consider a test in the form of a questionnaire containing several questions or items, say, on a scale of 0 to 5. An example is the assessment of ability to perform activities of daily living (ADL) by a geriatric population, where items such as ability to dress, to bathe, to walk around, and to eat are scored from 0 for complete inability (full dependence) to 5 for complete independence requiring no assistance. It is expected that the ability score on one item would correspond to the score on other items. If there were a difference, it would generally persist across subjects. In fact, all items are different facets of the same entity—the ADL in this case. Uniformity of the underlying construct across all items of a test is an important prerequisite for measuring internal consistency. If that is so, the responses will be consistent with one another provided the items are properly framed and the questions appropriately asked.

One way to measure internal consistency is to split the test into ostensible equal halves where feasible. This is generally possible for a questionnaire by randomly dividing questions into two parts. The other method is to put odd-numbered questions in one-half and even-numbered questions in the other half. The product–moment correlation coefficient between total scores in the two parts across several subjects is a measure of internal consistency. This is called split-half consistency. Note that there is no one-to-one correspondence between one item in one-half of the test and an item in the other half of the test. Thus, intraclass correlation cannot be used in this case, and the usual product–moment correlation between total scores is used to assess split-half consistency.

Split-half implies that the number of items available for calculating the total score is one-half of the items in the whole test. Such reduction in the number of items adversely affects reliability assessment. An adjustment, called the **Spearman–Brown formula**, can be used to estimate the reliability if the test were to consist of all the items. For details, see Groth-Marnat [1].

Split-half is commonly used for consistency measure in questionnaire development. Wang et al. [2] used this for psychometric evaluation of the questionnaire of health-related quality of life among rural-to-urban migrants in China, and Yoshii et al. [3] used it for assessing reliability of the workplace social distance scale in Japan.

## spot map

Maps are a powerful medium for showing the spatial distribution of a disease or of a health condition. A dot can represent one or many cases (such as 1 dot = 10 cases). A concentration of dots in any area indicates that the incidence of disease is high in that area. Figure S.16a is a map of India for human immunodeficiency virus prevalence rate in persons with sexually transmitted disease in 2005. Areas with higher incidences have many dots. Such a map is called a spot map and can be used to investigate a localized outbreak of a disease. Figure S.16b shows the spot map of tularemia case in the United States in 1990–2000.

Ward et al. [2] developed a spot map of their catchment area in the United States and identified areas where nonaccidental trauma occurs with increased rate. Jent et al. [3] provided a spot map showing areas requiring close monitoring for fecal contamination in Puerto Rico.

## standard deviation

Dispersion, scatter, and variability all connote the same phenomenon. Standard deviation (SD) is the most widely acceptable and most commonly used measure of **variation** in quantitative values. Its magnitude depends on the extent of the difference between a value and that of the others. Instead of calculating so many differences, it is convenient to compute the difference of each from a central value, namely the mean. Let the sample observations be $x_1$, $x_2$, …, $x_n$ and the mean $\bar{x}$. The difference $(x_i - \bar{x})$, where $i = 1, 2, \ldots, n$, is called the deviation of the $i$th value from the mean. Some of these deviations would be positive and some negative. An average of these deviations could be a measure of dispersion, but this would always be zero. One way out is to ignore the sign, get the absolute values, and calculate the average $\Sigma|x_i - \bar{x}|/n$. This is called the **mean deviation**. Absolute values are mathematically difficult to handle. It is easy to get rid of the minus sign by squaring the deviations. The average of squared deviations $(x_i - \bar{x})^2$ is $s^2 = \Sigma(x_i - \bar{x})/n$. This is called the sample **variance** and is a very useful and popular measure of dispersion. For population variance, use $\mu$ in place of $\bar{x}$ and denote by $\sigma^2$. Thus,

$$\text{population variance: } \sigma^2 = \Sigma(x_i - \mu)/N,$$

where $x_i$ now refers to the $i$th value in the population, and the sum is over all $N$ values in the population. It is seen in the case of samples that the denominator $(n - 1)$ in place of $n$ gives a better estimate of the population variance in the long run (called **unbiased**), but the population variance is calculated with $N$ in the denominator.

Variance has been extensively studied and found to be a very adequate measure. The only difficulty is that its calculation is such that the unit of the variable values is also squared (e.g., square meters for area). The original unit is retrieved by taking the square root. The quantity obtained as the positive square root of the variance is called the **standard deviation** (SD). Thus,

$$\text{population SD: } \sigma = \sqrt{\Sigma(x_i - \mu)/N},$$

$$\text{and sample SD: } s = \sqrt{\Sigma(x_i - \bar{x})/(n-1)}.$$

The term "standard deviation" was first proposed by Karl Pearson in 1894 as a substitute for cumbersome "root mean square deviation" [1].

See Figure S.17 to get an idea of what variance measures, where scatter of three medical measurements is shown. The serum iron varies in this figure from 50 to 170 μg/L in healthy subjects and has a larger variance relative to systolic blood pressure (BP) that varies between 115 and 140 mmHg; BP has a larger variance than serum sodium since it varies within a narrow range of 135–144 mEq/L.

### *Calculation of Variance and SD in Ungrouped Data*

Ungrouped data are the original values as measured in exact quantities. As already explained, the formulas for ungrouped data can be stated as follows:

$$\text{sample variance: } s^2 = \frac{\Sigma(x_i - \bar{x})^2}{n-1} \text{ and sample SD: } s = \sqrt{\frac{\Sigma(x_i - \bar{x})^2}{n-1}}$$

Calculation of the variance and SD of the systolic BP for the two groups of subjects is shown in Table S.17 where one group has compact values from 128 to 132 mmHg, and the other group has widely scattered values from 100 to 150 mmHg. SD in group 2 is more than four times the SD in group 1. The value of SD can be legitimately used to conclude that the variation in group 2 is nearly four times than that in group 1.

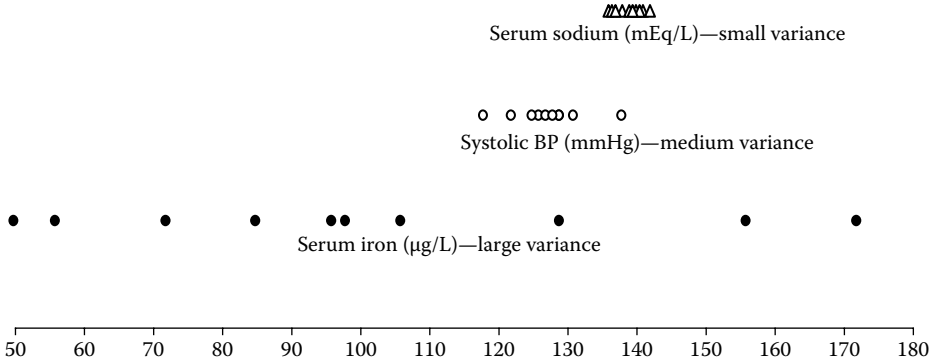

**FIGURE S.17** Schematic of differential variance in three measurements.

**TABLE S.17**
**Calculation of Variance and Standard Deviation (SD) in Two Disparate Groups**

| Group 1 | | | Group 2 | | |
|---|---|---|---|---|---|
| SysBP ($x$) | Deviation ($x-\bar{x}$) | Squared Deviation $(x-\bar{x})^2$ | SysBP ($y$) | Deviation ($y-\bar{y}$) | Squared Deviation $(y-\bar{y})^2$ |
| 134 | 4 | 16 | 110 | –20 | 400 |
| 132 | 2 | 4 | 140 | 10 | 100 |
| 124 | –6 | 36 | 118 | –12 | 144 |
| 132 | 2 | 4 | 150 | 20 | 400 |
| 128 | –2 | 4 | 132 | 2 | 4 |
| **Total** $\Sigma(x_i-\bar{x})=0;\Sigma(x_i-\bar{x})^2=64$ | | | **Total** $\Sigma(y_i-\bar{y})=0;\Sigma(y_i-\bar{y})^2=1048$ | | |
| Sample variance $\frac{\Sigma(x_i-\bar{x})^2}{n-1}=\frac{64}{4}=16$ | | | $\frac{\Sigma(y_i-\bar{y})^2}{n-1}=\frac{1048}{4}=262$ | | |
| Sample SD $\sqrt{\frac{\Sigma(x_i-\bar{x})^2}{n-1}}=\sqrt{16}=4$ | | | $\sqrt{\frac{\Sigma(y_i-\bar{y})^2}{n-1}}=\sqrt{262}=16.2$ | | |

SD is invariant under the change of origin, that is, it is not affected by addition or subtraction of each value by a constant. This implies that the SD of 5, 10, 15, and 20 is the same as that of 105, 110, 115, and 120. However, it is affected by scale. If you divide each value of $x$ by 4, the SD also will be one-fourth. In general,

$$\text{SD}(a+bx)=b^*\text{SD}(x).$$

Since SD is heavily dependent on mean $\bar{x}$, it can give a weird result when the mean is not an adequate central value. Thus, avoid using SD for data where mean is not appropriate such as when outliers are present or when the distribution is highly **skewed**.

The value of the variance (or of SD), just as of the mean, depends on the unit of measurement. It would be high if the unit was micrograms per liter instead of milligrams per liter. The SD of serum iron values in healthy subjects may be 25 when measured in micrograms per liter but would be only 0.025 when measured in milligrams per liter.

### *Variance and SD in Grouped Data*

Let there be $K$ intervals $(a_0, a_1)$, $(a_1, a_2)$, …, $(a_{K-1}, a_K)$ and their midpoints $x_k=(a_{k-1}+a_k)/2$, $k=1, 2, \ldots, K$. Let the frequency in the $k$th interval be $f_k$. Then, for

$$\text{grouped data: sample variance } s^2=\frac{\Sigma f_k(x_k-\bar{x})^2}{n-1},$$

and for

$$\text{grouped data: sample SD } s=\sqrt{\frac{\Sigma f_k(x_k-\bar{x})^2}{n-1}},$$

where $\bar{x}=\Sigma f_k/n$ and $n=\Sigma f_k$. As in the case of the mean for grouped data, SD also involves approximation in that all observations in an interval are assumed centered on the midpoint. This works fairly well when the width of the intervals is not large.

Sometimes, as when the data do not have a Gaussian distribution, interquartile range or range is used as a measure of dispersion in place of SD. However, SD may still be needed for specific applications such as for meta-analysis. For estimating the sample mean and SD from the sample size, median, range, and/or interquartile range, see Wan et al. [1].

### *Variance of Sum or Difference of Two Measurements*

Mean has the property that mean$(x+y)$ = mean$(x)$ + mean$(y)$. But variance or the SD does not have this feature. The SD of sum or difference of the values is not the sum or difference of SDs. In a specific situation when $x$ and $y$ are linearly independent, variance$(x+y)$ = variance$(x)$ + variance$(y)$. In general,

$$\text{variance}(x+y)=\text{variance}(x)+\text{variance}(y)+2^*\text{covariance}(x,y),$$

**TABLE S.18**
**Illustration of Relation of Variance($x - y$) with Variance($x$) and Variance($y$)**

| | SysBP | DiasBP | Pulse Pressure |
|---|---|---|---|
| | $x$ | $y$ | $x - y$ |
| | 116 | 72 | 44 |
| | 124 | 82 | 42 |
| | 145 | 89 | 56 |
| | 139 | 87 | 52 |
| | 140 | 93 | 47 |
| | 118 | 77 | 41 |
| | 136 | 85 | 51 |
| | 127 | 79 | 48 |
| | 129 | 84 | 45 |
| | 110 | 67 | 43 |
| | 115 | 79 | 36 |
| | 128 | 83 | 45 |
| **Mean** | **127.25** | **81.42** | **45.83** |
| **Variance** | **124.20** | **52.08** | **29.24** |
| **Covariance($x$, $y$)** | **73.52** | | |

where **covariance**$(x, y) = \Sigma(x_i - \bar{x})(y_i - \bar{y})/(n - 1)$. This is the sum of the product of deviations and is applicable when each value of $x$ has correspondingly one value of $y$. Note that $(x + y)$ can be calculated only in such paired case. For variance of $(x - y)$, the sign before the covariance becomes negative. For linearly independent $x$ and $y$, covariance becomes zero. The following example illustrates a situation where the difference of values is used, and such equations could be useful.

Pulse pressure is the difference between systolic pressure (SysBP) and diastolic pressure (DiasBP). A value around 45 mmHg is considered normal. A genuine low value such as less than 25 mmHg may occur in shock or aortic stenosis. A high value such as more than 60 mmHg may indicate stiffness of major arteries or a leak in the aortic valve. Thus, the pulse pressure itself is an important medical parameter irrespective of actual values of systolic and diastolic levels.

Suppose 12 persons have systolic and diastolic levels as shown in Table S.18. Pulse pressure is also shown, as well as the mean and SDs of $x$ and $y$. Note that mean$(x - y)$ = mean$(x)$ – mean$(y)$, but variance$(x - y) \neq$ variance$(x)$ – variance$(y)$. In this case, covariance$(x, y) = 73.52$—thus, the variance of pulse pressure = $124.20 + 52.08 - 2 \times 73.52 = 29.24$. This is the same as obtained in Table S.18 by directly computing the variance of differences.

In case you are interested, see the topic **confidence interval (CI) for variance**. The CI for the SD is obtained by taking the square root of the lower and upper limits of the CI for variance.

1. Wan X, Wang W, Liu J, Tong T. Estimating the sample mean and standard deviation from the sample size, median, range and/or interquartile range. *BMC Medical Research Methodology* 2014, **14**:135. http://www.biomedcentral.com/1471-2288/14/135/

## standard error (SE), *see also* sampling distribution of proportion $p$ and mean $\bar{x}$

The term *standard error (SE)* is used for the **standard deviation** (SD) of the sample summaries such as mean, proportion, correlation coefficient, median, and odds ratio. This presumes that a large number of samples are available, and this kind of summaries can be computed for each sample, which would differ from sample to sample, giving rise to the need to measure intersample variation. However, in practice, a large number of samples are not needed, and the SE can be worked out in most cases by theoretical derivations. For example, the SE of mean is generally smaller than that of sample median, which implies that means do not differ as much from sample to sample as medians do. Let there be no confusion: the SD is a measure of variation of individual values from subject to subject, and the SE is a measure of variation of sample summaries, called sample "statistics" in plural.

SEs are needed to assess the **reliability** of the estimates, for constructing **confidence intervals** (CIs), and for constructing **test criterion** for statistical tests of hypotheses. Reliability of the estimation is the inverse of the SE—the higher the SE, the lesser the reliability. As will be seen shortly, SEs heavily depend on the sample size, and for any fixed sample size, the statistics with lower SEs are considered better relative to those with higher SEs since a lower SE implies more reliability—the estimates with low SEs do not differ as much from sample to sample as do the estimates with higher SEs. For example, the SE of the mean is $\sigma/\sqrt{n}$, and that of the median from a Gaussian distribution is nearly 1.25 times the SE of the mean—thus, the mean is preferred over the median in most situations.

The most commonly used SEs are for sample mean $(\bar{x})$ and sample proportion $(p)$, which are described in the topic **sampling distribution**. For SE of attributable risk, correlation coefficient, difference between means and proportions, median, odds ratio, predicted $y$ in simple linear regression, regression coefficient and intercept in simple linear regression, relative risk, and variance, see the concerned topic on **confidence interval**. The SEs mentioned therein are based on **Gaussian conditions** that are generally fulfilled with large samples; small sample counterparts for most of these SEs are intricate.

An important feature of the SEs is that they heavily depend on sample size, and $n$ is invariably in the denominator, meaning thereby that the SE decreases as $n$ increases. This sounds intuitive also as we expect that the reliability of an estimate increases as the sample size increases. Higher sample size and consequent lower SE imply narrower CIs (which means more confidence in the results) and higher statistical **power** to detect a specified difference by tests of hypothesis.

## standardization of values, *see* *Z*-scores

## standardized death rates

Standardized death rate is the one that is "standardized" for age–sex structure of the population so that the effect of differential age–sex structure is eliminated and the rate becomes comparable across populations. Standardization is a method of adjustment for increasing the comparability. This is generally done for age differentials as just stated but can also be done for other factors. The objective is to remove the effect of differential structure of the subgroups in the two populations under comparison. The rates are then brought to a common base and thus made comparable.

Different types of **death rates** are computed depending upon groups of interest, for example, groups classified by age and gender. The most common of these is crude death rate (CDR) computed as deaths per 1000 population per year irrespective of the age and sex structure of the population. It is called *crude* as it disregards the age–sex structure of the population. If people in an area are predominantly old, a high CDR is not as bad as in an area where

the population is predominantly young. Thus, a CDR of 8 per 1000 population in Sweden should not be construed to mean that the health status is nearly the same as in India, where also the CDR is nearly the same. The CDR in this case is misleading since India has only 8% of its population with age 60 years or above, whereas Sweden has more than 20%. The death rate among old people is naturally high, and therefore the CDR becomes high. A valid comparison is obtained when the rate is recomputed by assuming the same age structure in the two countries. This is one form of standardization. The other brings the age-wise mortality pattern to a common base. Both require age-specific death rates (ASDRs) and also assumption of a standard or a reference population. This could be real or hypothetical, but in both cases, the standard is arbitrary (see the example in this section). The same can be done for sex differentials also, but let us keep that aside for our discussion. In case of age standardization, the standard may have a predefined age structure or a predefined ASDR. These two methods of standardization can give entirely different results.

### *Direct and Indirect Standardized Death Rate*

In the direct method, actual ASDRs in the study population are used on the standard population that has a predefined age structure. Thus,

$$\text{directly standardized death rate} = \frac{\Sigma_k P_{ks} d_k}{\Sigma_k P_{ks}};\ k = 1,2,\ldots,K,$$

where the population is divided into $K$ age groups.

$P_{ks}$ is the predefined standard population (in percent or count) in the $k$th age group.
$d_k$ is the ASDR in the $k$th age group of the study population.

Thus, the age structure is standardized. When such a standardization is done for two populations, any difference between the two can be ascribed to the difference in their ASDRs.

Direct standardization is possible only when ASDRs in the study population are known. If they are not known, the **indirect method** is used. In this method, predefined values of ASDRs in the standard population are used on the actual age structure of the study population. Thus,

$$\text{indirectly standardized death rate} = \frac{\Sigma_k p_k D_{ks}}{\Sigma_k p_k};\ k = 1,2,\ldots,K,$$

where

$p_k$ is the actual *study* population (in percent or count) in the $k$th age group.
$D_{ks}$ is the predefined ASDR in the $k$th age group of the standard population.

When this is done for two populations, both are then based on the same ASDRs, and any difference between the two would be due to their differential age structure.

### *Comparison between Direct and Indirect Methods*

Comparison between these two methods of standardization can be easily studied by means of an example. Consider the data in Table S.19 on age distribution of population of the United States and Venezuela in 2002, and the age-specific death rates [1].

The standard population given in Table S.19 is as suggested by the World Health Organization (WHO) [2]. We proposed the standard ASDRs in the last column. No widely acceptable standard is available for ASDRs.

Note that the CDR in the United States is nearly twice of the CDR in Venezuela. Also, note that the United States has more people in the old age group. From the formula given earlier, the directly standardized death rate is given as follows:

$$\text{for the United States} = \frac{1.7\times 8.9 + 0.2\times 17.3 + \cdots + 148.3\times 0.6}{8.9 + 17.3 + \cdots + 0.6}$$

$$= 5.5 \text{ per 1000 population,}$$

and

**TABLE S.19**
**Population and Death Rates in Different Age Groups in the United States and Venezuela, and the WHO World Standard**

| | United States 2002 | | Venezuela 2002[a] | | Standard | |
|---|---|---|---|---|---|---|
| Age Group (Years) | Population (%) | ASDR per 1000 | Population (%) | ASDR per 1000 | Population (%) | ASDR per 1000 |
| A | B | C | D | E | F | G |
| 0–4 | 6.8 | 1.7 | 11.1 | 3.5 | 8.9 | 10.0 |
| 5–14 | 14.2 | 0.2 | 21.6 | 0.3 | 17.3 | 1.0 |
| 15–24 | 14.1 | 0.8 | 19.4 | 1.8 | 16.7 | 0.5 |
| 25–34 | 13.8 | 1.0 | 15.6 | 2.1 | 15.5 | 0.5 |
| 35–44 | 15.6 | 2.0 | 12.9 | 2.4 | 13.7 | 1.0 |
| 45–54 | 13.9 | 4.3 | 9.2 | 4.5 | 11.4 | 5.0 |
| 55–64 | 9.2 | 9.5 | 5.5 | 8.8 | 8.3 | 10.0 |
| 65–74 | 6.3 | 23.1 | 3.2 | 21.5 | 5.2 | 15.0 |
| 75–84 | 4.4 | 55.6 | 1.3 | 52.4 | 2.4 | 35.0 |
| 85+ | 1.6 | 148.3 | 0.3 | 140.0 | 0.6 | 100.0 |
| **Total** | **100.0** | **8.5 CDR** | **100.0** | **4.2 CDR** | **100.0** | **5.0 CDR** |

[a] Data from United Nations Statistics Database.

$$\text{for Venezuela} = \frac{3.5\times 8.9 + 0.3\times 17.3 + \cdots + 140.0\times 0.6}{8.9 + 17.3 + \cdots + 0.6}$$

$$= 5.8 \text{ per } 1000 \text{ population.}$$

The difference has now almost vanished after standardization.

The indirectly standardized death rate is as follows:

$$\text{for the United States} = \frac{10.0\times 6.8 + 1.0\times 14.2 + \cdots + 100.0\times 1.6}{6.8 + 14.2 + \cdots + 1.6}$$

$$= 6.8 \text{ per } 1000 \text{ population,}$$

and

$$\text{for Venezuela} = \frac{10.0\times 11.1 + 1.0\times 21.6 + \cdots + 100.0\times 0.3}{11.1 + 21.6 + \cdots + 0.3}$$

$$= 3.9 \text{ per } 1000 \text{ population.}$$

This death rate for Venezuela is much lower.

Note the following for this example:

1. Venezuela has a higher population in younger age groups, and the ASDRs are also higher in younger age groups.
2. For direct standardization of death rate in the United States, ASDRs in column C are multiplied by the standard population in column F, added, and divided by the total of the standard population in column F. The numerator so obtained is the expected number of deaths that would have occurred if the age structure were standard. For direct standardization of death rate in Venezuela, its ASDRs in column E are multiplied by the standard population in column F.
3. For indirect standardization, the population (column B for the United States and column D for Venezuela) is multiplied by the ASDRs in the standard population (column G), added, and divided by the total population in the country, i.e., the total of column B for the United States and of column D for Venezuela. The numerator in this case is the expected number of deaths that would have occurred if the ASDRs were the same as in the standard population.
4. Directly standardized DR is less than the CDR in the United States because the standard population is less in the age groups where the United States ASDR is high. When the standard population is greater in higher mortality groups as in Venezuela, the directly standardized DR is greater than the CDR.
5. Directly standardized rate brings the age structure of the two populations to the same pattern. When this is done, the death rate in the United States becomes nearly the same as that in Venezuela.
6. Indirect standardization has a different effect in this case. The indirectly standardized DR is higher in the United States. The difference between the indirectly standardized rates in the United States and Venezuela is mostly due to the difference in age structure in the two countries.
7. In this example, the age structure is given in terms of percentages, but the actual population can also be used in the same formulas.
8. In this example, the two methods of standardization can give entirely opposite results. Thus, it is important that the method be correctly chosen in accordance with your objective of doing the standardization. In addition, the interpretation of the standardized rate should be proper for the method used.

The standardized rate depends heavily on the standard chosen. No universal standard is available, and this is arbitrarily chosen. If a desirable structure exists or can be constructed, then that can be chosen as the standard. If not, a structure that is of middling type or commonly seen or easy to implement can be chosen as the standard. Column F of Table S.19 gives the WHO World Standard population [2] as mentioned earlier. This actually extends to age 100 years and above and is given in 5-year intervals, but in this table, an abridged version with 85 years and above as the last group and age intervals of 10 years is given.

Since the standard is arbitrary anyway, it should be simple. This is not the case with the WHO World Standard population. The ASDRs in column G are our own standards and are simple. For interregional comparison within a country, the age structure of the total country or its ASDRs can be used as the standard.

The direct method seems more appropriate in most cases because this gives the death rate that is expected for standard age structure. But this method cannot be used when the ASDRs are not known. Also, this method should not be used when ASDRs are unstable and are based on a small number of subjects. Indirect standardization is generally used for disease mortality because of unstable ASDRs. This, when used for small groups instead of the general population, is called the standardized or adjusted mortality rate and leads to a popular measure known as the **standardized mortality ratio**. Such an adjustment can be done not only for age but also for any other factor that might influence the mortality pattern.

The illustration in our example is for population mortality as it is the most common application of standardized death rate. However, this can also be used for disease-specific mortality. For example, if age-specific death rates for circulatory diseases are known and if the purpose is to compare two age-wise diverse populations, the comparison should be based on standardized rates. For emphasizing the importance of the choice of the standard in this context, Ahmad et al. [2] show for the year 1995 that the standardized death rate due to circulatory disease in males in the United States using WHO World Standard is 285 per 100,000 population but is 372 when a Scandinavian standard is used. This reflects a large difference of 23% and underscores the heavy dependence of standardized death rate on the standard chosen for this purpose.

## standardized deviate, *see* *Z*-score

## standardized mortality ratio (SMR)

The standardized mortality ratio (SMR) is the ratio of the number of observed deaths in a study group to the number that would be

expected if the study group had the same specific rates as in a standard group (see **standardized death rates**). This procedure is the same as the indirect method of standardization. The ratio is sometimes multiplied by 100 for expressing it in terms of percentage. Thus,

$$\text{SMR} = \frac{\text{observed number of deaths}}{\text{expected number of deaths}} * 100,$$

where the denominator is based on the specific rates in the chosen standard population. These are not necessarily age-specific but could be gender-specific, exposure-specific, or specific for any other categorization. An SMR greater than 100 is interpreted as indicating that the study group has excess mortality relative to the standard. In this method, more stable rates of the larger population are applied to the smaller study group to obtain the expected number of deaths. The SMR gives a measure of the likely excess or reduction in mortality in the study group. Note that the SMRs in two groups can be compared only when they are based on the same standard population. The study and the standard group can be disease and control groups, respectively, in a case–control study or general populations of two types or any other groups of interest. The following example illustrates its application.

Stress of work, exposure to fiber dust, and other factory environmental factors are known to cause excess mortality in the staff of a textile mill. Their age distribution and calculation of SMR are shown in Table S.20.

Expected deaths are obtained in this example by applying the national age-specific death rates (ASDRs) to the number of textile workers in different age groups. Since the national rate for the age group 25–34 years is 3.0 per 1000 population, the expected deaths in 400 workers of this age group are 3.0 × 400/1000 = 1.2; the same goes for other age groups. If the total number of observed deaths is 10 and the expected deaths based on the national rates are 6.8, then from the formula given earlier, SMR = (10/6.8)100 = 147. This shows that the mortality level of textile workers (in this mill) was 147% of the national average. This is 47% higher than that experienced by the national population. Excess mortality in textile workers was never in doubt, but SMR delineates the exact magnitude of this excess.

For a similar but more extensive application of SMR, see Johansen and Olsen [1]. They investigated mortality from amyotrophic lateral sclerosis (ALS) and other chronic disorders among male employees of electric supply companies in Denmark. The 21,236 men included in the study accrued nearly 303,000 person-years of follow-up. They observed 14 deaths from ALS when only 6.9 deaths were expected on the basis of the national ASDRs. This yielded an SMR of nearly 200. This means that these employees are dying from ALS nearly twice as much as the general population. These excess deaths can be attributed to the risks present in the company environment.

**TABLE S.20**
**Calculation of Standardized Mortality Ratio (SMR) in Textile Workers**

| Age Group (Years) | ASDR[a] in the National Population per 1000 | Textile Workers | |
|---|---|---|---|
| | | Number of Workers | Expected Deaths |
| 25–34 | 3.0 | 400 | 1.2 |
| 35–44 | 5.0 | 300 | 1.5 |
| 45–54 | 8.0 | 200 | 1.6 |
| 55–64 | 25.0 | 100 | 2.5 |

## STARD statement

An acronym for Statement for Reporting Studies of Diagnostic Accuracy, STARD consists of a checklist of 25 items and a flow chart that authors can use to ensure that all relevant information is present in their report on research on diagnostic accuracy of a medical test [1]. This is one of the resources used to improve reporting of diagnostic accuracy studies, and it is realized that complete and informative reporting can only lead to better decisions in health care.

Medical tests are quite commonly used in clinical setups for providing a certain degree of assurance and to confirm the diagnosis for a disease or any other health condition. The term *medical test* is generic and refers to any method of obtaining additional information on the patient, and includes not just laboratory and imaging tests but also history and examination. Thus, it can be only signs and symptoms. These tests help in initiating a treatment and in deciding when to modify or stop the treatment. However, the problem is that these tests rarely, if ever, provide infallible results, and the validity of the results depends on a host of factors such as condition of the patient, method of administering the test, the inherent qualities of the test, quality of reagents, care in following the recommended procedure, etc.

Whenever a new test is developed (call it *index test*), it is expected that its performance will be evaluated against the existing procedure (or a reference standard) and its superiority would be established. The superiority could be either in terms of efficacy as measured by sensitivity and specificity (or predictivities) or could be efficiency in terms of convenience, cost, and time. The test is tried on a series of subjects and results are reported. It has been observed that sometimes this reporting is incomplete, and the reader is not able to comprehend all aspects. STARD statement is an attempt to standardize the reporting so that nothing is missed and all steps of the study are properly described. Its first version appeared in 2003. The latest version (2015) is given in Table S.21, and the flow chart is in Figure S.18.

Ever since STARD statement has been issued, it is being increasingly used for reporting of diagnostic studies, and the reporting quality seems to be improving [2]. Cheung et al. [3] used this format to report assessment of breast specimens with or without calcifications for diagnosing malignant and atypia for mammographic breast microcalcifications without mass, and Alcoba et al. [4] used this to report results of their study on proadrenomedullin and copeptin in pediatric pneumonia.

## TABLE S.21
## STARD Statement

| Section and Topic | No | Item |
|---|---|---|
| | | **Title or Abstract** |
| | 1 | Identification as a study of diagnostic accuracy using at least one measure of accuracy (such as sensitivity/specificity, predictive values, or area under the curve) |
| | | **Abstract** |
| | 2 | Structured summary of study design, methods, results, and conclusions |
| | | **Introduction** |
| | 3 | Scientific and clinical background, including the intended use and clinical role of the index test |
| | 4 | Study objectives and hypotheses |
| | | **Methods** |
| Study design | 5 | Whether data collection was planned before the index test and reference standard were performed (prospective study) or after (retrospective study) |
| Participants | 6 | Eligibility criteria |
| | 7 | On what basis potentially eligible participants were identified (such as symptoms, results from previous tests, inclusion in registry) |
| | 8 | Where and when potentially eligible participants were identified (setting, location, and dates) |
| | 9 | Whether participants formed a consecutive, random, or convenience series |
| Test methods | 10a | Index test, in sufficient detail to allow replication |
| | 10b | Reference standard, in sufficient detail to allow replication |
| | 11 | Rationale for choosing the reference standard (if alternatives exist) |
| | 12a | Definition of and rationale for test positivity cutoffs or result categories of the index test, distinguishing prespecified from exploratory |
| | 12b | Definition of and rationale for test positivity cutoffs or result categories of the reference standard, distinguishing prespecified from exploratory |
| | 13a | Whether clinical information and reference standard results were available to the performers or readers of the index test |
| | 13b | Whether clinical information and index test results were available to the assessors of the reference standard |
| Analysis | 14 | Methods for estimating or comparing measures of diagnostic accuracy |
| | 15 | How indeterminate index test or reference standard results were handled |
| | 16 | How missing data on the index test and reference standard were handled |
| | 17 | Any analyses of variability in diagnostic accuracy, distinguishing prespecified from exploratory |
| | | **Results** |
| Participants | 18 | Intended sample size and how it was determined |
| | 19 | Flow of participants, using a diagram (Figure S.18) |
| | 20 | Baseline demographic and clinical characteristics of participants |
| | 21a | Distribution of severity of disease in those with the target condition |
| | 21b | Distribution of alternative diagnoses in those without the target condition |
| | 22 | Time interval and any clinical interventions between index test and reference standard |
| Test results | 23 | Cross-tabulation of the index test results (or their distribution) by the results of the reference standard |
| | 24 | Estimates of diagnostic accuracy and their precision (such as 95% confidence intervals) |
| | 25 | Any adverse events from performing the index test or the reference standard |
| | | **Discussion** |
| | 26 | Study limitations, including sources of potential bias, statistical uncertainty, and generalizability |
| | 27 | Implications for practice, including the intended use and clinical role of the index test |
| | | **Other Information** |
| | 28 | Registration number and name of registry |
| | 29 | Where the full study protocol can be accessed |
| | 30 | Sources of funding and other support; role of funders |

## statistical reviews

As is true for almost all **empirical research**, nearly all medical research articles are full of numbers. Proper designing and execution, satisfactory collection of data, adequate processing of data, and correct interpretation are the key for appropriate conclusions, as well as for assessment of the confidence in those conclusions. In an editorial in a reputed magazine *Science*, McNutt [1] stated that there have been far too many cases where the quantitative analysis of those numbers has been flawed, causing doubts about the authors' interpretation and uncertainty about the result. Since subject matter experts generally are not in data analysis, statistical reviews are gaining increasing attention. Effective 1 July 2014, *Science* has established a Statistical Board of Reviewing Editors, consisting of experts in various aspects of statistics and data analysis, to provide better oversight of the interpretation of observational data. Many medical journals have also realized the importance of statistical reviews and have expert biostatisticians in their panel.

There are a large number of studies that have established that statistical quality, and hence of conclusions, is rather poor in many articles. This happens because the spread of knowledge of statistical methods among medical professionals has not kept pace with the speed with which statistical applications are done due to wide availability of software packages. This availability seems to have propelled many researchers to use these methods as a **black box** without understanding the intricacies. This has resulted in an urgency for statistical reviews.

In a comparison of articles in two top medical journals, namely, the *New England Journal of Medicine* and the *Nature Medicine*, Strasak et al. [2] observed that while nearly 90% of the articles they reviewed contained inferential statistics, the documentation of

statistical methods applied in the articles was generally poor or insufficient, and recommended that closer attention to statistical issues should be considered to raise the standards. In another study by the same authors [3] on Austrian journals, the findings were even worse.

The problem is compounded by the availability of huge data that are now stored online for various interactions and transactions. According to EMC International Data Corporation Digital Universe Studies [4], there were close to 4 zetabytes ($10^{21}$) of information stored in 2013 with doubling every 2 years. This, however, lacks quality but is almost indiscriminately used to draw inferences. Expert data analysts that can filter meaningful messages out of such noisy data are not many yet. In the context of medicine, results of laboratory and imaging investigations and genotyping may be of good quality, but there is a question mark on the quality of research articles that are now so vociferously published across the world. It is not just the analysis and interpretation, but also the quality of data that go into empirical studies can be questionable and seems to have been rarely assessed. It may be a good idea if each journal periodically undertakes audit of what it has been publishing, and implement the lessons learned.

## statistical significance, *see* significance (statistical)

## statistics, *see also* biostatistics

The term *statistics* is used in two senses—(i) as plural as in day-to-day language for data and (ii) as singular for the science dealing with data. As plural, statistics are just plain facts, mostly numerical measurements or counts, and it is in this sense that we talk about industry statistics, geographical statistics, and even health statistics such as how many people are dying of what causes and how many doctors of various types we have in a community. These statistics are collected for reference or for information. They can be primary (directly collected from the source) or secondary (collected by someone else and put to use by somebody else). For example, the government may collect data on a number of cases admitted of various diseases in different hospitals so that they are primary for them, and researchers use them for analysis as secondary data. In addition, different data can have different **scales of measurement** such as nominal, ordinal, and metric. These characteristics are utilized for deciding the method of summarizing the data and their presentation for easy understanding and to be able to use them later for analysis.

As singular, statistics is a science, a discipline that extracts meaning out of data. This can be viewed as comprising two distinct entities (Figure S.19). The first is *data science* where there is no probability component, such as data mining from enormous data that are now generated online or otherwise, which is done to explore for patterns and configurations that can help, for example, in marketing or in assessing health sector demands by different segments of population. This can also be termed as quantitative information focused on specific groups. Collection and presentation of data in terms of tables, graphs, and maps are part of this exercise.

Statistics is best defined as the science of managing uncertainties [1], particularly their measurement, control, and communication. Basically it is an inferential science where probabilities play a vital role, and all conclusions are attached with a measure of uncertainty. Processing and analysis of data are the main tools that propel this activity. Models that express a complex phenomenon in simple terms, such as regressions and structural equations, are built up based on probability theory so that most features of the data are captured and the model can be effectively utilized in practice. Many times extrapolations are done such as forecasting of future events, and sometimes interpolations for intermediary unobserved values are done using these models. However, the main strategy requiring probabilities is inferring about a "population" from a "sample." When successful, making inferences becomes much less expensive and possibly more accurate with this strategy as better methods can be used to obtain data on a fraction of subjects instead of all the subjects. Sample **designs** and design of experiments such as clinical trials help in controlling uncertainties, and quantities like ***P*-value** measure the uncertainties and are used for communicating the results.

Inferential statistics too can be subdivided into two distinct components—one that deals with estimation and the other that is concerned with testing of hypothesis. These are discussed in detail under the topics **estimate** and **confidence intervals (the concept of)** for estimation, and the topic **testing of hypothesis (philosophy of)** for testing. Both these methods are based on samples and are heavily based on probabilities.

**Uncertainties** pervade so much in medical sciences that statistics in this discipline has acquired a new identity called medical **biostatistics**. This "branch" of statistics is more medical than mathematical, whereas statistics by itself is mostly a mathematical science.

## stepwise methods, *see also* best subset method of choosing predictors

In a **regression model** setup, including logistic regression, stepwise methods are used for variable selection when a large number of candidate variables are available as regressors. Including all these regressors together (called the "enter" method) (i) may compromise the applicability of the model and lose its parsimony; (ii) may require an inordinately large sample that may not be feasible; (iii) may cause the cost of obtaining data on so many variables to become prohibitive; and (iv) may increase the chance of multicollinearity that adversely affects the efficiency of the regression models. For example, for predicting thyroid status, more than 100 signs and symptoms can be identified such as tremors, hoarseness of voice, altered skin texture, and brittle nails. Including all of them in a regression will require an enormous sample, and even if this kind of sample is available, the model so obtained based on so many regressors can hardly be used. Thus, it is imperative to look for a subset of the regressors that can still predict or explain a phenomenon with a reasonable degree of validity. The best option is to select the variables based on their biological relevance for the outcome—include ones that are more relevant and exclude the others. When the biological picture is not clear, or when all the variables seem to have nearly equal relevance, methods based on the **statistical significance** of the variables in explaining the outcome can be used. In many situations, statistical selection of variables tends to overfit—more variables would be added than required. Thus, it is advisable to use a strict criterion for addition of the variables.

Variable selection by itself is not an end. Ultimately, the model finally arrived at must serve the purpose. Beware that the model so chosen may have no biological relevance—that is not the consideration in this method and this must be separately assessed.

Stepwise is one of the many methods available for variable selection. This is one of a set of statistical methods for automatically selecting a "better" (although not necessarily the best) subset of **regressors** for regression analysis. The dependent (outcome) in the regression can be quantitative (ordinary regression), qualitative (logistic regression), or hazard (Cox regression), and the method is applicable to all types of regressions. According to Morozova et al. [1], such automatic stepwise methods in regression often perform poorly in terms of both the variable selection and estimation of the coefficients, especially when the number of independent variables is large and multicollinearity is present. The model arrived at from these methods tends to work well on the data used for their development but works poorly on a new set of data. If a subset of variables is to be treated as a group because of biological relevance or for any other reason, this method does not allow that because it is blind to such configurations unless specific provision for this is made at the time of analysis. Yet, stepwise algorithms remain the dominant method in medical and epidemiological research for variable selection. Also, these automatic selection methods can render an explanatory model ineffective since the objective of explanatory models is to find the overall adjusted effect, and the adjustment in case the case of automatic selection is only for the variables that remain after such selection. All these are large sample methods; small samples relative to the number of variables under consideration can give weird results. The most commonly used stepwise methods are forward selection, backward elimination, and a combination of both of these, also known as stepwise method. For alternative methods, see Morozova et al. [1].

### *Forward Selection*

In the forward selection method, the start is made with no variable in the model, and sequentially one is added at a time depending on a preset criterion. Once a variable is included, it stays. The criterion used to decide whether to add a particular variable to an existing model could be one of the following in ordinary quantitative regression: (i) The statistical significance of the reduction in the **residual sum of squares** (RSS) resulting from including that variable in the model. Incidentally, this is the same as the increase in the regression sum of squares whose significance is tested by ***F*-test**. This test will give the ***P*-value** for each variable that measures the statistical significance. Add that variable first for which the reduction in RSS has the least *P*-value (i.e., statistically the most significant). The process is repeated for the remaining variables. You can preset another criterion such as any variable with reduction yielding a *P*-value greater than, say, 0.10 will not be added. This procedure is called *P*-value to add. (ii) A similar procedure is when *P*-value is obtained directly for the variable and not for the RSS. Statistical software packages generally have provision for these two procedures. (iii) The third criterion could be the difference in the value of the **coefficient of determination** $\eta^2$ (which becomes **multiple correlation coefficient** $R^2$ in case of **linear regression**) when the variable is added. In this case, statistical significance would take you back to the first criterion, but you can decide on the basis of the absolute addition in place of the statistical significance. Do not add variables that you find are not substantially increasing the value of $\eta^2$. (iv) There are other criteria such as **Akaike information criterion**, **adjusted $R^2$**, and univariate **correlation coefficient** with the outcome variable. All these may give the same result. For logistic and Cox regression, the criterion changes to the **chi-square**–based **deviance**. Further details of forward selection method have been provided by Harrell [2].

For forward selection in action, see Akbar et al. [3] who used this as one of the methods for selecting best predictors of retention time of phenolic compounds in a chromatography. Wang et al. [4] used the forward selection method to confirm their findings regarding best biomarkers of neonatal sepsis identified by other methods.

### *Backward Elimination*

Now consider starting with all the potential regressors and delete one by one as per their nonsignificance assessed by a prefixed criterion, and the regressors once deleted remain outside the purview of inclusion. In the case of forward selection, the regressors are added one at a time based on their significance, but in backward elimination, the regressor with, say, the highest *P*-value is deleted first. This method deletes all nonsignificant regressors, whereas forward selection retains only the significant ones. To understand the difference, just realize that the regressors not significant are not necessarily the same as the complement of the significant ones. This method is more appropriate when the candidate variables are not too many and you want to throw out some that are less relevant. On the other hand, forward selection is better when you have a large number of variables and you want to select a few most relevant ones.

Pina et al. [5] used the backward elimination method for selecting variables related to pain intensity in cancer, and used the criteria of $P = 0.2$ for deletion. Bucsa et al. [6] also used this method for evaluating demographic characteristics, comorbidities, medications, and laboratory monitoring, and quantified the patients with serum creatinine and potassium levels above the upper normal limit in logistic regression to identify significant predictors of combination therapy in hospitalized patients on angiotensin-converting enzyme inhibitors.

### *Real Stepwise Method*

This is a combination of the forward selection and backward elimination in the sense that the regressors once included by forward selection are assessed again at the next stage, and deleted if any of them loses statistical significance. Thus, the option of exclusion of one or more of the existing regressors is exercised after inclusion of a new regressor as per their significance. This can help in fine-tuning the model more than any of the two previously described methods. The significance can be tested either by using *t*-test for the regression coefficients or criteria such as *F*-to-enter and *F*-to-remove based on the entire model at hand at successive stages. These and *P*-values have to be decided beforehand. It is very important not to delegate your responsibility to the computer—you should examine the model for its biological adequacy so that it is medically justified and can be properly explained.

## stillbirth rate/ratio

Generally, pregnancy terminations are considered stillbirths when the fetus or the infant is born dead and weighs at least 500 g or has body length (crown–heel) of at least 20 cm. When these measurements are unavailable, the gestational age should be at least 28 weeks. Such deaths are also called late fetal deaths. Volume of stillbirths in a community can be measured by one of the two ways as follows:

$$\text{stillbirth ratio} = \frac{\text{stillbirths}}{\text{live births}} * 1000$$

$$\text{stillbirth rate (SBR)} = \frac{\text{stillbirths}}{\text{still} + \text{live births}} * 1000.$$

The first has only live births in the denominator, whereas the second has live births + stillbirths; thus they are called "ratio" and "rate," respectively.

Stillbirths are a great public health issue as they jeopardize the life and health of the mother besides the moral and ethical questions. After expecting a child, a stillbirth can be a devastating trauma for the family. Some 2.6 million stillbirths occurred worldwide in 2009 according to the first set of comprehensive estimates [1]. Maternal obesity is considered as the dominant risk factor. Intensive efforts are made to control such births such as those outlined by Yoshida et al. [2].

## stochastic processes

Stochastic process connotes a system that changes over time in an uncertain manner. Because of uncertainty, probability is an integral part of such a system, hence the name stochastic. Consider a single characteristic such as amount of drug present in the body. This changes over time in an uncertain manner—thus it is a stochastic process. Sex does not change at all over time, and age does not change in an uncertain manner—thus none of these is a stochastic process. Characteristics such as amount of drug in the body can be continuously measured over time that will give rise to continuous time process, or can be measured each morning to give rise to discrete time process.

The characteristic (e.g., amount of drug) at time $t$ can be denoted by $x(t)$, which is now a **random variable**, and $t$ can be any value between, say, 0 and $T$ for continuous time process and would be $t = 1, 2, \ldots, T$ for a discrete time process. On the other hand, a characteristic such as developing a sign of a disease is a discrete event (the sign will develop or not develop), which will give rise to discrete state process, which can also be for continuous or discrete time. Discrete state process is for counts, whereas continuous state process is for continuous variables. Thus, there are four types of stochastic processes: continuous state, continuous time; continuous time, discrete state; discrete time, continuous state; and discrete time, discrete state.

A basic discrete state process generates **Poisson distribution** when (i) the probability of at least one occurrence of the event in a given time interval is proportional to the length of the interval (if the time interval is large, the probability of occurrence is also high); (ii) the probability of two or more occurrences of the event in a very small time interval is negligible; and (iii) the numbers of occurrences of the event in disjoint time intervals are mutually independent. Consider deaths occurring in a hospital where the chance of death occurring in any given 30 h is more than the chance of occurrence in any given 10 h; the chance of occurrence of two deaths within a short span of time is negligible; and the number of deaths occurring on any day does not depend on how many occurred on any other day. Thus, all the conditions are fulfilled for deaths in a hospital in the normal course for this to be called a *Poisson process*. Since deaths occur in an uncertain manner (cannot be predicted in advance how many deaths will occur), it is a stochastic process. This process can be studied with the help of Poisson distribution, for example, to find the probability that more than 4 deaths will occur in the next 24 h. The number of accidents occurring in a county in a day and the number of cases of myocardial infarction admitted in a hospital in a week are other examples of variables with Poisson process.

There are several types of stochastic processes such as Weiner process, Dirichlet process, and Gaussian process, but the most talked about is the Markov process.

### *Markov Process*

This is the process under which change in status (such as from health to disease) depends only on the existing condition, and the past or the history does not play any role. The transition depends only on the current value and is independent of past values. Also, there must be only a few states such as full health, mild disease, severe disease, and death. But the most severe restriction in Markov process is that the probability of transition from one state to another is the same for all the subjects. This is named after the Russian mathematician Andrei Markov who proved this in 1909 [1].

Andrei Markov

When a birth takes place, the population count increases by one from the existing count, and when a death takes place, the population decreases by one from the existing count. If the chance of birth is the same and the chance of death also remains the same whatever the population count, the **birth–death** is a Markov process as far as count of people is concerned. What happens next does not depend on where the process started—whether the population is 1000 or 100,000, a birth will increase it by one and a death will decrease it by one. As long as you know the current count, the number of births or deaths that occurred previously does not matter. The same is true for an *arrival–departure process* such as for patients coming in and going out from emergency in a busy hospital. In this case, departure could be by way of admission to the regular ward from emergency, by patients leaving against medical advice, by death, or by discharge. The only condition is that the probability of arrival and departure of each patient should be the same. This may not be so, particularly for departure, since it depends on the severity of the condition of the patient. If the chance varies from patient to patient, it is not a Markov process.

Realize that Markov is a stochastic process in the sense that the change from one state to another depends on chance. It is not deterministic and cannot be predicted. Second, under the conditions just stated, a Markov process stabilizes—the population in different states will become stable at some time in the future. When stable conditions exist, modeling by Markov process helps to estimate the predictivity of transition from one state to another.

In a clinical setup, the conditions of Markov process may be fulfilled for a patient moving from disease to healthy to disease states where relapse occurs. Recurrent conditions such as epilepsy and angina episodes may also be eligible for modeling by Markov process. Borisenko et al. [2] used this to study four states of inoperable patients with functional mitral value regurgitation in German settings while getting repair of percutaneous mitral valve. These are New York Health Association (NYHA) functional classes reported by them as NYHA-I to IV. Markov process modeling helped them to work out the transition probabilities from one state to another. They used this to do cost–utility analysis.

## stochastic variables, *see* variables

## stopping rules (for trials), *see also* O'Brien–Fleming procedure, Lan–deMets procedure

Stopping rules are used in clinical trials to decide to stop a trial either when enough evidence is available for the desired efficacy or when sufficient evidence is available for the futility of continuing the trial. Suppose you decide a priori that a regimen is not worth pursuing unless it has at least 30% efficacy, and decide to do a trial on $n = 500$ subjects that should give at least $500 \times 0.3 = 150$ positive responses on average in repeated trials. Since the standardized Gaussian (normal) deviate (which can be used in this case in view of large $n$) $z = (x - 150)/\sqrt{(500 \times 0.3 \times 0.7)} > 1.96$ gives $x > 170.084$, at least 171 successes are needed to be reasonably assured that the efficacy is at least 30% at 2.5% level of significance. If after 400 subjects, only 70 respond positive, you know that if all the remaining 100 respond positive, the number will not become 171. Thus, it is futile to continue the trial, and the trial should be stopped. Even if 100 respond in the first 400 subjects that gives estimated efficacy of 25%, the chance that at least 70 will respond out of the remaining 100 at this rate is $P[z > (70 - 25)/\sqrt{(100 \times 0.25 \times 0.75)}] = P(z > 10.4)$, which gives $P < 0.001$. Since the chance is less than 1 in a thousand (in fact, almost zero), it seems futile to continue the trial.

As already stated, an ongoing trial can be stopped for two reasons. One is that adequate evidence emerges of the desired efficacy of the regimen, and the other reason is that the efficacy is found too low to go any further. The first is stopping for efficacy, and the second is stopping for futility. Futility has special appeal for phase II trial because the primary aim of this phase is to provide proof of concept in the sense that the regimen has minimum efficacy. Futility will save it from going through the expensive phase III. Stopping for efficacy has application to both phase II and phase III but has special appeal to phase III as it can save substantial time and resources. For these reasons, stopping rules are relatively relaxed for phase II trials as they allow early stopping for futility if the concept is not found sufficiently rigorous. Phase III trials do not want to stop early unless the evidence of efficacy is firm. This is further explained in the following.

### *Stopping for Futility*

Statistical changes in an ongoing trial are done in a manner that the prefixed **level of significance** and statistical **power** of detecting a prespecified effect remain unaltered. The procedure to decide futility becomes intricate in view of these constraints, and assistance of a good software package is required. Among many procedures, the following, called *Simon method*, is relatively simple to understand [1].

As an illustration of a two-stage design, consider $\pi_0 = 0.20$ as the null, $\pi_a = 0.30$ as the alternative, power $(1 - \beta) = 0.90$, and $\alpha = 0.05$. Software can be asked to find a suitable $n_1$ for an interim look at the data in the first stage and propose a final $n$ in the second stage. The algorithm that minimizes the expected requirement of total $n$ gives $n_1 = 19$ and $n_2 = 35$ for a total of $n = 54$ in this case [2]. This is more than the size obtained for a single-stage trial for the same power.

However, there is a chance that the trial is stopped early in the case of two-stage design. The software will also tell that if the number of positive responses is ≤4 in the first stage out of $n_1 = 19$, it is futile to continue, as the efficacy of 0.30 is extremely unlikely to accomplish at completion when the number of responses is so few at the first stage.

The computer package may take a substantial time to arrive at these numbers, as the computations are enormous. You can see how complicated this procedure could become if there are two arms (case and control) and many stages. For such rules for some other values of $\pi_0$ and $\pi_a$, see Simon [1].

Single-stage design promises a large $n$ upfront, but this can expose such a large number of needy patients to an unproven regimen that may also have side effects. A two-stage **group sequential design** can partially be saved from these vagaries. Stopping rules for futility for two-stage design can also be worked out by following a similar procedure with the help of an appropriate software package, and the method can be extended to multistage sequential design and **multiarm trials**.

### *Stopping for Efficacy*

This requires that the level of significance α is judiciously apportioned at each appraisal such that the total Type I error does not exceed α. A simple though inadequate approach is to spend α in $K$ equal parts if $K$ appraisals are planned including the final analysis of all the data. This means that the hypothesis at the first appraisal is tested at $\alpha/K$ level of significance, the second at $2\alpha/K$ level of significance, and the last at α level of significance. More generally, in this case, level of significance at the $k$th appraisal is $\alpha(\tau_k) = \tau_k\alpha$, where $\tau_k$ is the proportion covered at the $k$th appraisal. If $\alpha = 0.05$ and $K = 2$ (only one midterm appraisal), use $\alpha = 0.025$ level of significance to test the null at the midterm stage. This implies for two-tailed Gaussian $z$-test that the critical value will be ±2.24 (from Gaussian table for $\alpha = 0.025$) in place of the conventional ±1.96. This, in fact, is more stringent than it apparently looks because, at this stage, the sample size available is also one-half of what would be eventually available. If the results meet this criterion, reject the null of equality of the test and the control group, conclude that you have enough evidence available in favor of the alternative hypothesis, and stop the trial.

Statistically, the equal-α spending procedure just stated is too liberal than what it should be to control Type I error, and rejects the null relatively easily. It sounds reasonable to have a procedure that is even more stringent at initial stages. For equally spaced group sequential designs, one such popular procedure is due to **O'Brien–Fleming**. An improvement over this is due to **Lan–deMets**, which is flexible and accommodates unequally spaced appraisals. This can be used for equally spaced sequential designs as well. This preserves the overall Type I error regardless of timing of the appraisals but makes it difficult to stop the trial early unless there is a strong evidence of the desired efficacy.

No matter which method is used, there would be a bias involved in early stopping. If you plan $n = 400$ subjects in a trial and stop it after analysis of data on 150 subjects since the data tell you that strict significance has been reached, the question arises whether these 150 are as representative of the population as 400 would have been. If the first 150 subjects are not random, further bias is apparent. For further details, see Chow et al. [3].

## stratified randomization, *see* block, cluster, and stratified randomization, and minimization

## stratified random sampling

Stratified random sampling is the random selection of the units after dividing the population into relevant groups. A big drawback of **simple random sampling** (SRS) is that it can fail to give adequate representation to one or more subgroups of interest. For example, in a study on the relationship of maternal complications with parity, it is necessary that women of different parities are included in the sample. The definition of the **sampling unit** in this case could be a currently pregnant woman reporting in a particular group of antenatal clinics. An SRS of size, say, 60 women in this case can yield a sample in which by chance parity 4 is not represented at all or inadequately represented. Note that the objective of the study is not met unless all parities have adequate representation. The procedure therefore should be to first divide the **sampling frame** by parity status such as 1, 2, 3, 4, 5, and 6+ and then draw an independent SRS of size, say, 10 from each division. Such a division of the frame is called **stratification** and each division is called a **stratum**.

Consider the data on waist–hip ratio (WHR) and triglyceride (TG) levels of 100 subjects in the total population in Table S.22. In this table, the strata could be WHR categories as given at the bottom of the table. One may decide how many units to be selected from different strata—they need not be equal. This procedure of choosing the sample is called stratified random sampling (StRS). The characteristic chosen for stratification is either the one suspected to affect the variable under study or the one that makes groups of interest for which separate results are required. After this, the sample would adequately represent the stratifying characteristic but not necessarily other factors that may be of consequence. For example, in a study on mortality in diabetes mellitus, the subjects may be stratified by the maximum level of plasma glucose, but the sample may still not be representative for obesity, age–gender, coexisting diseases, patient cooperation, etc. All these can affect the prognosis or

**TABLE S.22**
**Five-Year Survival Rate of Gastric Cancer Cases with Different Types of Operation**

| Type of Operation | Total Cases | Five-Year Survival | | |
|---|---|---|---|---|
| | | Rate (%) | Survived | Died |
| Distal subtotal gastrectomy | 678 | 37.2 | 252 | 426 |
| Total gastrectomy | 466 | 32.4 | 151 | 315 |
| Proximal subtotal gastrectomy | 354 | 20.1 | 71 | 283 |
| **Total** | **1498** | **31.6** | **474** | **1024** |

the outcome. Thus, care is always needed in extrapolation of results even after adopting stratified sampling.

In Table S.13 in **simple random sampling**, the subjects are divided into thin, normal, and obese according to WHR ≤ 0.89, 0.90 ≤ WHR ≤ 1.09, and WHR ≥ 1.10. These are the strata in this case. With this categorization, the SRS of 16 subjects marked with * in this table happens to contain 2 thin, 11 normal, and 3 obese subjects. However, the actual numbers of thin, normal, and obese in the population according to this categorization are 14, 38, and 48, respectively. The obese are clearly underrepresented in the sample. If you divide the population in the first instance and then take a sample, the result could be very different. A commonly adopted strategy in this case is to take a **proportionate sample** from each stratum. In this case, 16 out of 100 gives a sampling fraction of 0.16. Applying this to the strata gives a sample of 2 from the first stratum, 6 from the second stratum, and 8 from the third stratum. These, when randomly drawn by us, are subject numbers 28 and 62 from the first stratum; 5, 21, 33, 47, 76, and 95 from the second stratum; and 8, 54, 58, 63, 69, 73, 85, and 99 from the third stratum. You may get different subjects. The means are now calculated separately for each stratum. These means the TG levels of subjects in our sample are 122.50, 155.83, and 169.62, respectively. These are multiplied by the respective stratum size and divided by the population size, i.e.,

$$\text{mean in stratified sample: } \bar{x}_{st} = \sum N_k \bar{x}_k / N,$$

where $N_k$ is the size of the $k$th stratum, and $\bar{x}_k$ is the mean obtained for the $k$th stratum. In our sample,

$$\bar{x}_{st} = (122.50 \times 14 + 155.83 \times 38 + 169.62 \times 48) / (14 + 38 + 48) = 157.8.$$

The stratum size is now the "weight" for calculation of the mean. A similar formula is required to calculate the sample standard deviation. This sample mean for StRS is slightly greater than the population mean of TG in this example. It is natural for such a difference to arise in any sampling. Now the sample has adequate representation of each WHR category.

In the case of proportionate samples as in this example, the probability of selection of each subject is nearly the same in different strata. The advantage with this is that the sample becomes self-weighting. This can be explained as follows.

Proportionate sample implies that the sample from each stratum is in the same proportion as in the population. This means

$$\frac{N_k}{N} = \frac{n_k}{n} \text{ for all the } k \text{ (i.e., for each stratum).}$$

When this is substituted, we get

$$\text{mean in stratified sampling: } \bar{x}_{st} = \Sigma n_k \bar{x}_k / n.$$

This can be easily seen to be the same as the usual sample mean. Thus, in the case of proportionate samples, the mean for the stratified sample can be calculated just as a usual unweighted mean is calculated. This property is called *self-weighting* of the sample.

Nonetheless, proportionate samples are not a requirement for stratified sampling. If 5 subjects are selected from each stratum in this example, the probability of selection is 5/14, 5/38, and 5/48 for subjects in the first, second, and third strata, respectively. Such unequal probabilities do not render StRS invalid. Many medical investigations use equal samples from strata of different sizes. It is important to realize that the probabilities for different units can be unequal despite random samples, and they impose a restriction of the type illustrated by the formula of $\bar{x}_{st}$. However, in this case, the estimate of mean in different strata would have different precision, and it is difficult to justify mixing estimates of varying precision for obtaining the combined estimate.

## STROBE statement

Strengthening of reporting of observational studies in epidemiology (STROBE) is a guideline for fully reporting the results from an observational study. This contains a checklist of 22 items on the contents of the article on results of observational studies, and is endorsed by a large number of biomedical journals. Some points are separate for prospective, retrospective, and case–control studies, and others are common for all observational studies. For example, for cohort studies, one item is "summarize follow-up time" (e.g., average and total amount), which is not required for other studies.

The statement requires that scientific background and rationale for the study should be clearly stated and also requires a cautious overall interpretation of results considering the objectives, limitations, multiplicity of analyses, results from similar studies, and other relevant evidence. A discussion of the existing external evidence is particularly important for studies reporting a small increase in risk.

As of now, STROBE does not specifically require that new findings be put into context by conducting a systematic review of other similar studies. This obviously would be a positive feature as "this could alert us about consistency of findings, allow exploration of sources of heterogeneity and would ensure, in the same way as it does for randomized trials, that research effort is not spent on rediscovering the same finding again" [1].

For details and the latest on STROBE, see Ref. [1].

## structural equation models

Structural equation models (SEMs) define a set of data analysis tools that allow for the testing of theoretically derived and a priori–specified causal (or just dependence) hypothesis [1]. Most dependence hypothesis exploring methods such as analysis of variance and regression can be regarded as special cases of SEM, but its immediate predecessors are **path analysis** and confirmatory **factor analysis**. SEM can be viewed as a combination of these two methods, where path analysis provides the structure of the relationship and the factor analysis provides the latent variables. **Latent variables** are those that cannot be directly observed such as mental capabilities, courage to face adverse situations, and beliefs. These are also called latent factors or common factors or constructs because they are mostly construed to be explained by a combination of observed variables. The observed variables are also termed as *exogenous variables* and the latent variables as *endogenous variables*. SEMs try to reduce a large set of observed variables to a small set of latent variables based on the covariance structure—thus incorporating the measurement errors by adjusting the correlations and the path coefficients accordingly. Path analysis by itself assumes that all measurements are perfect, while that is not so with SEMs. The development of structural models follows the seminal work of Joreskog [2] in 1973, who presented a general method of estimating a linear structural equation system, and the work is still in progress.

As in all **model** fitting, the process of building up SEM involves stages such as initial model conceptualization, specification of parameters and estimation of these parameters, model fitting and assessment of its adequacy, and model modification as needed after this assessment. Of these, the most challenging is model conceptualization, which requires brainstorming and meticulous thinking so that the specified model represents the theories of the underlying biological process fairly well. Lack of consonance between the two can render the entire exercise futile. The conception of this model can come from the path analysis, which helps to visualize the structural part, and the factor analysis, which is based on the measurement part. The next stage of parameter specification requires that the number of parameters, $K$, must be substantially less than the number of unique covariances of the observed variables. Mostly the method of **maximum likelihood** is used for estimation of the parameters, although distribution-free methods such as generalized least squares also exist. The preceding two steps would provide the model. Whether this is an adequate model or not is the question answered in the third stage. This is generally done by chi-square test that compares the observed values with the values predicted by the model. An improvement over chi-square is provided possibly by **Akaike information criterion** that penalizes for a large number of parameters. If the model so arrives is good to your satisfaction, the work is done, and if not, the exercise may give some leads of what changes are needed.

Since the method itself is in the making, the reporting of the results of SEM too is not standardized yet. McDonald and Ho [3] have presented a detailed account of what should be reported and how. See Lee et al. [4] for SEM in action. They have used the SEM approach for studying the impact of noise on self-rated job satisfaction and health in open-plan offices in China and Korea.

For more details of SEMs, see Loehlin [5].

## Studentized range, *see* Tukey test for multiple comparisons

## Student *t*-distribution

William Gosset, who wrote under the pseudonym of Student, first proposed *t*-test while optimizing yeast composition in 1908 [1]. This is defined as

$$\text{Student } t\text{: } t_{\upsilon} = \frac{z}{\sqrt{\chi^2/\upsilon}}, \tag{S.3}$$

where $z$ is a standard Gaussian variable, i.e., $z \sim N(0, 1)$, and $\chi^2$ has chi-square with $\upsilon$ degrees of freedom (df's), which is independent of $z$. The statistic $t$ also has the same df's as the chi-square in the denominator. Student $t$ has different distribution for different df's just as people of different age has different distribution of systolic blood pressure. Review the topic on the concept of **degrees of freedom** if that is not clear. The shape of the distribution of Student $t$ is symmetric, which gives a feeling that it is Gaussian but has relatively a larger variance (Figure S.20). For large df's, the distribution is approximately Gaussian, and for infinite df's, it is exactly Gaussian.

William Gosset

Student $t$ has wide applications in statistical testing of hypothesis problems. For example, this is used for testing the statistical significance of difference in means (paired and unpaired), one-sample comparison with prespecified mean, and regression coefficient. Test for **regression coefficient** is separately presented, and others are discussed under the topic **Student *t*-test**. All these can be shown to have the same basic form as given in Equation S.3 under the null hypothesis when **Gaussian conditions** hold. For example,

$$\text{Student } t\text{-test (one sample): } t_{n-1} = \frac{\bar{x} - \mu_0}{s/\sqrt{n}}$$

actually is

$$t_{n-1} = \frac{(\bar{x} - \mu_0)/\left(\dfrac{\sigma}{\sqrt{n}}\right)}{\sqrt{\dfrac{\Sigma(x-\bar{x})^2/\sigma^2}{n-1}}},$$

where $\sigma$ cancels out from the numerator and the denominator. If you carefully notice, under Gaussian conditions, the numerator $(\bar{x} - \mu_0)/\left(\dfrac{\sigma}{\sqrt{n}}\right)$ is a standardized Gaussian deviate $z$ =

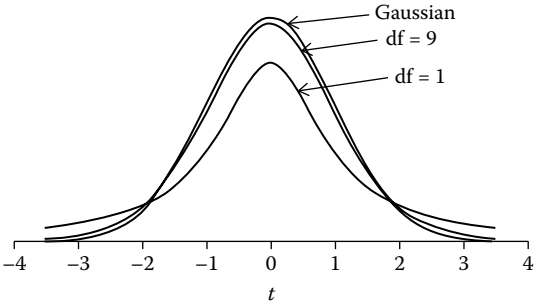

**FIGURE S.20** Student $t$ distribution has larger variance but approaches Gaussian as df's increase.

(estimate – mean)/(SE of the estimate) under the null hypothesis that the population mean is $\mu_0$, and the denominator $\sqrt{\frac{\Sigma(x-\bar{x})^2/o^2}{n-1}}$ is $\sqrt{\chi^2/\upsilon}$ with $\upsilon = n - 1$ since $\Sigma(x-\bar{x})^2/o^2$ is chi-square, being the sum of squares of the standard Gaussian deviates, provided the observed values are independent. Also it is theoretically established that the denominator is independent of the numerator. All Student *t*-tests can be similarly explained.

1. Student. The probable error of mean. *Biometrika* 1908 Mar:g(1):1–25. http://www.york.ac.uk/depts/maths/histstat/student.pdf

## Student *t*-tests

Two common problems handled by Student *t* are discussed in this section. First is comparing the mean in a sample of subjects with a prespecified value, and the second is comparing the mean in one sample with that in another sample. The two samples could be paired or may represent two different groups. **Gaussian conditions** are required for Student *t* to be valid. Among others, it is also used for **comparison of two regression coefficients** as separately explained.

### *Comparison with a Prespecified Mean*

Let the interest be in finding whether patients with chronic diarrhea have the same average hemoglobin (Hb) level as normally seen in healthy subjects in the area. Suppose the normal level of Hb is 14.6 g/dL. This is assumed to be known and fixed for the present example. Since chronic diarrhea can only decrease the Hb level, and not increase it, it is a one-tailed situation. In an unlikely event of sample mean being >14.6 g/dL, the evidence is immediate that Hb level does not decrease in chronic diarrhea patients, and there is no need to proceed further. A higher mean can occur by chance in the sample.

Suppose further that a random sample of 10 patients with chronic diarrhea is investigated, and the average Hb level is found to be 13.8 g/dL. Thus, the sample mean is lower than normal, and this could occur if the sample happens to comprise subjects with a lower level. Such subjects are not uncommon in the healthy population as well. If another sample of 10 patients is studied, the average could well be 14.8 g/dL. Can it be concluded with reasonable confidence based on the previous sample that patients with chronic diarrhea indeed have a lower Hb level on average?

There is only one sample in this example, and the comparison is with the known average in the healthy subjects. It is a one-sample problem, although the comparison is of two means—one observed in the sample and the other known for the healthy population.

The null hypothesis in the preceding example is $H_0$: $\mu = 14.6$ g/dL. Since the possibility of a higher average Hb level in patients with chronic diarrhea is ruled out, the alternative hypothesis is one-sided. That is, $H_1$: $\mu < 14.6$ g/dL. If $H_0$ is rejected, then $H_1$ is considered true.

The first step is to choose an appropriate criterion to test this hypothesis. The value of this criterion is then calculated assuming that $H_0$ is true. Then the probability of the observed or a more extreme value is obtained. This is the ***P*-value**. If this probability is very small, $H_0$ is considered not plausible and rejected. The conclusion reached is that $H_1$ is true. If the *P*-value is not sufficiently small, say not less than 0.05, the null hypothesis is conceded with the rider that this does not imply that $H_0$ is accepted. It is just that it cannot be rejected on the basis of that sample because sampling fluctuation is not adequately ruled out as a likely explanation.

Heuristically, the answer depends on the magnitude of the difference between the sample mean and the known mean of the healthy subjects. In the preceding example, this difference is 13.8 – 14.6 = –0.8 g/dL. This magnitude is assessed relative to the expected variation in means from sample to sample. This variation is measured by the standard error (SE) of the mean, $\sigma/\sqrt{n}$. In a rare case when $\sigma$ is known, the criterion is

$$\text{Gaussian test: } z = \frac{\bar{x} - \mu_0}{\sigma/\sqrt{n}}.$$

This follows Gaussian distribution provided the underlying distribution of *x*'s is also Gaussian. The value of this criterion is compared with its value in the Gaussian table to find if the *P*-value is sufficiently small for rejecting the null.

In practice, the SD $\sigma$ would be rarely known and is replaced by its estimate *s*. Thus, the criterion for this setup is

$$\text{Student } t\text{-test (one sample): } t_{n-1} = \frac{\bar{x} - \mu_0}{s/\sqrt{n}},$$

where $\mu 0$ is the value of the mean under $H_0$. This criterion is valid under mild conditions such as the observations are independent. In the context of this example, this means that the Hb level in one subject should not have any influence on the level in other subjects. This is clearly satisfied in this example, but an example is given later where independence is violated. The other condition is that the distribution of *x*'s themselves is Gaussian. This condition can be relaxed if the sample size is large. The higher the value of *t*, the greater the chance that the sample has not come from a population with mean $\mu 0$. In that case, the decision to reject $H_0$ would have less chance of error. When this probability of Type I error is low, say less than 0.05, $H_0$ can be safely rejected. For *t* in the formula given in the just mentioned equation, df = $(n - 1)$. This is specified as a subscript of *t*.

Consider again the example of the Hb level in chronic diarrhea patients. Suppose that in a random sample of size $n = 10$, the levels in g/dL are as follows:

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| 11.5 | 12.2 | 14.9 | 14.0 | 15.4 | 13.8 | 15.0 | 11.2 | 16.1 | 13.9 |

These give mean $\bar{x} = 13.8$ g/dL and SD $s = 1.67$ g/dL. The hypothesis under test is that the average Hb level in the patients with chronic diarrhea is the same 14.6 g/dL that is normal in healthy subjects. Thus, $H_0$: $\mu = 14.6$ g/dL. The alternative as already explained is $H_1$: $\mu < 14.6$ g/dL. In this case, under $H_0$,

$$t_9 = \frac{13.8 - 14.6}{167/\sqrt{10}} = -1.51.$$

A statistical package gives $P(t < -1.51) = 0.0827$. This is the probability of getting the sample mean this much or more extreme in favor of $H_1$. Since this $H_1$ is one-sided, the probability required is also one-tailed. The distribution of *t* is also symmetric just as is the Gaussian distribution. Thus, $P(t < -a) = P(t > a)$. In this case, *P* is greater than 0.05 because 1.51 is less than the critical value 1.833 of Student *t* at 9 df. Thus, the chance is more than 5% that $H_0$ is true. Therefore, this $H_0$ cannot be rejected. The difference between the sample mean 13.8 g/dL and the population-normal 14.6 g/dL is not statistically significant. This sample does not provide sufficient

evidence to conclude that the mean Hb level in chronic diarrhea patients is less than normal.

The conclusion in this example is partly the result of the high variability in the Hb level in the sample patients: whereas it was only 11.2 g/dL in one patient, it was 16.1 g/dL in another. Widely scattered values gave a high value of sample SD *s* and led to the expectation of high intersample variability. Consequently, it became difficult to say anything definite about the lower mean Hb in the patients.

### *Difference in Means in Two Samples*

Now let us consider a situation where two samples are available. These could be from two groups such as males and females, patients suffering from disease A and disease B, or patients of age 20–39 years and age 40+ years, or could be from one group only, which is measured before and after a treatment. The latter is called a **paired samples** setup. The general form of the criterion in a two-sample setup is

$$\text{Student } t \text{ (two-sample)} = \frac{\text{sample mean difference} - \text{population mean difference under } H_0}{\text{estimated SE of difference in sample means}}.$$

This takes a different form in paired setup compared with that in independent samples setup.

*Paired samples setup*: The procedure used to calculate the SE of the difference in case of paired samples is different from that of unpaired samples. Observations are said to be paired when they are obtained twice for the same subject, such as blood pressure (BP) before and after treatment or erythrocyte sedimentation rate (ESR) measured by two methods in the same group of subjects. They are also considered paired when the subjects in the two groups are one-to-one matched such as in some case–control studies. This is an example where the observed values are not independent. In the case of paired samples, obtain the difference between the pairs as $d_i = (x_{2i} - x_{1i})$, $i = 1, 2, \ldots, n$, where $n$ is the number of pairs. These differences are independent of one another. Calculate the SD of these $d$'s as usual by

$$s_d = \sqrt{\frac{\sum (d - \bar{d})^2}{n-1}}.$$

The null hypothesis of interest for rejection in this case is $H_0$: $\mu_1 = \mu_2$ (or $\mu_1 - \mu_2 = 0$), where $\mu_1$ is the mean of one population and $\mu_2$ is the mean of the other population. For example, these could be mean diastolic BP before and after treatment, mean ESR obtained by two methods, or mean of any other such population. Under this $H_0$, the criterion, from the formula given earlier for one sample setup, is

$$\text{Student } t_{n-1} \text{ (paired samples)} = \frac{\bar{d}}{s_d/\sqrt{n}}.$$

Basically, this is the same as the one-sample formula for $H_0$: $\mu_d = \mu_1 - \mu_2 = 0$. After the differences are obtained, the paired sample problem reduces to a one-sample problem for these differences with the null hypothesis that the mean difference is zero. When Student *t* is significant, the null is rejected. Since the point estimate of the difference $(\mu_1 - \mu_2)$ is $(\bar{x}_1 - \bar{x}_2)$, this is the estimate of the treatment effect in the case of measurements before and after treatment.

Given below are the serum albumin levels (g/dL) of six randomly chosen patients with dengue hemorrhagic fever before and after treatment. The null hypothesis is that the mean after is the same as the mean before, i.e., the treatment of dengue fever (this treatment is mostly symptomatic) has not altered the albumin level.

| | | | | | | |
|---|---|---|---|---|---|---|
| Before treatment | 4.8 | 4.1 | 5.3 | 3.9 | 4.5 | 3.8 |
| After treatment | 5.2 | 4.9 | 5.2 | 4.8 | 4.6 | 4.4 |
| In this case, difference, $d_i$: | 0.4 | 0.8 | –0.1 | 0.9 | 0.1 | 0.6 |

Mean differences, $\bar{d} = 0.45$, and SD of differences, $s_d = 0.3937$.

Thus, under $H_0$: $\mu_1 = \mu_2$,

$$t_5 = \frac{0.45}{0.3937/\sqrt{6}} = 2.80.$$

Since there is no assertion in this case that the albumin level after the treatment will increase or decrease, the alternative hypothesis is $H_1$: $\mu_1 \neq \mu_2$. For this $H_1$, a two-tailed probability $P(|t| > 2.80)$ is needed. For $(n - 1) = 5$ df, this is $P = 0.038$ from statistical software. Because the probability of a Type I error is sufficiently small ($P < 0.05$), reject $H_0$ and conclude that the mean albumin level after the treatment is different from the mean before the treatment.

*Unpaired (independent) samples setup*: Paired observations are highly desirable in the situation of our example, but it is possible that the albumin investigations could not be done before the treatment started. Suppose that a separate group of six similar but randomly drawn patients was investigated for albumin level before the treatment. Thus, there are a total of 12 patients—6 in each group. The two groups are now independent. In such cases, the first step is to check that the variances in the two groups are not widely different since this is one of the requirements for validity of Student *t*. Generally, a ratio $s_1^2/s_2^2 < 3$ is considered adequate if each $n$ is around 10 or 15. If $n$ is smaller, even $s_1^2/s_2^2 < 4$ can also be tolerated. If $n$ were 30 or greater, a ratio of 3 may be too high. The conventional statistical test for $H_0$: $\sigma_1^2 = \sigma_2^2$ is $F = s_1^2/s_2^2$ with higher SD in the numerator. However, it is necessary for this test that the underlying distribution is Gaussian, at least approximately. One should prefer the **Levene test** for equality of variances because it is valid even in the case of departure from the Gaussian pattern. The Student *t*-test is applicable even when the underlying distribution is very different from Gaussian provided that $n$ is sufficiently large. The Levene test is also applicable in this situation. Now there are two possibilities.

(i) *Population variances are equal*: In this case, the samples can be combined to obtain a more reliable estimate of the variance. This is given by

$$\text{pooled variance: } s_p^2 = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{(n_1 - 1) + (n_2 - 1)},$$

where $s_1$ is the SD in the first sample and $s_2$ in the second sample, and $n_1$ is the size of the first sample and $n_2$ of the second sample. Now, calculate

$$\text{SE (mean difference)} = s_p\sqrt{1/n_1 + 1/n_2}.$$

S

From the formula given earlier, the criterion for testing $H_0$: $\mu_1 = \mu_2$ is

Student $t$ (two independent samples): $t_{n_1+n_2-2} = \dfrac{\bar{x}_1 - \bar{x}_2}{\sqrt{s_p^2(1/n_1 + 1/n_2)}}$,

where $\bar{x}_1$ and $\bar{x}_2$ are the respective sample means. The degrees of freedom for $t$ in this formula are $(n_1 + n_2 - 2)$.

(ii) *Population variances are unequal*: You would be rarely interested in equality of variances per se. Statistically, it is kind of a **nuisance parameter** that we have to deal with anyway. Realize though that when means are very different, there is a good likelihood that variances would also differ. A group with higher mean may have higher variance too. In that sense, equality of variances becomes a major issue. If the population variances are known to be unequal or if the sample variances are very different from one another, then the samples cannot be pooled and the formula for pooled variance is not valid. In this case, calculate the separate variance Student $t$ (two independent samples) as

$$t_v = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{s_1^2/n_1 + s_2^2/n_2}},$$

where the degrees of freedom

$$v = \frac{\left(s_1^2/n_1 + s_2^2/n_2\right)^2}{\dfrac{\left(s_1^2/n_1\right)^2}{n_1 - 1} + \dfrac{\left(s_2^2/n_2\right)^2}{n_2 - 1}}.$$

The case of unequal variances in two samples is popularly known as the **Welch test**. Note that this reduces to the usual Student $t$ in case of equal $n$ and equal variances.

For an example, consider the same data as in the previous example, but now the observations are for 12 different patients in place of pairs of observations on 6 patients. The patients measured before treatment are not the same as those measured after the treatment. In this case,

mean albumin level in before treatment group, $\bar{x}_1 = 4.40$ g/dL
SD in this group, $s_1 = 0.5797$ g/dL
mean albumin level in after treatment group, $\bar{x}_2 = 4.85$ g/dL
SD in this group, $s_2 = 0.3209$ g/dL

In this example, $n_1 = 6$, $n_2 = 6$ so that df $= n_1 + n_2 - 2 = 10$.

For such small samples, the SDs do not differ too much and we can pool them. Thus,

$$s_p^2 = \frac{5 \times 0.5797^2 + 5 \times 0.3209^2}{10} = 0.2195.$$

Therefore,

$$t_{10} = \frac{4.40 - 4.85}{\sqrt{0.2195(1/6 + 1/6)}} = -1.66.$$

The alternative hypothesis continues to be two-sided. The probability of getting these sample values or more extreme in favor of $H_1$ when $H_0$ is true is $P(|t| > 1.66)$. From a statistical package, this $P$-value is 0.1272, which is large relative to the usual $\alpha = 0.05$. Thus, the null hypothesis of equality of means cannot be rejected. The evidence is not strong enough to conclude that the mean albumin level after the treatment is any different from the mean before the treatment.

### *Some Features of Student* t

Our examples very aptly illustrate the following features of Student $t$:

1. The $t$-test is based on the magnitude of the difference and its variance but ignores the fact that five of the six patients in the paired setup in our example showed some rise. If the interest is in the *proportion* of subjects showing a rise and not in the magnitude of the rise, then use the methods for proportions.
2. The same difference is statistically significant in the paired setup in our example but not significant in the unpaired setup. This occurred because the difference in the paired setup is fairly consistent, ranging from –0.1 to +0.9 g/dL. Each patient served as his/her own control. In the unpaired setup, the interindividual variation is large. A paired setup may be a good strategy in many situations. Advice of matching of controls with cases is given since such matching simulates pairing and reduces the effect of at least one major source of uncertainty.
3. The size of the sample is 6 in the paired setup and a total of 12 in the unpaired setup. Both are small. Recall that Student $t$ is valid only when means follow a Gaussian pattern. When $n$ is large, this pattern is nearly always Gaussian due to the **central limit theorem**, whether or not the underlying distribution of the individual measurements is Gaussian. Where $n$ is small (say, less than 30), the $t$-test is valid only if the underlying distribution is Gaussian. This is the assumption made in these examples. If the underlying distribution is far from Gaussian and $n$ is small, other methods such as nonparametric (e.g., **Wilcoxon**) tests are used.
4. One should always examine whether the data meet the requirement of $\sigma_1^2 = \sigma_2^2$. The ratio $s_1^2/s_2^2$ in this example is $0.5797^2/0.3209^2 = 3.26$. For a sample of size 6 each, this may be within the tolerance limit. Many statistical software packages would automatically test this. In case of violation, the $P$-value is obtained by using Welch $t$ in place of the pooled variance $t$. Some statistical software would also do this automatically or would provide $P$-values based on both types of $t$. However, caution is required when using a separate variance estimate. When the variances are different, it is clear that the two populations are different. Then equality of means may not be of much consequence as the distribution pattern is different anyway. If it is known, for example, that body mass index is much more variable in women than in men, equality of their means would rarely help. Thus, use of a separate variance estimate in a two-sample $t$ is rare.
5. In some cases, e.g., in estimation of antibody titers, the conventional (arithmetic) mean is not applicable and the **geometric mean** (GM) is used to measure the central value. The logarithm of GM has the same features as the

usual arithmetic mean. Thus, the Student *t*-test and other means-based tests can be carried out on geometric means after taking the logarithm of the values. However, in this case, the conclusions will be applicable to log values and not to the values themselves. You should carefully examine whether or not the results obtained on log values can be extended to the original values. In many cases, such extension does not cause any problem.

6. All statistical tests give valid conclusions for the groups and not for individuals. The *t*-test is for the *average* values in the groups. Individuals can behave in an unpredictable way even when the difference in means is statistically significant. Thus, use caution in applying results to individual subjects. Clinical features of a person may completely override the means-based conclusions.
7. Statistical inference is not valid for nonrandom samples. In our examples, we may not have mentioned this explicitly, but this is implied.
8. The fundamental requirement for the Student *t*-test is that the sample values are independent of each other. In our unpaired example, the albumin level in one patient is not going to affect the level in any other patient, and thus the values are independent. In the paired example, there is no such independence because of paired setup, but once the difference is obtained, these differences would be independent. Paired *t*-test is based on the differences.

   Consider the blood pressure measured for two or more subjects belonging to the same family. **Familial aggregation** for medical measurements is well known, and thus values belonging to the members of the same family are not independent. The Student *t*-test cannot be used for such values unless family effect is first removed. Ingenious methods may be needed for removing this effect. Most practical situations do not have this constraint and Student *t* can be safely used.

### *Effect of Unequal* n

The Student *t*-test for two independent samples does not have any restriction on $n_1$ and $n_2$—they can be equal or unequal. However, equal *n*'s are preferred because of two reasons: (i) When a total of $2n$ subjects are available, their equal division among the groups maximizes the statistical **power** to detect a specified difference; and (ii) two-sample *t* is not robust to $\sigma_1^2 \neq \sigma_2^2$ unless $n_1 = n_2$. If a smaller sample has larger variance, the problem is aggravated. To reiterate what was stated earlier, if you have prior knowledge or find from the data that $\sigma_1^2 \neq \sigma_2^2$, further testing for equality of means may not be relevant since the distributions are different anyway owing to different SDs. If the interest persists, Welch test should be used in place of Student *t*.

Although equal *n*'s are desirable, in many medical situations, this may not be a prudent allocation. In clinical trials, many times controls are easy to investigate and more than one control per case could be a good strategy. Thus, it is not necessary to have equal *n*, although that is highly desirable.

## study designs, *see* designs of medical studies (overview)

## subjective probability, *see* probability

## sum of squares (types of)

Sum of squares (SS) actually is $\Sigma_i x_i^2$, where $x_1, x_2, \ldots, x_n$ are the observed values for *n* subjects in the sample, but the convention in statistics is to adjust all the values by the mean. Thus,

$$\text{sum of squares} = \Sigma_i (x_i - \bar{x})^2,$$

where $\bar{x}$ is the sample mean. This is the numerator of variance, and many times it is used as its surrogate. For example, in **analysis of variance** (ANOVA), it is the sum of squares that is broken up into its components (and later divided by the degrees of freedom) but is called components of variance. The setup in **one-way ANOVA** is that there are *J* groups and $x_{ij}$ is the *i*th value ($i = 1, 2, \ldots, n_j$) in the *j*th group ($j = 1, 2, \ldots, J$), which actually implies that there are $n_1$ observations from the first group, $n_2$ from the second group, etc.; the mean of the *j*th group is denoted by $\bar{x}_{\bullet j}$ and the overall mean is denoted by $\bar{x}$. With these notations, the basic equation in one-way ANOVA is the following:

$$\begin{aligned}\Sigma_{ij}\left(x_{ij} - \bar{x}_{\bullet\bullet}\right)^2 &= \Sigma_{ij}\left[(x_{ij} - \bar{x}_{\bullet j}) - (\bar{x}_{\bullet j} - \bar{x}_{\bullet\bullet})\right]^2 \\ &= \Sigma_{ij}\left[(x_{ij} - \bar{x}_{\bullet j})^2\right] - 2\Sigma_{ij}\left[(x_{ij} - \bar{x}_{\bullet j})(\bar{x}_{\bullet j} - \bar{x}_{\bullet\bullet})\right] \\ &\quad + \Sigma_{ij}\left[(\bar{x}_{\bullet j} - \bar{x}_{\bullet\bullet})^2\right] \\ &= \Sigma_{ij}\left[(x_{ij} - \bar{x}_{\bullet j})^2\right] + \Sigma_{ij}\left[(\bar{x}_{\bullet j} - \bar{x}_{\bullet\bullet})^2\right]\end{aligned}$$

(the middle term can be shown to be zero for independent values),

where it is evident that the first term on the right side is based on the deviation of values from the mean of their respective group (thus within-groups SS), and the second term is based on the deviation of group means from the overall mean (thus between-groups SS). This gives

$$\text{total SS} = \text{within-groups SS} + \text{between-groups SS}.$$

These SSs are divided by the respective df's to get mean squares. Within-groups SS is also called **error sum of squares** and when divided by the df becomes **mean squares due to error** (MSE). The term on the left side is deviation of values from the overall mean (thus is the total SS).

It can be similarly shown for a **two-way ANOVA** that total SS = Factor 1 SS + Factor 2 SS + Interaction SS + Error SS. Similar decomposition of the total SS can be obtained for multiway ANOVA. Factorwise SS measures how much each factor is contributing to the total variation—thus helps in assessing whether the factors have significant effect or not when compared with error SS. Factor SS should be substantially higher than the error SS for the effect of the factor to be statistically significant. This is done by the ***F*-test**. However, the "devil is in the details" as explained next.

### *Type I, Type II, and Type III Sums of Squares*

When the number of factors is two or more, various SSs can be calculated in at least three different ways. Each has relevance in a particular setup. We are explaining these for two-way ANOVA, but they are similar for higher-way ANOVA.

*Type I SS*: For a two-way ANOVA, Type I SS measures the effect $\alpha$ of factor 1 after adjusting for $\mu$ (overall mean), measures the effect $\beta$ of factor 2 after adjusting for $\alpha$ and $\mu$, and measures the effect of the interaction $\theta$ after adjusting for $\beta$, $\alpha$, and $\mu$. Thus, this assesses the incremental effect of parameters in the order they appear in the

model or in the order as specified by the user while using the software package. If the effect of sex and body mass index (BMI) is being studied on creatinine level, Type I SS would require that you decide which is to be entered first. If sex is the first, Type I SS would assess the significance of sex when nothing is in the model (or just overall mean), would assess the significance of BMI when sex is in the model (called sex-adjusted effect), and would assess the interaction when both sex and BMI are in the model.

*Type II SS*: This is used for assessing the effect of those parameters that do not include it. Since interaction includes both $\alpha$ and $\beta$, Type II SS measures the effect $\alpha$ after adjusting for $\beta$ and $\mu$ but not $\theta$, and the effect $\beta$ after adjusting for $\alpha$ and $\mu$ but not $\theta$. This is rarely used.

*Type III SS*: This assesses the effect of parameters after adjusting for all other terms in the model. Thus, this measures the effect $\alpha$ after adjusting for $\theta$, $\beta$, and $\mu$, and the effect $\beta$ after adjusting for $\theta$, $\alpha$, and $\mu$. This is the same as Type II SS if there is no interaction in the model. This type of SS is used to assess the significance of the effect of each factor when all other parameters are present in the model. In our example, this means the effect of sex when BMI and interaction are in the model, the effect of BMI when sex and interaction are in the model, and the effect of interaction when sex and BMI are in the model.

*Type IV SS:* This is used for missing cells such as in partially factorial designs. It is similar to Type III SS but has different strategy because of missing cells. If there are no missing cells, Type IV SS is the same as Type III SS.

In most situations, Type III SS is computed and it serves the purpose well. This also is the default in most statistical software packages.

## surrogate measurement/variables

Surrogate measurement is a proxy for something that is either impractical to measure or is impossible but still gives a fairly good idea about the state of the difficult-to-measure characteristic. For example, most people want to keep their income confidential, but an idea of income can be obtained by the type of housing, cars, amenities in the household, etc. Health is almost impossible to measure because of its high personal overtones but can be guessed by finding the number of sick days, severity of disease if any, feeling of comfort, etc. A perfect measurement for many medical conditions is not available, and a surrogate is used, perhaps as much as the surrogate has positioned itself as the actual measurement of interest. Severity of disease is a common example for which no widely acceptable scale is available, and scales such as APACHE and Glasgow coma scale are used as surrogates. In a clinical setup, sometimes color of lips and fingernail beds are used as surrogates for the outcome of heart surgery. Many times cholesterol level is used as a surrogate endpoint, whereas actual interest may be in incidence of cardiac ailments; waiting for these ailments to develop may take an inordinately long time. In all such cases, it is important that the characteristic being used as a surrogate is strongly linked to the actual condition of interest.

The problem arises when conclusions are drawn on the actual variable of interest forgetting that only surrogate has been studied. For example, significant reduction in mean cholesterol level by a regimen should not be construed to mean that cardiac ailments will definitely reduce or the cardiac mortality will reduce. There might be several other intervening factors that determine the final outcome. In addition, it stands to reason that the conclusions based on surrogates will have a larger margin of error than what it apparently looks.

Bárcena et al. [1] found CD94hi/HLADR+ phenotypic profile a useful marker for natural killer cell clonality that otherwise lacks a universal and specific marker, and Moriceau et al. [2] examined whether time-to-treatment can be a good surrogate for cancer quality of treatment in France, and came to a negative conclusion.

## surveys, *see* sample surveys

## survival analysis, *see also* survival curve/function

Survival is complementary to mortality, but the statistical use of the term is for the duration of survival. The duration of survival of a patient with cancer after detection of malignancy and median survival time in cases of leukemia are common examples. Sometimes the interest is in the percent surviving for a specific duration such as 5-year survival rate of end-disease renal patients on dialysis.

In a generic sense, the method of survival analysis is used to analyze any data on duration. This can also be understood as time-to-event data. It could be duration of stay in the hospital, birth interval, duration of immunity, or any such duration. This could be any failure such as occurrence of metastasis, toxicity, or relapse, or any success such as recovery, discharge from the hospital, or disappearance of a complaint. Although the term *survival* is used generically to measure time to any event under investigation, other terms such as *waiting time*, *failure time*, and *transition time* are also used. A follow-up is an integral part of survival studies.

Why can durations not be analyzed as any other quantitative variable? One difficulty is that most durations do not follow a Gaussian pattern, and the distribution is highly skewed. This is not a big problem since this can be overcome by choosing a sample of sufficiently large size. The real problem arises when the duration for some subjects is not fully observed because the person moves out, dies due to an unrelated cause, refuses to cooperate after some follow-up, etc. The primary cause of such incomplete observation, however, is that the end-point event does not occur during the follow-up period, and the study is terminated after a fixed time. All these result in incomplete segments, called **censored observations**. The method

of survival analysis is geared to meet this contingency, which can rarely be handled in any other manner.

Consider an example of the follow-up of breast cancer cases. If the follow-up is for a period of 6 years, there might be cases that are still alive at the end of the follow-up. Their duration of survival will not be known except that the survival is for *at least* 6 years. Also, in such a follow-up study, there is always a likelihood that some patients withdraw or are lost to follow-up. If a patient was alive at the 24-month visit and lost thereafter, the survival duration again is not known. The statistical technique used to analyze such data is called the survival analysis.

Knowledge of survival pattern helps patients and physicians to decide which treatment or health strategy to prefer and when. For example, short-term survival may be better (in terms of percentage) with one regimen and long-term survival with another. The survival patterns are lessons to health care providers and seekers about what to expect in specific cases. The actual experience in individual cases would be different but not too much if the survival curves are valid and reliable.

Besides modeling the survival pattern over a period of time, the other objectives of survival analysis are (i) to investigate factors that influence the duration of survival, (ii) to compare two or more modalities of treatment for survival pattern, and (iii) to estimate the future survival of individuals or groups with specified features.

It goes without saying that for any duration, there must be a beginning (entry) point and an end (exit) point. In the case of diabetes, for example, the beginning point can be the time when the first symptom was noted, when the disease was first diagnosed, when blood glucose level showed a significant rise from the preexisting level, when a treatment was started, or any other point of time considered appropriate. The end point can be when blood glucose was first noted back to the normal level, when the treatment was discontinued, when the person is able to eat normally, or any other. Because of multiple choices, you can see that both the beginning point and the end point should be sharply defined for the duration to be observed without error. It is also important to decide whether the intervening period between the entry and exit has to be completely free of events and whether the occurrence of other events is to be disregarded.

For convenience of presentation, we are using the terms *survival* and *mortality* in this section, but they really mean change from one state to the other. Survival time is any time-to-event duration.

## Survival Data

Although the duration of survival can be studied in terms of probability of outcome within a specified duration, such as chance of recurrence of sputum positivity in tuberculosis within, say, a 6-month period after the treatment was discontinued in the middle of the course, this is a by-product of the survival analysis that models the entire pattern of survival from the beginning to the end point. When a single summary measure is required, the choice goes to median survival time instead of the mean because of the highly skewed distribution of survival time in most situations. Some other features of survival are described in this section.

In the case of survival studies, not all the subjects of a cohort necessarily begin at the same point of time. The subjects can join and leave at any point. The joining time is considered time zero, and all durations are measured from this point. Other features of survival time can be described as follows.

Survival time data can be obtained in a variety of ways. The method of data collection can have important implications on the interpretation and sometimes on the method of analysis because different collection methods give rise to different kinds of censoring.

The most convenient method is to take a cross-sectional random sample of subjects who have the condition of interest and inquired when the condition started. This can be done when the starting point is known to the subjects, and they are capable of reporting it correctly. Thus, this method can be adopted when the beginning point is well defined, for example, by appearance of complaints. It can be defined by laboratory assessment if the concerned laboratory report is available with each subject. Any other record of interest may also help to identify the time of beginning of the condition. If there is no follow-up, the end point will remain unknown in this method. One alternative in this situation is to consider the duration for all subjects as censored at the time of inquiry. This censoring for *all* subjects is not admissible. In fact, incomplete segments for survival analysis should not be far too many, certainly not more than the complete segments. If there are no or very few subjects with complete segments, the pattern would not be known, and no worthy analysis can be performed.

The only way to assess the end point in case of a cross-sectional sample is to follow up the subjects until the end point is reached. This should be done for at least one-half of the subjects who should be a random subsample so that no bias creeps in. Because of such a follow-up, the strategy does not remain cross-sectional but hopefully would still provide a representative picture of the target population.

The second method of collection of survival time data is to take a general sample from the target population and inquire if they ever (or in the previous few years) had the condition of interest—when it started and when it finished. This entirely depends on proper recall and again can be adopted for those conditions only for which the beginning and the end points are known to the subjects.

The third method is to take a random sample of those who have just experienced the end point and find out when the condition started. For example, this can be adopted for death due to Alzheimer's disease. The time of start of the disease can be obtained by inspecting records. A great advantage of this method is that there are no incomplete segments. See if it is easier for you operationally to assess survival time in this manner.

The most satisfying but perhaps most difficult method is to enroll people at the beginning of the condition and follow them up till the end point. If the end point is death, the total follow-up period could be quite long. Thus, the observation can be terminated after a prefixed reasonable time so that most subjects are able to reach the end point. Some who do not could be considered as censored values.

Before proceeding ahead with survival analysis, assess that there is no discernible pattern in the durations or in reaching to the end point when arranged by enrolment. After reordering by the date of entry, confirm that deaths and durations of survival are randomly distributed (see **censoring of observations**). Early recruiters should not have unusually high (or low) death rates or unusually long (or short) duration of survival.

## Statistical Measures of Survival

Because of censoring of values, computation of mean survival time is problematic. If these are ignored, the mean of the remaining known durations can be unreliable and biased: unreliable because the $n$ available now is smaller whereas actually there are more subjects in this study, and biased because the subjects excluded from this calculation due to incomplete observations could be very different. If this is the duration of survival after a treatment, the persons alive at the end of follow-up are exactly those that may have benefited. If these censored observations were included with truncated values, the means would obviously be an underestimate. Thirdly, survival duration is known to have highly skewed distribution since some people

tend to survive for long duration. And for such highly skewed values, it is known that mean is not a valid representative value.

If mean is not appropriate for survival, which summary measure should we use? The choice immediately falls on median, which is much less affected by such vagaries. **Median survival time** is indeed used as a summary to measure the central value of the duration of survival and to compare two or more groups, although you can see that this too is not completely free of bias because of incomplete segments.

For varying durations, one can think of person-years as the denominator and come up with an average such as 2.7 deaths per person-year. Although person-year can take care of the incomplete segments, this annoyingly considers first year after treatment on the same pedestal as say the fifth year. Clearly this is not true for survival as the risk of death increases as the time passes—one because of advancing age and two because the effect of treatment generally wanes. Thus, a measure such as deaths per person-year (or 100 person-years) is also ruled out for survival studies.

Beside median survival time, the other appropriate measure is survival rate such as 5-year survival rate. This can be adjusted for censored values through the method of survival analysis, and is a commonly used parameter in survival studies.

The most popular measure of duration of survival is **expectation of life**. This is discussed as a separate topic and requires that there are no incomplete segments. Main methods of survival analysis with incomplete segments include the **life table method** and the **Kaplan–Meier method**, which are also separately presented. These are the core methods that delineate the pattern of survival for a group on a particular regimen. Both these methods do not consider prognostic factors affecting the durations. The methods of assessing the role of various factors in affecting the duration are presented in the topic **Cox regression**. For comparing the survival pattern in two groups, **log-rank method** is generally used.

## survival bias, *see* bias in medical studies and their minimization

## survival curve/function, *see also* Kaplan–Meier method

The term *survival curve* is used for graphical representation of the pattern of survival over time, and survival function is its mathematical counterpart. The curve is drawn on the basis of the function. This is obtained as follows.

Consider first the life table method where survival is recorded at intervals of time rather than continuous. Under the **life table method**, where the data are obtained at intervals of time and not continuously,

$$p_k = \frac{n_k - d_k - c_k/2}{n_k - c_k/2};\ k = 1,2,\ldots,K;$$
$$= 1 - \frac{d_k}{n_k - c_k/2},$$

where

- $p_k$ is the proportion surviving the $k$th interval among those who survived the $(k–1)$th interval (the estimated conditional probability).
- $n_k$ is the number of subjects known to be alive at the beginning of the $k$th interval.
- $d_k$ is the number of deaths in the $k$th interval.
- $c_k$ is the number of subjects with incomplete segments in the $k$th interval whose fate is unknown.

The numerator of this formula is the number of survivors and the denominator is the number of subjects at risk. Both contain half of those with incomplete segments. The cumulative probability of surviving the $k$th interval can be estimated using this equation. By product rule for conditional probabilities, this is

$$s_k = p_k p_{k-1} \ldots p_2 p_1;\ k = 1, 2, \ldots, K.$$

This probability of survival can be obtained for each of the $K$ intervals. This is what is called the *survival function*. Its plot versus time $k$ is called the *survival curve*. Since each $p_k \le 1$, the survival probability $s_k$ is nonincreasing and will eventually decline as time passes. Statistical software can easily do these calculations and plot the survival curve. Note that this method is nonparametric as it does not depend on any particular form of distribution of survival period.

For illustration, consider the following data on survival time of 15 patients following radical mastectomy for breast cancer. The study started in January 2011 and continued till December 2014. Thus, the maximum follow-up was 4 years. However, many patients joined the study after January 2011 as and when radical mastectomies were being performed.

Survival time (months):

6 8 20 20 20+ 24+ 25+ 30+ 35+ 37 37 38+ 40+ 42 45+,

where + means that the patients are lost to follow-up or not followed up after this period. They are the incomplete segments. Their exact survival time is not known, but it is at least as many months as shown. The patients are deliberately ordered by survival time. This order is not important but makes the presentation simple. The sample size is small and there are many incomplete segments, which is not desirable for survival analysis, but the data are still adequate to illustrate the method.

The survival curve is shown by the dotted lines in Figure S.21. Median survival time corresponds to survival function = 0.5, which is the same as the time at which 50% survive only if there are no censored observations. Thus, 50% survival and survival function = 0.5 can be different. More exactly, median is calculated as the smallest survival time at which survival probability is at least 0.5. From the figure, this can be worked out to nearly 43 months in this example.

Since the duration of survival time is generally highly skewed, mean is not used. However, if needed, mean survival time is estimated by the area under the survival curve. Some software packages use only uncensored time points for calculation of mean, but that tends to give a biased estimate.

Dispense with the restriction that survival is recorded in time intervals. Assume that continuous monitoring is done and the exact time of death is recorded. Analysis of such survival data is done with

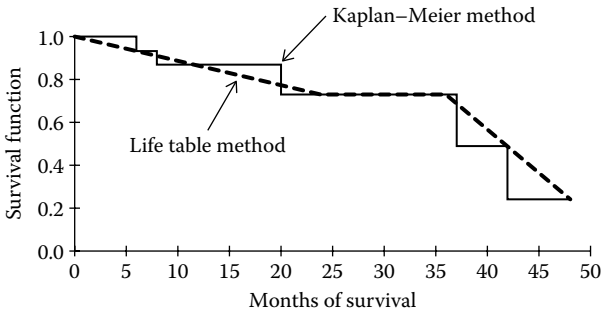

**FIGURE S.21** Survival function of breast cancer cases: life-table method and Kaplan–Meier methods.

the help of the **Kaplan–Meier method**. As explained in that topic, the survival function in this case is

$$s_t = p_t p_{t-1} \ldots p_2 p_1;\ t = 1, 2, \ldots, T,$$

where

$$p_t = \frac{n_t - d_t}{n_t};\ t = 1, 2, \ldots, T.$$

$p_t$ is the proportion surviving the $t$th time point among those who survived the $(t-1)$th time point.
$n_t$ is the number of subjects at risk of death at the $t$th time point, i.e., those who are still being followed up (this excludes those with incomplete segments, i.e., $n_{t+1} = n_t - c_t - d_t$).
$c_t$ is the number of subjects with incomplete segments.
$d_t$ is the number who died at the $t$th time point.

This is the estimated survival function in this case. It is basically the same product as in the formula given earlier but is now computed for each time point instead of the time interval. Only unique time points are considered. If a time point is applicable to two or more subjects, it is counted only once. This method requires the calculation of as many survival rates by the product rule as there are events, unless several events occur at the same time. Hence, the Kaplan–Meier (K-M) method is also called the **product-limit** method. The larger the $T$, the smoother the survival curve. The K-M method for estimating survival probability at the last time point is usually very unreliable because of heavy censoring toward the end of the trial.

Consider the same duration of survival of breast cancer patients after radical mastectomy as in the previous example, but now there is no grouping of survival time. The survival curve is shown in Figure S.21. Since time is continuously observed in this setup, many deaths at one time point are shown by a stepladder. The median duration corresponding to 50% survival (0.5 on $y$-axis) is nearly 37 months. This is very different from the 43 months arrived at by using the life table method.

For other types of survival function, see **hazard functions**.

## survival rate, *see also* survival analysis

This is the proportion of subjects that survive for a particular time during the follow-up in survival studies. Thus, a 5-year survival rate would be different from a 10-year survival rate. Duration is a necessary ingredient of all survival studies, and survival rate is no exception. Computation of this is not straightforward because of **censoring** in survival data but can be easily computed when the **survival function** is available.

Survival rates at any point in time are like proportions, and the comparison of two groups can be easily done by chi-square when the usual validity conditions of this test are fulfilled. These survival rates are calculated by the **life table method** when the observation of survival time is in the intervals, and by the **Kaplan–Meier method** when it is continuously observed. Survival–deaths in the two groups will give a 2 × 2 table, which will provide chi-square with 1 df as usual. The procedure remains essentially the same if there are more than two groups. A weakness of the procedure is that the time points chosen for calculating survival rate can be arbitrary, and different time points can give different results. The procedure to compare the overall survival pattern is the **log-rank**, but this procedure fails to detect if a big and significant difference exists at one or two specific time points, and not at other time points.

Survival in gastric cancer patients depends on a large number of factors, but this example is restricted to the type of surgical operation. Zhang et al. [1] have presented 5-year survivals as shown in Table S.22.

Censored observations are excluded, although, as mentioned earlier, this may cause bias. Now the last two columns of the table are a regular 3×2 **contingency table**, and the statistical significance can be tested by the usual chi-square. In this case, $\chi^2 = 31.66$, which is highly significant ($P < 0.01$) for 2 df. Thus, there is sufficient evidence to conclude that gastric cancer cases with three types of operations have different 5-year survival rates.

With such a large $n$ as in this example, statistical significance is a foregone conclusion. The actual utility of this type of analysis is that the survival in proximal subtotal gastrectomy is nearly half of that in distal gastrectomy. Deaths are 79.9% in proximal and 62.8% in distal. This tends to quantify the hazard of death and says that the hazard ratio for death in proximal operation is nearly 1.3 relative to the distal operation (this is based on deaths and not on survivals). Not many studies of this type aim at this kind of a useful conclusion.

For the confidence interval on survival rate, we need its standard error (SE). If the expression for **survival function** is messy, the SE cannot be simple. However, if deaths are not too many at any time point and if you started with a sufficient number of subjects so that the number of survivors remains reasonably large at the end, the SE is approximated by

$$\mathrm{SE}(st) = \sqrt{\frac{s_t(1-s_t)}{n_t}},$$

where $s_t$ is the survival function at time $t$, and $n_t$ is the total number of subjects at risk at time $t$. This SE is the same as for the usual proportions and is applicable to the individual time points. The SE would be different for different points of time, just as survival $s_t$ and the number of subjects $n_t$. For life-table survival also, the approximate SE is the same—just that the subscript $t$ is replaced by subscript $k$. This is not applicable to small $n$, and even when $n$ is large, note from SE that it increases (the precision declines) with time as the survival reduces, and it is based on fewer and fewer subjects. For cumulative survival till time $T$,

$$\mathrm{SE}(S_T) = s_T \sqrt{\sum_{t \le T} \frac{d_t}{n_t(n_t - d_t)}},$$

where $d_t$ is the number of deaths at time $t$. The interest in survival analysis is mostly in this SE to find the confidence interval for the survival function. The confidence interval is obtained as usual by ±1.96*SE under Gaussian conditions.

## systematic random sampling

A sampling is called systematic random when the first unit is selected at random from the initial set as per the **sampling fraction** and the remaining automatically as per the same sampling fraction. If 25 subjects are planned to be in the sample out of a total population of 200, the sampling fraction is 1 out of 8, and the first is selected at random out of first 8. Others are selected by an automatic procedure by adding the sampling fraction. If the first randomly selected is number 3, the next in our example will be number 11, then 19, etc. This presumes that the subjects have a defined sequence, that is, you know the serial number of each patient. If the subjects are not in sequence, this sampling scheme requires that each subject of the population be assigned a serial number before the sampling is executed.

Let there be $N$ subjects in the total population, numbered 1 to $N$ in any order. If the size of the sample is $n$, the sampling fraction is $I = N/n$; in fact, the fraction is $n/N$, but for systematic sampling, it is easier to work with $I = N/n$. If $I$ is not an integer, then the integer part is taken. The first unit is selected at random from the first $I$ units. Suppose this is the $r$th unit. Then the subsequent units in the sample are $(r + I)$th, $(r + 2I)$th, etc. Thus, the first selected unit determines the entire sample.

Let there be $N = 101$ subjects in the target population out of which $n = 8$ are proposed to be selected by the systematic method. The sampling interval is $I = 101/8$, and its integer part is 12. If the randomly selected unit (subjects in this case) out of the first 12 is the 9th, then the remaining units have numbers 21, 33, 45, 57, 69, 81, and 93.

Although the systematic method works well when the sampling interval is an integer, two kinds of anomalies can occur in other cases: (i) The last few units may never have a chance to be included in the sample. In the preceding example, if the first selected number is the maximum 12, then the last number in the sample is 96. Thus, unit numbers 97–101 can never be selected. (ii) In some cases, the sample size may increase by one. In this example, if the first randomly selected unit is the 4th, then the last would be the 100th. The sample then would contain nine units instead of the stipulated eight. However, this is not serious when $n$ is large, say greater than 30. A way out of this mess is **circular sampling**, in which the start is made from a random number between 1 and $N$, and every $I$th thereafter is selected in a cyclical manner, i.e., the $(N + 1)$th unit becomes the first unit again. This is done until $n$ units are selected.

Systematic random sampling (SyRS) has the following merits: (i) It is very easy to execute. When the patients are coming to a clinic, every eligible $I$th after the random first can be easily pulled out for inclusion in the study. It is also very quick relative to simple random sampling (SRS), where each unit is to be selected at random. (ii) SyRS does not need a full **sampling frame**—knowledge about the total number of units in the population is enough. If you know that a clinic generally gets $N = 275$ patients a month and a sample of size $n = 30$ is to be chosen from among the patients coming in a particular month, then $I = 9$. If the first randomly selected patient is the 7th, then the others in the sample are the 16th, 25th, etc. These can be chosen according to the sequence of arrival, and no list of patients is required for sampling. (iii) In some situations, it can yield a much more representative sample than SRS since equally spaced selection until the end gives the opportunity to all sections of the population to be represented. If a sex clinic runs 6 days a week with Mondays and Thursdays reserved for teenagers, Tuesdays and Fridays for male adults, and Wednesdays and Saturdays for female adults, then SyRS would automatically give proportional representation to each of the three groups of patients when the sampling includes all the days.

SyRS is not without demerits: (i) The SyRS could yield a biased sample if a periodicity or trend is hidden in the subjects as you go from 1 to $N$. (ii) As in the case of SRS, this method can fail to give adequate representation to some specific groups of interest.

For an example, see Vitolo et al. [1] who describe results of a study in Sao Leopoldo (Brazil) for evaluating risk factors of folate deficiency among adolescents. In the first stage, they selected census regions, then they selected random blocks and street corners where sampling would start, and finally houses were sampled systematically one in three. All individuals of age 10–19 years in the selected houses constituted the sample. In this study, systematic sampling was done at the last stage to select the houses. In most large-scale studies where such multistage sampling is used, systematic sampling can be at one or more stages.

## systematic reviews, *see also* Cochrane collaboration/reviews

Aptly called research into research, systematic reviews are focused reviews of the relevant literature on a particular topic or on a defined outcome, and are done with the objective to filter a common message and to highlight the discrepancies as reported by different studies. Being systematic requires that the following steps are listed in the **protocol** and rigorously followed: (i) identify all published and unpublished evidence on the topic of focus through scanning of literature databases, libraries, government documents, and all other sources (for this, it is helpful to list your search criteria upfront); (ii) prepare a set of criteria for inclusion and exclusion of reports in your review in a manner that all relevant documents are included and the irrelevant ones are excluded; (iii) select studies for inclusion that meet this preset criteria; (iv) assess the quality of each study on the basis of some established norms such as representative sample, design that controls the bias, adequate analysis, and clear exposition; (v) prepare a subset of documents that meet the defined quality standard; (vi) read these documents thoroughly, filter the common findings keeping any flaws in mind, and synthesize the varying results without any personal bias (for this, help of **meta-analysis** can be taken but that is not necessary); and (vii) interpret the findings and present a unified conclusion—in case of significant differences among studies, report that prominently. These differences could be due to varying background characteristics of the population under study, difference in design for collection of data, difference in analytical strategies, altered focus of the authors or the agency publishing the report, etc.

Systematic reviews require a lot of critical thinking about the possible bias of the investigators as most authors like to further their own hypothesis, and their report may be silent on issues unfavorable to their hypothesis. In addition, the **publication bias** can completely distort the findings as the negative results rarely find their way into quality journals. Perhaps one way out is to give extra weight, say double, to negative results assuming that only one of the two negative findings are published (the situation though seems to be rapidly changing). Extra care is required if both qualitative and quantitative evidences are to be synthesized because they require special expertise.

Systematic reviews provide high **level of evidence** and are respected in medical sciences because many times wide variation is seen in findings of different workers, and it becomes necessary to scan them closely to come to a unified conclusion. Most respected are **Cochrane reviews** [1]. They do help the medical fraternity to confidently use a new method of prevention, diagnosis, or treatment when such a systematic review gives a positive recommendation. They also reveal the areas where the evidence is nonexistent or week, and thus where the new research ought to be focused.

A large number of systematic reviews are published each year, which are peer-reviewed for credible evidence, but some are not as meticulous and can mislead. Thus, the results of all systematic reviews cannot be blindly accepted.

For further details, see Cochrane Consumer Network [2].

## tabular presentation of data and results

Tabular presentation is a summary of data in the form of a table. Tables are powerful tools to display the data in an intelligible and precise format. They tend to condense and summarize the information and sometimes are able to communicate the intricacies better than text. Tables are also made to highlight specific features of a data set. Generally, only the salient features of the data sets or of the results are presented in the form of tables and the unimportant features are ignored. Data that are not easy to describe in a couple of sentences in text are generally tabulated.

The purpose of a table is to give an overall view of the data or results—thus, it should not be too complex since then it is not able to fulfill its purpose. All row headings and column headings must be unambiguous. Sometimes, it is not feasible to explain all column and row headings in a proper manner, or sometimes, numbers are inconsistent, which requires additional explanation. For readers to understand the table in one shot, add footnotes to the table where necessary. Footnotes should be marked with *, **, †, @ in this order or with superscripts 1, 2, 3, 4, and so on. Also, you may have to explain abbreviation in a footnote.

If you have two or more tables with identical rows or columns, examine if they can be combined. The message that a table is supposed to convey should be obvious at a glance. When writing about the table in the text, it should be straightforward in that it explains the key points of the data in the table in a couple of sentences; preferably, the table should be self-explanatory. The table titles, format, and presentation should be consistent throughout the report. A thorough exposition of the design and usage of tables is given in Ref. [1]

Primarily, a table presents the number of subjects in different categories such as the frequency with different cholesterol levels like 100–149 mg/dL, 150–199 mg/dL, and 200+ mg/dL categories, or cases with cancer at different sites in various years. The purpose is to see the **distribution** of subjects—what values are more common and what values are rare, whether the values are highly concentrated or pretty much evenly scattered, whether the dispersion is large or is it small, and so on. For this purpose, the old method is of tally marks as described in the topic **frequencies** but now almost everybody uses the "bins" for quantitative data, which are defined with the help of a software package. The system of manual tally marks in any case is unsuitable for large sets of data as it is time consuming and prone to errors.

For an adequate tabular presentation of numerical data, it is necessary that the bins are suitably constructed. Customarily, categories beginning with digits 5 or 0 are made such as 97.0–97.4, 97.5–97.9, and so on, for body temperature (in degrees Fahrenheit), and <20.0, 20.0–24.9, 25.0–29.9, and so on, for body mass index (in kilograms per meter squared), but that is being gradually replaced with "natural" categories dictated by the data. Generally, 6 to 10 bins are considered adequate to represent the distribution, but you can have more bins for large data sets. See the topic **class-intervals** for open categories at the beginning and end of the data values. Percentages of frequencies should be based on appropriate total and the number of subjects in each group should be mentioned, preferably in the column heading. Ensure that the numbers in different tables are consistent with one another. Specify the unit of each measurement.

For **qualitative measurements**, there is hardly any opportunity to choose the "bins"—the qualities generally determine the number of categories. For example, the categories for blood groups have to be O, A, B, and AB, and the categories for site of cancer for males have to be lung, prostate, esophagus, brain, blood, and so on. However, in this case, all the uncommon sites can be lumped together in an "others" category so that the number of categories does not become unmanageable and the number of subjects in each category is adequate for statistical analysis. For other details of these kinds of frequency tables, see the topic **contingency tables**.

### *Types of Tables*

Simple tables are the usual tables that we are not discussing but, in contrast, are composite tables that contain detailed information on two or more groups such as the use of smokeless tobacco in males and females of some Southeast Asian countries (Table T.1) and combined for both sexes. Table for each sex is what we are referring to as a simple table.

Table T.1 does not contain frequencies, but instead contains percentage prevalence. The table illustrates the following:

- The title of the table should be as specific as possible without being lengthy. The title of Table T.1 explains that these are prevalences in percentages and are given for different age-groups and sex for some countries. It also says that the data belong to the years 2006–2009.
- All entries are with one decimal. Some are NA and the footnote at the bottom of the table explains that NA means "not available."
- There is another footnote explaining what the asterisk sign stands for. The data for Bhutan are restricted to one city only.
- There are separate blocks for males, females, and persons (where "persons" stands for both the sexes combined).

Data on groups you want to compare should be in columns. For example, if your objective is to compare cases with controls, data on cases should be in one column and data on controls should be in adjacent column. If you want to compare males and females, data on these two groups should be in column (and not two rows). Table T.1 on tobacco use primarily compares prevalence in different countries as the countries are in the columns. When two or more tables present results on the same set of variables, the order of variables should be the same.

Beside frequency tables (or percentages), statistical results are also presented in tabular form as done for logistic results in Table T.2. This is on the factors affecting postoperative pain relief in patients who have had bariatric surgery. The factors considered are (i) the kind of support, if any, that the patients walked-in with; (ii) preoperative continuous positive airway pressure (preop CPAP) done or not; (iii) STOPBANG score; and (iv) body mass index (BMI) at the

[a] Preoperative continuous positive airway pressure for sleep apnea—information not available for four patients.

time of admission. Support and preop CPAP were categorical and STOPBANG score and BMI were continuous. The table gives the number of subjects in different categories, the logistic coefficients (*b*), their standard error (SE), odds ratio, which is $e^b$, and the 95% confidence interval (CI) for the logistic coefficient. It illustrates that the tables containing statistical results have a format very different from that of the tables containing number and percentage of subjects in different categories.

Such tables give structure to the answer and provide concrete evidence as large set of summary statistics can be meaningfully recorded in the table. However, they can also be a source of confusion when not properly drawn—thus, exercise due care. Tables on statistical significance should contain exact *P*-values that give more insight to the reader than just saying $P < 0.05/P > 0.05$ or significant/not significant, but $P < 0.001$ is acceptable. Customarily, only two or three decimal places are used in values of *P*. Use capital *P* since lowercase *p* is used to denote proportion in the sample. When feasible, also give the name of the statistical test on which *P*-value is based, but do not give a value for the test statistic such as *t*, *F*, and $\chi^2$ in a report unless required by the organization for whom the report is being prepared or by the journal to whom a paper is being sent for publication. State the CIs wherever applicable.

**TABLE T.3**
**Tabular Presentation of Analysis of Variance Results and Multiple Comparisons (Too Much Information Packed in One Table): Scores of Peritonitis Patients in Physical and Mental Domains of Quality of Life at Baseline and 1, 2, and 3 Months after Two Types of Surgical Regimens**

| | | Surgery 1 | | | Surgery 2 | | | Differences in the Two Surgeries | |
|---|---|---|---|---|---|---|---|---|---|
| Domain and Time | n | Mean Score | *P*-Value for Time Differences (*F*-Test) | Tukey Test for Time Differences | Mean Score | *P*-Value for Time Differences (*F*-Test) | Tukey Test for Time Differences | *P*-Value (*F*-Test) | Tukey Test |
| **Physical** | | | | | | | | | |
| Baseline | 20 | 10.25 | <0.001 | Sig from 1, 2, and 3 months | 10.30 | <0.001 | Sig from 1 and 2 months | 0.085 | NS |
| 1 month | 20 | 12.20 | | Sig from 2 and 3 months | 12.35 | | Sig from 2 and 3 months | | NS |
| 2 months | 20 | 13.05 | | Sig from 3 months | 11.15 | | Sig from 3 months | | NS |
| 3 months | 20 | 14.30 | | | 10.70 | | | | NS |
| **Mental** | | | | | | | | | |
| Baseline | 20 | 9.95 | <0.001 | Sig from 1, 2, and 3 months | 10.15 | <0.001 | Sig from 1, and 2 months | 0.167 | NS |
| 1 month | 20 | 11.65 | | Sig from 2 months | 11.60 | | Sig from 3 months | | NS |
| 2 months | 20 | 11.70 | | Sig from 3 months | 11.25 | | Sig from 3 months | | NS |
| 3 months | 20 | 13.65 | | | 9.90 | | | | NS |

*Note:* All Tukey tests at the 5% level of significance. NS: not significant.

Presentation of statistical results for repeated measures and for multiple comparisons can be very difficult. Table T.3 illustrates the problems encountered in this presentation and suggests one way of presentation. The table contains the means and SDs of quality-of-life scores in physical and mental domains in peritonitis patients at baseline and at 1, 2, and 3 months after two types of surgical intervention. Although this provides an overview of the results, this looks too congested for the reader. You might be able to devise a more ingenious way of presenting these kinds of results such as splitting the table to have one for the physical domain and another for the mental domain and having a separate table for difference between two surgeries.

A statistical table can be prepared in a large number of other formats also depending on the data they contain. We can have a table of random numbers (see the topic **random numbers**), a table of features of studies included in a meta-analysis, a life table (see the topic **expectation of life and life table**), and several other types of tables.

## Taguchi designs

Developed by Genichi Taguchi in 1960 and explained fully by him in 1987 [1], Taguchi designs seek to integrate **quality control** into product design when he identified that the loss is minimized by operating on target with minimum variance. Thus, these designs integrate quality engineering with statistical methods and emphasize that design rather than inspection is important for quality control. The conventional quality control relies on the inspection of the products (such an inspection is actually for manufacturing processes). Taguchi brought design (before manufacturing) to the center of quality control process.

Genichi Taguchi

The basic premise of the Taguchi design is a loss function based on deviation from the target value. This means that if the target of a treatment process is to provide relief to at least 62% of cancer patients, but if the actual relief rate is 61%, there is a loss. In the conventional quality control group, 61% may be within the tolerance range and ignored for any corrective steps. In the Taguchi method, there is no defined tolerance range, and any deviation from the target contributes to the loss. It is concerned with the design of the product such that the variance around the target value is minimized.

Actions taken after the manufacturing process in the conventional setup increase the cost, whereas in the design, the cost is much less, because it is constructed before the process.

Historically, the best way of controlling variation was by the use of specifications: for example, $\tau \pm \Delta x$, where $\tau$ is the target and $\Delta x$ is the tolerance limit. Within the specification, the product was deemed satisfactory, and outside the specification, the product was deemed to be unsatisfactory. Say, we had $\tau = 100$ and $\Delta x = 10$: the specification was (90–110). With a stream of units with values 108, 102, 96, 92, and 90, the units passed and the production process were deemed satisfactory because all of them are within limits. However, suppose the sixth unit had a value of 89 and everyone suddenly panicked! Inspectors inspected incoming raw materials, and project teams brainstormed the process. All of this greatly increases the cost associated with the production of this product. Most importantly, note that the difference between the fifth unit (90) and the sixth unit (89) was less than any of the differences between earlier successive units, yet the fifth unit was deemed to be satisfactory and the sixth unit was deemed to be unsatisfactory in the conventional method! There was a real need for a better way of controlling variation in the manufacturing process, and that is where Taguchi designs came in.

There are instances of useful applications of the Taguchi approach in health and medicine. Emami et al. [2] discussed formulation and optimization of solid lipid nanoparticle formulation for pulmonary delivery of budesonide using the Taguchi design. They studied the impact of various process variables such as surfactant type and concentration, lipid content and organic and aqueous volume, and sonication time on particle size, zeta potential, mean dissolution time, and so on. Azadeh and Sheikhalishahi [3] discussed how this approach can be useful in performance optimization of health, safety, environment, and ergonomics in generation companies based on sensitivity analysis and maximum correlation.

The study by Cogdill and Drennen [4] is a useful resource in this respect. For further details of Taguchi designs, see Ryan [5].

## Tanimoto dichotomy coefficient, *see* association between dichotomous characteristics (degree of)

## tapping

Health measurement scales (particularly the **Likert scale**) are based on the concept of "tapping" [1]. Likert developed the concept of measuring participants' attitudes to a topic by asking them to respond to statements about that topic (particularly as to how much they agreed with these statements), thereby tapping into the cognitive components of these attitudes. Tapping here relates to the measurement of the underlying phenomenon under investigation. This affects the design of a **questionnaire** by helping to decide what items in the questionnaire to use. This is important since no amount of statistical maneuvering after completion of the questionnaire can compensate for poorly chosen questions.

The motivation for developing a new tool (such as a Likert scale/questionnaire) comes about because the researcher believes that previously used methods are inadequate for one reason or another or do not completely cover the construct under study. The researchers can start with new items that may come from four different sources: clinical observation, theory, research, or expert opinion, although the lines between these sources are not firm. New items are chosen based on how well they are expected to tap into the underlying construct. Once the items have been chosen from one or more of these four sources, the researcher would ideally have more items than will actually end up on the scale. Conversely, we can argue whether the scale has enough items to tap with for adequately covering the domain under investigation. The technical term for this is **content validity**.

These concepts arose from achievement testing in schools where students are assessed to determine if they have learned the material in a specific content area, such as in the passing of medical school exams. Each item on the test should tap into one of the course objectives so that the items have content relevance. Conversely, each part of the syllabus should be represented by one or more questions so that the content is adequately covered. The criterion for selecting items is to eliminate those that are ambiguous or incomprehensible and to include items on those aspects that are left uncovered.

See Streiner and Kottner [2] for a good working example on this topic.

## target population, *see* population (the concept of)

## Tarone–Ware test, *see also* log-rank test (Mantel–Cox test)

This test compares two survival curves in a manner similar to what a **log-rank test** does, but provides differential weights to different time points, weight being dependent on the number of subjects available at various time points.

The log-rank test compares two survival curves without reference to any particular point of time but is valid when all time points are equally important. Sometimes, time points with a higher number of subjects at risk are given more weight. Naturally, later time points have lesser number of subjects because of accumulation of deaths (or failures) as the time passes. In that case, another method such as the **Breslow test**, which gives weight proportional to the number of subjects at risk at different time points, could be used. However, this sometimes becomes overdone as the initial time points where the number of subjects at risk is higher tend to decide the statistical significance. As a middle path between the log-rank test and the Breslow test, some prefer the Tarone–Ware test [1], which gives

weight proportional to $\sqrt{n_t}$, where $n_t$ is the number of subjects at risk at time point $t$. All these are **nonparametric tests** since they do not require any specific pattern of survival duration, and they belong to the same family of tests [2].

Consider the equation to calculate the $\chi^2$ value in the log-rank test where group 1 contributes $(\Sigma d_{1t} - \Sigma e_{1t})^2$, where $d_{1t}$ is the number of deaths at time point $t$ in group 1 and $e_{1t}$ is the expected number of deaths at this time under the null hypothesis of equality of survival curves. This gives equal weight to each failure time when combining (observed – expected) failures. This does not have to be the case and a weight $w_j$ can be given to each failure time and use $[\Sigma w_t (d_{1t} - e_{1t})]^2$. The most common weighting is $w_j = n_j$, where $n_j$ is the total number at risk in the two groups, referred to earlier as the Breslow test. This has been observed to be more powerful in detecting specified differences when the survival distribution is **log-normal** but may have less power in the case of heavy **censoring**. On the one hand, the log-rank test is more powerful for **Weibull** survival distributions and equal censoring at different time points. The Tarone–Ware test, being the middle path with $w_j = \sqrt{n_j}$, can have reasonable power across a wide range of survival functions, although it may not be as good in some specific situations as listed.

Sanna et al. [3] calculated *P*-values for log-rank, Breslow, and Tarone–Ware tests for their data on survival using quartiles of NT-pro-BNP levels in outpatients undergoing elective cardioversion of persistent atrial fibrillations and reported nearly similar results by the three tests. Statistical software packages generally have options to perform all the three tests and you can choose the one most appropriate for the data in hand.

## telephone sampling

Telephone sampling is an effective instrument in developed countries as almost every household has a phone, and the listing is available separately for homes and commercial establishments (white and yellow pages). Any of the methods of probability or nonprobability sampling can be used to select telephone numbers. However, keep in mind four rather severe limitations: (i) Many households have two or more phone numbers. (ii) Some households without telephones can never appear in the telephone sampling. This is a serious limitation for areas where many households are without phones. These households are likely to have a relatively low socioeconomic status and a bias can creep in if the condition under investigation is associated with the socioeconomic status. (iii) Some households suppress their telephone numbers and their numbers are not listed. (iv) Attrition (nonresponse) rate is generally very high in telephone surveys compared with personal interviews, and this can increase the bias. However, in telephone sampling, a replacement is easy to make for nonresponse. This kind of sampling enables a much cheaper and faster data collection from geographically scattered samples compared to field interviews and may also be better than postal surveys because of the personal voice contact.

According to an evaluation of telephone sampling design carried out in 1978 by Landon and Banks [1], the increasing cost of personal interviewing and the higher crime rate in cities have made personal interviewing less practical. Telephone sampling is feasible in areas where telephone penetration is nearly 100%, but the basic problem is in eliciting responses in the first place and getting the right response in the second. Since the nonresponse could be substantially high, the resulting bias can render results doubtful. The latest telephone directory, particularly the printed one, if available, lends itself to a good **sampling frame**, but **stratified random sampling**, say, by age or sex, or even socioeconomic status, is nearly impossible. Only a **simple random sampling** can be done with all its advantages and disadvantages. For refusals or not-at-home responses, callbacks can be arranged, but the sample finally available with responses may still be biased.

Thomas and Purdon [2] discuss the pros and cons of telephone sampling.

## tertiles, *see* quantiles

## test criterion

A statistical test criterion is a validly established rule by which certain sample summaries are considered relatively probable and others relatively improbable for a particular hypothesis [1]. Such a criterion plays a crucial role in empirical sciences where the decisions are based on the available values. These criteria are also called tests of statistical significance or just **test statistics**. The distributional form of these criteria has been studied and is mostly known. This depends on (i) the nature of the data (qualitative or quantitative); (ii) the form of the distribution such as Gaussian or non-Gaussian when the data are quantitative; (iii) the number of groups to be compared (one, two, or more than two); (iv) the parameter under consideration (it can be the mean, median, correlation coefficient, etc., in case of quantitative data; it is always a proportion $\pi$ or a ratio of proportions in the case of qualitative data), or difference; (v) the size of the sample (small or large); and (vi) the number of variables considered together (one, two, or more). All this is analogous to saying that the criterion for assessing the health of a person depends on the age, gender, purpose, general health or organ-focused health, and so on.

Besides the considerations mentioned in the preceding paragraph, the criterion is constructed in a manner that it involves the parameter of interest, and the distribution of the criterion, especially under the null hypothesis, is known. Then, only the probable and improbable values can be identified. The decision depends on what is called the ***P*-value**. The procedure to obtain a *P*-value corresponding to a null hypothesis requires identifying a criterion (such as **Student *t***, **chi-square**, and ***F***) that is suitable for the scenario in hand. For example, the criterion $F = \dfrac{s_1^2/\sigma_1^2}{s_2^2/\sigma_2^2}$ involves the parameters $\sigma_1^2$ and $\sigma_2^2$ whose distribution under $H_0$: $\sigma_1^2 = \sigma_2^2$ is $F$ with $(n_1 - 1)$ and $(n_2 - 1)$ df, where $n_1$ and $n_2$ are the respective sample sizes. It is only when such distribution under the null is known that *P*-values can be obtained.

As another example, consider $z = \dfrac{\left(\frac{1}{2}\ln\frac{1-r}{1+r}\right) - \left(\frac{1}{2}\ln\frac{1-\rho}{1+\rho}\right)}{1/\sqrt{n-3}}$, where $r$ is the sample correlation coefficient and $\rho$ is the population correlation coefficient, which becomes $z = \dfrac{\left(\frac{1}{2}\ln\frac{1-r}{1+r}\right)}{1/\sqrt{n-3}}$ under $H_0$: $\rho = 0$ and we know that it follows a **Gaussian** (Normal) **distribution** for large $n$.

The conventional statistical criteria generally require that the sample values come from a specified distribution. For example, Student $t$ requires that the values are from a Gaussian distribution. Certain very general conditions such as independent observations and large $n$ may also be required for some criteria. Nonparametric criteria are relatively free from such encumbrances but still want independence of values.

In addition to the test criteria, there are other statistical criteria for purposes other than tests of hypothesis. Examples are the **Akaike information criterion**, which is used to determine the adequacy of a model without "test of hypothesis" overtones, and **coefficient of determination**, which is also used as a criterion for the same purpose.

Statistical test criteria have a long history—for an interesting account, see Ekstrom [1].

## tests of hypothesis (philosophy of)

Statistical tests of hypotheses are commonly used but are also abused because of lack of understanding of their philosophy. This is amply illustrated by the following examples. Ptolemy in the second century AD propounded that the sun revolves around the earth. This remained the "truth" for 14 centuries until Galileo came up with evidence against it in the 16th century and established a new truth, which says that the earth revolves around the sun. Newton's laws of mechanics were accepted until Einstein discussed circumstances in which some of them did not hold. Peptic ulcers were believed to be caused by acidity until sometime ago when *Helicobacter pylori* was found to be a culprit in some cases. As of today, coronary heart disease is not considered to be caused by any infection, but who knows that a rebuttal will come soon. The moral is that the "truth" changes as new convincing evidence emerges. Tests of hypothesis in statistics also follow the same system and look for evidence against a given hypothesis.

The philosophy is best understood with the help of an example of a court decision in a crime case. Consider the possibilities mentioned in Table T.4a. When a case is presented before a court of law by the prosecution, in most societies, the judge is supposed to start with the presumption of innocence. It is up to the prosecution to present evidence against the innocence of the person. The evidence should be enough to change the initial opinion of the judge. Guilt should be proven beyond reasonable doubt. If the evidence is not sufficient, the person is acquitted whether he/she actually committed the crime or not. Sometimes, the circumstantial evidence is strong and an innocent person is wrongly pronounced guilty. This is considered a very serious error. Special caution is exercised to guard against this type of error even at the cost of acquitting some criminals.

An empirical strategy in science is to find evidence against a hypothesis that is stated in **null** form. If this evidence is sufficient, the null hypothesis is rejected; otherwise, it continues to be considered "truth" by default. By analogy, in the development of a new therapeutic regimen, it seems reasonable to demand evidence against the hypothesis that there is no effect at all. Similar is the case with diagnosis (Table T.4b) where enough indication must be present that the disease is present. Statistical testing also follows the same process (Table T.4c). Decisions in all the three setups involve the same kind of errors. Statistical **Type I** and **Type II** errors that occur in testing of hypothesis setup are explained separately.

This process is difficult to implement without setting up a null hypothesis. As testing proceeds, philosophy involves not accepting any null (statistically, this is different from rejecting any null) but only rejecting whenever sufficient evidence is present. The statistical hypothesis testing parallels the court judgment just illustrated. This process is also called the **test of significance** because the effect seen in samples is checked whether it is significant enough to be considered most likely real. Martin explores the analogy further [1].

Since samples by their very nature are uncertain, the conclusion depends on what sort of data are obtained from the subjects. Statistical tests of significance are precisely meant to deal with uncertainties arising from **sampling fluctuations**. They provide the answer to the question: What is the likelihood of sample values given that null hypothesis is true? If this likelihood is exceedingly small, say, less than 5%, the null is considered implausible and rejected. At the same time, it would be ridiculous to accept a hypothesis whose likelihood of giving the obtained sample is only 15%. Thus, the only conclusion drawn in this case is that the sample fails to provide sufficient evidence to reject the null hypothesis. It is not accepted and the situation reverts to what it was before that study.

Many would consider it idiosyncratic that the sample values are searched for evidence against a null without recourse to finding what they are for—what they support. Perhaps another example would be more convincing. Consider the claim of a pharmaceutical company

**TABLE T.4**
**Errors in Court Judgment, Diagnosis, and Statistical Decision**

| (a) Court Setting | | | (b) Diagnosis | | | (c) Statistical Decision | | |
|---|---|---|---|---|---|---|---|---|
| | Assumption of Innocence | | | Disease Actually Present | | Statistical Decision | Null Hypothesis | |
| Judgment | True | False | Diagnosis | No | Yes | | True | False |
| Pronounced guilty | Serious error | ✓ | Disease present | Misdiagnosis | ✓ | Rejected | Type I error | ✓ |
| Pronounced not guilty | ✓ | Error | Disease absent | ✓ | Missed diagnosis | Not rejected | ✓ | Type II error |

that their drug is superior to the existing angiotensin-converting enzyme inhibitors in improving insulin sensitivity in diabetic hypertensives. In a trial of matched cases, improvement was seen in 7 out of 10 patients who were given the new drug compared with 6 out of 10 who were given the existing drug. It is evident that the sample size $n = 10$ in each group is small and the difference is too small to provide confidence to pronounce that the new drug is better. The difference could have arisen as a result of sampling fluctuation. If so, the claim of superiority is not tenable. The manufacturer needs to withdraw the claim forever or until such time that more evidence is available for scrutiny. The medical fraternity is expected to continue with their existing practice and not take cognizance of the claim until the claim is adequately substantiated.

If a null hypothesis, denoted by $H_0$, turns out to be false, what alternative is there? This is what is named the **alternative hypothesis**, denoted by $H_1$. This must be true when $H_0$ is found not to be so. For example: if the null ($H_0$) is that a drug is not effective, and this is shown not to be true, then the alternative ($H_1$) has to be that it is effective. In the preceding example, the claim is that of the superiority of the new drug. This is the alternative hypothesis. This is a one-sided alternative if inferiority is ruled out.

The following example may help one to further understand the steps and the philosophy behind the statistical tests. Suppose an argument erupts concerning the percentage of births in a community that are premature. Based on everyday experience, a practitioner asserts that exactly 10% of births are premature, neither less nor more. To test this assertion, a random sample of 60 births is systematically observed and 8 of them are found to be premature. This is 13.3%. Can we conclude that the percentage of premature births in the population is not 10%? Assertion of 10% premature births in this case is the null hypothesis. This is what is to be tested (and possibly to be refuted). Thus, $H_0$: $\pi = 0.10$. Since there is no assertion about a particular direction of difference, it could be negative or positive, and the alternative hypothesis is $H_1$: $\pi \neq 0.10$. Let the **level of significance** be fixed at $\alpha = 0.05$. That is, the chance of error of Type I should be less than 5%. Quantity of consequence in this case naturally is the proportion, $p$, actually observed in the sample. For this sample of 60 births, $p = 8/60 = 0.1333$. Since $n$ is 60 and $np \geq 8$, invoke the **central limit theorem** and assume that $np$ will approximately have a Gaussian distribution. Since $H_1$ is two sided, it is easily seen that $P = 0.39$. This is certainly very high in comparison with the conventional threshold 0.05. If $H_0$ is rejected, the chances of its being wrongly rejected are as much as 0.39 (or 39%). Since this is too high an error, we cannot reject the null.

The sample in this example can provide sufficient evidence to reject some other values of $\pi$. For the purpose of illustration, change $H_0$ to $\pi = 0.25$. Under this value of $H_0$, the usual **$z$-test** reveals $P = 0.038$. Since this is less than 0.05, this $H_0$ is not plausible and is rejected. It is concluded that the percentage of premature births is not 25. The percentage (13.33%) observed in the sample is sufficiently different from 25 in a statistical sense but not sufficiently different from 10. Thus, the $H_0$ that the premature births are 25% can be rejected but not the $H_0$ that they are 10%. The example illustrates the philosophy of statistical tests, explaining how sample values are considered consistent with some hypothesized values of the parameters and not consistent with other values.

The above example also illustrates one more dilemma that some of us face: if we decide to accept, which value should we accept? If we start accepting in place of not being able to reject, there would be multiple values for acceptance. In this example, we are not able to reject the null that the percentage is 10%. If the procedure is repeated for $H_0$: $\pi = 0.11$, this will also not be rejected, and we will not be able to reject $H_0$: $\pi = 0.12$ either. If we accept, which value do we accept? Thus, the only conclusion reached is that the null is not rejected. It only means that the value propounded under the null cannot be denied.

## tests of significance, *see also* tests of hypothesis (philosophy of)

*Tests of significance* is the other name for **tests of hypotheses** and follows the same philosophy. We have discussed a large number of tests of significance in this book under different topics. Table T.5a

### TABLE T.5a
### Statistical Tests of Significance for Qualitative Data (Proportions)

| Parameter of Interest and Setup | Conditions | Main Criterion for Test of Significance |
|---|---|---|
| **Proportions in All of the Following Small-Sized Tables** | | |
| One dichotomous variable | Independent trials | |
| | Any $n$ | Binomial |
| | Large $n$ | Gaussian $Z$ |
| One polytomous variable | Independent trials | |
| | Large $n$ | Goodness-of-fit chi-square |
| | Small $n$ | Multinomial |
| Two dichotomous variables ($2 \times 2$) | Two independent samples | |
| | Large $n$ | Chi-square or Gaussian $Z$ |
| | Small $n$ | Fisher exact |
| | Detecting a medically important difference—large $n$ | Gaussian $Z$ |
| | Equivalence test | TOSTs |
| | Matched pairs | |
| | Large $n$ | McNemar |
| | Small $n$ | Binomial |
| | Crossover design | |
| | Large $n$ | Chi-square |
| | Small $n$ | Fisher exact |
| **Bigger Tables, No Matching** | | |
| Association | $2 \times C$ tables—large $n$ | Chi-square |
| Trend in proportions | $2 \times C$ tables—large $n$ | Chi-square for trend |
| Dichotomy in repeated measures | Many related $2 \times 2$ tables | Cochran $Q$ |
| Association | $R \times C$ tables | |
| Association | Three-way tables | Chi-square |
| | Test of full independence | Chi-square |
| | Test of other types of independence (log-linear models) | $G^2$ |
| $I \times I$ table | Matched pairs | McNemar–Bowker |
| Association in stratified tables | Stratified into many $2 \times 2$ tables | Mantel–Haenszel chi-square |

**TABLE T.5b**
**Statistical Tests of Significance for Relative Risk (RR) and Odds Ratio (OR)**

| Parameter of Interest and Setup | Conditions | Main Criterion for Test of Significance |
|---|---|---|
| Relative risk, odds ratio, and attributable risks | Large $n$ required | |
| ln(RR) or ln(OR) | One group | Wald |
| ln(RR) or ln)OR) | Two independent samples | Gaussian $Z$ or chi-square |
| RR or OR | Matched pairs | Gaussian $Z$ or McNemar |
| | Stratified | Mantel–Haenszel chi-square |
| AR | Two independent samples | Chi-square or Gaussian $Z$ |
| | Matched pairs | McNemar |
| Homogeneity of RRs or ORs across strata | Large sample | Breslow–Day |
| | Small sample | Zelen test |

summarizes when to use a particular test for qualitative data (proportions), Table T.5b summarizes when to use a particular test for odds ratio and relative risk, and Table T.5c summarizes when to use a particular test for quantitative data including (survival) durations and distributions. This is still not an exhaustive list but covers those that are relatively more commonly used. Consider this list as just a guideline as the conditions are given in brief—for details, see the topic on the concerned test. Choose the test from this list and go to the topic that describes that test to find the actual conditions where the test is appropriate.

## test–retest reliability

**Reliability** is the ability of a tool to perform and maintain functions in routine circumstances, as well as under unexpected circumstances that do not vary much from the routine. In a slightly different form, reliability is **repeatability** that is concerned with stability of the responses with repeated use of the instrument. The measurement of repeatability essentially involves administering the test twice or more to the same subjects under the same condition within a short period. This is therefore known as test–retest reliability. It can be validly calculated for an instrument that does not provide any learning to the respondent, and the second-time responses are not affected by the first-time responses. The scores or the responses obtained on the two occasions are checked for agreement. These can be checked itemwise, but generally the total score is compared. The extent of agreement is measured by **intraclass correlation** (ICC) if the responses are quantitative and by **Cohen kappa** if they are qualitative. If the value of these measures is more than 0.7, the test is considered reliable, and a value less than 0.5 is considered unacceptable.

Suppose one wants to find out whether laboratory A is more reliable than laboratory B in measuring plasma glucose levels. One strategy for this could be to split each blood sample into six parts. Send three parts to laboratory A and three to laboratory B. Do this for, say, 25 subjects and keep the laboratories blind regarding sending aliquots of the same sample. If the laboratory is reliable, the measurement on the different parts of the same sample will give nearly the same values, yielding a high value of the ICC coefficient. The laboratory with significantly higher ICC would be more reliable.

**TABLE T.5c**
**Statistical Tests of Significance for Quantitative Data (Means, Variances, Correlations, Survival)**

| Parameter of Interest and Setup | Conditions | Main Criterion for Test of Significance |
|---|---|---|
| | **Mean or Central Value** | |
| One group | Comparison with prespecified—Gaussian | |
| | σ known | Gaussian $Z$ |
| | σ not known | Student $t$ |
| Comparison of two independent groups | Paired—Gaussian (σ not known) | Student $t$ |
| | Paired—non-Gaussian | |
| | Any $n$ | Sign test |
| | $5 \le n \le 19$ | Wilcoxon signed-ranks $W_S$ |
| | $20 \le n \le 29$ | Standardized $W_S$ referred to Gaussian Z |
| | $n \ge 30$ | Student $t$ |
| | Unpaired—Gaussian | |
| | Equal variances | Student $t$ |
| | Unequal variances | Welch |
| | Unpaired—non-Gaussian | |
| | $n_1, n_2$ between (4, 9) | Wilcoxon rank-sum $W_R$ |
| | $n_1, n_2$ between (10, 29) | Standardized $W_R$ referred to Gaussian Z |
| | $n_1, n_2 \ge 30$ | Student $t$ |
| | Crossover design—Gaussian | Student $t$ |
| | Detecting medically important difference | Student $t$ |
| | Equivalence tests | Student $t$ (TOSTs) |
| Comparison of three or more independent groups, equal variances | One-way, two-way, or multi-way layout—Gaussian | ANOVA $F$ |
| | One-way nonparametric | |
| | $n \le 5$ | Kruskal–Wallis $H$ |
| | $n \ge 6$ | $H$ referred to chi-square |
| | Two-way layout—Gaussian | ANOVA $F$ |
| | Two-way nonparametric (one observation per cell) | |
| | $J \le 13$ and $K = 3$ | Friedman $S$ |
| | $J \le 8$ and $K = 4$ | Friedman $S$ |
| | $J \le 5$ and $K = 5$ | Friedman $S$ |
| | Larger $J$, $K$ | $S$ referred to chi-square |
| | Multiple comparisons—Gaussian | |
| | All pairwise | Tukey $D$ |
| | With control group | Dunnett |
| | Few comparisons | Bonferroni |

**TABLE T.5c (CONTINUED)**
**Statistical Tests of Significance for Quantitative Data (Means, Variances, Correlations, Survival)**

| Parameter of Interest and Setup | Conditions | Main Criterion for Test of Significance |
|---|---|---|
| Repeated measures | Gaussian | ANOVA $F$ with Huynh–Feldt correction for sphericity |
| Comparison of three or more groups, unequal variances | Gaussian | |
| | Large samples | Welch |
| | Small samples | Brown–Forsythe |
| | **Variance** | |
| One group | Comparison with prespecified—Gaussian | Variance ratio $F$ |
| Two independent groups | Gaussian | Variance ratio $F$ |
| | Non-Gaussian (Mild) | Levene |
| More than two independent groups | Gaussian | Bartlett |
| | Non-Gaussian (Mild) | Levene |
| Homogeneity of covariance matrices | Gaussian | Box $M$ |
| Outliers | Gaussian | Grubbs |
| | **Correlation** | |
| One sample | Gaussian | $z$-test after Fisher $z$ transformation |
| Comparison of two independent groups | Gaussian | $z$-test after Fisher $z$ transformation |
| In repeated measures | Gaussian | Mauchly |
| Autocorrelation | Gaussian | Durbin–Watson |
| | **Survival Curve** | |
| Comparison of two independent groups | Nonparametric—large samples | |
| | Same weight to all time points | Log-rank |
| | Weight proportional to $n_t$ | Breslow |
| | Weight proportional to $\sqrt{n_t}$ | Tarone–Ware |
| | **Distribution** | |
| One sample | Nonparametric—large sample | Kolmogorov–Smirnov |
| | Gaussian or non-Gaussian—small sample | Anderson–Darling |
| | Gaussian—moderate sample | Shapiro–Wilk |
| Two samples | Nonparametric—large samples | Kolmogorov–Smirnov |

Note that the reliability may be higher even when there is a constant bias in the measurement since correlation coefficient, including the ICC, ignores constant bias. It is possible that a laboratory has an ICC of 0.90 but consistently reports values lower or higher than the actual value. There must be an external check for this kind of bias.

Russo et al. [1] tested a 36-item health survey form (SF-36) on 36 outpatients with chronic schizophrenia (incidentally, in this example, the sample size $n = 36$ and the number of items = 36 are equal). The form was completed in writing as well as orally by each patient. The test–retest reliability showed that SF-36 is an appropriate outcome measure for schizophrenic outpatients. Mathewson et al. [2] investigated the short-term test–retest reliability of resting regional power and asymmetry in a sample of 38 active older adults in Canada and observed ICC in excess of 0.90 for regional power at different sites (closed eyes), indicating that individual differences before and after the task were clearly preserved.

## test statistic, *see* test criterion

## tetrachoric correlation

This is the correlation between two quantitative variables each with a **Gaussian** (normal) **distribution** but observed in dichotomous categories. Suppose you are dealing with HDL cholesterol (HDL-C) and LDL cholesterol (LDL-C) levels in healthy subjects—both of which have Gaussian distribution but the observations are made only regarding how many subjects have an HDL-C level of 60 mg/dL or less and how many have an LDL-C level of 100 mg/dL or more. The correlation coefficient between such dichotomous categories would be obtained by tetrachoric correlation. Tetra is derived from Greek for "four," which comes from a $2 \times 2$ classification. If the number of categories is 3 or more, this is called a *polychoric correlation*.

Although other measures of association such as **odds ratio** and **contingency coefficient** are available for double dichotomous data, those do not use Gaussian pattern of values even if known. Also, the term *correlation* is more familiar and seems to have a wider appeal. Tetrachoric correlation ranges from −1 to +1 just as the ordinary correlation coefficient does, but different cutoffs of the underlying values can provide different values of the tetrachoric correlation. Software packages easily calculate tetrachoric correlation by considering various combinations that yield a **2 × 2 table** closely corresponding to the one actually observed.

To understand this correlation, consider that the distributions of the two random variables are put at right angles to each other (Figure T.1),

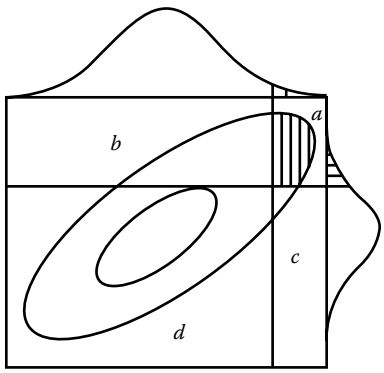

**FIGURE T.1** A graphic of a correlation ellipse divided into four regions based on $x$ and $y$ cutpoints on two Gaussian distributions.

as suggested by R Graphic Manual [1]. The tails of each distribution are marked out using two cutpoints ($x_0$, $y_0$), say, by two raters: $x_0$ on the $x$ axis and $y_0$ on the $y$ axis. Draw two ellipses, one inside another. Within the frame, the shaded region has $x > x_0$ and $y > y_0$. To the left of this, $x < x_0$ and $y > y_0$; underneath that, $x_0 < x$ and $y_0 < y$; and at the bottom right-hand corner, $x > x_0$ and $y < y_0$. The proportions $a$, $b$, $d$, and $c$, respectively, denote the proportion of cases that fall in these regions defined by the two thresholds. For example, $d$ is the proportion below both raters' thresholds (bottom left-hand corner) and is therefore considered "negative" by both. A software package is used to find the values of $a$, $b$, $c$, and $d$ for the given data and to calculate the value of the tetrachoric correlation. An approximation is as follows:

$$\text{Tetrachoric correlation: } r = \frac{\theta - 1}{\theta + 1},$$

where $\theta = \left(\frac{ad}{bc}\right)^{\pi/4}$ ($\pi = 3.14159$) if $a, b, c, d > 0$. If $a = 0$ or $d = 0$, then $r = -1$, and if $b = 0$ or $c = 0$, then $r = +1$.

Brunault et al. [2] used tetrachoric correlation for testing the factor structure in a factor analysis of dichotomized food addiction scale values and eating behavior scale values. Even though this kind of correlation is meant to be used when both the variables are intrinsically quantitative but dichotomized, there are instances when this condition was not strictly followed. For example, Behrsin et al. [3] used this for correlation between the diagnostic accuracy of adenosine deaminase (P-ADA) with histopathology in pleural tuberculosis cases in Brazil where P-ADA was divided with an optimum cutoff value of 40 IU/l as determined by the ROC but histopathological findings were not quantitative. The tetrachoric correlation coefficient was 0.563 but was termed high correlation.

See Uebersax [4] for a good exposition of the subject.

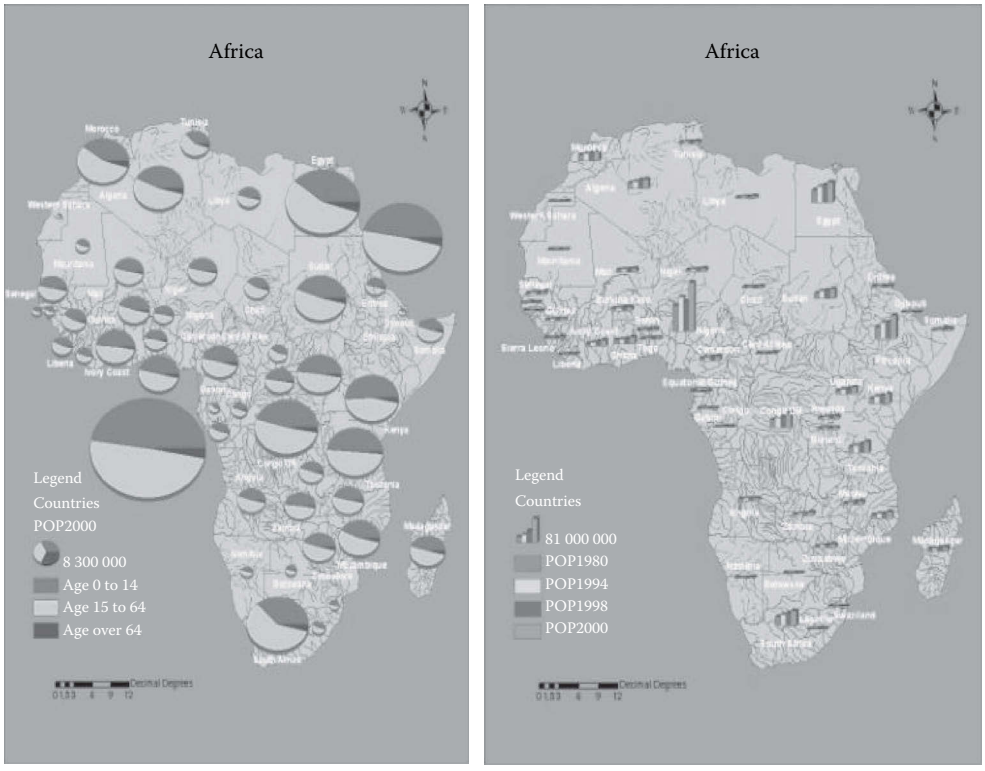
## thematic map, *see also* choroplethic map

This is a type of statistical mapping for values of an indicator in different areas—thus, it displays spatial pattern of values in contrast to the usual maps that show locations, boundaries, land features, and so on. Using different shades or colors is one type of display that makes it what is called a **choroplethic map**, but other methods such as dots and proportional symbols can also be used in a thematic map. Generally, only one indicator (theme), such as density of doctors, is shown; for two or more indicators, a combined index



(a) (b)

**FIGURE T.2** Thematic maps of African countries with regard to the age structure (a) by pie and (b) by bar diagram. (From Andrea P. Building geodatabase 6, Thematic maps, simple analyses methods. *Digitalis Tankonyvtar.* http://www.tankonyvtar.hu/en/tartalom/tamop425/0027_BGD6/ch01s02.html.)

T

may have to be devised such as the **human development index** for the combination of education, income, and health. Nonetheless, it is possible to produce maps to show multivariate data by imposing a pie diagram, a bar diagram, and so on, on the areas, although that may defy the defining principle of keeping a map simple for the user to be able to visualize the theme. Marks and symbols should be easy to understand. Figure T.2 shows a thematic map of age structure (0–14, 15–64, and 65+ years) in African countries where it is shown by pie diagrams on the left side and by bar diagrams on the right side. The size of the pies and bars is according to the total population. Thus, they depict not only the percentage of population in the different age-groups but also the differences in the total population among the countries [1]. See this reference for the method to draw such maps.

Quite often, the categories in thematic maps are arbitrarily chosen of equal width and the number of categories also remains arbitrary. For example, for excess relative risk of heart diseases, Haining et al. [2] used categories 0.3–1.0, 1.0–1.5, and 1.5–2.0. This introduces considerable subjectivity in the cognition and perception obtained from the maps. A discussion on this aspect is given by Indrayan and Kumar [3] who advocate that the categories should be natural, as dictated by the data, in place of arbitrary choices. These natural categories can be identified by consensus in the groups obtained by various methods of clustering and the picture thus obtained can be substantially different from the one based on equal-width categories.

Thematic maps can be used for exploratory purposes, spatial data analysis such as identifying patterns, generating or even confirming a hypothesis, and of course data presentation.

(From Minto C. *Response Surface Modelling of Drug Interactions.* http://www.eurosiva.org/Archive/Vienna/abstracts/speakers/minto.htm.) (b) Distribution of palpable breast cases in different age-groups by histopathological diagnosis.

## therapeutic trials, *see* clinical trials

## 30 × 7 sampling, *see* cluster sampling

## three-dimensional diagrams, *see also* response surface

These are the diagrams that show height also in addition to length and breath. Thus, a three dimensional (3-D) diagram can depict three variables simultaneously.

Many computer packages readily draw 3-D diagrams. The additional variable is shown on a third axis (hence, here we have *x*, *y*, and *z*). A 3-D representation of a given relationship is a **response surface** of the type shown in Figure T.3a. This shows how the response flattens when two drugs have a high dose [1].

Another 3-D diagram is in Figure T.3b, which shows the distribution of palpable breast cases in different age-groups by their histopathological diagnosis. This is a bar diagram in 3-D with three axes. You can also have a 3-D diagram with just two axes, where, for example, bars are shown in 3-D but there is no third variable.

## three-way tables, *see* chi-square test for three-way contingency tables

## three-sigma limits, *see also* six-sigma methodology

Among several properties of a **Gaussian** (Normal) **distribution**, one is that the limits from (mean – 3σ) to (mean + 3σ) cover the measurements of exactly 99.7% of subjects, where σ is for the standard

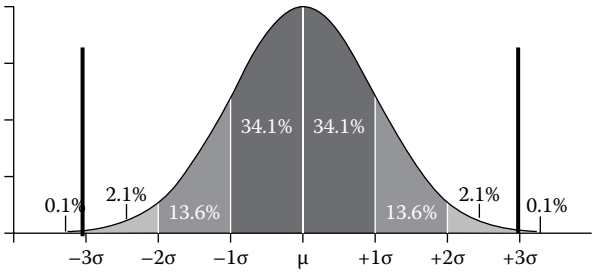

**FIGURE T.4** Three-sigma limits in a Gaussian distribution.

deviation (SD) (Figure T.4). These are referred to as ±3SD limits or sometimes as three-sigma limits.

Three-sigma limits are primarily used in **quality control** charts to set the upper and lower control limits. If the measurement of a product in a line reaches beyond these limits, the product is considered defective as its chance of being "within control" is less than 1%. However, this works when the inherent variation, measured by the standard deviation (σ), is small. Another use of these limits is in ***Z*-scores** of growth parameters of children such as

$$Z\text{-score} = (\text{Weight} - \text{Mean})/\text{SD}$$

for weight. Since Z-score already has SD in the denominator, the limits for this are from −3 to +3. Any weight with Z-score beyond these limits is considered unusually high or unusually low.

## ties in values, *see* ranks

## time-dependent covariate, *see* Cox regression

## time series, *see also* periodogram, autoregressive moving average (ARMA) models

Recording the values of a variable at regular intervals over a long period gives rise to what is known as a time series. The observed movement and fluctuations within such a time series are generally made up of four components: (i) "secular trend" (the underlying smooth movement of a time series), (ii) seasonal variation, (iii) cyclical variation, and (iv) irregular variation called random. For example, the incidence of an infectious disease recorded monthly over several years in a population is a time series, where all these components may operate. In some time series, such as on incidence of some noncommunicable diseases, one or more of these components may be absent.

The primary purpose of studying time series is to explore and understand the trend over time and sometimes to forecast values for the near future. Time series analysis comprises decomposing the series into seasonal, cyclical, and secular trend—the remaining being random variation as just mentioned. Secular trend provides the long-term trend such as declining incidence of infectious diseases over the past 50 years. This trend is generally assumed linear, which implies a constant rate of either growth in case of an increase or decay in case of a decrease. The systematic variation could be cyclic, such as a 5-year cycle for dengue in India similar to the one depicted in Figure T.5. Parainfluenza is seen to have a 2-year cycle [1] whereas dengue hemorrhagic fever is seen to have a 5-year cycle in Latin America [2]. Seasonal trend is mostly within a year, such as that of swine flu occurring at the start of winter and that of dengue with a peak around the month of October in India every year, as is clear from Figure T.5. Such cyclic trend is visibly seen each day as circadian rhythm in blood pressure, heart rate, and so on, or when a drug is taken such as three times a day. It is necessary that the hourly/daily/weekly/monthly values are available to study these components, and any time series has to be necessarily long for any adequate analysis, that is, for, say, at least values for 50 time points.

Time series models are very useful for short-range forecasting problems. They assume that whatever forces have influenced the variables in question in the recent past will continue to operate in the near future. Because of the complexity owing to seasonal, cyclical, and secular trend, forecasting in a time series setup has to follow certain steps. As a first step, the series is smoothened so that the random variation is removed as much as possible. This involves some form of local averaging, such as **moving average**, which tends to cancel out the negative and positive irregular (random) component. If real outliers are present, perhaps the local median of a few successive values can be tried in place of the arithmetic mean generally used in moving "average." The appropriate lag for this is identified by **periodogram** analysis. Other smoothing methods such as **cubic splines** can also be used. Being local, these methods tend to highlight seasonal pattern but not cyclical pattern. The cyclical pattern is explored mostly with trigonometric functions such as sine waves. For secular trend, regular regression methods can be tried—a simple linear method can be used if the trend is anticipated to follow a linear trend, whereas a curvilinear method can be used if the long-term trend seems to follow a curve.

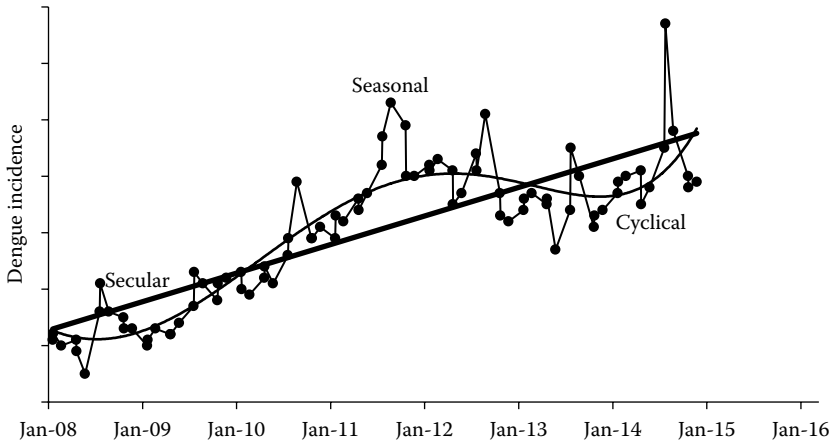

**FIGURE T.5** Seasonal, cyclic, and secular trend in a time series.

In analyzing time series data, it is necessary to take account of any serial correlation (also known as **autocorrelation**), since the values depend serially on the value on previous occasions. Such serial correlation can occur because the time effect by itself may not be able to take care of other factors that may be simultaneously changing, such as population size.

Further analysis can be carried out using the **autoregressive moving averages (ARMA)** method. Other methods can also be used. For example, Been et al. [3] studied monthly incidence of asthma cases and respiratory tract infections in four UK counties over the period 1997 to 2013. They used generalized additive mixed models since their objective was to see the effect of smoke-free legislation introduced at that time. However, this also accounted for autocorrelation between data points. Ngo et al. [4] used spectral analysis to study electroencephalogram time series in the United States.

## titration study

A titration study is where a patient is sequentially administered graded doses of a drug with predetermined rules to determine at what dose the response is optimal. Optimality could be defined in terms of maximum response without substantial side effects or in any other appropriate manner. Typically, the study starts with a low dose that is gradually increased until the dose can no longer be tolerated or until the desired response is obtained. This kind of study can obviously be done only when the drug has no adverse response, where "response" is usually some objective measurement: for example, the reduction of blood pressure below a certain level. Thus, a titration study is actually a dose-finding study, mostly oriented to an individual.

The work by Blonde et al. [1] provides an example of titration in practice, although this was done on a large group of patients. The aim of their study was to compare the efficacy and safety of two fasting plasma glucose (FPG) titration targets using a patient-directed algorithm for once-daily basal insulin in insulin-naïve subjects with type 2 diabetes suboptimally treated with an oral antidiabetes drug. In this 20-week randomized controlled study, 244 insulin-naïve subjects with type 2 diabetes were equally randomized to one of two treatment arms using 80–110 or 90–110 mg/dL FPG as titration targets. Once-daily insulin detemir (a long-acting human insulin analog for maintaining the basal level of insulin) doses were adjusted using algorithm-guided, patient-directed titration to achieve the target FPG values. Another such example is a continuous positive airway pressure titration study where the objective is to find the right amount of air pressure with sleep disorder [2].

Chuang [3] used the life table method and a dose–response model to illustrate the analysis of a titration study that investigated the efficacy of an anti-hypertensive compound. Care is required since treatment effect may be confounded with time, and the titration process might be correlated with safety issues as mentioned earlier. For further details of titration studies, see Chow [4].

## tolerance interval

A tolerance interval covers a stated proportion of a population distribution with a given **confidence level**. It is used to determine whether or not a process is capable in the sense that the process does not exceed a certain failure rate as determined using present specifications. The basic difference with confidence interval (CI) is that CI is for a population parameter whereas tolerance interval is for a specified proportion of the population. For example, the interest may be in tolerance interval within which at least 90% ($\pi = 0.90$) of blood samples have values with probability $(1 - \alpha) = 0.95$ after a treatment. A CI, such as $\bar{x} \pm 1.96s/\sqrt{n}$ for mean, does not consider the sampling fluctuation in the estimate $\bar{x}$ and $s$, whereas tolerance interval considers this fluctuation. Consequently, it becomes mathematically complex. The CI can be greatly reduced by increasing the sample size, but not the tolerance interval because it also considers variance in addition to sampling fluctuations in the estimates. A large tolerance interval implies too much variation in the values.

Figure T.6 presents the concept of a tolerance interval graphically. The solid line in this figure represents the actual population distribution. The dotted line distributions result from the uncertainty of knowing the true location of the population mean. The difference in location of the mean as a result of this uncertainty is defined by the CI. Because of this, the tolerance interval extends beyond the tail areas of the actual population distribution. For tolerance interval, it is necessary to consider the uncertainty of knowing just where the mean of the population distribution lies.

A two-sided tolerance interval can be calculated as follows:

$$\bar{x} \pm k_2 s,$$

where $\bar{x}$ is the sample mean, $s$ is the sample standard deviation (SD), and $k_2$ is a factor for a two-sided tolerance interval defining the number of sample SDs required to cover the desired proportion of the population. This is also called the tolerance factor and is different if 50% of the population values are to be covered than, say, 75% of the values of the population.

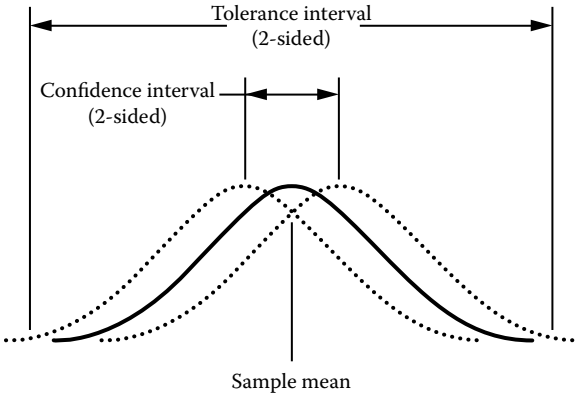

**FIGURE T.6** Graphical depiction of a tolerance interval. (From Propharma Group. *Understanding Statistical Intervals Part III. News and Blog*, 2015. http://www.propharmagroup.com/blog/understanding-statistical-intervals-part-iii-tolerance-intervals.)

Exact values of $k_2$ are tabularized in ISO 16269-6 [2]. These values of $k_2$ were calculated iteratively using a numerical integration process. However, in practice, a reasonable approximation of $k_2$ can be obtained using the formula below:

$$k_2 = \sqrt{\frac{(n-1)\left(1+\frac{1}{n}\right)z^2_{(1-\pi)/2}}{\chi^2_{1-\alpha,n-1}}},$$

where

$n$ is the sample size

$z_{(1-\pi)/2}$ is the standard Gaussian (Normal) variate corresponding to $(1 - \pi)/2$, where $\pi$ is the proportion of the population to be covered

$\chi^2_{(1-\alpha),n-1}$ is the critical value of the chi-square distribution with $n - 1$ degrees of freedom surpassed with probability $(1 - \alpha)$, the statistical confidence

The formula and tables for one-sided tolerance intervals are provided by Natrella [3].

Consider an example of prostatic specific antigen (PSA) measured for a random sample of $n = 40$ healthy males with mean = 3.5 ng/mL and SD = 0.7 ng/mL. What are the tolerance limits for $\pi = 90\%$ of the subjects with confidence $(1 - \alpha) = 0.95$? For $(1 - \alpha) = 0.95$ and df = 40 − 1 = 39, the critical value of chi-square $\chi^2_{0.95,39} = 54.572$, and $z_{(1-\pi)/2} = z_{0.05} = -1.645$. These give $k_2 = \sqrt{\frac{(40-1)\left(1+\frac{1}{40}\right)(-1.645)^2}{54.572}} = \sqrt{\frac{39.975 \times 2.7060}{54.572}} = \sqrt{1.9822} = 1.41$.

Thus, the 95% tolerance range for 90% population is $3.5 \pm 1.41 \times 0.7$, or 2.11 to 4.89. This means that in this population, there is a 95% chance that 90% of the subjects have PSA between 2.11 and 4.89 ng/mL. Note that this is much larger than the 90% CI.

The validity of a tolerance interval is highly dependent on the distribution of the underlying data. In practice, data are assumed to be distributed in a **Gaussian** manner; this assumption can be verified by using the **Anderson–Darling test**.

There is another statistical use of the term *tolerance*. This is to measure the effect of **multicollinearity** on the variance of the model's parameter estimates. A formal measure of collinearity between covariate $x_k$ and the other covariates is given by the proportion of the variance in $x_k$ explained by the other covariates when $x_k$ is regressed on the other covariates. In fact, this is the square of the **multiple correlation coefficient**, denoted here by $R_k$. It can be shown that the variance of the regression coefficient $b_k$ is proportional to $1/\left(1-R_k^2\right)$; thus, large values of $R_k^2$ are associated with imprecise estimates of $\beta_k$. The **variance inflation factor (VIF)** for a covariate $x_k$ is defined to be $1/\left(1-R_k^2\right)$, and the tolerance is the reciprocal of this: $1 - R_k^2$. A small value of tolerance, for instance, less than 0.10, indicates that collinearity is a problem and needs to be tackled.

## total fertility rate, *see* fertility indicators

## tracking

Tracking is a term often used for follow-up observations from earlier values as sometimes used for examining **longitudinal data**. At face value, tracking would imply that the subjects with the largest values of the response variable at the start of the study will tend to continue to have relatively larger values throughout the study. This is measured by a quantity called *tracking coefficient* that could be simply correlation coefficient or any other such measure. If a correlation coefficient is used for tracking, it is highly unlikely to be negative in this setup, and the effective range is 0 to 1. If the effect of some factors is to be removed, the adjusted correlation coefficient can be computed. A value of at least 0.6 is considered a good correlation for tracking. Note that a tracking coefficient is just a pure measure of longitudinal changeability and does not tell the direction of individual change.

An example illustrating this is given by Kagura et al. [1]. They studied hypertension in South Africa to examine if hypertension in adulthood can be traced back to childhood. Since there is a scarcity of longitudinal data on pediatric blood pressure (BP) in African populations, the authors set out to assess the prevalence of hypertension in children and to evaluate BP tracking between childhood and late adolescence through a cohort of South African black children. A Birth to Twenty cohort of children born in Soweto, Johannesburg, in 1990 was available ($n = 3273$, 78.5% black). Data on BP were collected at six follow-up periods between ages 5 and 18 years (14 years). Pearson correlation coefficients and relative risk (RR) were used to describe tracking of BP between childhood and late adolescence. Tracking coefficients ranged from 0.20 to 0.57 for systolic BP and 0.17 to 0.51 for diastolic BP in both sexes over the period of 14 years. RR of having elevated BP ranged from 1.60 at 5 years to 2.71 at 18 years of age. The authors concluded that this study reported high prevalence of elevated BP, which tracks from early childhood into late adolescence. They emphasized the importance of early identification of children at risk of developing elevated BP and related risk factors plus timely intervention to prevent hypertension in adulthood.

Ulmer et al. [2] have explained tracking well in the context of cardiovascular risk factors.

## transformations

Four types of transformations are popular in statistics: (i) linearizing, (ii) normalizing, (iii) variance stabilizing, and (iv) distributional Gaussianizing. For the last, see **Box-Cox power transformation**. This includes **logarithmic transformation** for highly skewed data. The others can be explained as follows.

### *Linearizing Transformation*

Linear relation means that the rate of change in one variable with respect to another is uniform, and it can be depicted by a straight line. Linear relations are easy to understand and easy to model and use. In mathematical form, this is expressed as $y = a + bx$. Linearizing transformations are those that convert a nonlinear or curvilinear relation to linear form—thus making it easy to interpret. The most simple of linearizing transformations is the logarithmic, which is used for multiplicative values such as titers and radiation doses. This arises from the fact that $\log(m*p) = \log m + \log p$. This kind of transformation works very well for the exponential relationship $z = ce^{bx}$ since then $\ln z = \ln c + bx$, which is the same as $y = a + bx$ with $y = \ln z$ and $a = \ln c$. In many setups, the linearizing transformation is obtained by running the **regression**. Suppose the regression of total glomerular filtration rate (GFR) on plasma creatinine level (in milligrams per deciliter) in patients with chronic renal failure is GFR = 2.7 + 150(1/creatinine). This implies that the reciprocal of creatinine linearizes the relationship. After this transformation, the relationship can be represented by a straight line. Without the transformation, it is a curve.

### *Normalizing Transformation*

Normalizing is transforming the data within the range [0, 1], keeping the order preserved. This is achieved by using the transformation

$$(x - \text{Min})/(\text{Max} - \text{Min}).$$

This is different from standardization: $(x - \text{Mean})/\text{SD}$ that leads to ***Z*-scores**. For further details, see the topic **normalization**.

Recognizing the association of *Z*-scores with the so-called normal distribution, some believe that the *Z*-score transformation is "normalizing" and that this can make their data normally distributed. This actually is not so as these are linear transformations that do not alter the basic shape of the distribution.

### *Variance Stabilizing Transformations*

These transformations are used to achieve **homoscedasticity** so that the variances across groups are nearly equal as is required for some statistical methods such as analysis of variance and regression. These transformations are separately discussed under the topic **variance stabilizing transformations**. One of these, the logarithmic, can be explained as follows.

Sometimes, the residuals from regressing the data are large for larger values of the dependent variable. Such a trend often occurs when the change in the outcome variable is often not an absolute value but a percentage of the value. For the same percent error, a larger value of the variable means a larger absolute error, leading to the residuals also becoming larger. In this case, taking logarithm helps in obtaining uniform variance.

## trend

Trend is the smoothed pattern of values over a period, or over values of the other variables. For example, the trend of systolic level with age is upward linear for males and a slight curvilinear for females with quick upward move after menopause. A trend is called linear when the change in the value of one variable ($y$) is the same per unit change in the value of another variable ($x$), at least on average, and is called curvilinear when the rate of change in $y$ changes with $x$, such as fast rise for initial values of $x$, slow for middling values of $x$, and fast decline for large values $x$ (this is the trend lung functions follow as age increases). For details, see **linear regression** and **curvilinear regression**. We can also have **nonlinear** trend as discussed in this topic. All regressions are for the mean of $y$ for given $x_s$. Regression is one method of obtaining smooth trend. For others, see **smoothing methods**.

The term *trend* is also used for seasonal, cyclic, and secular as used for **time series** for intra-year and long-term pattern. This term is also used for the pattern of frequencies or of proportions in ordinal categories such as mortality in none, mild, moderate, serious, and critical conditions. This is assessed by the **Cochran test for linearity of trend**. The trend will be increasing mortality with increasing severity of disease, but the increase is sharp for some diseases and shallow for other diseases.

Graphs and diagrams, particularly the line diagram, are very helpful in trend assessment, as they can give at least a gross idea of what kind of trend, if any, exists in the data. Precise statistical study is done by fitting regressions, time series analysis, trend in proportion, and so on, as just mentioned. Studying trends helps us evaluate the result of our actions, such as for control of disease, and to project the future, and become prepared accordingly such as devising a strategy for changing the trend. This is mostly done by studying the effect of various covariates on the outcome of interest. For example, the study reported by Rahman et al. [1] has shown that satellite-based vegetation health indices are highly applicable for the malaria assessment trend in Bangladesh. Blaxill [2] observed that comparison of autism rates in the United States and the United Kingdom by year of birth for specific geographies provides the strongest basis for trend assessment. For world health situation and trend assessment from 1948 to 1988, see the article by Uemura [3].

## trials, *see* clinical trials

## trimmed mean

This is the mean obtained after discarding some extreme values from the data. In some analyses, the question of rejection or correction of data values may not be an issue, but it is well known that occasional extreme values do occur in many medical setups. They may or may not be **outliers**. It is natural to look for a method so that the outliers do not significantly affect the results and might seek an estimator that is less influenced than the mean (for example) by such extreme values. The sample median is the most widely used method in such situations, but another method is the trimmed mean, which is calculated after deleting generally a fixed proportion of values in each tail of the distribution of values. This is also called the *truncated mean* and is more **robust** than the usual mean.

Note that removing transparently erroneous data is not trimming. Trimming occurs when you discard data values that are legitimate (or cannot be identified as illegitimate) but small or large with respect to the sample as a whole. But isn't throwing away data a bad idea? In truth, the mean with small trimming is nearly as good as $\bar{x}$ for approximately normal data and a much safer bet than $\bar{x}$ for heavy-tailed data.

There are two types of trimmed mean that deserve mention: α-trimmed mean and α-**Winsorized mean**, where "α" is not as it is usually used in statistics; that is, it is not the probability of a Type I error. Alpha (α)-trimmed mean requires deleting a proportion α of the observations from both ends of the sample and calculating the mean of the remainder. If $x_{[1]}, x_{[2]}, \ldots, x_{[n]}$ represent the ordered sample values from the minimum to the maximum, then

$$\alpha_{\text{trimmed mean}} = [1/(n-2K)]\sum_{i=K+1}^{n-K} x_{[i]},$$

where $K$ is the smallest integer greater than or equal to $\alpha^* n$. For simplicity, we have considered the same trimming in both the tails but they can be unequal.

For example, a 5% trimmed mean is obtained by deleting 5% of the highest values and 5% of the lowest values, leaving 90% of the original values upon which a mean is then calculated. If we have the following 20 data points:

3.52, 6.60, 2.95, 2.18, 7.60, 5.21, 6.45, 5.87, 3.65, 6.99, 0.83, 1.21, 7.38, 4.74, 8.53, 5.08, 3.04, 7.24, 17.54, 2.43,

proceed by first putting the data in ascending order:

0.83, 1.28, 2.18, 2.43, 2.95, 3.04, 3.52, 3.65, 4.74, 5.08, 5.21, 5.87, 6.45, 6.60, 6.99, 7.24, 7.38, 7.60, 8.53, 17.54,

then 5% trimming removes 1 lowest out of 20 and 1 out of 20; that is, 0.83 and 17.54 are deleted. The 5% trimmed mean is based on the 20 − 2 = 18 remaining values, and in this example, this is 5.04. The untrimmed (usual) mean of all 20 values is 5.46. The difference is primarily due to the value 17.54, which is too high relative to the other values.

Incidentally, the median of a distribution is nearly a 50% trimmed mean, that is, you remove 50% of the lowest data values and 50% of the highest data values and are left with one number as an estimate of the center of the distribution. You can think of 25% trimmed mean that would be based on the middle 50% values. The trimmed mean sits between the mean and the median in terms of its statistical properties, with advantages of both and possibly not so many disadvantages. The only difficulty is with regard to its mathematics—its statistical distribution, standard error, confidence interval, test of hypothesis, and so on. For this reason, it fails to find favor with statisticians. Discarding some valid values is also not considered a good statistical strategy.

The alpha (α)-Winsorized mean is another method of estimating the mean of a population in a way that is less affected by the presence of extreme values or outliers than is the usual mean. Essentially, the $K$ smallest and $K$ largest observations, where $K$ is the smallest integer greater than or equal to $\alpha^* n$, are replaced in value to the next remaining observation and counted as though they had these values. Specifically,

$$\alpha_{\text{Winsorized mean}} = 1/n^* \left[ (K+1)(x_{[K+1]}) + (K+1)(x_{[n-K]}) + \sum_{i=K+2}^{n-K-1} x_{[i]} \right],$$

where $x_{[1]}, x_{[2]}, \ldots, x_{[n]}$ are the ordered sample values. Winsorizing differs from trimming since a certain proportion of lowest and highest values are replaced by the lowest and highest values in the remaining data set, and not deleted.

Returning to the previous example, if these data are Winsorized at 10%, then the smallest and largest values after the two lowest and two highest (10% of 20 = 2) values are 2.18 and 7.60, respectively. The Winsorized data set becomes

2.18, 2.18, 2.18, 2.43, 2.95, 3.04, 3.52, 3.65, 4.74,
5.08, 5.21, 5.87, 6.45, 6.60, 6.99, 7.24, 7.38, 7.60, 7.60, 7.60.

The 10% Winsorized mean is the average of these 20 values with the repeats, which is 5.02, as compared to the usual sample mean of 5.46. Similarly, Winsorized standard deviation can also be calculated.

It is not right to use the standard method of constructing confidence intervals for mean when using trimmed means (for one, the remaining values in the trimmed data set are no longer independent or identically distributed since the trimming is not at random). The correct standard error for an α-trimmed mean is $s_w/[(1-\alpha)\sqrt{n}]$, where $s_w$ is the standard deviation of the α-Winsorized sample. The correct standard error for the 10% trimmed mean in our example is 0.58, and a 95% confidence interval for the 10% trimmed mean is $5.02 \pm 2.13(0.58) = (3.78, 6.26)$, where 2.13 is the appropriate critical value from the Student $t$ distribution with 15 (the number of values left after deleting two smallest and two largest − 1) = 15 degrees of freedom (i.e., $t_{0.975,\,15} = 2.13$). It is interesting to note that this CI in our example omits the lowest eight and the highest eight values and just keeps the middle four.

## triple blinding, *see* blinding

## trivariate distribution

This is the distribution of subjects by three characteristics. An example is in Table T.6 where 279 users of tobacco are classified by (i) age, (ii) sex, and (iii) type of tobacco use. In this distribution, the values of a continuous variable would be grouped such as for age in Table T.6.

Ordinal and nominal groups may appear as such without any numeric assigned as are sex and types of tobacco use in Table T.6, and continuous variables also remain as such in a distribution although they may have to be categorized for tabular presentation. For a discrete variable, the values may appear as such, for example, 0, 1, 2, 3, 4, and 5+ for parity. The last category in this case is also a group.

A one-way **contingency table** describes a univariate distribution, a two-way table describes a **bivariate distribution**, and a three-way table describes a **trivariate distribution**.

**TABLE T.6**
**Distribution of 279 Tobacco Users by the Type of Tobacco**

| Age-Group (Years) | Chewing Only | | | Smoking Only | | | Dual Use | | | Total Tobacco Users | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | M | F | P | M | F | P | M | F | P | M | F | P |
| <19 | 1 | 0 | 1 | 7 | 2 | 9 | 2 | 0 | 2 | **10** | **2** | **12** |
| 20–29 | 16 | 11 | 27 | 19 | 13 | 32 | 13 | 6 | 19 | **48** | **30** | **78** |
| 30–39 | 5 | 1 | 6 | 53 | 42 | 95 | 2 | 7 | 19 | **60** | **50** | **110** |
| 40–49 | 10 | 1 | 11 | 14 | 4 | 18 | 2 | 7 | 9 | **26** | **12** | **38** |
| 50+ | 3 | 4 | 7 | 9 | 14 | 23 | 6 | 5 | 11 | **18** | **23** | **41** |
| **Total** | **35** | **17** | **52** | **102** | **75** | **177** | **25** | **25** | **50** | **162** | **117** | **279** |

*Note:* F, female; M, male; P, person.

It is worth mentioning **marginal distributions** and *conditional distributions* at this stage. The former refers to the probability distribution of a single variable (or indeed a number of variables) when the other variables are collapsed. In Table T.6, the bottom row is the marginal (bivariate) distribution of the tobacco users by sex and type of tobacco use. The age has been collapsed. Similarly, the last column is the marginal distribution of the tobacco users by age disregarding sex and type of tobacco.

Conditional refers to the probability distribution of a random variable (or maybe the joint distribution of a number of variables) when one or more other random variables are held fixed. In Table T.6, the first three columns contain conditional distribution of tobacco chewers by age and sex. This is conditioned on type of tobacco use = chewing only. Similarly, the distribution in the next three columns is the conditional distribution for tobacco use = smoking only. The marginal distributions help in deriving conclusions for specific variables and conditional for specific groups.

## truncated values/distributions

Truncation in health and medicine often occurs owing to limitations of the tools such as truncation of CT projection by limited field of view relative to large patient anatomies. They do provide truncated data and can introduce serious artifacts. However, the concern in this section is as follows.

Truncated data are values where larger or smaller values than a given fixed value are either not recorded or not observed. Where the ignored values are larger, this leads to right truncation, and where the ignored values are smaller, this leads to left truncation. Truncation is a variant of **censoring** that occurs when the incomplete nature of the observation is due to the study design. Censoring occurs when an observation is not complete because of some random cause, whereas truncation is deliberate and can also be done after the data are available. Figure T.7 has one full Gaussian distribution (broken lines) and two truncated distributions: one (thick solid line) left truncated at −0.25 and another (thin solid line) truncated at +1. It should be evident that the mean and standard deviation (SD) of the truncated distribution will not be the same as of a full distribution.

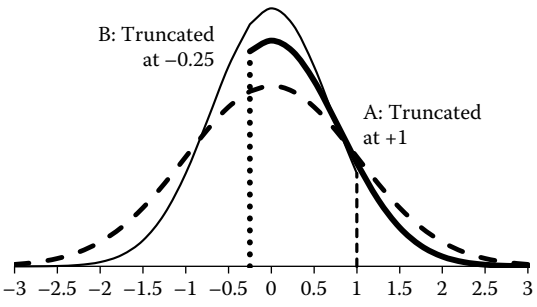

**FIGURE T.7** Truncated Gaussian distributions.

Truncation might be an operational necessity. For example, a study on cataract may restrict itself to only people of age 60 years or more. In this case, the age distribution will be left truncated at age = 60 years. The mean age of onset in these people cannot be termed as mean age of onset of cataract in the general population because people less than 60 years are not included. Age at onset of these who are not included will not be known. If people more than 90 years are excluded for some reason, the age distribution will be right truncated at age = 90 years. We can have truncation on both sides such as when including people of age 60 to 90 years. Note that this is truncation with respect to age. If the outcome of interest is the visual acuity, there is no truncation with respect to this outcome. This truncation can happen if, for example, you decide to exclude people with normal vision after obtaining the data on all.

Values with a truncated distribution cannot be analyzed in the usual way because the underlying requirement of many parametric methods may be violated. This, however, applies to only the stochastic variable such as the dependent variable in regressions. Such truncation does not affect the regression if it is for independent variables. In our example, if age is one of the regressors, its truncation to between 60 and 90 years will not affect the logistic or ordinary regression where the outcome is visual acuity except that the regression is valid for people with age 60 to 90 years. However, if age is the dependent variable, the regression will have restricted utility.

The problem compounds when truncation is applied to some values and others are fully observed. Piccorelli and Schluchter [1] discussed modeling for serial measurement of pulmonary function ($FEV_1$% predicted) and survival in cystic fibrosis patients using registry data where some patients enter late and not followed from birth, whereas for others, full data from birth is available. In this case, the truncation is with respect to age and not $FEV_1$%.

Truncation is frequently used in survival studies. This is in addition to censoring as mentioned elsewhere. For analysis of such data, see Kline and Moeschberger [2].

## *T*-score, *see also* *Z*-scores

Generally speaking, a *T*-score of a value is how many sample standard deviation (SD) away is this value from sample mean. That is $t = \frac{x - \bar{x}}{s}$, where $\bar{x}$ and $s$ are the sample mean and sample SD, respectively. The difference with ***Z*-score** is that $Z$ uses the population mean and population SD; that is, $Z = \frac{x - \mu}{\sigma}$. Since these parameters are rarely known, they are replaced by their sample counterparts to give a *T*-score.

However in medical applications, particularly for bone mineral density (BMD), *T*-score is used to convey how far a person's BMD is from the ideal. That is, in this case, the mean is replaced by the ideal value, which, in the case of BMD, is generally considered to be the average BMD of 30-year-old healthy adults when BMD is usually is at its peak. This is also referred to as the expected BMD. The denominator should be the population SD $\sigma$ for this *T*-score that also may be known from population studies. Thus, in this case,

$$T\text{-score} = \frac{x - \mu_0}{\sigma_0},$$

where $\mu_0$ is the peak average BMD and $\sigma_0$ is the SD of BMD of 30-year-old healthy adults. A value of $T \geq -1.0$ is considered normal, $-2.5 \leq T < -1.0$ indicates osteopenia, and $T < -2.5$ suggests osteoporosis. For easy understanding, *T*-scores are simultaneously converted to have mean = 50 and SD = 10. Thus, you can say, for example, that the BMD of a person is 20 points above the expected when the actual *T*-score is +2.0. In the case of BMD, *Z*-score is calculated for each age and sex using mean and SD for that exact age and sex, whereas *T*-score always uses the ideal BMD.

Gourlay et al. [1] have made an ingenious use of *T*-scores to determine the time required for women 67 years and older with normal BMD or mild osteopenia ($T \leq -1.50$) to progress to osteoporosis ($T \leq -2.5$), and estimated it to be as much as 15 years. However, Doshi et al. [2] argue that the testing interval for BMD should be guided by an assessment of risk factors and not *T*-scores.

## *t*-test, *see* Student *t*-tests

## Tukey test for additivity

Tukey test for additivity is used to test the statistical significance of **interaction** between two factors in a **two-way ANOVA** setup when there is only one observation per cell. When the interaction is absent, the factor effects are additive for their combined effect, which is the reason that it is called test for additivity. The usual method of testing interaction between factors does not apply when the value for only one subject is available for each combination of levels of factors because then the error sum of squares becomes zero. Unfortunately, sometimes it is not feasible to make more than one observation under the same conditions. For instance, it is not possible to ask the same participant the same question twice, when only a limited number of subjects are available. Tukey test for additivity is a great way for testing the significance of the interaction in a two-way analysis of variance with one observation per cell, although there are certain restrictions.

Suppose there are 3 drugs under trial and each has 4 doses. Thus, there are a total of $3 \times 4 = 12$ combinations. If only one subject gets each of these combinations, there will be 12 subjects in this trial. This is no replication. In this case, the interaction between drug and dose cannot be tested by the usual methods because of just one observation per cell but can be tested by the Tukey test for additivity. The test was introduced by John Tukey in 1949 [1].

Consider the scenario of two factors in which the response is modeled with $\alpha_j$ as the main effect of the $j$th level of the first factor and $\beta_k$ as the main effect of the $k$th level of the second factor. Let the interaction between the $j$th level of factor 1 and the $k$th level of factor 2 be denoted by $\gamma_{jk}$. For simplicity, we consider the case when both the factors are fixed and assume $\gamma_{jk} = D\alpha_j\beta_k$. This is the restriction that we mentioned earlier and says that the interaction is multiplicative of the individual effects. Under these conditions, the test is given by

$$\text{Tukey test for additivity: } T = \frac{SS_{AB}}{MSE},$$

where $SS_{AB} = \frac{[\Sigma_{jk} y_{jk}(\bar{y}_{j\cdot} - \bar{y}_{\cdot\cdot})(\bar{y}_{\cdot k} - \bar{y}_{\cdot\cdot})]^2}{\Sigma_j(\bar{y}_{j\cdot} - \bar{y}_{\cdot\cdot})^2 \Sigma_k(\bar{y}_{\cdot k} - \bar{y}_{\cdot\cdot})^2}$ and $\text{MSE} = \frac{SSE - SS_{AB}}{JK - (J + K)}$.

This follows an $F$ distribution with $(1, \nu)$ df, where $\nu = JK - (J + K)$. The basic difference is the way $SS_{AB}$ is computed in this case.

The critical assumption in this case is $\gamma_{jk} = D\alpha_j\beta_k$, where $D$ is some constant. This is based on the consideration that if $\gamma_{jk}$ is any second-degree polynomial function of $\alpha_j$ and $\beta_k$, then it must be of this form [2].

## Tukey test for multiple comparisons, *see also* multiple comparisons

The Tukey test is one of the several methods of **multiple comparisons** of group means after the analysis of variance (ANOVA) results indicate that there is a significant difference among the groups somewhere. In the case of pairwise comparisons, for example, if there are 4 groups, the comparisons are group 1 with group 2, group 1 with group 3, group 1 with group 4, group 2 with group 3, group 2 with group 4, and group 3 with group 4. There are a total of six pairwise comparisons. In addition, one can test the difference between, say, group 1 with the average of groups 2, 3, and 4 combined, and so many others of this type. This is what we mean by multiple comparisons. Means of two groups are generally compared by the Student *t*-test, but repeated application of this test at, say, 5% level of significance on the same data blows up the total probability of **Type I error** to an unacceptable level. If there are 15 tests on the same data, each done at the 5% level, then the overall (experiment-wise) Type I error could be as high as $1 - (1 - 0.05)^{15} = 0.54$. Compare this with the desired 0.05.

Type I error allowed for each individual comparison is called *comparison-wise error rate*, whereas the total error for all the comparisons together is called *experiment-wise error rate*. To keep the probability of (experiment-wise) Type I error within a specified limit such as 0.05, many procedures for multiple comparisons are available. Each of these is generally known by the name of the scientist who first proposed it. Among them are **Bonferroni, Tukey, least significant difference, Duncan,** and **Dunnett**. The Bonferroni and Tukey procedures are commonly used in medical and health literature and are also the most suitable ones.

The Tukey test is the most suitable when the interest is in *all* pairwise comparisons. The procedure works as follows. Corresponding to the df($J$,$v$), where $J$ is the number of groups to be compared and $v$ is the df associated with **mean square error** (MSE) in the ANOVA table, a value $Q$ is obtained from what is called the **Studentized range distribution** for a specified **level of significance** α such as 0.05. This distribution is based on the maximum difference in means, which is the difference between the largest mean and the smallest mean. Critical values of $Q$ are available in tables for different numbers of groups and different error df when α is 0.05 [1]. Use this $Q$ value and calculate

$$\text{Tukey test: } D = Q\sqrt{\frac{\text{MSE}}{n/J}},$$

where $n$ is the total number of subjects in all the groups together and MSE is the mean square error in the ANOVA table for those data. Any pairwise difference exceeding $D$ in group means is considered statistically significant. This keeps the experiment-wise probability of Type I error limited to the specified α level. This test was developed by John Tukey in 1949 [2] and is also called *honestly significance difference* test.

John Tukey

The requirements of the Tukey test are essentially the same as those of Student $t$-test for independent groups, namely, the homogeneity of variance, independent observations, and Gaussian (Normal) distribution or large sample, with independence being the most important and Gaussian distribution being the least important especially if the group sizes are equal. The Tukey test need not be preceded by the ANOVA $F$-test, but the MSE is required anyway.

Consider an observational study on the effect of maternal smoking (duration and quantity—both observed in three categories each) on child birth weight. Suppose that the effect of duration of smoking was statistically significant and the effect of quantity was not significant. To find which category of duration or categories were making a significant impact, researchers compared mean birth weights for different categories of duration. Hence, all pairwise comparisons were needed, which makes a Tukey test appropriate. The number of levels of this factor is $J = 3$ in this example. Also, the total number of subjects in this study is $n = 75$. The ANOVA table obtained from a computer package revealed MSE = 0.022 and the error df $v = 66$ since there were three categories of quantity of smoking as well, and the interaction term was also required. From Studentized range tables, the value of $Q$ at $\alpha = 0.05$ for (3, 66) df is approximately 3.39. Thus,

$$D = 3.39\sqrt{\frac{0.022}{75/3}} = 0.10.$$

This is the critical difference that should be present between the means for it to be statistically significant at $\alpha = 0.05$. The mean birth weights (in kilograms) in the three duration-of-smoking categories were 3.44, 3.39, and 3.25, respectively. These categories were <18 weeks, 18–31 weeks, and 32+ weeks, respectively. The difference in mean birth weight between <18 weeks and 18–31 weeks does not exceed the critical value but exceeds between other durations. Thus, the real culprit in this example is smoking for 32+ weeks, which significantly lowered the mean birth weight.

Multiple comparison tests, particularly the Tukey test, may sometimes give results at variance with the results of the $F$-test. It is possible for the $F$-test to be significant without any of the pairwise differences being significant. Conversely, the $F$-test may not show significance, but comparison for one or more specific pairs may still be significant. The reason for this is that both the $F$-test and the Tukey test require a Gaussian pattern, but the underlying distribution may not be exactly Gaussian. The $F$-test and the Tukey test behave differently in this case. The problem may arise more frequently for small $n$ and then for large $n$ because large $n$ is an insulation against violation of a Gaussian pattern in most cases.

It may be instructive to compare the Tukey test with Student $t$-test. In our example, the critical difference between two means for Student $t$-test is $d = 1.98\sqrt{\frac{0.022}{25/2}} = 0.083$, where 1.98 is the value of Student $t$ at 25 + 25 − 2 = 48 df (the sample size in each group being 25 in this example). Note how small this $d$ is compared with Tukey critical difference $D = 0.10$. This tells that the critical difference should be larger in pairwise comparisons for keeping the Type I error at the same level.

## twin studies

In 1875, Francis Galton wrote "Twins have a special claim upon our attention; it is, that their history affords means of distinguishing between the effects of tendencies received at birth, and those that were imposed by the special circumstances of their after lives" [1] ("after life" referring to life after birth).

The classical twin study design involves studying twins raised in the same family circumstances. Monozygotic (identical) twins share all of their genes, while dizygotic (not identical) twins share only approximately 50% of them. In addition, they share exactly the same environment in utero. Thus, when researching a particular characteristic, if a researcher compares the similarity between one set of identical twins and the similarity between sets of nonidentical twins, then any excess likeness between the identical twins should be due to the genes rather than the environment.

Identical twins have the same genome as they develop from a single fertilized egg. Hence, any differences between identical twins arise from their environments, not from genetics. The insight gained

from studying twins improves our understanding of nature versus nurture and how the two work together. For a very long time now, researchers have compared traits in twins trying to determine the extent to which certain traits are inherited, such as eye color, and which traits are acquired from the environment, such as diet.

When only one of the identical twins gets a disease, the environment is suspected to be the culprit, but if both get the same disease almost at the same time, the suspicion is on the genetic component. This theory is strengthened when several twins are seen to follow the same pattern. For example, in schizophrenia, it has been found that in approximately 50% of identical twins, both have the disease, while this is true in only approximately 10%–15% of nonidentical twins [2]. Hence, one can argue that there is a strong genetic component in susceptibility to schizophrenia. If both identical twins in a pair do not develop the disease 100% of the time while others do, this indicates that other environmental factors are also involved.

Analysis of quantitative data from twin studies is usually done by **variance components** analysis by considering the observed value $y = g + e + r$, where $g$ is the genetic component (called heritability), $e$ is the effect of shared environment, and $r$ is the residual. The extent of agreement between monozygotic and dizygotic twins can be measured by **intraclass correlation**, and ***F*-test** can be used to check statistical significance when the conditions of this test are fulfilled. For more information on analysis of twin data, see Balding et al. [3].

## two-by-two tables

A two-by-two contingency table is a table with two rows and two columns formed by cross-classifying a group of subjects by two binary characteristics. One could be like characteristic present or absent, and the other could be group I and group II such as with and without disease, with disease A and with disease B, treatment and control, male and female, young and old, or any other such groups. These groups are independent and the scenario is essentially bivariate. Since both the variables have two categories, this is also known as a *fourfold table*. It is a key table when dealing with most proportions at the analysis stage.

The general form of such a table is given in Table T.7, where $O_{rc}$ is the observed count in the $(r, c)$th cell and $\pi_{rc}$ is the corresponding probability ($r = 1, 2$; $c = 1, 2$); dots denote the sum for the corresponding row or column.

**TABLE T.7**
**General Structure of a 2 × 2 Contingency Table**

| | Variable 1 (Antecedent) | | |
|---|---|---|---|
| **Variable 2 (Outcome)** | **Present** | **Absent** | **Total** |
| Present | $O_{11}$ ($\pi_{11}$) | $O_{12}$ ($\pi_{12}$) | $\boldsymbol{O_{1\bullet}(\pi_{1\bullet})}$ |
| Absent | $O_{21}$ ($\pi_{21}$) | $O_{22}$ ($\pi_{22}$) | $\boldsymbol{O_{2\bullet}(\pi_{2\bullet})}$ |
| **Total** | $\boldsymbol{O_{\bullet 1}(\pi_{\bullet 1})}$ | $\boldsymbol{O_{\bullet 2}(\pi_{\bullet 2})}$ | $\boldsymbol{n}$ |

### *Structure of a 2 × 2 Table in Different Types of Study*

Table T.7 is stated in the classical antecedent–outcome format. The following three scenarios are possible in this setup.

*Structure in a **Prospective Study***: Because the investigation is from antecedent to outcome in a prospective study, the column totals $O_{\bullet 1}$ and $O_{\bullet 2}$ are fixed in advance. They can also be denoted by $n_1$ and $n_2$, respectively. These are the numbers of exposed and nonexposed subjects followed up for appearance of outcome. The row totals $O_{1\bullet}$ and $O_{2\bullet}$ become known only after the investigation is over and are random variables. The relevant **null hypothesis** in this case is $H_0$: $\pi_{11} = \pi_{12}$. This states that the incidence rate of outcome in the two groups is the same. In this case, $\pi_{11} + \pi_{21} = 1$ and $\pi_{12} + \pi_{22} = 1$. Thus, $H_0$ is equivalent to $\pi_{21} = \pi_{22}$. The analysis of the data in this setup is mostly done in terms of **relative risk**, although **chi-square** can be used to test association.

*Structure in a **Retrospective Study***: The direction of the investigation in a retrospective study is from outcome to antecedent. Thus, the row totals $O_{1\bullet}$ and $O_{2\bullet}$, say, with and without disease, are fixed in advance and the column totals $O_{\bullet 1}$ and $O_{\bullet 2}$ are obtained during the study. The fixed row totals can also be denoted by $n_1$ and $n_2$. The null hypothesis now is that the rate of presence of antecedent in those with a positive outcome is the same as in those with a negative outcome; that is, $H_0$: $\pi_{11} = \pi_{21}$. In this case, $\pi_{11} + \pi_{12} = 1$ and $\pi_{21} + \pi_{22} = 1$. $H_0$ implies $\pi_{12} = \pi_{22}$ as well. Analysis of data in this setup is mostly done in terms of **odds ratio**, although chi-square can also be used to test association in this case.

*Structure in **Cross-Sectional Study***: In this case, $n$ subjects are simultaneously cross-classified by the antecedent and outcome. Neither the column totals nor the row totals are fixed in advance and both become known only after study of the participants is over. In this case, $\pi_{11} + \pi_{12} + \pi_{21} + \pi_{22} = 1$. According to the law of multiplication of probabilities, the antecedent and outcome are independent if and only if $H_0$: $\pi_{rc} = \pi^*_{j\bullet}\,\pi_{\bullet c}$ ($r, c = 1, 2$) holds, where $\pi_{r\bullet} = \pi_{r1} + \pi_{r2}$ and $\pi_{\bullet c} = \pi_{1c} + \pi_{2c}$. Analysis of data in this setup is mostly done by chi-square.

$H_0$ in the prospective and retrospective scenarios is called the hypothesis of homogeneity (column homogeneity and row homogeneity, respectively), and $H_0$ in the cross-sectional scenario is called the hypothesis of independence. All these situations can be viewed as participants divided by two qualitative characteristics with the objective of investigating whether one characteristic has any association with the other—whether one is occurring more commonly with the other than expected by chance. Luckily, the statistical test for all the three scenarios is the same in terms of chi-square for large samples and of the **Fisher exact test** if any cell count is less than 5.

## two one-sided tests (TOSTs), *see* equivalence, superiority, and inferiority tests

## two-phase sampling

This is a sampling method that involves two distinct phases. In the first phase, information about a particular auxiliary variable of

interest is collected on every member of a relatively large sample. This may already be available in records, and personal contact may not be needed. In the second phase, a subsample of the individuals in the original sample is taken and additional information about these is collected. This is also called **double sampling** and is used for **ratio estimate** of the parameter of interest or for **stratification**. Do not confuse it with two-stage sampling, where the sampling unit for the two stages is different such as cities in the first stage and hospitals in the second stage. In a two-phase sampling, some of the same units are generally sampled again for collecting additional information, although another set of units can also be selected. Also, some researchers use the term *double sampling* whenever a population is sampled twice for some reason. This is a nontechnical use of the term and not actually double sampling in the sense that we describe here.

An example of where this method of sampling might be useful is when estimating prevalence based on results provided by a potentially fallible, but inexpensive and easy-to-use diagnosis of the true disease state of all the sampled individuals. The diagnosis might then be confirmed for a subsample through the use of a more accurate diagnostic test.

This methodology can be extended in several ways. (i) The second sample may not be out of the first sample but the second sample should also collect the auxiliary information. (ii) You can use this method to estimate mean instead of proportion. For mean, there is another method called regression estimate. (iii) Double sampling is also used for **stratification** where the first sample is used to estimate stratum sizes. These sizes are required for estimating the mean or proportion based on **stratified random sampling**. Some details are given later in this section, and more details of all these are available in the classic book by Cochran [1]. (iv) Two-phase sampling is also used in **acceptance sampling** where the objective is to determine whether the lot (of, say, medical devices) has defectives less than a prefixed threshold. In this situation, accept the lot if the proportion of defectives in a sample is less than, say, $p_1$, reject the lot if the proportion of defectives is more than $p_2$, and take another sample if the proportion of defectives is between $p_1$ and $p_2$. In this setup, the second sample is not out of the first.

To formalize, the conventional method of two-phase sampling can be described in the following manner:

Step 1: From the available population, select a first-phase sample of large size $n_1$ and observe $x$, where $x$ is some auxiliary information that can be easily obtained.

Step 2: Treat the first-phase sample $n_1$ as the population and select a second-phase sample of size $n_2$, and observe another variable $y$. Information on $x$ for this sample is already available from the first phase.

Here, the probability of being selected as a second-phase sample is often determined by the value of $x$ obtained from the first-phase sample. Because of this, the probability for inclusion of a subject in the second-phase sample is a random variable: its value changes as the first-phase sample changes.

There are other variations of this method. Yiannoutsos et al. [2] used a double-sampling methodology for improving the estimate of HIV mortality in patients on combination antiretroviral therapy. The two samples were patient outreach and vital registries. Ekelund et al. [3] used the term *double sampling* for two blood samples in pregnancies affected by trisomy 21 and control—one at the early stages of pregnancy and the other at a late stage to assess their screening performance.

### *Two-Phase Sampling for Stratification*

Stratification helps in obtaining reliable estimates for each stratum and can improve the reliability of the overall estimate as well. In some situations, the required information on the stratifying characteristic is not available and has to be collected. This is done in phase I of double sampling by selecting, say, $n_1$ units. These units are stratified, and suppose we find that there are $n_{1h}$ units in stratum $h$. The first phase helps estimate the sample proportion in each stratum by $w_h = \frac{n_{1h}}{n_1}$. This is a random variable in this setup in contrast to stratified random sampling where the stratum size and hence proportion is fixed and known in advance. In this case, $w_h$'*s* also give an idea of how the subjects are distributed. More importantly, $w_h$ serves as weight for estimating the means after phase II as per the following procedure.

Phase II sampling is done using these strata with $n_{2h}$ units from the $h$th stratum, $\Sigma_h n_{2h} = n_2$. Let the value of the $i$th unit of the $h$th stratum be denoted by $y_{ih}$. The mean of these would be $\bar{y}_h = \frac{\Sigma_i y_{ih}}{n_{2h}}$. Then, the mean of all the units in the second sample can be obtained as

$$\text{Mean in two-phase sampling for stratification: } \bar{y}_{st} = \Sigma_h w_h \bar{y}_h.$$

The weights $w_h$ are based on the first-phase sampling results as already stated. This would be an **unbiased estimator** of the population mean when the sampling in both phases is simple random.

For example, consider a study on estimation of prevalence of diabetic neuropathy in diabetic subjects. This is suspected to be related to sex. Take a random sample of, say, $n$ = 1000 diabetic subjects from something like a diabetes registry and find, for example, that 580 of them are females and 420 are males. This gives the ratio of female diabetic subjects to male diabetic subjects. Now, take a phase II sample of $n_2$ = 200 subjects from these 1000, 100 for each sex after stratification. If the prevalence of diabetic neuropathy is 5% in females and 8% in males, what is the estimate of diabetic neuropathy in those appearing in the registry? This is an example of proportions and not means, but the method is the same. The estimate for prevalence of diabetic neuropathy is $\bar{y}_{st} = \frac{580}{1000} \times 0.05 + \frac{420}{1000} \times 0.08 = 0.0626$, or 6.26% of diabetics in this registry have diabetic neuropathy. Note that this estimate, on the basis of only the phase II sample of $n_2$ = 200, would have been (5 + 8)/2 = 6.5%. These two estimates are close but not the same. In some situations, they can be very different.

### *Two-Phase Sampling for Ratio Estimate*

In case there is a strong relationship between the variable $x$ on which information is collected in the first phase and the variable $y$ on which information is collected for a subsample (information on $x$ is already available for this sample), the reliability of the estimate can be improved. For details, see the topic **ratio estimator**.

Further information about two-phase sampling can be found in a book by Ahmad et al. [4]

## two-sided alternative, *see* one- and two-tailed alternatives/tests

## two-way ANOVA, *see also* analysis of variance (ANOVA)

Refer to the topic **analysis of variance (ANOVA)** for the fundamentals of ANOVA. Consider a **clinical trial** in which three doses (including a placebo) of a drug are given to a group of anemic male and female subjects to assess the rise in hematocrit (Hct) level. Thus, there are two factors in this trial, namely, dose and sex, and the analysis of such data would require a two-way ANOVA. If it is suspected that the response for different doses may be different for males than for females, conclusion about the effect of factors would require that this **interaction** is also investigated. This makes it imperative to adopt a two-way design. The details of interaction are given a little later in this section. Consider the design aspect first.

### *Two-Factor Design with Fixed Effects*

There are two factors in the trial just mentioned: the dose of the drug and the sex of the subjects. These factors are fixed in the sense that the interest is limited to these specific doses and sex. The response of interest in this experiment is a quantitative variable, namely, the rise in Hct level. The objective of the trial is to find the effect of dose and sex and their interaction on the response. Such a setup with two factors is called a two-way ANOVA situation. Note that there are three dose groups of male subjects in this trial and another three dose groups of female subjects. The researcher may wish to have $n = 10$ subjects in each of these six groups, making a total of 60 subjects. To minimize the role of other factors causing variation, these 60 subjects should be as homogeneous as possible with respect to all the other characteristics that might influence the response; for example, they may be of the same age-group, they may be of normal build (say, BMI between 20 and 25), and they may not be suffering from any ailment that may alter the response. Once 30 male and 30 female eligible subjects meeting the inclusion and exclusion criteria are identified, they need to be randomly allocated 10 each to the three dose levels. Such allocation then increases the confidence in asserting that any difference that occurs is mostly, if not exclusively, attributed to the factors under study, namely, the dose of the drug and the sex of the subjects in this example. A post hoc analysis can be done to check that other influencing factors, such as age and BMI, are indeed almost equally distributed in the six groups under study. Informed consent and other requirements of **ethics**, in any case, must be met. Blinding may be required to eliminate possible bias of the subjects, of the observers, and even of the data analyst.

The following notation would be clear if you can imagine another trial in which a drug is administered in $I = 3$ doses, a dietary supplement of $K = 4$ types (e.g., vitamin A, vitamin D, zinc, no supplement) is given to a group of subjects, and bone mineral density (BMD) gain ($y_{ijk}$) from baseline is measured after 90 days for the $i$th subject in the $j$th dose group and the $k$th diet group. The gain could be negative also in some cases, which means that the BMD declined. Under this notation, for example, $y_{423}$ is the BMD gain of the fourth person ($i = 4$) getting a second ($j = 2$) dose and a third ($k = 3$) supplement. Response in such a two-factor design with $J$ levels of factor 1 and $K$ levels of factor 2 with $n$ subjects at each treatment combination (**balanced design**) can be modeled as

$$y_{ijk} = \mu + \alpha_j + \beta_k + (\alpha\beta)_{jk} + \varepsilon_{jk};\ i = 1, 2, \ldots, n;\ j = 1, 2, \ldots, J;\ k = 1, 2, \ldots, K,$$

where $y_{ijk}$ is the response of the $i$th subject at the $j$th level of factor 1 and the $k$th level of factor 2, $\mu$ is the overall mean response (mean BMD gain of all persons combined in our example), $\alpha_j$ is the main effect of the $j$th level of factor 1 (such as the effect of dose 1 on BMD gain), $\beta_k$ is the main effect of the $k$th level of factor 2 (such as the effect of vitamin D on BMD gain), $(\alpha\beta)_{jk}$ is the effect of interaction between the $j$th level of factor 1 and the $k$th level of factor 2, and $\varepsilon_{ijk}$ is the error, which is the remainder after all these effects are considered.

In another two-factor design, say, with three doses of drug A and two doses of drug B, you can randomly allocate subjects to any of the six combinations of the doses. However, if factor 2 is something like sex, there is no way that you can randomly allocate subjects to these six combinations—you will have to allocate males (randomly) to one of the three doses and females to one of the three doses as well. If factor 1 is also something like obesity (thin, normal, or obese), the subject's category is fixed—there is no random allocation. The best option in this situation could be random selection of subjects from male obese and female obese subjects in the population.

### *The Hypotheses and Their Test in a Two-Way ANOVA*

The null hypotheses that can be tested in a two-way ANOVA situation are as follows:

- Levels of factor 1 have no effect on the mean response; that is, each level of factor 1 has the same response on average. This translates into

$$H_{0a}: \mu_{1\bullet} = \mu_{2\bullet} = \ldots = \mu_{J\bullet},$$

  where $J$ is the number of levels of factor 1.
- Levels of factor 2 have no effect on the mean response. That is,

$$H_{0b}: \mu_{\bullet 1} = \mu_{\bullet 2} = \ldots = \mu_{\bullet K},$$

  where $K$ is the number of levels of factor 2.
- There is no interaction between factor 1 and factor 2.

See the example that follows shortly.

The total sum of squares in a two-way ANOVA is broken into the **sum of squares** due to factor 1, due to factor 2, due to interaction, and the residual (also called error). These are divided by the respective degrees of freedom to get **mean squares**. Each of these mean squares is an independent estimate of the same variance $\sigma^2$ of the response $y$ when the corresponding $H_0$ is true. Mean square due to error (MSE) is an estimate of $\sigma^2$ even when $H_0$ is false. Other mean squares are compared with MSE, and the criterion $\boldsymbol{F}$ is calculated separately for each of the two factors and for their interaction. The

*P*-value is obtained as usual corresponding to the calculated value of *F*. The pair of df for different *F*'s are (i) for factor 1: $(J-1)$, $JK(n-1)$; (ii) for factor 2: $(K-1)$, $JK(n-1)$; and (iii) for interaction between factor 1 and factor 2: $(J-1)^*(K-1)$, $JK(n-1)$, where $n$ (≥2) is the number of subjects with the $j$th level of factor 1 and the $k$th level of factor 2 ($j = 1, 2, \ldots, J$; $k = 1, 2, \ldots, K$). This assumes that the trial has the same number of subjects for each combination. Separate decisions for factor 1, factor 2, and the interaction are made regarding their statistical significance. When the interaction is not significant, the factors are called **additive**. If the interaction is significant, the inference for any factor cannot be drawn in isolation, and it has to be in conjunction with the level of the other factor.

A two-factor trial can also be done with only $n_{ij} = 1$ subject in each group. In this case, however, interaction cannot be easily evaluated (see **Tukey test for additivity**). For simplicity, the preceding example had the same number of subjects in each group, and it is more than 1. If the situation so demands, you can plan a trial or an experiment with unequal $n$ in different groups. This is called an **unbalanced design** and is illustrated in Table T.8 for birth weight of children born to women with different amount of smoking and duration of smoking as explained in a short while.

The analysis of an unbalanced design such as in Table T.8 is slightly more complex, although the concepts remain the same. For example, the total df would be $\Sigma(n_{jk} - 1)$, where $n_{jk}$ (≥2) is the number of subjects for the $j$th level of factor 1 and the $k$th level of factor 2. When using a statistical software package, be careful in selecting an appropriate routine if the data are unbalanced. Our advice, though, is to plan and conduct a balanced design (equal $n$ for each group) wherever feasible so that such complications are avoided. Incidentally, equal $n_{jk}$'s also maximize the power for any given total sample size.

As an example, consider a study done by Wang et al. [1] on the effect of maternal smoking on birth weight in the United States. For our purpose, vary this study and assume that some women, who are otherwise habitual smokers, give up smoking off and on but not completely during pregnancy. Nonsmokers are excluded in this example. Suppose that such women are asked at the time of their last antenatal visit just before birth about the duration of smoking (factor 1) and the amount of smoking (factor 2). At the end of the pregnancy, the former is categorized as <18 weeks, 18–31 weeks, and ≥32 weeks. These are the three levels of factor 1. The amount of smoking is categorized as mild (1–9 cigarettes per day), moderate (10–19 cigarettes per day), and heavy (20+ cigarettes per day). The days in this calculation are only those when at least some smoking was done and the amount of smoking is the average per smoking day. These are the three levels of factor 2. The outcome of interest (response variable) is the birth weight of the children born to these women.

Some possible confounders in this case are race, age, nutrition, education, and parity since all these can affect birth weight. Suppose these factors could be satisfactorily matched in different groups such that the effect of such extraneous factors is minimal. Let the mean birth weight in different groups be as given in Table T.8. There are, for instance, 15 women who smoked an average of 1–9 cigarettes per day for a total of less than 18 weeks during the entire pregnancy. The average birth weight of their babies was 3.45 kg. There are 8 women who smoked an average of 1–9 cigarettes per day for a total of 18–31 weeks, and the average birth weight of their babies was 3.38 kg, and so on. Because of unequal $n$, the design is unbalanced as mentioned earlier.

The question to be answered is whether the difference in mean birth weight in different groups is really present in this population of antenatal women or whether it is just a chance occurrence in this sample. This can be examined in the following three ways:

- Differences in mean birth weight in the last row of Table T.8 for different amounts of smoking are significant or not.
- Differences in mean birth weight in the last column of Table T.8 for different durations of smoking are significant or not.
- Difference in mean birth weight, for instance, in those mildly smoking for 32+ weeks and those heavily smoking for 32+ weeks compared with the difference in those with similar smoking for <18 weeks are significant or not. This is the interaction.

The calculations are done on the original values of birth weight in $\Sigma n_{jk} = 75$ children. Suppose a software package reveals $P > 0.05$ for $F$ when calculated for amount of smoking (factor 2) and $P < 0.01$ for $F$ when calculated for duration of smoking (factor 1). The first is not statistically significant but the second is. The conclusion then is that this sample of women does not provide sufficient evidence to conclude that the amount of smoking makes a difference in birth weight on average, but the duration of smoking in the pregnancy does make a difference. Let $P < 0.05$ for $F$ for interaction. Thus, an interaction between amount of smoking and duration of smoking is present and implies that the effect of duration of smoking on birth weight is not uniform in the three categories of amount of smoking. This requires additional care in interpreting the significance of the effect of amount of smoking as that requires separate conclusion regarding this effect of smoking. ANOVA considers all categories nominal. In the above example, both factor 1 and factor 2 are ordinal, but this feature is overlooked in this analysis. Also, this analysis is valid only when the birth weights follow a Gaussian distribution

**TABLE T.8**
**Average Birth Weight of Children Born to Women with Different Amount and Duration of Smoking**

| Duration of Smoking in Pregnancy | Amount of Smoking | | | |
|---|---|---|---|---|
| | Mild | Moderate | Heavy | All |
| <18 weeks | 3.45 ($n$ = 15) | 3.42 ($n$ = 12) | 3.43 ($n$ = 7) | **3.44 ($n$ = 34)** |
| 18–31 weeks | 3.38 ($n$ = 8) | 3.40 ($n$ = 10) | 3.39 ($n$ = 6) | **3.39 ($n$ = 24)** |
| 32+ weeks | 3.35 ($n$ = 5) | 3.30 ($n$ = 3) | 3.18 ($n$ = 9) | **3.25 ($n$ = 17)** |
| All | **3.41 ($n$ = 28)** | **3.40 ($n$ = 25)** | **3.32 ($n$ = 22)** | **3.38 ($n$ = 75)** |

*Note:* Entries are average birth weight in kilograms.

and have the same variance across groups. Women in this setup are likely to be independent in the sense that the smoking status of one woman will not affect the smoking status of the others and thus the birth weights are independent as well.

There is no random allocation in this example, and the results of ANOVA are valid only if the women are randomly chosen from their respective groups. This is apparently missing in the example. The stipulation is that the women included in the study adequately represent the "population" of such antenatal women with respect to the influence of amount and duration of smoking on birth weight.

### *Main Effect and Interaction (Effect)*

ANOVA is primarily designed to determine the statistical significance of the differences between group means, but it can also be used to estimate the average effect of various levels of the factors, called main effects, and the magnitude of different interaction effects. In our birth weight example, the main effect of smoking for 32+ weeks is estimated by the difference of the mean in this category from the overall mean. This is 3.25 − 3.38 = −0.13 kg. That is, smoking for 32+ weeks in pregnancy reduced birth weight on average by 130 g compared with the overall average. (The average birth weight of 3.38 kg is determined from those who smoked since the study is based on smokers only.) Similar main effects can be estimated for the other categories of duration of smoking. They can be calculated for different categories of the amount of smoking as well, but that is inadvisable in this case because these differences are not statistically significant.

Main effects and interactions are easy to understand with the help of the following notations:

Estimated main effect of the $j$th level of factor 1:

$$\alpha_j = (\bar{y}_{\bullet j \bullet} - \bar{y}_{\bullet\bullet\bullet}); \; j = 1, 2, \ldots, J$$

Estimated main effect of the $k$th level of factor 2:

$$\beta_k = (\bar{y}_{\bullet\bullet k} - \bar{y}_{\bullet\bullet\bullet}); \; k = 1, 2, \ldots, K.$$

In our birth weight and smoking example, the main effect of smoking for less than 18 weeks is 3.44 − 3.38 = +0.06 kg and that of moderate smoking is 3.40 − 3.38 = +0.02 kg. The positive effect is not surprising since these are the effects on the birth weight *compared with the overall mean* of all categories that include heavy and long-duration smokers. It is easy to show by some algebra that under these notations, $\Sigma_j \alpha_j = 0$ and $\Sigma_k \beta_k = 0$. Consequently, only $(J - 1)$ α's and $(K - 1)$ β's are independently determined and each one is automatically determined by these conditions.

The interaction is obtained separately for each combination of the levels of the two factors. This is the excess mean after adjustment for the main effects of the concerned level of factor 1 and factor 2. Thus, the estimated interaction effect between the $j$th level of factor l and the $k$th level of factor 2 is

$$\begin{aligned}(\alpha\beta)_{jk} &= (\bar{y}_{\bullet jk} - \bar{y}_{\bullet\bullet\bullet}) - (\bar{y}_{\bullet j \bullet} - \bar{y}_{\bullet\bullet\bullet}) - (\bar{y}_{\bullet\bullet k} - \bar{y}_{\bullet\bullet\bullet}) \\ &= (\bar{y}_{\bullet jk} - \bar{y}_{\bullet j \bullet} - \bar{y}_{\bullet\bullet k} + \bar{y}_{\bullet\bullet\bullet}),\end{aligned}$$

where $\bar{y}_{\bullet jk}$ is the mean of $n$ (now assumed equal for easy notations) subjects in the $(j, k)$th group. Mathematically, this implies $\Sigma_j(\alpha\beta)_{jk} = 0$ and $\Sigma_k(\alpha\beta)_{jk} = 0$. For example, the estimate of the interaction effect between moderate smoking and smoking for 32+ weeks in Table T.8 is 3.30 − 3.25 − 3.40 + 3.38 = +0.03 kg. Thus, this combination of duration and amount of smoking increases birth weight by 30 g on average in this sample *relative to the means in respective categories*. Note, again, that the overall mean is based on all women including those who are heavy and long-duration smokers.

This example also illustrates that if the interaction is significant, one ought to condition the conclusion about one factor's effect on the level of the other factor. When the interaction is not significant, the focus is on the main effects. In that case, factor 1 levels should not be compared within factor 2 levels because factor 1 effects are not significantly different. Only the average is adequate.

The above equations define the main effects and the interactions relative to the overall mean, which is the most commonly used definition. However, if so desired, you can define them relative to a base value. In our example, the base could be the category with least smoking where the mean birth weight is 3.45 kg. In that case, for example, the estimated main effect of heavy smoking is 3.32 − 3.45 = −0.13 kg. That is, heavy smoking reduces birth weight by 0.13 kg on average compared with the mild smokers for less than 18 weeks. A similar interpretation can be given for the other main effects and interactions when measured from a base value.

Note the following for the two-way ANOVA procedure:

- As for a one-way ANOVA, criterion $F$ in a two-way ANOVA also provides an overall test about difference being present *somewhere*. **Multiple comparisons** procedures as described separately can be used after ANOVA to find the group or groups that are different from others. These can be done for factor 1 effects separately from factor 2 effects.
- Extension of ANOVA to three or more factors is straightforward with main effects and interactions similar to those in a two-way ANOVA. However, there would now be several two-factor interactions, three-factor interactions, and so on. The details are beyond the scope of this book. Interested readers may consult Doncaster and Davey [2].
- It is desirable to test higher-order interactions before lower-order ones because it is difficult to attach meaning to the lower-order interactions when higher-order interactions are present.
- As always, lack of statistical significance of interaction does not mean interaction is absent. It only means that this could not be detected from the available data. This might be more so in the case of ANOVA since the sample size is generally planned to detect main effects whereas a higher sample size is required for detecting interactions.

For two-way ANOVA with random effects, see **mixed effects models** when one factor is random and **random effects ANOVA** when both the factors are random.

## two-way designs, *see also* one-way designs

Take a study on hormone replacement therapy (HRT) in mice with continuous HRT, cyclic HRT, and no HRT, and introduce one additional factor, that is, the mice are normal estrous with ovary or ovariectomized. This factor has these two levels. With three levels of treatment and two levels of estrous status, this is a 3 × 2 experiment,

**TABLE T.9**
**A Two-Way Design (3 × 2) with 10 Mice in Each Group (Mice Number in Each Group Shown after Random Allocation) to HRT Categories**

| | Factor 2 | |
|---|---|---|
| **Factor 1** | **Normal Estrous** | **Ovariectomized** |
| Continuous HRT | 3, 7, 8, 14, 18, 30, 31, 37, 48, 52 | 1, 5, 10, 11, 15, 20, 27, 42, 43, 49 |
| Cyclic HRT | 4, 9, 13, 21, 32, 39, 44, 47, 50, 57 | 6, 17, 26, 33, 34, 40, 51, 56, 58, 59 |
| No HRT (control) | 12, 22, 23, 25, 36, 41, 45, 53, 55, 60 | 2, 16, 19, 24, 28, 29, 35, 38, 46, 54 |

necessitating a two-way design. With a total of 6 subgroups and 10 mice in each, this may look like as shown in Table T.9.

Each subgroup has the same number of mice in this example, but that is not a requirement for any *K*-way design. Only equal numbers make the analysis and interpretation a lot easier. A design with equal numbers is called **balanced**; otherwise, it is an unbalanced design.

The response in this experiment is the mitotic index. The two-way design allows study of response variation between levels of factor 1 as much as between levels of factor 2. It is possible in this case that the difference in mitotic index between continuous and cyclic HRT is not the same in estrous mice as in the ovariectomized mice. This is called **interaction**. In view of the importance of interaction in medical experiments, this is explained in detail under a separate topic. For analysis of the data from two-way designs, see the topic **two-way ANOVA**.

## two-way tables, *see* contingency tables

## Type I error, *see* level of significance

## Type II error, *see also* power (statistical) and power analysis

Data-based statistical decisions regarding rejecting or not rejecting a **null hypothesis** ($H_0$) can have primarily two types of statistical errors. See **level of significance** for details of the Type I error that occurs when a true null hypothesis is rejected. The Type II statistical error fails to reject $H_0$ when it is false. This occurs when a study fails to detect a real difference because the available data do not contain sufficient evidence. This corresponds to a missed diagnosis in a clinical setup as well as to pronouncing a criminal not guilty in a court of law. In a clinical trial scenario, this is equivalent to declaring a drug ineffective when it is actually effective. When this occurs, the society will continue to be without the drug just as it was before the trial and a drug that could possibly provide better relief to scores of patients is denied entry into the market. If the manufacturer believes that the drug is really effective, it will carry out further trials and collect further evidence. Thus, the effect of Type II error in this case is that the introduction of the drug is delayed but not denied, which is not so much of an error. Type I error is considered more serious, and the tolerance threshold for the chance of Type I error is always fixed in advance with a special name, that is, the level of significance.

The probability of Type II error is denoted by $\beta$ and is calculated for a specific value under the **alternative hypothesis** ($H_1$) after fixing the level of significance $\alpha$. For example, if the null is $\mu = 15$, the Type II error would be different for $H_1$: $\mu = 25$ and for $H_1$: $\mu = 20$.

Although the statistical procedures are based on chance of Type I and Type II errors, once a decision has been made, the researcher could have made only one error—wrongly reject the null or wrongly not reject the null—or have made no error. He/she would not know that this was the case unless he/she is divine to know the truth. Also, note that there is no Type I or Type II error if there is no test of hypothesis. For example, these errors do not arise while estimating the mean or proportion from the sample values. For more details, see the topic **power**, which is the complement of the probability of Type II error.

### *Balancing Type I and Type II Errors*

There is a trade-off between Type I and Type II errors. In terms of an analogy to the judiciary system, the courts' desire to convict a guilty person has a direct bearing on an innocent person being convicted. The latter is the Type I error. Type II error is preferred over Type I error in court to uphold civil rights. If the evidence is not sufficiently convincing, the person is set free because of doubt on whether the crime was committed or not. Similar is the case with statistical testing of hypothesis. It is better not to reject a false null than to reject a true null hypothesis.

Type II error and the level of significance have a direct relationship. The lower the level of significance, the higher the Type II error. Using 1% level of significance instead of the conventional 5% makes it difficult to reject a false null, and the Type II error increases. A relationship between significance level $\alpha$ and power $(1 - \beta)$ can be expressed by a receiver operating characteristic (ROC) curve similar to the **ROC curve** between sensitivity and (1 − specificity). Just how useful this is is debatable since $\alpha$ is mostly fixed in advance.

Also, the higher the **variance** of the data values, the higher the Type II error. When values are highly variable from participant to participant, the difference between two or more groups will not be easy to detect. Moreover, irrespective of the values of $\alpha$ and of variance, a smaller difference is more difficult to detect such that the corresponding Type II error is high. The larger the minimum **medically important effect**, the lower the Type II error (higher power to detect). Sample size is an all-important factor in this scenario. An adequately large sample can override any limitations brought about by low level of significance, high variance, and small, medically relevant effect for detection.

For further details of these two errors, see Rogers [1].

## Type III error

Type III error [1] occurs when the researcher chooses to use the wrong direction of the effect. For example, if the population value of the parameter under test is actually more than the null value, the sample might give a value so much below the null value that the researcher rejects the null and concludes that the population value is also below the null value. Similarly, the error may occur in the other direction as well. This can occur when the **alternative hypothesis** is two tailed.

Leventhal and Huynh [2] wrote an interesting article on what they call the "directional two-tailed test of statistical significance." They argue that the traditional two-tailed test does not allow directional decisions since the conclusion on rejecting the

null is that the tested parameter does not have a value equal to the value specified in the null hypothesis, and nothing can be stated in which of the two directions the actual value of the parameter differs from the null value. Where there is a direction of difference as in one-tailed $H_1$, we commonly conclude that the population follows the sample. Another possible procedure is the directional two-tailed test, also called a *three-choice test*. The three hypotheses entertained are parameter = null value, parameter < null value, and parameter > null value. With the three-choice test, one may make **Type I errors**, **Type II errors**, or Type III errors. Procedures for this are not well defined yet, but an indication of what possibly can be done is discussed in the next paragraph.

To reiterate, a Type III error concerns with the direction of the alternative hypothesis. When the null for a parameter is $H_0$: $\theta = \theta_0$, the alternative could be (i) $H_1$: $\theta > \theta_0$, (ii) $H_1$: $\theta < \theta_0$, or (iii) $H_1$: $\theta \neq \theta_0$. The last one is called nondirectional and is the one that can give rise to Type III error. When testing the usual nondirectional hypotheses, one can correctly reject the null yet make a Type III error. In this case, the probability of making a Type III error is included in a Type II error. In view of this, Leventhal and Huynh [2] suggest a revised definition of power: "the conditional probability of correctly rejecting the null hypothesis and *correctly identifying the true direction of difference* between the population value of the tested parameter and the null value." This includes direction that the conventional definition does not do. They also demonstrate that when conducting three-choice tests, the revised definition of power as above results in power being somewhat less than when using the traditional definition. They also show how to adjust traditional power and sample size calculations to take into account the possibility of a Type III error. Many researchers say that the probability of a Type III error in most setups will be so small that it is not really necessary to make any adjustment when computing power or sample sizes.

There is another interpretation of a Type III error. Kimball [3] wrote about "errors of the third kind in statistical consulting." The error he was referring to was that of giving the right answer to the wrong problem. He surmised that this error originated in poor communication between the statistical consultant and his client, and suggested that statistical consultants need to be taught communication skills or "people involving" skills. It is also defined as correctly rejecting the null hypothesis for a wrong reason. An example of this kind of Type III error is assessing the causes of interindividual variation within a population when the research question of interest is about causes of difference between populations or between periods. Schwartz and Carpenter [4] illustrate the consequences of this kind of a Type III error in investigating obesity.

# U

## unbalanced design, *see* balanced and unbalanced design

## unbiased estimator

Before the unbiased estimator, we need to explain a couple of other terms in biostatistics that would make it easy to understand this term. First, technically, a *statistic* is something we calculate on the basis of sample values. Note that this is singular, the plural of which is *statistics*. Sample mean, sample median, sample standard deviation (SD), etc. are all statistics in this sense. The values of the sample statistics vary from sample to sample, i.e., they are also variables. Second, the sample statistic formula used to estimate the value of the population **parameter** is called its *estimator*. For example, population mean $\mu$ is estimated by sample mean $\bar{x}$—thus, $\bar{x}$ is the estimator of $\mu$. Generally, the corresponding sample analogue is the estimator of any population parameter. Sample SD is the estimator of the population SD, and sample median is the estimator of the population median. Whether or not they are good at providing an adequate estimate is another question.

The validity of statistical estimators is generally assessed in terms of its bias [see **bias (statistical)**] and is different from **precision**. Unbiasedness is the ability of an estimator to reach the correct value of the parameter when the average of the values of the statistic over all possible samples of that kind is the same as the value of the population parameter. Statistically, this average of the statistic over all possible samples is called the *expected value*. A statistic is called an unbiased estimator of the parameter when it is established that the statistic has a tendency to reach the true value of the parameter when averaged over repeated samples. An unbiased estimator of parameter $\tau$ is the statistic whose average over different possible samples is the same as the correct value of $\tau$. Technically, this is stated as that a statistic is an unbiased estimator of a parameter when the expected value of the estimator is the same as the value of that parameter. Unbiasedness is one of the important criteria to judge whether an estimator is good or not. For most distributions, an unbiased estimator can be theoretically established without worrying about drawing so many samples.

An unbiased estimator easily can be illustrated with the help of a hypothetical example. Suppose you know for sure from a complete enumeration of a population that 9% of all women of age 30–39 years in an area have raised blood sugar (BS) level. Now, you take a sample of 200 women of that age from that population and find that 15 (7.5%) of them have raised BS level. You take another sample of 200, some of which may be the same women as in the first sample (called **sampling with replacement**), and find that the percentage now is 10.0. The third sample gives 8.5%, the fourth 11.5%, the fifth 9.0%, etc. The big question is what the average of such percentages will be when all possible samples are considered. If the average of all possible samples is 9%, which is the same as the true percentage in the population, the sample percentage is an unbiased estimator of the population percentage; otherwise, it is not. In brief, the sample mean is an unbiased estimator of the population mean in the case of random samples, but the sample median is generally not an unbiased estimator of the population median except for symmetric **distributions**. The sample variance is an unbiased estimator of the population variance only when the denominator is $(n - 1)$ instead of $n$. This is the reason that $(n - 1)$ is used in place of $n$ in this case.

When sampling is with replacement, as in this example, note that an infinite number of samples can be drawn. It is not practically feasible to study all possible samples. Thus, the help of theory is taken to find out whether an estimator is unbiased or not. Theoretical derivations have established that sample mean is an unbiased estimator of the population mean provided that the sample is drawn randomly. This does not hold for nonrandom samples. This explains why random samples are important for statistical methods. Sample variance is not an unbiased estimator of the population variance unless the divisor is $(n - 1)$ instead of $n$. Strange as it may sound, sample SD is not the unbiased estimator of the population SD even when the denominator is $(n - 1)$. This "aberration" occurs due to the square root sign in the SD, which does not occur in the variance. Sample proportion (or percentage) is an unbiased estimator of the population proportion. Sample median is an unbiased estimator of population median when the distribution is Gaussian but not necessarily so for other distributions. A qualifier in all these statements is that the samples are random.

## unbiased sample, *see* biased sample

## uncertainties, *see* aleatory uncertainties, epistemic uncertainties, medical uncertainties, parameter uncertainty

## uncertainty analysis, *see also* sensitivity analysis

Uncertainty analysis is the process to measure the impact on the result of changing values of one or more key inputs about which there is uncertainty. The study of the effect of varying the value of parameters included in the analysis is called **uncertainty analysis**. The need for this mostly arises due to the use of sample estimates for the parameters of the model. For uncertainty analysis, the inputs are varied over a reasonable range that can occur in practice. Uncertainty analysis can also be viewed as a method for checking the robustness of the results that would be established if the result does not change much when input values are changed within reasonable limits.

Models, particularly statistical models, are not unique. Different sets of parameters may reasonably reproduce the same sample values. Thus, agreement between a model and the observed data does not imply that the model assumptions accurately describe the underlying process, only that it is one of the plausible explanations and empirically adequate. Thus, the model needs to be checked under varying conditions. While **sensitivity analysis** refers to the study of the effect of changes in the basic premise, such as individual and

societal preferences or the assumptions made at the time of model development, uncertainty analysis is for the study of the effect of varying the value of estimates of the parameters included in the analysis. In essence, sensitivity analysis is primarily for **epistemic uncertainties**, whereas uncertainty analysis is mostly for **aleatory uncertainties**.

As is evident, uncertainty analysis pertains to **parameter uncertainty**. For example, in calculation of **disability-adjusted life years (DALYs)**, such parameters are incidence, prevalence, and duration of disease and mortality rates for various health conditions. The value of DALYs will naturally change if any of these are changed. Correct estimation of these parameters is vital to the validity of the DALYs obtained. The uncertainty surrounding these parameters can be reduced through more accurate measurement and by adopting a scientifically sound methodology of estimation. This is not possible for the preferences as required for sensitivity analysis.

In medicine, uncertainty analysis is generally done for a model that relates an outcome with its antecedents. For example, urinary excretion of creatinine can be reasonably predicted by age, dietary constituents, and lean body mass. If age is reported approximately in multiples of 5, such as 45 years instead of the exact 43, will the model still be able to predict nearly the correct value of urinary creatinine? If this example is not convincing, consider the effect of changes in diet from day to day on the urinary excretion of creatinine. If the outcome prediction remains more or less the same despite this change, the model is considered robust.

Uncertainty analysis incorporates three types of aleatory variations in the inputs: (i) First are random measurement errors, such as approximate age in the creatinine example. (ii) Second, natural variation that can occur in the input parameters such as dietary constituents can change from one day to another. If the model is based on the average diet over a month, the model may or may not be able to reflect the effect of daily changes. If it is based on diet of the previous day, what happens if the diet changes the next day? (iii) Third is variation in the multipliers used in the prediction. If ln(creatinine in mmol/day) is predicted as (0.012 × height in cm − 0.68) in children, what happens if the multiplier of height is 0.013 or 0.011? The multiplier 0.012 is an estimate, which is subject to sampling fluctuation, and this multiplier can change depending upon the subjects that happen to be in the sample. For further illustration, consider the following example.

Similar to the DALYs example cited earlier, consider the example of calculation of **health-adjusted life expectancy (HALE)** for any population. This requires three inputs: (i) life expectancy at each age, (ii) estimates of prevalence of various nonhealthy conditions at each age, and (iii) a method of valuing nonhealthy period in comparison to full health. All three are estimates and have built-in sampling and other variation. When the life expectancy of females at birth in Brazil is estimated as 72 years in 2015, it could actually be 71 years or 73 years. Life expectancy is relatively robust, but such variation is more prominent in prevalence rates of various diseases. Many of these prevalences are not known, and they are estimated by indirect methods. A statistical distribution can be imagined around all such estimates. Salomon et al. [1] have described a method to calculate the uncertainty interval around HALE for each member country of the World Health Organization based on such a premise. They used computer simulations for generating statistical distributions around input values and thus propagating uncertainty intervals.

An uncertainty interval is very different from the confidence interval (CI). In our HALE example, the CI would be based exclusively on the standard error (SE) of HALE without considering the variation in input values, and the SE can be reduced at will by increasing the sample size. The uncertainty interval would be much larger as it incorporates the effect of variation in each of the inputs and will not depend on the sample size. This variation depends on the repeatability of instruments, number of measurements, and other sources of variation that can contribute to disagreement between the predicted and the actual result. For a model reported by Xiridou et al. [2] that described the transmission of HIV and chlamydia among men who have sex with men (MSM) in the Netherlands, uncertainty analysis was carried out for model parameters without establishing the validity of the model.

Uncertainty analysis is strongly advised if the proposed model has serious consequences. This is also recommended when it is necessary to disclose the potential bias associated with models that use a single value of the parameters, particularly when your calculations indicate the need for further investigation before taking any action. Our discussion is in the context of health outcomes, but the major application of uncertainty analysis has been in the context of costing. Health care cost can substantially vary depending on the quantity and quality of various inputs, and uncertainty analysis helps to delineate the range of costs for varying inputs.

## uncertainty principle, *see also* equipoises

In the context of clinical trials, the uncertainty principle espouses that the researcher is genuinely uncertain about the outcome of the trial for the type of patients proposed to be enrolled. This is considered a moral prerequisite for proceeding with a trial. This principle also applies to the individual patients and says that the outcome must be uncertain in the patient chosen for the trial. If the researcher already knows which regimen is better, rightly or wrongly, there is no point in conducting the trial. Thus, the uncertainty principle provides a valid basis not just for random allocation of the patients but also for conducting the trial.

The term *uncertainty principle* actually belongs to quantum mechanics in the context of the position and momentum of a particle, where if one is known with high precision, the other will not. This can be directly applied to tissue cells, such as done by Barbieri et al. [1], who adopted the uncertainty principle associated with the task of detection of position and orientation as the main tool to provide quantitative bounds on the family of simple cells concretely implemented in the primary visual cortex. In clinical trials, uncertainty about the outcome is helpful in producing valid results without worrying much about other aspects. Using the uncertainty principle should allow the process of providing information and gaining consent to become much closer to what is appropriate in normal medical practice [2]. Although the principle has been adopted in some trials, it is many times impossible to gauge whether this is genuine or just a pretense by a particular trialist, since this could also be based on wrong information or wrong assessment. That the concept is trialist centered is among the severest criticisms of this principle.

The uncertainty principle is intimately related to the concept of **equipoise**. This could be personal equipoise similar to the uncertainty

just discussed, clinical equipoise for collective uncertainty of the medical community, or patient equipoise. For a debate on the uncertainty principle and clinical equipoise, see Weijer et al. [3].

## under-5 mortality rate, *see* mortality rates

## uniform distribution

A variable $x$ is said to have a uniform distribution when all its values within a specified range have the same chance of occurrence. The simplest illustrations are tossing a coin and throwing a die, where each face has the same chance. You can say that sex at birth has a uniform distribution, with equal probability for male and female, and possibly, incidence of cancer is uniformly distributed over various months of a year. The latter in effect means that season does not increase or decrease the chance of onset of cancer. Uniform distribution can be used to check whether or not the event of interest is equally likely to occur within a range. For example, one may want to investigate whether myocardial infarctions (MIs) are uniformly distributed over the 24 h period in a day, whether there is preponderance of any particular time such as early morning [1], or whether a particular material such as EndA is uniformly distributed in the membrane of cells and not localized [2]. It can also be used to check **digit preference**.

Graphically, a uniform distribution for a continuous variable looks like a line over its range $(c, d)$ (Figure U.1a), and has an obvious mean $(c + d)/2$ and not-so-obvious variance $(d - c)^2/12$. Compare this with, for example, a **Gaussian distribution**, which has a peak in the middle and tapering off on both the sides. Here, there is no peak and no tapering off, but it, too, is symmetric. If the variable is discrete, it will be depicted by bars (or spikes) (Figure U.1b) with as many bars as its possible values. If the number of possible values is $K$, the mean is $(K + 1)/2$, and the variance is $(K - 1)(K + 1)/12$. If the 24 h period is divided into 8 intervals of 3 h each for investigation of preponderance of MI in any time interval, there would be $K = 8$ such bars, one for each interval, and the number (or the proportion) of MIs in different time intervals would be on the vertical axis. If the distribution is uniform, the mean time of MI would be $(K + 1)/2 = 9/2$, or the 4.5th time interval, i.e., 12 noon when the time is measured from 00:00 hours. If the mean time of MI is substantially different from this, you know that the distribution of time of MI is not uniform over the 24 h period. This example also illustrates how the mean could be an absurd quantity in some setups.

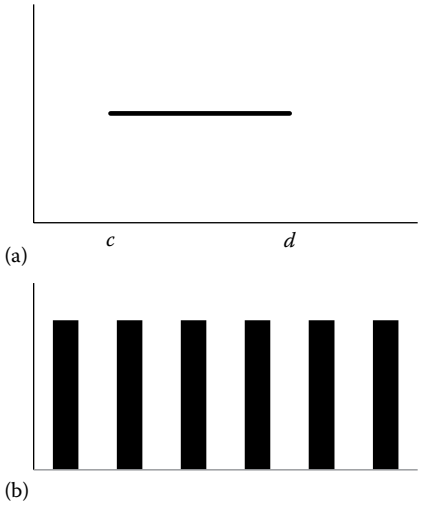

**FIGURE U.1** Uniform distribution: (a) continuous; (b) discrete.

## union and intersection of events, *see* Venn diagrams

## unit (statistical)

Unit is an element that is complete in itself in some sense, although this can be a part of a system or a process. In the context of medicine, we can think of a unit of investigation, e.g., blood or urine, a person or a patient for an inquiry, an organ such as an eye or bone for examination, an area or a family such as for sampling, etc. We also have a unit of measurement, such as milligram per deciliter for cholesterol level, and a unit of analysis, such as a test group and a control group in a clinical trial. Important among these for biostatistics are the unit of inquiry, unit of sampling, and unit of analysis.

### *Unit of Inquiry*

The **unit of inquiry** is the entity on which the information is obtained. In an investigation on household pollution, a household will be the unit of inquiry; for infant mortality rate (IMR), a city or a state can be the unit of inquiry; for growth of children, a child is the unit of inquiry; for cancer survival, a patient would be the unit of inquiry. The database will contain information on each unit with no further breakdown for subunits. For example, if the unit of inquiry for IMR is a state, no city-wise breakdown would be available. But city can also be the unit of inquiry for IMR. Thus, the unit of inquiry should be carefully decided depending on the objectives of the study.

### *Sampling Unit*

A **sampling unit** is that which is used for selection of the subjects. In a community survey on protein energy malnutrition, the sampling unit could be a family, but the unit of inquiry could be a child younger than 5 years. One sampling unit can have multiple units or no unit to inquire on. Sometimes, the sampling is done in stages, such as selection of some hospitals in the first stage, wards or departments within the selected hospitals in the second stage, and then patients in the selected wards in the third stage. These are the sampling units at

various stages. The unit of inquiry could be a patient, but sampling units are multiple in this kind of sampling.

In the case of multistage sampling, the first-stage sampling unit is generally termed **primary sampling unit (PSU)**. For example, in the US National Health and Nutrition Examination Surveys, the PSU is typically a county [1]. The size of the PSU and the **intraclass correlation** among subunits within the PSUs can substantially alter the variance of the estimates.

### *Unit of Analysis*

This is the basic unit for which the results would be available. For example, for an average, the unit is a group—there must be individual measurements within each group. The term *group*, in a generic sense, incorporates any aggregation; for example, it could be the average of one person over time when repeated measurements are taken, or a school whose children have been studied for, say, vision problems. A single value cannot be the unit of analysis, as this cannot be "analyzed," although a single value could be the unit of observation, such as an outlier, which may be an important observation by itself. An outlier by itself does not involve any statistical analysis.

The unit of analysis intimately depends on the objectives of the study. In a clinical trial, the treatment and control groups are the conventional units of analysis in the sense that all estimates are obtained for these two groups, but it can also be different time points in the case of repeated measures, such as to find the time with maximum response. Other examples of unit of analysis are age group, sex, disease severity group, cases responding early to a treatment, and vaginal swabs from women aged at least 50 years. In a multistage sampling, such as a state, county, and family, the unit of analysis may be any or all of these for, say, computing averages or generating estimates: this setup may require **hierarchical models** for analysis.

## univariate analysis

This analysis considers one variable at a time. Contrary to general perception, this refers to the **stochastic variable**: "fixed variables" can be many in a univariate analysis. In a classical regression setup, all the regressors are considered fixed, and only the dependent variable is considered stochastic. Thus, even if you have $K$ regressors, the analysis is still univariate. For $K \geq 2$, this is called multiple regression and not multivariate regression. The same is true with logistic regression, although you may occasionally find this wrongly referred to as multivariate logistic regression in the literature, particularly the old literature, when the number of regressors is more than one. The following example illustrates a univariate analysis.

If the presence or absence of kidney disease is being studied as dependent on creatinine level, glomerular filtration rate (GFR), age, and sex, this would be a univariate logistic regression. Similarly, if creatinine level, GFR, and blood urea nitrogen are studied separately as dependent on age, sex, and weight, each of these is a univariate analysis. It becomes multivariate when all three kidney functions are studied together in a holistic manner. Examples of multivariate analysis methods are cluster analysis, factor analysis, multivariate analysis of variance (MANOVA), and multivariate multiple regression. Chi-square can be used for both multivariate and univariate analyses, but Student $t$-test, analysis of variance, and ordinary and logistic regression are univariate analysis methods unless specifically mentioned as multivariate.

Results obtained by a combination of univariate analyses could be very different from the results of multivariate analysis because the multivariate methods also consider the correlation between the variables, which univariate analysis does not do. However, univariate analyses are relatively very simple to do, are easy to interpret, and in many cases provide focused conclusions. For example, if three kidney functions are studied together in a multivariate setup and the dependence is statistically significant, it would be difficult to say which of the three kidney functions is affected and which not. Univariate results would answer this kind of question but fail to account for the correlations between different kidney functions. Thus, in some situations, both analyses may be required to give a comprehensive account of what is going on.

## up-and-down trials

An up-and-down trial is used for calibrating the dose where a series of patients is involved in the rule of stepping up the dose by a prefixed amount following a negative response and decreasing the dose following a positive response. The prerequisite is that the higher dose of the regimen is more likely to give a positive response. This can also be used for dose escalation studies as in a phase I cancer trial. The trial can be carried out on one patient also, provided that the validity conditions of ***n*-of-1 trials** are met. The first test should be performed at a dose close to your guess of the median effective dose. The method is also known as *sensitivity experiment*, and also as the Dixon and Massey method, although this is believed to have been introduced by Dixon and Mood [1] in 1948. The up-and-down methodology is rarely used for the usual drug trials because of the risk of an unacceptable level of toxicity. For details, see Le Tourneau et al. [2].

Consider a trial starting with 7 mg of intrathecal hyperbaric bupivacaine for an anesthetic effect in lower limb surgeries that failed to produce a satisfactory response in a particular patient. If the increment fixed in advance is 1.5 mg, the next patient will get 8.5 mg. If that also fails, the next will get 10 mg. If that succeeds, the next will now get a lower dose, 8.5 mg. If that also succeeds, then next will get 7 mg. Success will decrease the dose, and failure will increase the dose each time by the fixed margin (Figure U.2). Some clinicians may find the up-and-down method very convincing for identifying a minimum critical dose that is effective. Although the dose in this method is increased or decreased by a fixed margin, the up-and-down method helps estimate the exact mean dose, which could be in between those tried. In most situations, the dose quickly settles near the mean or median. The method generally requires fewer tests than a method with groups on preassigned doses.

As just mentioned, for this kind of trial, fix a dose step that you think would be appropriate escalation or reduction at successive steps, and also guess a median dose using your clinical acumen or past experience. For stepping up or down, generally, 1 standard

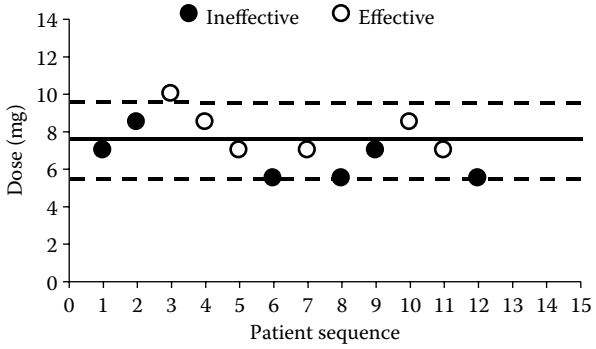

**FIGURE U.2** A trial with up-and-down method.

deviation (SD) works fine, particularly for a Gaussian distribution, after taking the logarithm of dose. Give the anticipated median dose to an eligible patient and assess if it is effective. If effective, step down the dose by the prior fixed step; if not effective, step up the dose for the second patient; and so on. An essential prerequisite for this kind of trial is that such variation in dose should not be unethical.

The trials can be conducted on as many patients as decided in advance, but generally, a trial on 10–15 patients is considered adequate. In most cases, the dose will converge to a definite dose that is the minimum to achieve a positive response. In any case, once the data are available for successive doses and success–failure information, they can be analyzed to estimate least mean effective dose, and confidence interval (CI) can also be obtained using the method mentioned in a short while. This type of trial cannot easily estimate other locations, such as $ED_{95}$—the dose effective in 95% cases. But one drug can be compared with another for the least mean effective dose; for example, hyperbaric bupivacaine can be compared with isobaric bupivacaine, and the one with a lower mean dose can be recommended.

The following method can be used to analyze data from an up-and-down trial when the response is of the yes/no type. The analysis is in terms of estimating the least effective dose and obtaining a CI. Generally, the least effective dose in this case is defined as the same as the median effective dose. The procedure for obtaining the median effective dose is as follows:

Step 1. Calculate the logarithm for all the doses you tried from minimum to maximum. Find the mean of the differences of successive log-doses. Denote this mean difference by $\bar{d}$.

Step 2. Separately list doses that were effective in different patients after excluding the ineffective ones. Calculate the mean of the logarithm of these doses and SD of these logarithms. Denote them by $\bar{y}$ and $s_y$, respectively.

Step 3. Median effective dose = $\exp(\bar{y} - 1/2 * \bar{d})$.

Calculation of the CI requires a constant *G*, which is obtained from a figure given by Dixon and Massey [3]. See this reference for the method to obtain the CI. The following example illustrates the method.

There is considerable uncertainty regarding the minimum dose requirement of local anesthetics administered intraspinally for surgery. Sell et al. [4] conducted a study to estimate the minimum effective dose of levobupivacaine and ropivacaine in hip replacement surgery. Forty-one patients were randomly allocated to one of the two local anesthetic groups in a double-blind manner. The authors used the up-and-down strategy, determining the initial dose based on previous experience. The minimum effective dose was defined as the median effective dose. The up-and-down method found the minimum effective dose of levobupivacaine to be 11.7 mg (95% CI, 11.1–12.4) and that of ropivacaine 12.8 mg (95% CI, 12.2–13.4). The authors concluded that these doses are smaller than those reported earlier for single-shot anesthesia. The overlapping CIs indicate that the doses of the two anesthetic agents under this trial are not significantly different.

Dixon [5] has presented a modified method that should work for small samples under which median = (final test level) − *k*(step-up dose), where *k* is the value from the table he provided in his paper.

## U-shaped curve/distribution, *see also* bathtub curve/distribution

This refers to the curve obtained when the response (*y*) is high for low values of the antecedent (*x*), levels off to a low level for middling values of *x*, and is high again for high values of *x* (Figure U.3a). This kind of relationship has been observed by Merghani et al. [1] between exercise and cardiac morbidity, where morbidity is extremely high when exercise is absent or very low and also when exercise is very strenuous. This is similar to the **J-shaped curve**, but now, the low tip of *J* on the left rises to make a *U* shape.

Figure U.3b is an inverted U-shaped curve between age and lung function, showing that lung function increases with age to a limit, plateaus between ages 30 and 40 years, and then declines with ageing. This curve is not exactly inverted U-shaped and may apparently look Gaussian, but it is not so, because of the flat peak and the sharp rise and decline on either side. Moreover, the term *Gaussian* is used for a statistical **distribution**, while here, we are discussing just a relationship between any two variables. It becomes a distribution when the vertical axis is frequency or proportion, which is not the case with either of the two curves we have shown. However, Leboeuf-Yde et al. [2] have reported a U-shaped distribution of "percentage of weeks in one year with bothersome low back pain in all 7 days" by patients with chronic low-back pain in Denmark. The distribution of patients reporting a low percentage of weeks was very high, and that of patients reporting a high percentage was also very high, while that of patients reporting pain in 30–70% of weeks (15–35 weeks in a year) was low. This, in effect, means that the patients with chronic low-back pain mostly had either a few weeks of persistent pain in a year or had many weeks of persistent pain.

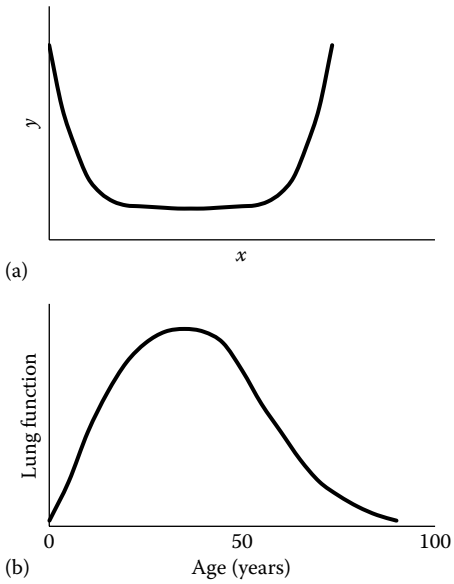

**FIGURE U.3** (a) A U-shaped curve between exercise and cardiac mortality and (b) an inverted U-shaped curve between age and lung function.

Davis and Svendsgaard [3] studied risk assessment implications of a U-shaped dose–response curve and concluded that this kind of curve raises important issues in the identification of no-observed-effect levels and trade-offs between potential risks and benefits of the intervention, where *no observed effect* pertains to the low levels in the U-shaped curve.

# V

## vaccine trials, *see* clinical trials

## validation sample/study, *see also* validity, robustness

In the context of biostatistics, validation is the process of confirming the adequacy of a medical tool or of the results of a medical study for the specified application. The tool can be a **questionnaire**, a diagnostic test or criterion, a **scoring system**, a treatment strategy, or any such device proposed to be used in a particular setup. Study results also are validated for their applicability to a particular setup.

As is evident, validation is done not just for newly discovered tools and procedures but also for established tools when they are proposed to be applied to a new setup. The new setup, where a particular tool is proposed to be used, may have some peculiarities, and you may not have sufficiently convincing previous evidence of applicability of these tools to this new setup. If so, it is desirable, if not essential, that the tool be checked for its **validity** to perform well in this particular setup.

Among the procedures available for validation, the simplest is *peer validation*. This may be of two types: (i) find out from other potential users about their experience in a setting similar to the new one where the tool is proposed to be utilized, and (ii) look at a full-scale or pilot study of other researchers who may have carried out validity checks of similar tools in a similar setup. Often, the workers who develop the tool also do some kind of validation. They may do *internal validation* by splitting the available sample of subjects in two equal or unequal parts—use one for developing the tool and the other for validation, sometimes called the training set and the validation set, respectively. The tool developed on the first part of the sample is tried on the second part of the sample to check if it is working satisfactorily. Each part must be reasonably large and adequate representative to generate confidence. Since internal validation is on part of the same sample, the tool under test may give good results even when it is not really as good for applications elsewhere. Thus, *external validation* is preferred where an independent validation study is done on another sample drawn from the same milieu—sometimes even from a different milieu—to check if the tool works in altered settings or not. In this case, this other sample is the validation sample. If your own setup does not reasonably match with the setup of the sample on which the tool was developed or validated, it is desirable to carry out your own validation study on a random sample of subjects for whom this tool is intended. For example, the McGill pain score has been validated to work in different languages and different setups.

See **validity** for further details.

## validity, *see also* validity (types of)

The validity of a tool is its ability to assess correctly or its appropriateness for use in a particular setup. In medicine, the term is used for devices, factors, data, designs, estimates, evidence, tests, results, scoring systems, studies, and a host of other tools. Do not confuse this with accuracy. Accuracy is generally for a single measurement, whereas validity is the ability to hit the target on average.

There is some confusion in the literature about the terms *validity* and **reliability**. The difference between the two is aptly illustrated in Figure V.1. Reliability is hitting the same point in repeated attempts, although this may be far away from the target (see third panel). Validity is hitting around the target (second panel). If hits are close together and near the target every time, both reliability and validity are high (fourth panel). Lack of validity can be due to systematic bias or for any other reason. See **bias in medical studies and their minimization** for further details on the types of bias that can affect validity. If the bias is small, we say that the tool has high validity, and if the bias is large, we say that the validity is low.

What signs and symptoms or hematological parameters (such as hematocrit) can correctly identify cases of dengue fever in early stages (because serological evidence takes time)? Is BP > 140/90 mmHg the right definition for hypertension, or is BP > 160/95 more correct? Both definitions are used. (See Refs. [1,2]. These, incidentally, are nearly consecutive articles in the same journal but with varying definitions.) This means that those with BP = 150/92 are considered hypertensive by one definition but not by the other. How can one distinguish, without error, a hypothyroid condition from euthyroid goiter? How can one correctly ascertain the cause of death in an inaccessible rural area where a medical doctor is not available? How can age be correctly assessed when a dependable record is not available? Can the diet content of an individual be adequately assessed by taking a 3-day history? How can physical activity be validly measured? Many other examples can be cited where validity is an important concern.

Validity is context specific; for example, high validity of a tool in hospital A does not necessarily mean that this will be so in hospital B as well. A highly valid tool in better-nourished children may not

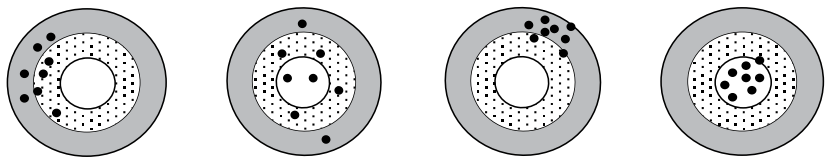

**FIGURE V.1** Darts illustrating the difference between validity and reliability.

work well in undernourished children. It intimately depends on the case mix. Thus, validity is qualified for the type of subjects evaluated.

### *Validity of Diagnostic Tests*

In practice, no medical test is 100% perfect. A computed tomography (CT) scan can give a false-negative or false-positive result, and a negative histologic result for a specimen is no guarantee that proliferation is absent, although in this case, positive **predictivity** is nearly 100%. The values of measurements such as creatinine level, platelet count, and total lung capacity are indicative of different medical conditions rather than absolute; i.e., they mostly estimate the *likelihood* of a disease. Signs and symptoms seldom provide infallible evidence and have to be supplemented with other clinical information to come to any conclusion worth implementing.

Because all these tools are imperfect, decisions based on them are also necessarily probabilistic rather than definitive. Their validity in a particular setup is generally measured in terms of indices such as **sensitivity and specificity** and positive and negative **predictivities** (see these topics for details). These terms are applied not just to conventional laboratory and radiological tests but also to other clinical evaluation tools, such as signs and symptoms, and attitudes and behavior. These indices measure the validity of these tools on a scale of 0 to 1, with 0 indicating that they are not helpful at all and 1 indicating that they are perfect in reaching a right conclusion. The details under the respective topics will tell you that sometimes a highly sensitive test and sometimes a highly specific test is more valid for a particular application. Also, sensitivity and specificity are evaluated on subjects who are already known to have or not have a disease or condition, whereas predictivities provide a valid measurement of the diagnostic utility of tools in a local context. You may also want to review the topic **receiver operating characteristic (ROC) curves**; these provide information on overall performance of quantitative tests on the basis of sensitivity–specificity of the quantitative tests at different cutoffs.

### *Validity of Medical Information*

Besides diagnostic tools, other "tools" used in health and medicine include information on a patient or a person obtained in a variety of ways—previous records, interview, examination, and investigations. None provides perfect information that would be right in all cases all the time. Which method of eliciting information provides more valid information regarding the health of a person?

Laboratory and radiological investigations are generally believed more than others as they are objective and have the least human element. However, validity of laboratory results, for example, depends on whether or not the apparatus, reagents, and procedures used are fully standardized. Even then, as mentioned earlier, they do provide **false-negative and false-positive** results in some cases. Moreover, some clinicians believe that nothing surpasses the feeling they get of the condition of the person by clinical examination. For them, investigations are just for support or confirmation and do not have much value by themselves. This is because, first, laboratory results can be in error; second, some people have so-called abnormal levels even when they are completely healthy; and third, health is more of a perception of the affected individual than his/her organic state. The same is generally true for radiological investigations. In most cases, the holistic picture obtained by the combination of clinical information and investigation results provides much more valid information about the condition of the patients.

The preceding discussion may have given you an idea of how difficult assessment of validity is. Each tool has multifarious aspects, and its performance in providing correct information depends on a host of features. Consider, for example, forms for eliciting and recording information, as commonly used in working up patients in clinics and most research studies, including surveys. A form could be a **questionnaire**, **schedule**, **or proforma**. See this topic for their relative merits and demerits. The validity of the information obtained by these tools depends on, among others, their contents. For example, the burden of smoking is assessed generally by the duration and number of cigarettes smoked. Sometimes, information on the type of smoking (cigarette, cigar, pipe, water pipe, bidi, etc.) is also obtained. In some rare cases, the age at initiation and time elapsed since quitting by ex-smokers is also obtained as done for the Global Adult Tobacco Surveys in different countries [3]. But how to validly combine all these aspects of smoking into a single index is a question addressed by the **Indrayan smoking index**.

Validity of response also depends on interview technique, patient cooperation, biases and prejudices of both the interviewer and the interviewee, rapport between them, and the like. It also depends on the sequence of questions, the length of the questions and of the questionnaire, their wording, etc., besides the statistical **scale** (metric, ordinal, nominal polytomous, or nominal dichotomous) used to elicit and record the response. For example, a **Likert scale** is commonly used to elicit opinion or satisfaction with gradation from most adverse to most favorable. The response on this scale may differ if you use scores from 0 to 6 compared to scores from –3 to +3 despite both being 7-point scales. This illustrates how the concept of validity becomes intricate as we go deeper.

In the context of a questionnaire or a schedule, validity is assessed in terms of, for example, its ability to distinguish between a sick and a healthy subject or a very sick and a not-so-sick subject. This means that the scores received or the responses obtained from one group of subjects should be sufficiently different from those of another group when the two groups are known to be different with respect to the characteristic under assessment. Consider a questionnaire containing 20 items measuring quality of life. If the response on one particular item, say on physical independence, from healthy subjects is nearly the same as from mentally retarded subjects, this item is not valid for measuring quality of life in those types of subjects, and the item can be deleted. A shorter questionnaire is always better than a longer questionnaire—thus, deletion always helps. But the number of items finally left should be adequate to assess all the domains of the construct under evaluation.

### *Validity of the Design, Variables under Study, and Assumptions*

Medical researchers commonly face the problem of validity of their design, variables to be studied, and assumptions. When any of them lacks validity, the results will be affected.

A valid design is one that would rightly answer the question the study is intended to answer. For example, a **one-way design** cannot provide the right answer on the effect of two **nominal** factors on a **quantitative** outcome. Kaestner [4] found that the preintervention versus postintervention design with a **control group** for studying the effect of state Medicaid expansion on mortality in low-income adults is invalid because prior trends in the treatment and control states differed significantly. A **case–control** design, for that matter, any **observational study**, is generally not valid for reaching a **cause–effect relationship** as this type of study provides associational results except when a set of other strict criteria is met.

Similarly, one has to choose the right variables or factors to get valid results from a study. For example, for studying correlates of an outcome such as duration of hospitalization, severity of condition

at admission by itself may not be valid, and you may have to consider other factors also such as age, treatment strategies, nursing care, and overall health of the person for response to the treatment. Operational definitions of each of these variables should also be valid. For example, nursing care could be assessed in terms of responding to the specific needs of the patient throughout the stay, sticking to the prescribed regimen, proper entries in bedhead tickets, etc. If something is missing or not properly recorded, validity will suffer in the sense that the right answers to the questions of what correlates affect the duration of hospitalization and by how much will not be obtained. For statistical methods such as regression, the choice of regressors is a big consideration in getting valid results. For example, Creemers et al. [5] selected a core set of valid variables for ankylosing spondylitis activity out of a large number of possibilities for developing a disease activity score.

Assumptions for a particular method are requirements under which that method gives valid results. This applies to statistical methods as much as to most other methods. For example, an important requirement for analysis of variance (ANOVA) is that values have the same variance in different groups. For running a regression, linearity of the relationship and Gaussian distribution of the residuals is a frequent assumption. Even nonparametric methods require independent values. Different statistical methods have different assumptions, and checking the validity of these assumptions is an important part of the statistical analysis. We have presented methods for checking their validity.

### *Validity of Data, Measurements, Scoring Systems, Estimates, Statistical Methods, and Models*

Data are considered valid when they reflect the true status. If a person's age is 36 years and is inadvertently recorded as 63 years, if a male person is shown to be pregnant, or a woman of age 27 years married 4 years ago is shown to have a daughter of age 7 years from the same marriage, the error is obvious. In a hospital setup, this can occur when, for example, the date of surgery is recorded as before the date of admission, liver abscess is wrongly shown as biliary disease, diagnosis and type of surgery are entered in switched columns, etc. If a person's sex in wrongly entered, the error may not be detectable at all at the time of analysis—thus, due care is required at the time of data entry. **Missing data** and intentional wrong reporting as in some medicolegal cases also reduce the validity of the data.

For validity of a measurement, realize that many characteristics can be measured in a variety of ways. Choosing the right index that measures a characteristic correctly can be difficult in some setups. Consider measuring obesity in the context of its impact on cardiovascular diseases (CVDs). This can be measured by body mass index (BMI), waist–hip ratio, waist–height ratio, Broca index, skinfold thickness, etc. Which of them is more valid in the context of CVDs is a moot question. In addition, how valid is it to divide BMI into thin, normal, obese, and morbid categories, or should one always use the actual values without any categorization? **Categories** have their own advantages but also involve risks, as discussed under that topic. Categorization does affect the validity of the measurement, and different categorizations can give different results. Some characteristics defy measurement: intense debate is ongoing regarding how to measure stress and strains in life, psychological well-being, and personality traits. In the absence of a direct measure, **surrogates** are used. The validity of these surrogates for measuring the actual characteristic remains a concern.

A large number of **scoring systems** are used in the practice of medicine and research. They are primarily used for gradation of severity (e.g., **APACHE score**) and secondarily for diagnosis (e.g., risk of malignancy index [6]). The validity of severity scores is assessed in terms of correct prediction of prognosis, and of diagnostic scores in terms of correct classification of patients into diseased and nondiseased. For example, the authors of APACHE II found that prediction of survival or hospital death by this score is correct in 85% of cases for cases admitted to critical care in US hospitals [7]. This is the index of validity of this score. The risk of malignancy index has a diagnostic sensitivity of 85% and specificity of 97% for ovarian cancer [6]. These two are the indices of validity in this case. If you are using a scoring system in your practice or research, examine its validity for that particular use. Using sensitivity and specificity as indicators of diagnostic efficacy is an example of their invalid use.

There are questions about the validity of statistical measures also, such as odds ratio in a prospective study setup. Relative risk is a valid measure only when the two groups under comparison have identical features except that the factor for which relative risk is being computed is present in one group and absent in the other. A large number of examples of such statistical measures can be cited whose validity is confined to a narrow sense. Validity of statistical estimates is generally assessed in terms of their bias [see the topic **bias (statistical)**]. This is different from **precision** since precision is for reliability and not validity. In brief, sample mean is an unbiased estimate of the population mean, but sample median generally is not an unbiased estimate of the population median except for symmetric distributions. The sample variance is an unbiased estimate of the population variance only when the denominator is $(n - 1)$, which explains why $(n - 1)$ is used in place of $n$ in this case. An unbiased estimate of **parameter** $\tau$ is one whose average over all different possible samples is the same as the value of $\tau$. For most distributions, unbiasedness can be theoretically established without worrying about drawing so many samples.

Validity of a statistical method is its ability to provide correct inference as evidenced by the data. This is mostly assessed by the validity of the underlying assumptions, as already discussed. However, in isolated cases, there might be gross deviations, for example, some use relative risk for odds ratio, and vice versa. The term *validity* is also used for **statistical analysis** where, for example, it becomes invalid when a wrong computer command is used while running a statistical package. An invalid design command for computation while using a statistical package will result in an error message in some cases, but in many others, the package will give you an output that is not what you want. This can easily happen for hierarchical design or designs with random effects where computer commands require sufficient expertise. These computer commands require some training and some understanding of the implications of different commands.

The extent of validity of statistical models is evaluated on two criteria: (i) their biological plausibility, which says that a possible mechanism should be available that links the outcome with the inputs as stipulated in the model, and (ii) their ability to correctly explain or predict the underlying phenomenon. Since models, by their very nature, represent simplified versions of the actual process, they are not expected to be 100% valid. In case a model is for predicting a **dichotomous** or **polytomous** outcome, percent correctly classified is an accepted measure of validity. For example, the Dimodent equation, which uses measurements of certain teeth, was able to correctly identify sex in 78.7% of cases in a Lebanese population [8]. This quantifies the validity of this equation in that population, but the validity could be different in some other population. For ordinal outcome, the ***C*-statistic** can used to quantify the validity. For diagnosis of ovarian tumors as benign, borderline, primary invasive, or

metastatic on the basis of a risk prediction model, the value of the *C*-statistic was found to be between 0.57 and 0.64 in external validation for Belgium as reported by van Calster et al. [9]. On a scale of 0 to 1, this value is not particularly high to inspire confidence about his model. For continuous outcome, a predictive model is valid when the mean of residuals (predicted − observed) is close to 0. This is easy to achieve, for example, in regression, by suitably choosing the intercept. In this case, validity can also be assessed by percent correctly predicted, although the primary consideration in such models is the reliability measured by the variance of the residuals instead of the validity. The validity of many outcome models is assessed in terms of biological plausibility, as stated earlier, and their ability to serve their intended purpose.

### *Validity of Results and Conclusions*

Validity of results and conclusions can be divided into two broad categories. The first is *internal validity*, that pertains to the validity of the information available after the study, and second is *external validity*, which pertains to their generalizability to the target population. Internal validity depends on the use of proper methods on one hand and consistency of different results on the other. If alcohol intake is positively associated with liver disease in a segment of the population, and it is also observed that that mine workers take more alcohol, you should get the result that liver diseases are more common in mine workers. If this is not so in a sample, and no reason can be identified for this inconsistency, the results are not internally valid, and suspicion arises about the method of collection of the data or their analysis. Maybe the subjects have given wrong information, or confounding was not properly accounted for in the analysis.

External validity depends mostly on the adequacy of the subjects for a particular generalization. A representative sample is a definite help for validity of results of **descriptive studies**, but that is not a prerequisite for **analytical studies**. Some results based on subjects from a hundred years ago remain valid for the present population; e.g., "smoking causes lung cancer" is the conclusion derived from a study of people decades ago but is valid for the present population also. A cause–effect type of relationship generally transcends time and population. A second factor affecting the external validity is correctness of the information obtained from the study subjects (see **bias**). Remember that wrong information cannot lead to right conclusions howsoever immaculate analysis might be. Third, it also depends on the proper choice of variables and indicators for differentially assessing the antecedents and the outcomes.

## validity (types of)

Important types of validity for the purpose of medical applications are face, criterion, concurrent, content, and construct validity.

**Face validity** is an apparent correspondence between what is intended and what is actually obtained. Grossly speaking, ovarian cancer cannot occur in males, and prostate cancer cannot occur in females. Cleft lip, deafness, and dental caries cannot be causes of death. If any data show such inconsistency, these are not face valid. Face validity is also violated when a patient is shown as discharged from a hospital and cause of death within the hospital is also recorded. Current age cannot be less than the age at first childbirth. Thus, face validity is achieved when the observations look just about right. If a man states his age as 20 years but looks like a 40-year old, the response is not face valid. If a family reports consuming food amounting to 2800 calories per unit per day but the children are grossly undernourished, then again, the response or the assessment is not face valid.

An instrument or a method is called **criterion valid** if it gives nearly the same information that a criterion with established validity would. Carter et al. [1] report on the criterion validity of the Duke Activity Status Index with respect to standard pathologic work capacity indices in patients with chronic obstructive pulmonary disease. Whenever a new index, score, or any other tool is developed, it is customary that its criterion validity be established by comparing its performance with a standard. Our review of literature suggests that **correlation** is the statistical method generally used for this purpose, whereas the right assessment of criterion validity should be obtained by evaluating predictivity. If negative and positive **predictivities** are high, the tool can be considered criterion valid.

It is not uncommon in medical setups that no validated standard is available. For example, no valid measure is available to assess physical balance in people with vestibular dysfunction. The Berg Balance Scale is often used for this purpose but is not considered a fully valid measure. A relatively new tool is the Dynamic Gait Index, and the two can be investigated for **agreement**. This is different from correlation. If the agreement is good, the two methods can

be called **concurrently valid**. This means that both are equally good (or equally bad!). This, however, does not establish superiority of one over the other. Superiority can be inferred only when two methods under evaluation are compared with a known **gold standard**.

The fourth type is **content validity**. This is based on the domain of the content of the measurement or the device. Would you consider kidney function tests such as urea clearance and diodrast clearance content valid for assessing the overall health of kidneys? Such tests are restricted to specific aspects and do not provide a complete picture—thus, they are not fully valid for assessing the health of kidneys. Content validity is often established through qualitative expert reviews. Wynd and Schaefer [2] explain how the content validity of an osteoporosis risk assessment tool was established through a panel of experts. This is the most favored method for assessing the content validity of any tool.

The last is **construct validity**, which seeks agreement of a device with its theoretical concept. Body mass index is construct valid for overall obesity but not for central obesity, whereas waist–hip ratio is construct valid for central obesity and not for overall obesity. Construct validity is sometimes assessed by the statistical method of **factor analysis**, which reveals "constructs." If these constructs correspond well with the ones that are otherwise theoretically expected, the tool is considered construct valid.

## variability, *see* variation (measures of)

## variables

A variable is a characteristic that tends to vary from person to person, time to time, unit to unit, etc. All biological characteristics—age, sex, birth order, body temperature, duration of survival, disease severity, etc.—are variables. If the characteristic is a quality such as blood group or site of lesion, it is called a **qualitative** variable, and if the characteristic is numerical such as age, blood pressure (BP), or parity, it is called a **quantitative** variable. The latter is also called a **metric** variable.

Statisticians find it easier to work with notations, as they help in making generalized statements, denoting a characteristic by variable $x$. If many characteristics are considered, notations such as $x_1$, $x_2$, $x_3$, etc., or $x$, $y$, $z$, etc., can be used.

It is easier to work with variables when they are represented by numbers. Quantitative variables are already observed as numbers, and you can say that $x = 132$ mmHg for a particular person where $x$ denotes systolic BP. Each category of a qualitative variable is also assigned a number, called a **code**, such as 1, 2, 3, and 4 for blood groups O, A, B, and AB. If a person has blood group B, you can say that $x = 2$ for him/her where $x$ now is the notation for blood group. This coding, however, does not make the variable quantitative. In the case of qualitative variables, the main interest generally is in the number of subjects in different categories—how many of blood group A, how many of blood group B, etc., or the proportion or percentage; obviously, a quantitative summary such as mean is not applicable to these variables.

### *Dummy and Indicator Variables*

A **dichotomous** characteristic such as sex can be represented by $x = 0$ for females and $x = 1$ for males. This is called a **dummy variable** or an **indicator variable**. For blood groups with four categories, the dummy variables could be defined as follows:

$x_1 = 1, x_2 = 0, x_3 = 0$ for blood group A
$x_1 = 0, x_2 = 1, x_3 = 0$ for blood group B
$x_1 = 0, x_2 = 0, x_3 = 1$ for blood group AB
$x_1 = 0, x_2 = 0, x_3 = 0$ for blood group O

Three dummy variables are required to represent four **categories**, and these together uniquely identify the category. In general, $(K - 1)$ dummy variables are needed to identify $K$ categories.

Dummy variables are extensively used in statistics. We give one simple example that will illustrate their use. Consider the following simple linear regression of systolic blood pressure (sysBP) on age in apparently healthy adults:

$$\text{sysBP} = 120 + ½(\text{age}) - ⅛(\text{age})*x, \qquad \text{(V.1)}$$

where age is in years and $x = 0$ for females and $x = 1$ for males. This is the dummy variable. Note that this regression is

$$\text{sysBP} = 120 + ½(\text{age}) \text{ for females } (x = 0)$$

and

$$\begin{aligned}\text{sysBP} &= 120 + \tfrac{1}{2}(\text{age}) - \tfrac{1}{8}(\text{age}) \text{ for males } (x = 1)\\ &= 120 + \tfrac{3}{8}(\text{age}).\end{aligned}$$

Equation V.1 is now able to provide two regressions with the help of a dummy variable—one for males and the other for females. We have not used notations $y$ and $x$ for the variables sysBP and age in these equations, so that it remains easy to understand, but those notations can also be used.

### *Deterministic and Stochastic (Random) Variables*

A variable whose value is already known is called a **deterministic variable**. If you know that a person is male, $x = 1$ for him is deterministic. If a person with a particular disease is selected, that disease is deterministic. On the contrary are **stochastic variables**, whose values are not known and cannot be predicted with certainty, such as outcomes of the treatment. These are also called **random variables**. When a person comes to a clinic with certain complaints, his/her signs and symptoms are elicited as these can vary even when the disease is known. Stochastic means probabilistic—something that depends at least partly on chance. When a patient is selected for a clinical trial on the basis of presence or absence of, say, liver cirrhosis, it is not possible to correctly predict his/her age or diet pattern as these would vary from patient to patient. Thus, age and diet are stochastic (random) variables, particularly when diet is also identified by a numerical code, age already being numerical. Core statistical methods for inference are for random variables including,

but not restricted to, the effect of deterministic variables on random variables.

Strange as it may sound, **independent variables** in a **regression** setup are considered deterministic. In Equation V.1, sex represented by $x$ and age in years as is both are deterministic. This equation tells us what sysBP is expected in that population for adults of a specific age and sex. The equation works only when age and sex are *known* and plugged into the right side of the equation. Details given under the topic **regression** tell you that the regression gives the *average* of the dependent $y$ for fixed values of the independent $x$'s—in our example, average sysBP for fixed age and sex.

### Discrete and Continuous Variables

Some variables can take only a small number of values. Gender has only two possible values, and blood group has four possible values. Some others can take any of a large number of values, such as cholesterol level, ranging from 100 to 200 mg/dL, which can even be 132.7 mg/dL if an instrument giving such accuracy is available. On the other hand, the parity of a woman can be 1 or 2 but never 1.6. A variable that can take only a finite, generally small, number of values in a range is called **discrete**. Number of deaths in a hospital in a day, site of lesion, and diagnosis are other examples of discrete variables. Almost all qualitative variables are discrete, whereas quantitative variables can be discrete or continuous. Parity and family size are examples of quantitative but discrete variables.

It is common in medicine that discrete variables take only nonnegative *integer* values, but the definition does not require it to be so. Shoe size can be 7, $7\frac{1}{2}$, 8, $8\frac{1}{2}$, etc. but is still discrete. It can take only these four values between 7 and $8\frac{1}{2}$. Compare this with a variable such as age that can be measured accurately as 7.2613 years when needed. Although recording of age in terms of completed years is often considered adequate, particularly for adults, theoretically, age can take an infinite number of values between 7 and $8\frac{1}{2}$. Thus, this is not a discrete variable.

A variable that can take an infinite number of values in a range is called continuous. Age, cholesterol level, body temperature, enzyme level, and weight are examples of continuous variables, although in practice, it may be redundant to measure them to several decimal places. For example, it does not help to say that the hemoglobin (Hb) level is 14.038 g/dL; just 14.0 is enough. Weight is generally measured to the nearest kilogram, BP to the nearest millimeter of mercury, and Hb level to one-tenth of a gram per deciliter. It can be argued that such approximation makes the variable discrete, but the continuous character is not lost in practice as long as the measurement is sufficiently accurate. Inversely, variables such as heart rate, platelet count, and respiration rate are in fact discrete yet are considered continuous because of the large number of possible values. *Only variables that can take a small number of values, say less than 10, are generally considered discrete for practical applications.* Others can be treated as continuous for most practical purposes even when they are theoretically discrete. It would be instructive to note that variables such as heart rate and respiration rate per minute can be in decimals but noted as integers. In 1 min, you may find that the heart rate is 67, but if this is observed for 10 min, you may find 673 beats, giving the average of 67.3 per minute. All this can become intricate when better **accuracy** is required.

Classification of a variable into discrete or continuous is important because statistical methods for the two types of variables are different. For example, methods based on **binomial**, **multinomial**, and **Poisson distributions** are used for exact analysis of discrete variables, whereas methods based on **Gaussian distribution** are mostly used for continuous variables.

### Categorical Variables

A variable is categorical when its values identify a **category** instead of a single value. Statistical methods distinguish three kinds of categorical variables depending on the kind of category they identify.

First are nominal categories, which are just names with no order, such as disease names (migraine, dementia, cancer, etc.) and signs (pallor, distension, palpable spleen, etc.). Either codes or mostly dummy variables are used for analysis of data with these kinds of categories. The variable for two categories (yes/no or male/female, etc.) is called **dichotomous**, and the variable for more than two categories is called **polytomous**. The statistical method of choice in this case is **chi-square** for large samples, and binomial or multinomial for small samples.

Second are ordinal categories, such as disease severity categorized into none, mild, moderate, serious, and critical. These categories have an underlying continuum but are observed as categories generally because no satisfactory metric is available to measure the continuum. The concerned variable is called an **ordinal variable**. Sometimes, **scores** are used to measure this continuum. If so, ordinal categories become **metric categories**, which is the third kind of category. Metric categories are often used for **quantitative data** also. Age categories of child, adolescent, adult, and old are intrinsically metric since each category can be defined numerically in terms of years of age. Similarly, for example, parity can be divided into 0, 1–2, 3–4, and 5+ categories.

Statistical methods for analysis of ordinal variables are not fully developed yet. Mostly methods based on **ranks** are used, such as **nonparameric methods**. Sometimes, ranks are considered as the actual values, and the usual methods for quantitative variables are used on these ranks. This, however, has severe limitations because the difference, for example, between mild and moderate (ranks 1 and 2) is considered the same as between moderate and serious (ranks 2 and 3). In addition, the analysis that uses ranks as the actual values also will consider, for example, that 3*mild = 1*serious because both have value 3. In a study reported by Zagouri et al. [1] on heat shock protein 90 (Hsp90) in lobular neoplasia of the breast, the intensity of Hsp90 stain was an ordinal variable (0 = negative, 1 = low, 2 = moderate, 3 = high), but mean and standard deviation (SD) were calculated as though they were usual quantities, although they used a nonparametric **Wilcoxon test**. Further, the categorization may not be sharp and objective, since a patient may look mild to one physician and moderate to another. Ranks do need extra care in analysis and interpretation.

**Statistical analysis** of categorical variables for metric categories also has limitations. First, the actual values are lost. If the category for, say, pain score is 0–3, score 1 is treated the same as score 2 or score 3. Thus, the advantage of metric numbers is not available, and the results may not be the same as expected from exact values. Second, such categories are mostly arbitrary. You may form categories 0–2, 3–5, etc., and I may form categories 0–3, 4–7, etc. Results based on two different categorizations do not lend themselves well for valid comparison and can give different results for the same data. Third, a variable for metric categories can be analyzed as metric by using the midpoint as the actual value, which assumes all the subjects in that category have the same value as the midpoint. This obviously is not true but works reasonably well in cases where the sample size is large and categories are small.

### Dependent and Independent Variables

These are discussed in detail under the topic **dependent and independent variables**. This topic also includes other related terms

such as outcome, response, and target variables on one hand, and regressor, predictor, explanatory, concomitant, confounding variables, etc. on the other. All these variables can be either qualitative or quantitative.

### *Instrumental Variables*

The ordinary regression setup, which in its most simple form is $y = \alpha + \beta x + \varepsilon$, requires that the relationship between $y$ and $x$ is direct and the errors $\varepsilon$ are uncorrelated with $x$. However, in some situations, the error and $x$ values are correlated (e.g., the higher the value of $x$, the higher the error), which would imply that changes in $y$ are associated not just with changing $x$ but also with changing $\varepsilon$. This aberration produces a biased estimate of the regression coefficient $\beta$ and can happen when (i) $x$ cannot be directly measured but can be measured with some error that contributes to the error $\varepsilon$—thus, $x$ and $\varepsilon$ are correlated; (ii) $x$ causes $y$ and $y$ causes $x$; or (iii) $x$ is an endogenous variable. A more valid solution in such cases can be obtained by including another variable, called an instrumental variable, which is not of interest here but can be exactly measured and has a direct relationship with $x$ and not with the errors $\varepsilon$. In case there are many regressors, as in multiple regression, the instrumental variable/s should be uncorrelated with all the $x$'s.

Let the instrumental variable be denoted by $z$. Find the relationship between $x$ and $z$. Since they are directly related, the regression of $z$ on $x$ will be uncontaminated and believable. This information can be used to improve prediction of $y$ using the two-stage procedure of regression with instrumental variables, as discussed by Greenland [2].

Consider the example of dependence of the length of hospital stay of critical patients on the severity of condition at admission. Severity cannot be directly measured, and the error in measurement of severity will affect the duration of hospital stay. Suppose a measure such as an APACHE score is available that is closely related to severity at admission but is not related to the errors. If so, the APACHE score can be used as an instrumental variable for getting the relationship between severity and length of hospital stay. Nead et al. [3] used body mass index as the instrumental variable to assess whether insulinemia and type 2 diabetes are causally associated with endometrial cancer.

## variance components analysis

As the name suggests, variance component analysis is the partitioning of total variance into its components. **Analysis of variance (ANOVA)** also does the same with partitions, such as between factors and within factors, but the difference is that in conventional ANOVA, the effect of various factors is considered fixed, whereas variance component analysis is for random effects. You may want to review the topic **fixed and random effects** to understand the basics of these effects. The concept of random effects can be briefly explained as follows.

Consider a study in 4 hospitals and 10 patients undergoing a particular cancer surgery from each of these hospitals for studying their duration of stay in the hospital after the surgery. Duration of stay will surely vary from patient to patient, but the average can also vary because of the difference in nursing care from hospital to hospital, the hospital policies regarding when to discharge, etc. Patients in any case are considered a random sample, but if the inference is restricted specifically to these 4 hospitals, the hospital effect is fixed. If these 4 hospitals are a random sample from, say, a **population** of 50 hospitals and a generalized conclusion for these 50 hospitals is desired, the hospital effect becomes random. When the effect is random, the variance components method is used. Note that including all 50 hospitals in the study is generally not feasible, and if one has the resources to do this, the number of parameters for estimation in the statistical analysis, as illustrated later, becomes 49. This is too large and would require an extremely large sample. In a random-effect situation, these reduce to just one parameter, as explained later within this section. The fixed-effect model works well only for a small number of levels of the factors—in this example, the number of levels is 4, which is the number of hospitals. This is small, and a fixed effect surely can be considered if the interest is restricted to these 4 hospitals only.

The random-effect factor should be **categorical** for it to be treated by the variance components method. You can have more than one random-effect factor, and you can, at the same time, also have other factors with fixed effects—in which case this becomes a **mixed effects model**.

In the example just cited, there is only one factor, namely, the hospital. It has four levels in this example; consider these fixed for the time being. The outcome is the duration of hospital stay, which is quantitative. This is a **one-way ANOVA** setup where the **main effect** of hospital $j$ ($j = 1, 2, 3, 4$), if fixed, as in a conventional setup, can be denoted by $\alpha_j$. The corresponding mathematical formulation for conventional ANOVA is

$$y_{ij} = \mu + \alpha_j + \varepsilon_{ij},$$

where, in the context of our example, $y_{ij}$ is the hospital stay of the $i$th patient in the $j$th hospital, $\mu$ is the overall mean duration of stay of all such patients (estimated by the mean of all 40 patients in the study), $\alpha_j$ is the effect of the $j$th hospital (measured from overall mean $\mu$), and $\varepsilon_{ij}$ is whatever remains, called error. In this model, $\varepsilon_{ij}$ is considered to be independent and have a **Gaussian distribution** with mean 0 and variance $\sigma_\varepsilon^2$. The error $\varepsilon_{ij}$ is the only random quantity in this fixed-effect model and arises from the variation in hospital stay of individual patients. There are four hospital effect parameters, one for each hospital, namely, $\alpha_1$, $\alpha_2$, $\alpha_3$, and $\alpha_4$. When the natural condition, such as $\Sigma\alpha_j = 0$, is imposed, the effective number of these parameters is three.

When a hospital has a random effect, the interest shifts from the fixed effect of each hospital to the variance of the hospital effect—variance because now, the variation between hospitals is random.

The effect of the $j$th hospital can be denoted by $a_j$, and this will be considered to have, say, a Gaussian (normal) distribution with mean 0 and variance $\sigma_H^2$. This is written as $a_j \sim N(0, \sigma_H^2)$, where $N$ is for normal distribution. We prefer to call this distribution Gaussian since *normal* has a very different meaning in medicine. This says that hospital effects have a distribution—some hospitals will have a negative effect (when measured from the mean), some will have a positive effect on the duration of hospital stay, and the pattern is Gaussian. The interest is not in the effect of any particular hospital—example, the difference between hospital 2 and hospital 3 is not a consideration—but in how much the difference is between hospitals, that is, in the variance of the effects. The lesser the variance $\sigma_H^2$, the less is the effect of hospitals on duration of stay; that is, the hospitals then are more homogenous with respect to the duration of stay after that particular surgery. The **null hypothesis** in this case would be $H_0$: $\sigma_H^2 = 0$, which implies that the effect of all the hospitals is the same. If this cannot be rejected, you can say that the effect of hospitals on the duration of stay is not significant. Note that now, hospital effect is represented by just one parameter, namely, the variance $\sigma_H^2$.

The statistical problem now is to decompose the total variance across all 40 patients in our example into the variance among 4 hospitals and between 10 patients within hospitals. Incidentally, this decomposition is the same as done in the fixed-effect case, but the interpretation is different. See the topic **analysis of variance** for details of the decomposition in the fixed-effect case. In a one-factor case, as in our example, and when the number of units within each level of the factor is the same (10 patients from each hospital in our example), the mean sum of squares due to hospitals (MSB) theoretically can be shown to be an estimate of $\sigma_H^2 + n\sigma_H^2$, where $n$ is the number of patients within *each* hospital. In our example, $J = 4$ and $n = 10$. In any case, the estimate of $\sigma_\varepsilon^2$ is the mean square error (MSE). These terms are explained under the topic **one-way ANOVA**. Thus,

$$\text{estimate of } \sigma_H^2 = \frac{\text{MSB} - \text{MSE}}{n}.$$

Total variance = $\sigma_H^2 + \sigma_\varepsilon^2$, and the variance contributed by the hospitals is

$$\text{variance partitioning coefficient} = \frac{\sigma_H^2}{\sigma_H^2 + \sigma_\varepsilon^2}.$$

The validity requirement of this is that both kinds of random effects $a_j$ and $e_{ij}$ are uncorrelated with one another within and between groups. In the context of our example, this implies that the effect of any hospital is unrelated to the effect of any other hospital, the effect of the hospital is unrelated to the effect of the patient, and the effect of any patient is unrelated to the effect of patients in a different hospital. However, the effect of one patient is correlated with the effect of patients in the same hospital since they share exposure to the same nursing care, the same surgeons, the same policies, etc. This correlation among patients of the same hospital is measured by

$$\text{intraclass correlation coefficient (ICC): } \rho_I = \frac{\sigma_H^2}{\sigma_H^2 + \sigma_\varepsilon^2},$$

which is the same as the variance partitioning coefficient. Thus, the **intraclass correlation coefficient** is the fraction of the total variance contributed by the factor.

Variance components have an especially useful application to the analysis of data from hierarchical designs where one factor is nested within another. For example, in **multistage random sampling**, say, districts are randomly selected, then enumeration blocks within the selected districts, and families within the selected blocks. The response may be affected by the district, by the enumeration block, and by the family. All three are random effects in this case. When two or more factors are present, **interaction** between them may also be important. If districts are not randomly selected but all districts of interest are included in the study (this is easy when the number of districts of interest is small, say, ≤5), the district effect becomes fixed. In that case, the mixed effects model will be applicable since the effect of enumeration blocks and of families continues to be random. In either case, the value of $F$ is not necessarily obtained by dividing the concerned mean sum of squares by MSE. This is where the procedure is different from conventional fixed-effects ANOVA. Depending on whether the factor is random or fixed and depending on the hierarchical rank, sometimes, the divisor may be MSB or MSAB (mean square due to interaction) or some other value. For details, see Cox and Solomon [1].

## variance-covariance matrix, *see* dispersion matrix

## variance inflation factor

In a multiple-variable situation, variance inflation factor (VIF) is defined as

$$\text{variance inflation factor: VIF} = \frac{1}{1 - R^2},$$

where $R^2$ is the **multiple correlation** coefficient. Depending on where used, $R^2$ may be of **dependent** $y$ on the **independent** $x$'s or of one $x$ on other $x$'s. This is for linear regressions, but if nonlinear regression is considered, $R^2$ is replaced by the **coefficient of determination** $\eta^2$. It is called the variance inflation factor because it estimates how much the variance of a coefficient is "inflated" because of linear dependence on other predictors.

The most pronounced application of VIF is in assessing **multicollinearity** in a **multiple regression** situation. In this setup, the standard error (SE), and hence variance, of the estimates of regression coefficients increases when the regressors have multicollinearity. In a multiple regression equation that looks like $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + + \beta_k x_k + \ldots + \beta_K x_K$, VIF for the regressor $x_k$ is the ratio by which the variance of $b_k$ increases due to multicollinearity, where $b_k$ is the estimate of $\beta_k$. A VIF of 1.8 tells us that the variance (the square of the SE) of a particular coefficient is 80% larger than it would be if that predictor were completely uncorrelated with all the other predictors. If VIF = 4, the SE is $\sqrt{4} = 2$ times what it would be without multicollinearity. The VIF has a lower bound of 1 but no upper bound. VIF > 2.5 or $R^2 > 0.6$ is considered high for multicollinearity, and VIF > 5 (i.e., $R^2 > 0.8$) surely worth taking action.

VIF for regression coefficient $b_k$ is given by

$$\text{variance inflation factor for } b_k\text{: VIF}_k = \frac{1}{1 - R_k^2},$$

where $R_k^2$ is the multiple correlation coefficient of the variable $x_k$ when regressed on the remaining regressors in the model. This may have to be obtained for each regressor so that you will have $(K - 1)$ VIFs. Obviously, VIF = 1 means no multicollinearity of $x_k$, and a value more than 4 is generally considered large enough to be on guard. A value more than 10 for a particular variable is a definite indication that this variable can be removed from the list of regressors without any substantial effect on the efficacy of the regression equation. O'Brien [1] cautions against this approach as well as other approaches such as **ridge regression** and against combining two or more variables into a single index, and advises instead that VIF needs to be interpreted in the context of other factors that influence the stability of the estimates.

Sometimes, the term *tolerance* is used in a specific context; it is the inverse of VIF, i.e., tolerance = $1 - R_k^2$.

## variance ratio, *see also* *F*-test

This is the ratio of two variances $\sigma_1^2/\sigma_2^2$ that measures how different variation in one population is from another population on a ratio scale. The term was first used by Fisher way back in the 1920s. If you measure fasting blood glucose levels of healthy and diabetic subjects, there will be a huge difference not just in their mean levels but also in their variances. Blood glucose level is much more volatile across diabetic subjects than in healthy subjects. This probably is true for many measurements in healthy and sick subjects, underscoring the importance of the variance ratio. Statistically, this is important since a variance ratio different from 1 invalidates procedures such as ANOVA and regression. In their conventional format, these procedures examine difference in means provided that variances are the same between groups or for different values of the regressors, and this premise is violated when the variance ratio is very different from 1.

Statistically, the operational quantity is the sample analogue $s_1^2/s_2^2$. This is related to

$$F = \frac{s_1^2/\sigma_1^2}{s_2^2/\sigma_2^2}.$$

Under the null hypothesis $H_0$: $\sigma_1^2 = \sigma_2^2$, this reduces to $F = s_1^2/s_2^2$. When the two groups are independent and the values follow a Gaussian (normal) distribution, this ratio is $F$-test with $(n_1 - 1, n_2 - 1)$ degrees of freedom (df's), where $n_1$ and $n_2$ are the number of subjects in the two groups, respectively. Thus, this sample variance ratio can be used for testing equality of population variances when the just-stated conditions of its validity are fulfilled. This can be a two-tailed test for testing the alternative $\sigma_1^2 \neq \sigma_2^2$, but it is customary to call the one with larger variance group 1 so that we need to worry only about $F > 1$. In case needed, the property that $1/F$ is also $F$ with reversed df's and $(1 - P)$ probability can be used for the other alternative. The most common application of the variance ratio is in one-way ANOVA, where $s_1^2$ is the mean sum of squares between groups and $s_2^2$ is the mean sum of squares within groups.

Among other applications, an interesting one is illustrated in assessment of 24 h intake of vitamin K in older adults in Canada [1]. The study found intraindividual variation from day to day to be significantly higher than interindividual variation. The authors conclude that such pronounced intraindividual variation indicates that vitamin K intake assessment should be done at least six times for each individual to get a fair picture of the intake in older adults. They also worked out confidence interval (CI) for the variance ratio in their population. In general, for Gaussian distribution, this CI is given by

$$(100 - \alpha)\%\ \text{CI for variance ratio: } \frac{s_1^2/s_2^2}{F_{1-\alpha/2}} < \frac{\sigma_1^2}{\sigma_2^2} < \frac{s_1^2/s_2^2}{F_{\alpha/2}},$$

where $F_{1-\alpha/2}$ and $F_{\alpha/2}$ are the values of $F$ distribution for probabilities $(1 - \alpha/2)$ and $\alpha/2$, respectively, at $(n_1 - 1, n_2 - 1)$ df's.

## variance-stabilizing transformation

In case variance across groups is substantially different, variance-stabilizing transformation is used to achieve near equality. Equality of variances, technically called **homoscedasticity**, may be required for valid analysis of data, such as by analysis of variance (ANOVA).

Let the groups be denoted by **deterministic variable** $x$, that is, $x = 1$ for group 1, $x = 2$ for group 2, etc. These could be, for example, thin, normal, overweight, and obese groups with respect to body mass index (BMI). Let the outcome be denoted by **stochastic variable** $y$ such as, say, random blood glucose (RBG) level in this example. Restrict the subjects to those who are not under any treatment. As $x$ increases, it is possible that the mean of $y$ increases, but at the same time, the variance of $y$ may also show an increase. In our example, RBG level may not only be higher but may have much more variability from person to person in the obese group than in the group with normal BMI. Among a large number of possibilities, one simple possibility is that variance for any particular $x$, i.e., var($y|x$), is equal to $a^*\mu_x$, where $\mu_x$ is the mean of $y$ for a particular value of $x$. This says that variance in different groups is proportional to the mean in that group, and not uniform—thus violating homoscedasticity.

In our example, suppose the data on RBG are as in Table V.1, where you can see that variance $\approx 0.64^*\mu_x$. It can be theoretically established that square-root transformation stabilizes the variance when variance is proportional to the mean, provided that all values are positive (if not positive, add a constant to each value and adjust this after the results of the analysis are obtained). In this example,

**TABLE V.1**
**Mean, Standard Deviation (SD), and Variance of Random Blood Glucose Level in Various BMI Groups**

| | Random Blood Glucose Level in mg/dL ($y$) | | |
|---|---|---|---|
| **BMI Group** | **Mean ($\mu_x$)** | **SD** | **Variance (in sq. units)** |
| Thin ($x = 1$) | 132 | 9.2 | 84.64 |
| Normal ($x = 2$) | 141 | 9.5 | 90.17 |
| Overweight ($x = 3$) | 155 | 9.9 | 98.01 |
| Obese ($x = 4$) | 172 | 10.5 | 110.41 |

if you consider the square root of the RBG level instead of the RBG level itself, the variance would be nearly the same in each BMI group, and the usual analysis can be done after this transformation. However, this would require that the original units be retrieved by squaring the values after the results are obtained so that proper interpretation can be done.

If variance is proportional to the square of the mean, then log transformation will stabilize the variance. Log transformation may be appropriate also when **residuals** are a certain percentage of the $y$ values; for example, residuals are 7% of the original values rather than, say, around 7 mg/dL in absolute value. If the variance of $y$ increases very substantially with $x$, say in proportion of $\mu_x^4$, then inverse transformation may be appropriate. This can happen when most of the values of $y$ are close to 0 (but not 0) when $x$ is small and some values show a huge increase as $x$ increases.

For further details, see Weisberg [1].

## variation (measures of), *see also* coefficient of variation

Variation in statistics is the extent to which values differ from each other. This is also called **dispersion** and can also be understood as the spread of values or their scatter. In health and medicine, variation occurs due to a large number of sources, such as biologic, environmental, behavioral, and instrumental differences in the subjects and measurements. Some of the variation is due to unknown sources, called chance. Some characteristics show small variation, whereas others show large variation. Body temperature in healthy subjects is fairly stable from person to person, whereas total cholesterol shows huge variation. Opinions and behavioral variables generally show large variation not only across individuals but also within a person from time to time.

The following example may make it clear why a measure of variation is needed. Consider the systolic blood pressures (BPs) measured for two groups of five persons each:

Group 1: (in mmHg) 134, 132, 124, 132, 128
Group 2: (in mmHg) 110, 140, 118, 150, 132

Both groups have the same mean (130 mmHg) and the same median (132 mmHg). Despite this equality in groups with regard to central values, the groups are very different. The BP values in group 1 vary from 124 to 134 and in group 2 from 110 to 150—thus, their scatter or dispersion is different. Therefore, representation of data merely by a central value is incomplete, and it needs to be supplemented by a measure of dispersion as well. Figure V.2 shows two **Gaussian** (normal) **distributions** with the same mean but different variation.

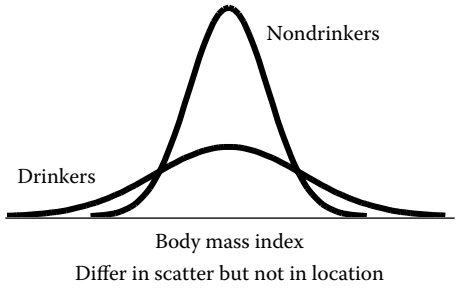

**FIGURE V.2** Body mass index in drinkers and nondrinkers illustrating Gaussian distributions with same mean but different variation.

When variation is large, obviously any, conclusion is liable to a wide margin of error. In this situation, the **reliability**, also called precision in statistical parlance, suffers, and our confidence level in the conclusion is low. A measure of variation gives us an idea of the reliability of the measurements. The most commonly used measures are described next.

### *Range*

In the case of quantitative values, one measure of variation could be from minimum to maximum. This is called the **range**. You can say that normal body temperature varies from 97.8°F to 99.1°F, and normal LDL cholesterol ranges between 50 and 120 mg/dL. That certainly gives an idea of the variation among healthy people, although it does not rule out a lower or higher value than these limits. In the case of actual data, range is easily affected by extreme values. For survival duration of a sample of 20 cancer patients, the range could be from 1 to 10 years, but if one patient happens to survive for 20 years, the range shoots to 1–20 years. This example also highlights another limitation of range. Most values may be close to 3 and 4 years, and if only a few values are very different, the range can alter very substantially. Range is based entirely on the minimum and the maximum, and we would like to have a measure that considers all the values and not just the values at the two ends.

### *Mean Deviation, Variance, and Standard Deviation*

Since variation is the difference of values with one another, one can think of finding all these differences and calculating, say, their average. But this could require enormous calculations—10 values will have $(10 \times 9)/2 = 45$ differences, and 100 values will have $(100 \times 99)/2 = 4950$ differences. Let us look for something ingenious that requires fewer calculations and gives a more meaningful assessment. It has been theoretically established that the best measure of variation in most situations is obtained when differences are obtained from one central value rather than from one another. In most cases (though not all), the mean is considered most suitable central value for this purpose. In these cases, the difference of values from the mean, called deviation, is obtained. In notations, if $x$ is the value of the variable, deviation = $(x - \bar{x})$. Since this is from the mean, some deviations will always be negative and some positive, and their mean will always be 0. One alternative is to ignore the sign, consider their absolute value, and calculate the average as follows:

$$\text{Mean deviation} = \frac{\Sigma|x - \bar{x}|}{n},$$

where $n$ is the number of values. More fully, this is the **mean deviation** from the mean since we can also have mean deviation from the median. Sometimes, this is called mean absolute deviation, and the expression we have mentioned is the sample estimate. Mean deviation can be an adequate measure of variation, but the primary difficulty with this is that absolute values are not easy to handle mathematically. Negative and positive values, when occurring together, are easily handled by squaring. This gives

$$\text{variance} = \frac{\Sigma(x - \bar{x})^2}{n}.$$

Thus, variance is the average of the squared deviations from the mean. This is the most acceptable measure of variation but is in squared units. Units are restored by taking the square root, which becomes the popular standard deviation (SD):

$$\text{standard deviation, SD} = \sqrt{\frac{\Sigma(x-\bar{x})^2}{n}}\ .$$

Note that all these three measures are 0 when all values are equal since then, there is no variation. See **variance** for further details of SD and variance, and see **coefficient of variation** for another measure of variation based on mean and SD.

### *Semi-Interquartile Range*

Since the mean is not a good representative central value when extreme values are present or, in other words, when the distribution is highly skewed, SD, since it is based on the mean, is not a good measure of dispersion in this situation. A generally accepted alternative is the **interquartile range** (IQR) for this setup. This range is from the first **quartile** to the third quartile. Briefly, the first quartile ($Q_1$) is the value below (or at) which 25% of the values lie, and the third quartile ($Q_3$) is the value below (or at) which 75% of values lie. They are also called lower and upper quartiles, respectively. Thus, IQR encompasses the middle 50% of values and is considered an improvement over range in the sense that the extreme values (top 25% and bottom 25% of values) do not affect this measure. Often, half of IQR is used a measure of variation possibly to get a value comparable with SD. This gives

$$\text{semi-interquartile range} = \frac{Q_3 - Q_1}{2}\ .$$

To illustrate the calculations, consider the following strange-looking data on satisfaction with nursing services in a hospital on a scale from 0 to 6 from complete dissatisfaction to full satisfaction from 10 recently discharged patients after a complicated surgery:

6, 5, 0, 0, 5, 5, 0, 6, 1, 5

Three patients provided a score of 0, one patient gave a score of 1, four patients gave a score of 5, and two patients gave 6 out of 6. What do you think of the variation in these scores?

Range = 6 − 0 = 6
Mean = 3.3; median = 5
Deviations from mean: +2.7, +1.7, −3.3, −3.3, +1.7, +1.7, −3.3, +2.7, −2.3, +1.7
(You can check that their mean is 0.)
Mean deviation = (2.7 + 1.7 + 3.3 + 3.3 + 1.7 + 1.7 + 3.3 + 2.7 + 2.3 + 1.7)/10 = 2.4

$$\text{SD} = \sqrt{\frac{2.7^2 + 1.7^2 + \ldots + 1.7^2}{10}} = 2.5$$

$Q_1$ = 2.5th value in order = (0 + 0)/2 = 0; $Q_3$ = 7.5th value in order = (5 + 5)/2 = 5
Semi-interquartile range = (0 + 5)/2 = 2.5

### *Measure of Variation in Qualitative Data*

Perhaps the concept of variation is not applicable to qualitative data, and no good measure of variation is available for such data. Yet, one can think of variation = 1 (highest) when all categories have equal frequencies and no variation when all values are concentrated in just one category. If there are $n$ values divided into $K$ categories, equal frequency would mean $n/K$ in each category. If maximum frequency in any category is $f_m$, the excess is $[f_m - (n/K)]$, which can be, at most, $(n - n/K)$ when all $n$ values are concentrated in one category and there is no variation. Thus, the following can be considered as an index of variation on a scale of 0 to 1:

Index of variation for qualitative data:

$$\textit{variation ratio} = 1 - \frac{f_m - (n/K)}{n - (n/K)}\ .$$

Say the distribution of patients coming to a clinic is no illness, 10%; mild illness, 40%; moderate illness, 30%; serious illness, 15%; and critical illness, 5%. Variation ratio = 1 − (40 − 100/5)/(100 − 100/5) = 0.75. The higher the concentration in any one category, the less is the variation. In our example, if all patients coming to the clinic have mild illness, we can say that they do not have any variation with regard to the severity of illness. A drawback of this index is that it ignores the scatter of frequencies in the categories other than the maximum, although they also contribute to variation.

## varimax rotation

Varimax rotation is a special kind of rotation of axes in graphical form, generally used for multidimensional phenomena, which helps to present a clearer picture of what is happening. This strategy is commonly used for some statistical procedures such as **factor analysis** and **principal component** analysis.

See Figure V.3a, where many features of the bar diagram are obscure but become clear when the figure is rotated (Figure V.3b). In this case, we have rotated the $x$- and $y$-axes by 20° each. This figure is in three dimensions, but the same can be conceived for multidimensions. In Figures V.3, the axes continue to be perpendicular with each other (called *orthogonal*), although they may not appear so in the figure. However, methods are available that would do oblique rotation so that the axes are no longer orthogonal.

Rotation is just change of coordinates that define location. In the usual two dimensions, if a regression line has a slope of 30° and you rotate the ($x$, $y$) axes by 30°, the line will look parallel to the $x$-axis. This may be a big convenience in interpreting the implication of the line just as rotation in Figure V.3b is for clearly seeing various bars. Algorithms are available to devise rotations for increasing or decreasing the scatter.

*Varimax* stands for "maximizing the variance," where the variance is chosen depending on the application. For example, in the case of factor analysis, where this rotation is most commonly used, the variance to be maximized is the sum of the $K$-factor sample variances of the standardized **loadings**. The factors are supposed to be on different axes in this setup, and axes are orthogonal so that the factors are independent of each other. The rotation minimizes the complexity of the factors by making the large loadings larger and the small loadings smaller within each factor—thus maximizing the variance. This tends to minimize the number of variables with large loadings in each factor and helps in achieving clarity regarding the variables appearing in each factor. After this rotation, the variables with small loadings can be ignored, and only the factors with high loadings are considered for interpreting the factors. See **factor analysis** for more details.

There are other rotational methods. *Quartimax rotation* works in a somewhat inverse manner as it makes large loadings larger and

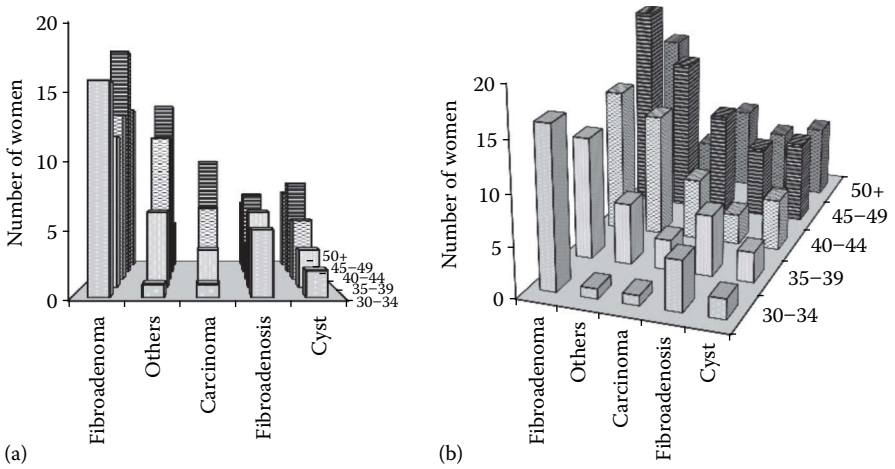

**FIGURE V.3** A three-dimensional bar diagram (a) without rotation of axes and (b) with rotation of axes.

small loadings smaller for factors within each variable. This works well when variables are sought to be explained by the factors. Note that factors in factor analysis consist of variables, whereas here variables, are considered to contain factors. *Equamax rotation* is a compromise that attempts to simplify both factors and variables. These are all orthogonal rotations. Oblique rotations are used when the factors are not orthogonal, i.e., correlated.

## velocity of growth in children

Velocity is the speed of movement in the aimed direction and is calculated as the distance traveled in the desired direction divided by the time taken. Although the term is used elsewhere in medicine, such as blood velocity and pulse wave velocity, we restrict it to its most common usage in assessing growth in children.

Growth velocity is the rate of growth per unit of time. Among various parameters of growth in children, height and weight are the most commonly used. For height, velocity is higher at the beginning of life and tapers off as age increases with a slight upswing, called midgrowth, around 6 or 7 years of age in some cases. A definite spurt is seen in adolescence. Velocity is indicated by the steepness of the curve and represents the incremental growth per unit of time. For body mass index (BMI) in children in the United States, the velocity is negative (BMI decreases with age) from 2 to 5 years and then high till the age of 15 years before slowing down (see Figure V.4 for girls). Velocity is also used to

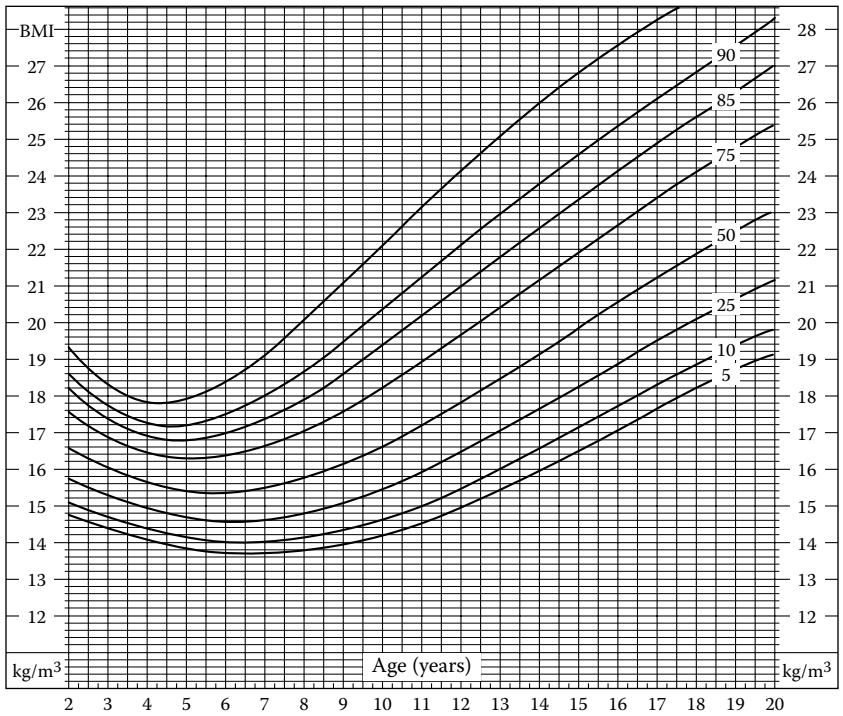

**FIGURE V.4** Age–BMI Centers for Disease Control and Prevention (CDC) chart for girls of age 2–20 years in the United States. (From CDC. *Body Mass Index-for-Age Percentiles: Boys*. http://www.cdc.gov/growthcharts/data/set1clinical/cj41c023.pdf.)

monitor growth and requires longitudinal measurements. A velocity less than normal for a child of a particular age indicates failure to thrive. Different percentiles may have different velocities, as in Figure V.4. In this figure, the fifth percentile has slow velocity and 95th percentile relatively high velocity, as indicated by the differential steepness of the curves. This really means that children with already-high BMI increase their BMI faster than those with lower BMI.

Conventional velocity charts involve two charts and hence are difficult to adopt in practice. A 3-in-1 weight-monitoring chart has been devised [2] for infants. It consists of conventional weight centiles complemented with extra lines called thrive lines, where the slope defines a cutoff for failure to thrive. The weight must be measured at 4-week intervals for this chart to be useful. This chart needs to be field-tested in different populations.

Weight velocity and height velocity can be used as indicators of growth in the immediate past and thus helps in detecting acute malnutrition. A sudden decline in weight velocity (or in weight gain) in a particular child may provide better insight into the existence of a health problem than a weight-for-age measurement. Weight for age is relatively slow to react and slow to show that a problem exists. Height for age and weight for age are also affected by hereditary factors, particularly the size of the parents, while velocity, when compared with the previous velocity of the same child, is relatively independent of heredity.

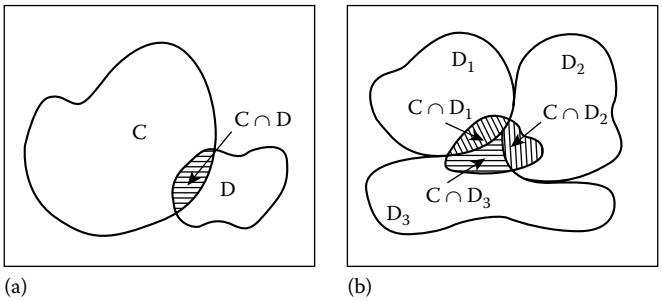
## Venn diagrams

A Venn diagram depicts combinations and commonalities among two or more collections of units of interest, called sets. In medicine, the group of patients with a particular complaint, for example, is one set, and the group of people with another complaint is another set. These two sets may be mutually exclusive in the sense that no unit is common (no patient has both complaints) or may overlap (some patients with complaint 1 also have complaint 2). In Figure V.5a, one set is denoted by C, and the other set is D. The shaded area is the area that is common to both. This is called the intersection and is denoted by $C \cap D$. The combination of C and D is called the union and denoted by $C \cup D$. This, however, contains $C \cap D$ only once, although this is part of C as well as D. We have used irregular shapes to depict sets—many use circles of equal radius, as shown in Figure V.6, even when the sets have unequal size.



(a) (b)

**FIGURE V.5** Venn diagrams showing unions and intersections of sets (a) two sets, (b) three sets.

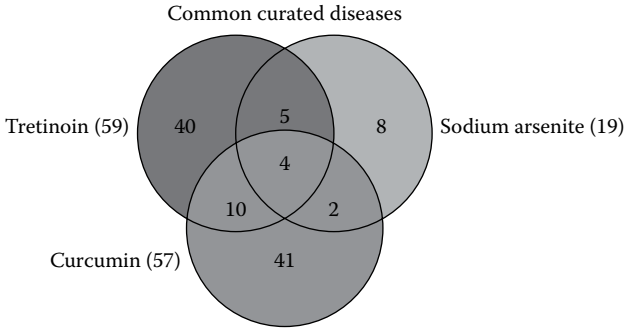


**FIGURE V.6** Venn diagram showing overlaps of different common curated diseases. (From Davis AP, King BL, Mockus S et al. *Nucleic Acids Res* 2011 Jan;39(Database issue):D1067–72. http://www.ncbi.nlm.nih.gov/pubmed/20864448, with permission.)

Figure V.5b illustrates another Venn diagram. This has three **mutually exclusive** sets denoted by $D_1$, $D_2$, and $D_3$ with no overlap. Set C is in the middle and intersects all the three sets. That is, union of $D_1$, $D_2$, and $D_3$ contains all of C. Thus, set C is the combination of $(C \cap D_1)$, $(C \cap D_2)$, and $(C \cap D_3)$, and these three also are mutually exclusive subsets in this case. Thus $C = (C \cap D_1) \cup (C \cap D_2) \cup (C \cap D_3)$. This illustrates how a Venn diagram makes it easy to understand the unions and intersections of various groups of people or events.

Application of Venn diagrams in statistics is in understanding and computing probabilities of two or more events that may or may not occur simultaneously, as in our example of complaints. As another example, suppose 12% of adults have hypertension and 7% have diabetes in a population. How many have both, and how many have only one of these two ailments? Such questions can be easily understood well with the help of a Venn diagram. Let C be for hypertension and D be for diabetes—thus, the intersection $C \cap D$ represents those who have both the diseases. If 3% have both the ailments, 9% will have hypertension alone (no diabetes), and 4% will have diabetes alone (no hypertension). A total of $12 + 7 - 3 = 16\%$ have either hypertension or diabetes or both.

Davis et al. [1] have discussed the use of Venn diagrams for discovering overlaps and unique attributes of any set of chemicals, genes, or diseases in the context of a comparative toxicogenomics database. One such diagram is in Figure V.6. For example, in this figure, there are 10 cases common to tretinoin and curcumin that are not in sodium arsenite. Note how different overlaps are clearly visible. This facility is rarely available in other kinds of depictions.

## visual display (of data), *see* graphs and diagrams

## vital statistics

Colloquially, vital statistics refer to bust, waist, and hip measurements, particularly of female adults, but they have a different meaning in the context of health and medicine. *Vita* means "relating to life," and vital statistics are the data on the most important events of life. These include birth, death, and marriage (and divorces), sometimes including migration also. An accurate recording of all births, deaths, and migration helps in keeping an updated register of the

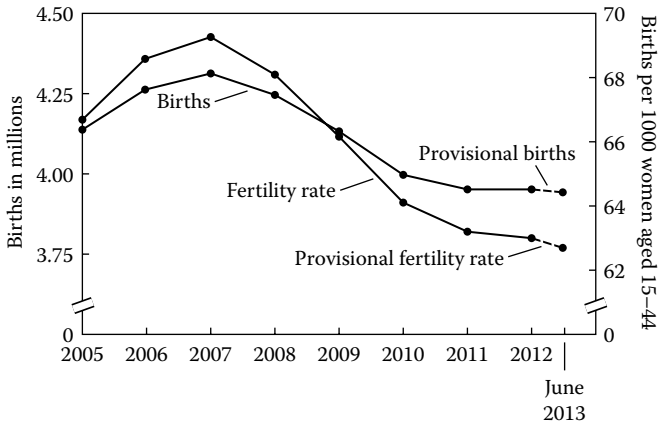

**FIGURE V.7** Trend of birth rate and fertility rate in the United States, 2005–2013. (From Hamilton BE, Sutton PD. *NCHS Health E-Stat*. http://www.cdc.gov/nchs/data/hestat/births_fertility_june_2013/births_june_2013.htm, last accessed January 4, 2014.)

population. When properly done, this provides a ready source of the count of people in an area.

When accurate vital statistics are available over a period of time, the trends can provide useful information regarding not just the increase or decrease but the rate also. For example, see Figure V.7 reported by Hamilton and Sutton [1], which shows that births and fertility rate increased in the United States between 2005 and 2007, and declined thereafter, with fertility rate exhibiting a more prominent trend than births.

There are finer points regarding some of the vital statistics. Births are sometimes defined to include live births and fetal deaths, and for this to be complete, a count of abortions, miscarriages, and stillbirths should also available. For comparison over time and across areas, birth rate, abortion rate, stillbirth rate, etc. can be calculated, which can tell a lot about the health of women and their health needs. Similarly, deaths generally include the cause and age at death, which help in assessing the gravity of various causes in different segments of the population. These details are important ingredients for assessing the health needs of people from the vital statistics. Trend over time can also provide clues on how effective health programs have been in controlling the mortality by different diseases, and projections can help in planning services. Age at death is used to construct life tables and to estimate **life expectancy**.

The best source of vital statistics is birth and death registration under what is called the civil registration system. This operates in almost all countries around the world but is nearly complete only in developed nations. In most developing countries, this registration is incomplete, and one has to rely on indirect estimation using other sources such as decennial census, sample surveys from time to time, and statistical models.

## volunteer-based studies

Medical research by its very nature is invasive. Laboratory investigations require samples of blood, urine, etc., and radiological investigations require the invasion of x-rays and ultrasounds. Medical interviews look benign but many times seek intimate information, and in any case, the patient's time and privacy is invaded. For this reason, the ethics of medical research require that informed consent must be taken from the subjects of research. A step forward is volunteer-based studies. Volunteers are those who not only provide consent but are willing, sometimes keen, to participate in a research endeavor either to further the cause of science or because they find a ray of hope for themselves or others in that research. By definition, volunteers do not expect anything in return for themselves, but indirect benefits accrue in terms of the satisfaction of doing something useful for society at large, a natural wider social acceptance, building up capacity, and the confidence to face challenges. Recent research has shown that volunteers get indirect health benefits in addition to social benefits [1]. Many institutions and organizations seek volunteers openly through their websites or otherwise for research studies after ethical clearance, and they do get some volunteers. This is relatively easy when the volunteers required are healthy subjects but may be difficult if the study is on subjects with specific diseases. However, in some situations, defining healthy subjects as generally needed to serve as controls in many studies may be difficult—they could be just those with an absence of any overt manifestation of disease, those who have a healthy hemoglobin level, or those able to cope with adverse conditions. Gierthmühlen et al. [2] discussed this aspect in the context of quality sensory testing (QST)-based studies, which illustrates the kinds of problems one can face.

Volunteer-based medical studies bring forth statistical challenges. Early **phases of clinical trials** are often done on volunteers who select themselves as the subjects. Volunteers tend to be very different from the general class of subjects as many of them are either hopeless terminal cases or are people with exceptional courage. Both affect the response, and the results are not applicable to the general class of patients. Notwithstanding this limitation, volunteer studies have a definite place in medicine as they do provide important clues on the toxicity of the regimen under test, the dose level that can be tolerated, the potential for further testing of the modality, etc.

# W

## waist–hip ratio, *see also* obesity (measures of)

Evenly distributed fat is probably not as harmful as accumulation around the waist. In place of just waist measurement, its comparison with hip measurement has been observed to be a more effective indicator of truncal obesity. In adults, this is measured by

$$\text{waist} - \text{hip ratio} = \frac{\text{waist circumference}}{\text{hip circumference}}.$$

The unit of measurement does not matter, but the numerator and the denominator must be measured in the same unit—either inches, centimeters, or any other. This ratio measures central **obesity** or abdominal obesity (or truncal obesity). The normal ranges are 0.8–1.0 for men and 0.70–0.85 for women. Note that a unit increase in this ratio is enormous, if not unlikely—thus, its coefficient in a regression (logistic or ordinary least squares) is to be interpreted with full caution.

A large waist–hip ratio (WHR) is found to be nearly as much associated as body mass index with the risk of some serious conditions such as ischemic stroke [1] regardless of height and build. It is also associated with diabetes and heart diseases. Siddiqui et al. [2] reported for Indian adults that a high WHR is associated with high concentrations of malondialdehyde and a low concentration of antioxidant enzyme, resulting in increased oxidative stress, which is a major causative factor of acute myocardial infarction. However, Borruel et al. [3] observed that waist circumference and body mass index are more accurate surrogate markers of visceral adiposity in young adults of Spain than WHR.

While waist size seems easy to measure, accurate measurements rely on the method of measurement and body posture. Waist circumference is best measured at its narrowest point when the person stands with the feet 25–30 cm apart with a relaxed abdomen. Measurement should be taken by positioning the tape horizontally placing a graduated, flexible but inelastic tape snugly against the skin without compressing the underlying soft tissue. The circumference is generally measured to the nearest 0.1 cm after the subject breathes out. The hip is similarly measured at its widest portion of the buttocks.

## Wald test

Among several versions, the most common form of the criterion of the Wald test for the **null hypothesis** $H_0$: $\theta = \theta_0$ is

$$\text{Wald criterion: } W = \left( \frac{\hat{\theta} - \theta_0}{\text{estimated SE}(\hat{\theta})} \right)^2,$$

where $\hat{\theta}$ is the estimate of the **parameter** $\theta$ and SE is its **standard error**, and estimated SE is the SE when $\theta$ is replaced by $\hat{\theta}$. The criterion $W$ follows a **chi-square** distribution for large $n$. Thus, the ***P*-value** for judging **statistical significance** can be easily obtained. The **degrees of freedom (df's)** of chi-square vary from situation to situation. This test is very versatile and can be used in a wide variety of situations for large samples, and it is attributed to Abraham Wald, from his paper published in 1943 [1].

Abraham Wald
(Courtesy of Konrad Jacobs. Archives of the Mathematisches Forschungsinstitut Oberwolfach.)

Apparently, the Wald criterion looks like square of the **Student *t***, but that really is not so. First, the Student $t$ requires that the underlying distribution is **Gaussian**. This is not a strict requirement for the Wald test. Second, the Student $t$ in the case of the mean, for example, uses the sample standard deviation with denominator $(n - 1)$, whereas Wald uses $n$. In this respect, this test is more like the ***z*-test**, although the $z$-test also requires Gaussian distribution and the SE itself in the denominator instead of its estimate.

The Wald test, as just mentioned, is for **quantitative variables**. If the variable is **qualitative**, the test can still be used, although in that setup, the estimated SE is difficult to compute. In fact, the most common use of the Wald test is in testing the statistical significance of coefficients in **logistic regression**, where the variable can be qualitative. For testing the significance of any one coefficient, df = 1, but the test can be used for testing the significance of two or more coefficients simultaneously, for which the df's will accordingly change. This test can be used as a replacement for the classical **likelihood ratio test** for finding whether or not the contribution of one or more regressors in a logistic regression is statistically significant. Asymptotically (i.e., for very large $n$), both are equivalent. In its general form, the Wald test can be used for a **multivariate** setup also.

## Ward method of clustering, *see also* cluster analysis

**Clustering** is the process of putting together quantitatively similar units in one group and dissimilar ones in different groups. Generally, the number of **clusters** is not predetermined, and as many clusters are formed as needed for internal homogeneity and external isolation of the units. It is hoped that these will be natural clusters as dictated by the data. Among popular algorithms to do this are **hierarchical** agglomerative and hierarchical divisive. The agglomerative algorithm is a bottom-up approach where units are successively merged into entities containing similar units one after the other starting from $n$ units, whereas the divisive algorithm is a top-down approach where all units are considered to form one big entity to begin with, and then this entity is sequentially split into smaller ones. Each of these algorithms has several methods. The Ward method is one of the methods of hierarchical agglomerative clustering.

While most other methods use the inverse of distance measures such as **Euclidean distance** for clustering, the Ward method, proposed in 1963 by Joe Ward Jr. [1], considers the within-entity variance as the criterion to decide which entities should be merged in an agglomerative algorithm. If there are four entities at a hierarchical stage containing, say, $n_1$, $n_2$, $n_3$, $n_4$, units, within-entity variance is calculated for entities obtained by merging $n_1$ and $n_2$ units, by merging $n_1$ and $n_3$ units, by merging $n_1$ and $n_4$ and then by merging $n_2$ and $n_3$ units, and by merging $n_2$ and $n_4$ units and then by merging $n_3$ and $n_4$ units. Whichever merging gives the least variance is done. Others are left as such. This process is sequentially followed till such time that the entities continue to have internal homogeneity in terms of small variance. If at some hierarchical stage, the within-entity variance suddenly inflates due to merging, the process can be stopped since this indicates that two very different entities that need to be in different groups are being merged. Entities obtained at such conclusion of the process are the required clusters obtained by the Ward method.

Sakagami et al. [2] used this method to identify groups of asthma patients with greater decline in lung functions and similar clinical features (a total of right variables). The method divided 86 patients into three clusters. Cluster 1 comprised women with late onset of asthma; cluster 2 had men and women with early onset, atopy, and long duration of disease; and cluster 3 mostly had older men with late onset. These were considered relevant groups to follow clinical guidelines. Gerlinger et al. [3] found the Ward method to be better than single, average, and complete linkage in discovering distinct clusters of records of bleeding diaries of women who were on various sex hormones containing drugs. They found four desirable and two undesirable bleeding patterns. Statistically, the Ward method prefers to join entities of nearly the same size rather than entities of widely different sizes. It is also very sensitive to outliers because they tend to inflate the variance.

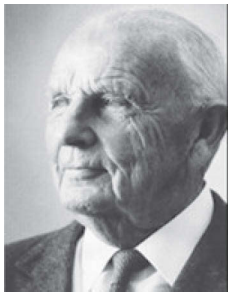
## washout period, *see* crossover designs

## Weibull distribution

Mathematically, a variable $x$ is considered to have a Weibull distribution if its **frequency curve** can be expressed as

$$\text{Weibull distribution: } f(x) = \alpha\beta x^{\beta-1} e^{-\alpha x^{\beta}},\ x \geq 0,\ \alpha > 0\ \beta > 0,$$

where α is called the scale parameter and β is called the shape parameter. These are its parameters, just as mean μ and standard deviation σ are for a **Gaussian distribution**. Note in Figure W.1a and b how the shape changes when the value of β changes but the shape basically remains same (peak toward left—Figure W.1b and c) when β remains the same but α changes. A large variety of patterns can be depicted by Weibull distribution. This is named after Waloddi Weibull, who described it in 1939 [1].



Waloddi Weibull

As explained for the term **distribution**, this is the pattern values follow in a population. For example, a **Gaussian distribution** has its peak (highest frequency) in the middle, and the pattern of decline on both the sides follows a specific and symmetric pattern. On the other hand, *skewed distributions* have their peak toward one side. A

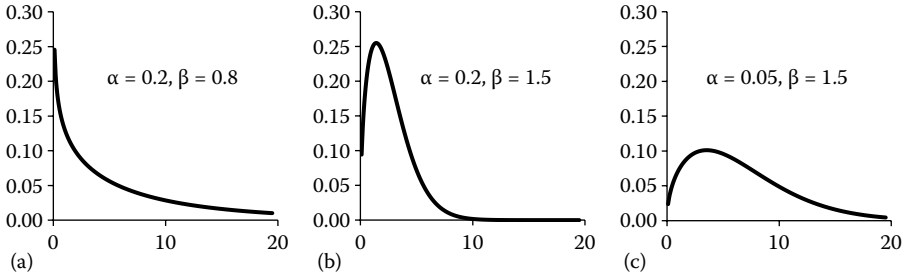


**FIGURE W.1** Different shapes of Weibull distribution.

Weibull distribution has a specific right-skewed pattern, with several important applications in medical sciences.

A Weibull pattern is usually followed by time-to-event (durations) type of variables. For example, duration of surgery or duration of hospital stay may follow a Weibull pattern since many patients have low duration, some have long duration, and few have very long duration. Kanters et al. [2] used a Weibull pattern to model duration of survival of HIV-positive men and women on antiretroviral therapy in Uganda and observed that part of the difference between sexes was due to late initiation of treatment among men.

Weibull distributions have an especially useful application in the study of hazards. For an explanation of this term, see **hazard** in this volume. Duration of survival in real life has a feature that the hazard of death increases as age increases in both healthy and sick subjects. Increasing hazard with higher values of the variable $x$ can be modeled to follow a Weibull distribution with $\beta > 1$. For $\beta < 1$, it represents decreasing hazards with the passing of time, called hardening. This may give rise to the pattern seen in Figure W.1a. An example is decreased "hazard" of birth with increasing age of women beyond 40 years. A constant hazard that remains the same for every value of $x$ gives rise to an **exponential distribution**. The hazard of occurrence of dengue fever can be the same for each age.

For further details, see Abernethy [3].

## weighted least squares

In its simplest form, weighted least squares is a **least squares method** of estimation that gives due weight to the variance of **residuals** (as in **regression**) and is used when the variance is not constant but varies for different values of the **independent variables**. If residual variance for a given value of $x_i$ is $\sigma_i^2$, then weight $w_i = 1/\sigma_i^2$. This gives more weight to the values with smaller variance of residuals and less weight to the values with larger variance. That sounds intuitively reasonable too as it rightly gives more importance to the values that give more precise information. Weighting overcomes the problem of non-**homogeneity of variances** since that is one of the requirements of the least squares method.

In Figure W.2, the variance of residuals is increasing with higher values of the independent $x$. This can happen, for example, in a study of the effect of age on systolic blood pressure (BP) in females in the general population since not only average BP increases with age, but the variation is also seen to increase as age increases. This pattern will remain the same when residuals are obtained after adjusting for the effect of age. If an increase in variance with age is statistically significant, the ordinary least squares method will not give valid results. Weighted least squares will provide valid estimates and their valid standard error.

In a study on the effect of yoga experience (lifetime hours) on positive attitude on a 7-point scale in women over the age of 45 years [1], attitude scores had high variation when yoga experience was short.

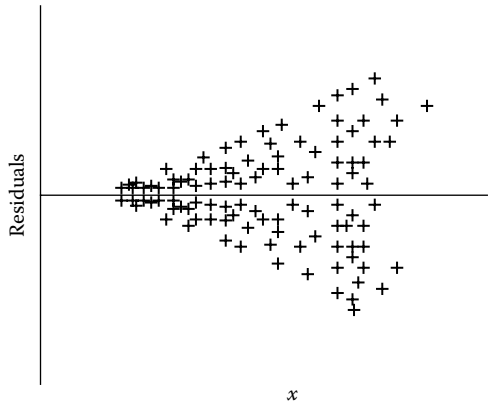

**FIGURE W.2** Fanning of residuals—increasing variance with higher value of $x$.

The scores stabilized as yoga experience increased. Thus, weighted least squares was the right method for regression as used in this study.

For running weighted least squares, check the options in your software package. Most packages have this facility under general linear models.

## weighted mean

The weighted mean is the mean after adjusting for the differential importance of different values. If the weight of $x_i$ is $w_i$,

$$\text{weighted mean: } \bar{x}_w = \frac{\Sigma w_i x_i}{\Sigma w_i}.$$

As an extreme example, consider the number of children of 100 couples who have been married for 5 years. The number of children would be 0, 1, 2, or 3 when more children in 5 years of marriage are ruled out. It would be foolish to say that the average number of children in these couples is $(0 + 1 + 2 + 3)/4 = 1.5$. The average would depend on how many couples have no child, how many 1 child, how many 2 children, and how many 3 children. If these numbers out of 100 are 30, 50, 19, and 1, respectively, the average number of children is $(30 \times 0 + 50 \times 1 + 19 \times 2 + 1 \times 3)/100 = 0.91$. The numerator is the total number of children to these couples, and the denominator is the total number of couples. In this case, the values of $x$ are 0, 1, 2, and 3, and the weights are the number of couples with different values of $x$. The statistical name for these numbers is **frequency**, denoted by $f$. Then weighted mean = $\Sigma f_i x_i / \Sigma f_i$.

Besides the situation of differing frequencies as described in the preceding paragraph, weighted mean has other applications also. Particularly in large-scale surveys, such as the **Demographic** and **Health Surveys**, each person in the sample represents a specified number of people of his/her type. Consider data in Table W.1 on smokers and the number of cigarettes smoked by male and female adults. In this population, there are 400,000 males and 500,000 females. But the sample happens to have 1000 males and 2000 females. Then, each male in the

**TABLE W.1**
**Weighted Mean When Samples Have Different Representations**

| Particulars | Males | Females | Combined | |
|---|---|---|---|---|
| Number in the population | 400,000 | 500,000 | 900,000 | |
| Number in the sample | 1000 | 2000 | 3000 | |
| Number of current smokers in the sample | 200 | 100 | 300 | |
| Prevalence of current smokers in the sample | 20% | 5% | Unweighted (20 + 5)/2 = 12.5% | Weighted by Sample Size (20 × 1000 + 5 × 2000)/3000 = 10% |
| Average cigarettes smoked per day by current smokers in the sample | 12 | 5 | Unweighted (12 + 5)/2 = 8.5 | Weighted by Sample Size (200 × 12 + 100 × 5)/300 = 9.67 |
| | **Weighted by Population Size** | | | |
| Estimated number of current smokers in the population | 20% of 400,000 = 80,000 | 5% of 500,000 = 25,000 | 80,000 + 25,000 = 105,000 | |
| Prevalence of current smokers in the population | 20% | 5% | (20 × 400,000 + 5 × 500,000)/900,000 = 11.67% | |
| Estimate of average cigarettes smoked per day by current smokers in the population | 12 | 5 | (80,000 × 12 + 25,000 × 5)/105,000 = 10.33 | |

sample is representing 400 persons, and each female in the sample is representing 250 persons.

Two kinds of weighting are shown in Table W.1: first with respect to sample size and second with respect to the population numbers. In the sample, 20% of males and 5% of females are current smokers. What is the prevalence when males and females are combined? The **unweighted mean** of these two is (20 + 5)/2 = 12.5%. But this is incorrect since their numbers in the sample are not equal. When you consider that the sample has 1000 males and 2000 females, the weighted mean is 10%. This is the prevalence in the sample of a total of 3000. However, in this case, the sample sizes of males and females are not in proportion to their respective numbers in the population. When this is considered, the estimate of the prevalence of current smoking in the population becomes 11.67%. This is the correct estimate. Similarly, the average number of cigarettes smoked by current smokers is 9.67 when weighted for sample numbers and 10.33 when weighted for population numbers. The latter is correct. Most studies will erroneously report the sample weighted mean and percentages, and conveniently forget about population weighting.

## Welch test

Developed by Bernard Welch in 1938 [1], this test is used for assessing equality of sample means in two or more groups in situations where the variances in different groups are different. The usual test for equality of means is the ***F*-test**, whose special case is the **Student *t*-test** for two groups, but these tests are valid only when the variances across groups are the same—a condition popularly known as **homoscedasticity**. This can be relaxed to some extent for these two tests when the group sizes are not much different. When homoscedasticity is violated, particularly if group sizes also are markedly unequal, the Welch test is used. The Welch test also requires that the values follow a **Gaussian** (normal) **distribution**, just as is the requirement for the *F*-test and Student *t*-test. This requirement can be waived when the sample sizes in each group are large. However, the Welch test also fails when the samples are small and very unequal, particularly if the variances differ in the opposite direction.

The steps generally followed for testing a difference in means is as follows. First, ensure that the values are independent of one another. This will come from the design for collecting the data. Second, check that they follow an approximate Gaussian pattern (see **Gaussianity, how to check**). This can be relaxed for large *n*. Third, check for homoscedasticity. For this, generally, the **Levene test** is used. If this test reveals that the variances are significantly different, use the Welch test. Thus, this test effectively makes the Levene test for equality of variances redundant, as this can be directly used. For two samples, the criterion for the Welch test also follows Student *t* distribution but with different **degrees of freedom** (df's):

$$\text{Welch test (two-sample): } t_v = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{s_1^2/n_1 + s_2^2/n_2}},$$

where the df

$$v = \frac{\left(s_1^2/n_1 + s_2^2/n_2\right)^2}{\frac{\left(s_1^2/n_1\right)^2}{n_1 - 1} + \frac{\left(s_2^2/n_2\right)^2}{n_2 - 1}}.$$

For multiple samples, the formula becomes complicated, but in this case, the ***F*-test** remains the appropriate test (just as in equal variances situation), although the df changes, as for the two-sample situation just described. The df of the Welch test is not a fixed number but depends on the sample values. One study with $n_1 = 10$ and $n_2 = 15$ can give different df than in another study of the same sizes. In the case of Student *t*, the df will remain the same so long as the sample sizes are the same. The Welch test is an approximate solution to the **Beherens–Fisher problem**, Beherens–Fisher also used an approximation.

## WHO growth charts

The World Health Organization (WHO) growth charts provide **percentile** trends over age of growth parameters such as height and weight of a cross-section of healthy children around the world. These are available in a WHO document [1]. One such chart is shown in Figure W.3 for body mass index (BMI) for boys of age 0–24 months. To construct these charts, data on healthy children were obtained from Brazil, Ghana, India, Norway, Oman, and the United States. Growth parameters covered in this document are length/height for age, weight for age, weight for length, weight for height, and BMI for age. These charts serve as important tools to assess whether a child or a group of children in an area are on the expected track of good health or not, and the extent of shortfall if any, or whether there is any excessive growth. Interventions and policies can be accordingly formulated.

As just mentioned, growth charts are drawn on the basis of measurements seen in a healthy segment of children. The WHO document [1] emphasizes the distinction between standard and reference charts. Standards are those values that *should* be attained by all children, whereas reference provides values that *are* attained. WHO growth charts are for standards and not for reference in this sense. The title of this document indicates that these efforts started for developing reference but ended up developing standards.

These WHO charts are based on a combination of **longitudinal** measurements of children during early life (<2 years) and mostly **cross-sectional** measurements thereafter. The total sample size was 8440 children. Data were cleaned for **outliers** and **missing values**. In addition, to discount the likelihood of extreme values, children with measurements beyond ±3 standard deviation (SD) for their age and sex were excluded. Since the distributions generally were highly **skewed** to the right, measurements beyond +2 SD were also excluded from the cross-sectional sample.

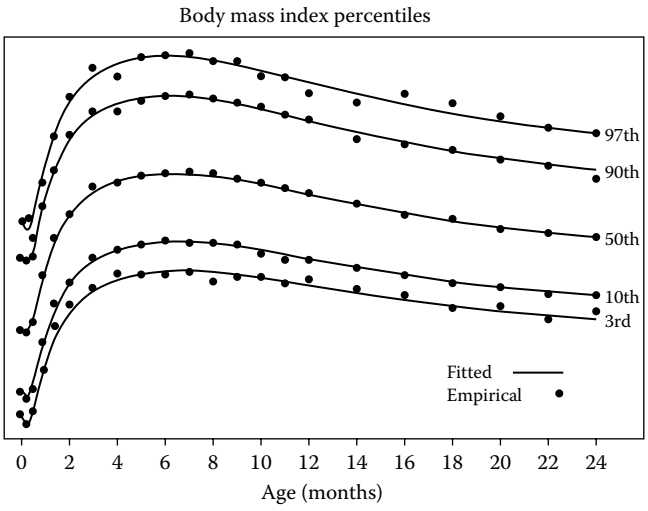

**FIGURE W.3** WHO chart for BMI for boys of age 0–24 months. (From WHO Multicentre Growth Reference Study Group. *WHO Child Growth Standards: Length/Height-for-Age, Weight-for-Age, Weight-for-Length, Weight-for-Height and Body Mass Index-for-Age: Methods and Development*. p. 239. World Health Organization, 2006. http://www.who.int/childgrowth/standards/technical_report/en/index.html.)

You can see that a large sample is imperative for constructing any such chart. The statistical method used to obtain the WHO growth charts is the **Box–Cox power exponential (BCPE)** since this considers **kurtosis** also in addition to skewness of the distribution of growth measurements. The method of **cubic splines** was used for smoothing of the percentile curves after age transformation. For testing goodness of fit, the ***Q*-test** was used. A nonmathematical explanation of these steps is given by Indrayan [2]. Figure W.4 shows that the obtained percentile curves after such rigorous methods are very close to the observed means at different ages. For further details, see the WHO document [1].

## Wilcoxon rank-sum test

The Wilcoxon rank-sum test [1] is a **nonparametric test** for assessing whether or not two independent samples have come from a population with the same **location**. The corresponding parametric test for this purpose is the **Student *t***, where the **parameters** under test are means. In the case of nonparametric tests, the mean is not the target parameter; rather, it is just the location (Figure W.4). The distributions can have any shape but should have same shape. Nonparametric tests compare the distribution as a whole for location and not any particular parameter. But they can be considered to compare medians, and some books describe them as **median tests**. Since the Student *t*-test has more **efficiency**, it can be used for large samples, and we can use the Wilcoxon test for small samples when the distribution is far from **Gaussian**. This is equivalent to the Mann–Whitney ***U*-test** [2]; both came at about the same time and were independently worked out. Thus, this is also called the **Mann–Whitney–Wilcoxon test**.

Suppose there are $n_1$ observations in the first sample and $n_2$ in the second sample. For the Wilcoxon rank-sum test, the two samples are combined, and these $n$ ($= n_1 + n_2$) observations are assigned **ranks** from lowest to highest. Ties, if any, are given average ranks. For convenience, assume that the labels are such that $n_1 \le n_2$. Now,

Wilcoxon rank-sum test: $W_R$ = sum of the ranks assigned to the $n_1$ observations in the first sample.

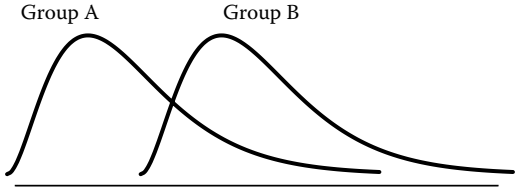

**FIGURE W.4** Two distributions with the same shape but differing in location.

Critical values of $W_R$ for $\alpha = 0.05$ under the **null hypothesis** $H_0$ of no difference between the two groups are given in Table W.2 for one-sided and two-sided **alternative hypothesis** $H_1$.

Frank Wilcoxon

Reject $H_0$ if the calculated value of $W_R$ is equal to or beyond the critical value for your $n_1$ and $n_2$. The table is only for values of ($n_1$, $n_2$) between 4 and 9. The Wilcoxon rank-sum test for two independent samples will not give any statistical significance at the 5% level if both $n_1$ and $n_2$ are less than or equal to 3 (also see the note below Table W.2). For the right-sided alternative, use the upper value, and for the left-sided alternative, use the lower value. For a two-sided alternative, use both values, as shown in Table W.1. An $\alpha = 0.025$ for a **one-tail alternative** is equivalent to $\alpha = 0.05$ for a **two-tail alternative** because the Wilcoxon criterion is symmetric.

When any of these sample sizes is 10 or more, use the following Gaussian approximation.

$$z = \frac{W_R - \mu_{W_R}}{\sigma_{W_R}},$$

where

$$\mu_{W_R} = \frac{n_1(n+1)}{2}, \text{ and } \sigma_{W_R} = \sqrt{\frac{n_1 n_2 (n+1)}{12}}, \; n_1 \le n_2 \text{ and } n = n_1 + n_2.$$

This $z$ follows a **standard normal distribution**, and the same critical values can be used for testing equality of locations. If each $n_1$ and $n_2$ is 30 or more, there is no need to use this criterion. A Student $t$-test for means can be safely used for such large sample sizes in practically every situation.

Note that the Wilcoxon rank-sum test, for that matter, any test based on ranks, is based on the order of the values and not the actual values. If one value is 10.1 and the next higher is 18.2, this receives the same rank as when the second value is 10.2. Thus, quantities lose half their relevance. For this reason, the Wilcoxon test and all other rank-based tests are sometimes not considered adequate. Many nonparametric enthusiasts consider this a strength of nonparametric tests. In any case, they are the best procedures available so far for small samples when the underlying distribution is far from Gaussian.

This test is valid only when all the rearrangements of the data are equally likely under the null. This condition is met if and only if the groups differ in location only and nothing else. For example, if variances differ, the test ceases to be a test for difference in location. It mixes the variance differences also.

## Wilcoxon signed-ranks test

The null hypothesis under test in the Wilcoxon signed-ranks test [1] is that two **paired samples** have the same location. Pairing could be before–after measurements or one-to-one matching. For the meaning of location difference, see Figure W.4 under **Wilcoxon rank-sum test**. The Wilcoxon signed-ranks test is

**TABLE W.2**
**Lower and Upper Critical Values of Wilcoxon Rank-Sum Test $W_R$ for ($n_1$, $n_2$) between 4 and 9**

| | α | | $n_1$ | | | | | |
|---|---|---|---|---|---|---|---|---|
| $n_2$ | One-Tailed | Two-Tailed | 4 | 5 | 6 | 7 | 8 | 9 |
| 4 | 0.05 | 0.10 | 11, 25 | | | | | |
| | 0.025 | 0.05 | 10, 26 | | | | | |
| 5 | 0.05 | 0.10 | 12, 28 | 19, 36 | | | | |
| | 0.025 | 0.05 | 11, 29 | 17, 38 | | | | |
| 6 | 0.05 | 0.10 | 13, 31 | 20, 40 | 28, 50 | | | |
| | 0.025 | 0.05 | 12, 32 | 18, 42 | 26, 52 | | | |
| 7 | 0.05 | 0.10 | 14, 34 | 21, 44 | 29, 55 | 39, 66 | | |
| | 0.025 | 0.05 | 13, 35 | 20, 45 | 27, 57 | 36, 69 | | |

| 9 | 0.05 | 0.10 | 16, 40 | 24, 51 | 33, 63 | 43, 76 | 54, 90 | 66, 105 |
| | 0.025 | 0.05 | 14, 42 | 22, 53 | 31, 65 | 40, 79 | 51, 93 | 62, 109 |

*Source:* Wilcoxon F, Wilcox RA. *Some Rapid Approximate Statistical Procedures*. Lederle Laboratories, 1964.

*Note:* No difference can be statistically significant by this test at $\alpha = 0.05$ (two-tailed) or $\alpha = 0.025$ (one-tailed) when both $n_1 \le 3$ and $n_2 \le 3$. However, significance at this level can be achieved if $n_1 = 2$ and $n_2 \ge 8$, or $n_1 = 3$ and $n_2 \ge 5$. Critical values for these situations are not given in this table. If needed, see Hollander and Wolfe [4].

used for small samples with non-**Gaussian distribution** because for large samples and for Gaussian distribution, the **paired *t*-test** performs better. The method for the Wilcoxon signed-ranks test is as follows:

Step 1. Let there be $n$ pairs and the observed value for the $i$th pair $(x_i, y_i)$, $i = 1, 2, \ldots, n$. Calculate the difference $d_i = (x_i - y_i)$ in the variable values for each pair. For the purpose of illustration, consider $x_i$ as the value before the treatment and $y_i$ the value after the treatment.

Step 2. Ignore the + or − sign of $d_i$ and assign rank starting from rank 1 for the smallest $|d_i|$ to rank $n'$ for the largest $|d_i|$, where $n'$ is the number of pairs with nonzero difference. The pairs with zero difference are omitted. Thus, $n' \le n$. If two or more $|d_i|$ are equal (ties), they are each assigned the average rank of the ranks they would have received individually if ties in the data had not occurred.

Step 3. Reaffix the + or − sign of the difference to the respective ranks. That is, indicate which ranks arose from negative $d_i$s and which from positive $d_i$s.

Step 4. Calculate the Wilcoxon test criterion as the sum of the positive ranks. That is,

Wilcoxon signed-ranks test:
$W_S$ = sum of the ranks with positive sign.

The minimum possible value of $W_S$ is 0 when no rank has a positive sign. The maximum occurs when all ranks are positive. If there were no difference between the groups, the criterion $W_S$ would take on a value close to its mean $n'(n' + 1)/4$. A big difference from this mean would be evidence against the **null hypothesis** ($H_0$) of no difference between the *before* and *after* measurements.

Step 5A. Find the ***P*-value** corresponding to the calculated value of $W_S$. Reject $H_0$ if $P$ is less than the predetermined **level of significance**. Described here is a procedure based on critical values of $W_S$ corresponding to $\alpha = 0.05$. For this $\alpha$ and $n' \le 19$, reject $H_0$ if

a. $W_S \ge w_r$ if $H_1$ is that *before* measurements are *higher* than *after* measurements (right-sided $H_1$)
b. $W_S \le w_l$ if $H_1$ is that *before* measurements are *lower* than *after* measurements (left-sided $H_1$)
c. Either $W_S \le w_1$ or $W_S \ge w_2$ if $H_1$ is that *before* measurements are *different* from *after* measurements (two-sided $H_1$)

The critical values $w_r$, $w_l$, or $w_1$ and $w_2$ for $\alpha = 0.05$ for $n'$ from 5 to 19 are given in Table W.3. The one-sided critical value for $n' = 5$ is 0 or 15. These are the minimum and maximum possible values with $n' = 5$. Thus, the decision to reject $H_0$ in favor of one-sided $H_1$ can be reached in this case only if all five differences are positive (or all negative). When $n' \le 4$, no difference can be statistically significant at the 5% level when $H_1$ is one-sided. If $H_1$ is two-sided, no difference can be statistically significant by this test at the 5% level for $n' \le 5$.

Step 5B. For $n' \ge 30$, it is safe to use the Student $t$-test for means. If $n'$ is between 20 and 29, use the Gaussian approximation to the Wilcoxon test. This is given by

$$z = \frac{W_S - \mu_{W_S}}{\sigma_{W_S}},$$

where $\mu_{W_S}$ is the mean value of $W_S$, given by $\mu_{W_S} = n'(n'+1)/4$, and $\sigma_{W_S}$ is the standard deviation (SD) of $W_S$ given by $\sigma_{W_S} = \sqrt{n'(n'+1)(2n'+1)/24}$. A one-tailed or two-tailed test can be carried out as usual with this $Z$.

**TABLE W.3**
**Critical Values of Wilcoxon Signed-Ranks Test $W_S$ for Matched Pairs ($\alpha = 0.05$)**

| | Right-Sided $H_1$ | Left-Sided $H_1$ | Two-Sided $H_1$ | |
|---|---|---|---|---|
| $n'$ | $w_r$ | $w_l$ | $w_1$ | $w_2$ |
| ≤4 | [a] | [a] | [b] | [b] |
| 5 | 15 | 0 | [b] | [b] |
| 6 | 19 | 2 | 0 | 21 |
| 7 | 25 | 3 | 2 | 26 |
| 8 | 31 | 5 | 3 | 33 |
| 9 | 37 | 8 | 5 | 40 |
| 10 | 45 | 10 | 8 | 47 |
| 11 | 53 | 13 | 10 | 56 |
| 12 | 61 | 17 | 13 | 65 |
| 13 | 70 | 21 | 17 | 74 |
| 14 | 80 | 25 | 21 | 84 |
| 15 | 90 | 30 | 25 | 95 |
| 16 | 101 | 35 | 29 | 107 |
| 17 | 112 | 41 | 34 | 119 |
| 18 | 124 | 47 | 40 | 131 |
| 19 | 137 | 53 | 46 | 144 |

*Source:* Wilcoxon F, Wilcox RA. *Some Rapid Approximate Statistical Procedures*. Lederle Laboratories, 1964.

[a] No difference can be statistically significant by this test at $\alpha = 0.05$ (one-tailed) when $n' \le 4$.

[b] No difference can be statistically significant by this test at $\alpha = 0.05$ (two-tailed) when $n' \le 5$.

A good statistical package will do all these steps for you. It will give the $P$-value, which you can interpret to draw conclusions. The following comments may be helpful:

1. The Wilcoxon test is less powerful than the Student $t$-test if the underlying distribution is Gaussian. Thus, it should not be used when the data follow a Gaussian pattern. Also, the **sign test** is less powerful than the Wilcoxon test because it ignores the magnitude of differences.
2. The Wilcoxon signed-ranks test, for that matter, almost all the nonparametric tests for quantitative data, is based on ranks. These tests are discrete and not continuous. For this reason, it is rarely possible to specify a critical value for exact $\alpha = 0.05$. The critical values given in Table W.3 actually have $\alpha \le 0.05$. In some cases, this could be substantially less. But that is the nearest one could reach if $\alpha$ is to be 0.05.

As an example, suppose the role of obesity in prolonged labor is examined in pregnant women of age more than 35 years with persistent occipitoposterior presentation. Seven obese (say, body mass index [BMI] ≥ 30) and seven nonobese women with such presentation, one-to-one matched for age, parity, hemoglobin (Hb) level, etc.,

**TABLE W.4**
**Duration of Labor in Obese and Nonobese Women**

| | Duration of Labor (Hours) | | | | | | |
|---|---|---|---|---|---|---|---|
| Obese | 18 | 15 | 17 | 20 | 14 | 12 | 18 |
| Nonobese | 17 | 15 | 18 | 18 | 11 | 10 | 14 |

**TABLE W.5**
**Calculation for Wilcoxon Signed-Ranks Test for Data in Table W.4**

| $d_i$ | 1 | 0 | −1 | 2 | 3 | 2 | 4 |
|---|---|---|---|---|---|---|---|
| Rank of $\|d_i\|$ | 1.5 | – | 1.5 | 3.5 | 5 | 3.5 | 6 |
| Signed ranks | +1.5 | – | −1.5 | +3.5 | +5 | +3.5 | +6 |

are included in the study. The data obtained are in Table W.4. Is the evidence sufficient to conclude that obese women have longer labor?

The calculations are shown in Table W.5. For positive ranks,

$$W_S = 1.5 + 3.5 + 5 + 3.5 + 6$$
$$= 19.5.$$

Since the pair with $d_i = 0$ is ignored, $n' = 6$ in this example. Note how the ranks have been assigned to the ties. Two pairs have the same absolute difference, namely, 1 h. They would have received ranks 1 and 2 but now receive rank 1.5 each because of the tie. The case with ranks 3 and 4, where the difference is 2 h, is also similar.

The alternative hypothesis here is one-sided ($H_1$: obese women have a longer duration of labor than nonobese women) because there is no stipulation for obese women to have a shorter duration of labor. Since the calculated value of $W_S$ is more than the cutoff 19 in Table W.3 for $n' = 6$, reject $H_0$ of no difference at $\alpha = 0.05$. Conclude that obese women do indeed have a longer duration of labor.

## Wilks lambda (Λ)

Wilks lambda (Λ) is the multivariate generalization of the ***F*-test** for assessing equality of a set of means in three or more groups. Samuel Wilks first proposed this in 1938 [1]. This has become the basic test in one-way **multivariate analysis of variance (MANOVA)**.

Samuel Wilks

Suppose you measure three lung functions (say, forced vital capacity, forced expiratory volume in 1 s, and total lung capacity) for male adults of age 40–44 years working in tire factories, paint factories, and coal mines, and as traffic police for at least 10 years. These are some of the workplaces where lung functions can be compromised because of prolonged exposure to dust, fumes, and chemicals. The interest is in finding whether or not average lung functions in these four groups are the same. Since there is a set of three measurements on each person and there are four groups, MANOVA is the statistical method of choice to find if the means are different. The interest is not in individual lung functions but to consider the set of measurements together. This is what makes it a multivariate setup. A statistical package will be needed for calculations, and that will give the value of Wilks Λ. The software will also convert this Λ to an *F*-test with appropriate degrees of freedom and will provide the ***P*-value** so that you can decide whether to reject or not reject the **null hypothesis** of equality of the set of means in these four groups.

Wilks lambda can be interpreted as the proportion of the variance in the outcomes that is not explained by the group differences. As for *F*, Wilks Λ also requires **independence** of observations, **homoscedasticity**, and **multivariate Gaussian**-ity of the residuals. Homoscedasticity in this case means equality of **dispersion matrices**. For further details, see **multivariate analysis of variance (MANOVA)**.

1. Wilks SS. Weighting systems for linear functions of correlated variables when there is no dependent variable. *Psychometrika* 1938;3:23–40. http://link.springer.com/article/10.1007%2FBF02287917#page-1

## Wilson interval

The standard error (SE) of the sample proportion $p$ is $\sqrt{[\pi(1-\pi)/n]}$, but the conventional method is to replace the population proportion $\pi$ with the sample proportion $p$ for calculating this SE. Recollect that when $\sigma$ is replaced by the sample SD $s$ while working out the SE of the mean for, say, calculating the **confidence interval (CI)**, the distribution becomes Student $t$ in place of Gaussian (normal). No such adjustment is done while calculating the CI for $\pi$, and Gaussian $\pm z_{(1-\alpha/2)}$*SE($p$) interval is used even after replacing $\pi$ with $p$. This introduces approximation that may not work even under **Gaussian conditions**.

Edwin Wilson, in his paper published in 1927 [1], refined the CI for a population proportion $\pi$ for a large sample using the algebraic quadratic equation to solve $(p-\pi)/\sqrt{\pi(1-\pi)/n} = \pm z_{1-\alpha/2}$. This is given by

$$\text{Wilson interval for } \pi\text{: } \frac{1}{1+z^2_{\alpha/2}/n}\left[p+\frac{z^2_{\alpha/2}}{2n} \pm z_{\alpha/2}\sqrt{\frac{p(1-p)}{n}+\frac{z^2_{\alpha/2}}{4n^2}}\right],$$

where $z_{1-\alpha/2}$ is the **Gaussian deviate** corresponding to the two-sided $100(1-\alpha)\%$ **confidence level** and $p$ is the proportion observed in the sample. For confidence level 95%, $z_{1-\alpha/2} = 1.96$. Compare this with the crude 95% CI given by $p \pm 1.96$*SE($p$), where SE($p$) is the **standard error** of $p$ estimated by $\sqrt{p(1-p)/n}$. Since the Wilson interval is based on the quantity $(p-\pi)/\sqrt{\pi(1-\pi)/n}$, which is also called score, this interval is sometimes also known as the Wilson *score* interval. This interval has good properties even for small $n$ and very small or very large values of $p$.

**TABLE W.6**
**Comparison of Gaussian Interval and Wilson Interval for Some Values of *n* and *p***

| | | 95% Gaussian Interval | | 95% Wilson Interval | |
|---|---|---|---|---|---|
| *p* | *n* | Lower Limit | Upper Limit | Lower Limit | Upper Limit |
| 0.1 | 10 | 0 (–0.086) | 0.286 | 0.018 | 0.404 |
| 0.1 | 30 | 0 (–0.007) | 0.207 | 0.035 | 0.256 |
| 0.1 | 100 | 0.041 | 0.159 | 0.055 | 0.174 |
| 0.4 | 10 | 0.096 | 0.704 | 0.168 | 0.687 |
| 0.4 | 30 | 0.225 | 0.575 | 0.246 | 0.577 |
| 0.4 | 100 | 0.304 | 0.496 | 0.309 | 0.498 |

Edwin Wilson

Presented in Table W.6 are the Gaussian CIs and Wilson CIs for two values of $p$, namely $p = 0.1$ and $p = 0.4$, and $n = 10$, 30, and 100. The Gaussian interval is far too deficient as it gives a negative lower limit of the CI when the observed sample proportion is 0.1 (even when $n$ is 30), which is obviously impossible for any probability (or population proportion), and we have to consider it to be 0. Only for $n = 100$, the limits corresponds well, particularly when the observed $p$ is 0.40.

The Wilson interval is a better approximation than the Gaussian and can be used for relatively small $n$, but this would still be different from the **exact confidence interval** for binomial $\pi$. The exact CI is valid for small samples too as it is based on **binomial distribution**.

## Wishart distribution

The Wishart distribution is the multivariate analogue of **chi-square** distribution, devised by John Wishart in 1928 [1]. The sample **dispersion matrix** follows this distribution when a set of variables observed together has a **multivariate Gaussian distribution**.

John Wishart

A dispersion matrix is the row–column arrangement of variances and covariances of the variables in the set. Thus, this can be used to test the **null hypothesis** that the sample has come from a multivariate Gaussian distribution with a diagonal dispersion matrix. A diagonal dispersion matrix in this case implies that variables in the set are independent. If your set contains variables measuring functions of different organs, for example, bilirubin level for liver function, creatinine level for kidney function, systolic blood pressure for cardiac function, and vital capacity for lung function, you can find out whether any of these affects the others. It is known that various kidney functions affect one another, but it probably is not known whether or not measurements on different organs are related. This might be useful when tested for, say, people who have a low hemoglobin (Hb) level and for people who have a normal Hb level. This might generate a hypothesis regarding functions of which organs, if any, are simultaneously compromised by a low Hb level. However, the Wishart distribution is applicable only if the variables jointly have multivariate Gaussian distribution.

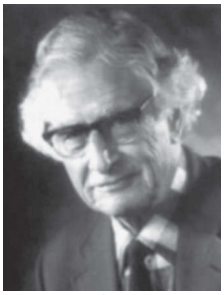
## Yates correction for continuity

This is the correction done to the **chi-square** criterion for testing the presence of association between two attributes in contingency tables for its better approximation to a continuous distribution. The correction is advised only for 2 × 2 tables and not for bigger ones. A contingency table contains the number of subjects in different cells—thus, it yields discrete values of the criterion. However, chi-square itself is a continuous distribution. When the Yates correction is applied, the value of the criterion tends to become continuous. This requires that 0.5 be subtracted from the difference between the observed and the expected frequencies in the numerator of the chi-square. The corrected chi-square criterion is as follows:

$$\text{Yates correction for continuity: } \chi^2 = \sum \frac{[(O-E)-0.5]^2}{E}.$$



Frank Yates

The correction was first suggested by Frank Yates in 1934 [1]. Any such correction becomes infructuous when the sample size is large because the result either way is nearly the same. Thus, this correction is advocated when any **cell frequency** in the contingency table is small, say, less than 5. The effect of this correction is that the value of the chi-square criterion is reduced because of this subtraction of 0.5 from each difference in the numerator that increases the *P*-value and makes it difficult to reject the null hypothesis of no association. Although this correction was accepted for a long time, it has been found to be too severe and to cause overcorrection in many situations, resulting in loss of statistical power to detect an association. The value of chi-square without correction has been found a better approximation than the one with the correction [2]. In any case, for small cell frequencies, we have the **Fisher exact test**, which does not need any such correction.

## Youden index, *see also* receiver operating characteristic (ROC) curve

The Youden index is used to assess the performance of quantitative diagnostic tests in terms of their **sensitivity and specificity** and is defined as

Youden index: $J$ = maximum value of (sensitivity + specificity − 1).

Note that this is maximum where sensitivity + specificity is maximum. Thus, the Youden index is a measure of the best performance of the test in terms of a combination of **sensitivity and specificity**. This was suggested by William Youden in 1950 [1].

For finding the Youden index, sensitivity and specificity are calculated for each value of the quantitative test. This is easily done when **receiver operating characteristic (ROC) curve** is drawn. In that case, the Youden index maximizes the vertical distance from the line of equality (diagonal line) to the point ($x$, $y$) on the ROC curve, as shown in Figure Y.1. The $x$-axis represents (1 − specificity), and the $y$-axis represents sensitivity. In other words, the Youden index $J$ is the largest distance of the ROC curve from the line of equality. The main aim of the Youden index is to maximize the difference between the true-positive rate ($s_n$) and the false-positive rate ($1 - s_p$), and a little algebra yields $J = \max(s_n + s_p - 1)$. For example, the Youden index of serum interleukin-18 (IL-18) at commencement of renal therapy of critically ill patients with acute kidney injury for hospital mortality was found to be 0.65 [2]. This is the maximum correct classification of the negative and positive cases by this test.

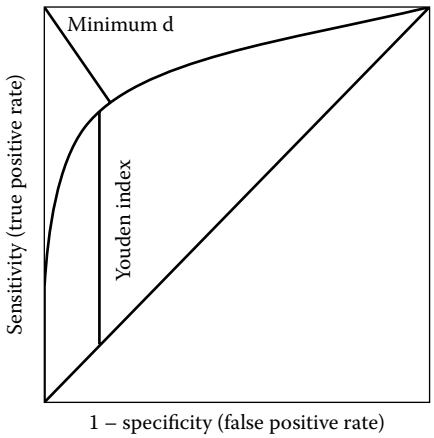

**FIGURE Y.1** ROC curve and Youden index.

Another purpose of the Youden index is to help locate the cutoff point of the quantitative test where its performance is best. For IL-18 in the example just cited, the best cutoff was 1786 pg/mL.

For further details and more applications of the Youden index, see Schisterman et al. [3].

## Zelen design

Also called **randomized consent design**, this design was originally introduced to deal with some of the ethical problems facing clinicians as they enter patients into randomized clinical trials. For example, the patients in the control arm who receive standard treatment are not given the chance to be treated with the new treatment even if the new treatment is potentially better than the standard treatment, unless of course it is committed in the study protocol that the participants in the control arm will be given the chance to take the new treatment after the trial is over. Also, those allocated to the new treatment may want to opt for the standard treatment.

Once the patient's eligibility for entering the trial has been established, the patient is randomized to one of the treatments: A or B. Under the randomized consent design, patients randomized to one particular group are approached for consent: are they willing to receive the allocated treatment for their illness? The researcher and the patient openly discuss all potential risks, benefits, and treatment options. If the patient does consent, he/she receives the allocated treatment. On the other hand, after the discussion has taken place, if the patient does not give consent, he/she is assigned to receive the other treatment. This could be the standard treatment that the patient would get in any case if he/she were not part of the trial. This, in any case, is part of the process of **informed consent** that is generally followed before assigning treatment, but under a randomized consent design, this is done after the allocation. This kind of design was suggested by Marvin Zelen in 1979 [1].

Marvin Zelen

The informed consent process of the conventional randomized controlled trial (RCT) design may be ethical on some occasions but is not always ethical from the patients' perspective. In some cases, obtaining prior consent is difficult if not impossible because of the age or the condition of the subjects or because of the difficulty in explaining the scientific issues. Many patients show reluctance in participating in randomized clinical trials, as they are suspicious of the outcome. Sometimes, the detailed explanation process exhausts patients, even brings a *nocebo effect* (the opposite effects of placebo), resulting in refusal to participate in the trial, which is truly a waste of energy for both the patients and the investigators [2]. The Zelen design seeks to overcome this difficulty.

This design has some distinct advantages over the conventional RCT. Foremost is that it is perfectly ethical; it is also able to include all eligible subjects, and the problem arising from seeking informed consent is avoided. A major problem, however, is that this design does not allow double-blinding, as the allocation is known—and this can create serious bias in the responses. Also, the analysis of data from this kind of trial is difficult because the number of participants in each arm becomes a random number instead of a fixed number. The problem is compounded if a large number of eligible subjects refuse to remain in their allocated group.

Nevertheless, the design has been used with some success. Hatcher et al. [3] describe a protocol of a study on a treatment package including problem-solving therapy compared to the standard treatment in people who present to hospital after self-harm in New Zealand where a Zelen design is proposed. Nio et al. [4] used this type of design for a trial in Japan on neoadjuvant chemotherapy with tegafur plus uracil for gastric cancer.

## Zelen test

This is an exact test for comparing the **odds ratio (OR)** or **relative risk (RR)** in several $2 \times 2$ tables that can arise due to stratification. If there are $K$ strata, the data would be expressed in a $K \times 2 \times 2$ table. The usual procedure for homogeneity of ORs across strata is the **Breslow–Day test**, and then Zelen test is an exact counterpart of this test. The test was devised by Marvin Zelen in 1971 [1].

The Zelen test can be regarded as an extension of the **Fisher exact test** as this also uses the probability of all possible $K \times 2 \times 2$ tables in favor of the alternative hypothesis with the same row, column, and stratum totals as the observed table and with the same sum of cell frequencies. The $P$-value is the probability of the observed frequencies conditioned on the fixed margins. Significance would mean that the OR is different in different strata, which also means, in this case, that the three-way interaction is significant. Patil [2] generalized this procedure for $I \times J \times K$ tables. However, Halperin et al. [3] cited examples where this test contradicts the data. Hirji et al. [4] have presented alternative approaches that are too intricate for our audience.

## zero-inflated models

Zero-inflated models are those that account for an unusually high number of 0's in the data.

In many medical situations, zero value of the variable of interest is quite common. This can happen with number of cigarettes smoked per day, where it is 0 for nonsmokers; number of extramarital sex encounters in 1 month by married persons, number of days with sickness in a month; number of angina attacks in a month in patients with cardiovascular diseases; etc. These examples are for counts, but 0 can commonly occur with continuous measurements also, such as with differences between values before and after a procedure. One such example is the deviation of organs with a tumor when irradiated for treatment. Sometimes, the deviations do not occur at all in this procedure, and sometimes, they are so small that even the most sophisticated computed tomography (CT) scan fails to detect them. Thus, the value would be 0o for many subjects. Just for context, if the deviation is large, radiation could damage the adjacent organs—thus, close track of deviations is kept.

Analysis of data with many 0's is problematic because such data do not conform to any of the established statistical distributions. Counts otherwise generally follow a **Poisson distribution**, but if mean $\mu = 2$, $P(x = 0) = e^{-2}\lambda^0/0! = 0.135$, i.e., only 13.5% of values are expected to be 0 under this model. If they are substantially more, say, 20% or more, the Poisson model will not be adequate to represent this variable. Similarly, if the measurement is continuous with mean = 1 mm and standard deviation (SD) = 0.5 mm for deviations of organs in our tumor radiation example (note in this case that the deviations in either direction are measured as positive—there are no negative values), and if any deviation < 0.25 mm is undetectable, the probability of zero value is $P(0 < x < 0.25|\ \mu = 1, \sigma = 0.5) = 0.044$ for Gaussian distribution. If zero or undetectable deviation is actually observed in half of the subjects against the expected 4.4%, obviously, the Gaussian distribution is not appropriate. In addition, in this case, Gaussian distribution will not be able to rule out negative values.

Among the many approaches suggested for analyzing data with many 0's, one is the **negative binomial distribution**. If this does not fit well, consider zero-inflated Poisson distribution for counts, which is stated as

$$P(x) = \pi + (1 - \pi)e^{-\lambda} \text{ for } x = 0 \text{ and}$$

$$P(x) = (1 - \pi)\ e^{-\lambda}\lambda^x/x! \text{ for } x = 1, 2, 3, \ldots,$$

where $\pi$ is the expected proportion of extra 0's and can be negative in a zero-deflated model, where the number of 0's is much less than expected with a Poisson distribution, and $\lambda$ is the usual Poisson parameter. This adjustment has been discussed by Rideout et al. [1]. The other approach suggested by Fletcher et al. [2] for continuous variables is combining ordinary (quantitative) and logistic regressions. Briefly, this requires splitting the data in two parts—the first with $x = 0$ and the second with $x > 0$. Two separate analyses are done: first logistic regression for the $x = 0$ part, and second using ordinary regression for the $x > 0$ part. These analyses are combined to get a unified conclusion.

**TABLE Z.1**
**Distribution of Multiple Births (Twins, Triplets, and Quadruplets) by Sex**

| Number of Female Children | Number of Male Children | | | | | |
|---|---|---|---|---|---|---|
| | **0** | **1** | **2** | **3** | **4** | **Total** |
| 0 | × | × | 17 | 5 | 0 | **22** |
| 1 | × | 25 | 6 | 2 | × | **33** |
| 2 | 12 | 3 | 0 | × | × | **15** |
| 3 | 4 | 0 | × | × | × | **4** |
| 4 | 1 | × | × | × | × | **1** |
| **Total** | **17** | **28** | **23** | **7** | **0** | **75** |

Our discussion is for observed 0's, that is, a value other than 0 was possible but happened to be 0 for some or many subjects in our sample. The other possibility is that zero value is bound to occur, called *structural zero*. Consider a study on multiple births—twins, triplets, and quadruplets. The births are classified by sex. The distribution may be as displayed in Table Z.1. There are some observed 0's in this table. In addition, there is a "×" sign in some cells where no frequency is possible. Such tables are called **incomplete tables**. Special methods are required to analyze such tables. For a summary of such methods, see Agresti [3].

## *Z*-scores

The *Z*-score of a quantitative value of measurement is an expression of how far this value is from its mean in standard deviation (SD) units. This is defined as

$$Z\text{-score: } Z = \frac{x - \mu}{\sigma},$$

where $x$ is the value of the measurement, $\mu$ its mean, and $\sigma$ its SD. Suppose the body temperature in a healthy person is 97.8°F and it is known that the population mean $\mu$ of healthy people is 98.6°F and population SD $\sigma$ is 0.4°F; then the *Z*-score of the person's body temperature is (97.8 – 98.6)/0.4 = –2. In case the distribution of body temperature has a **Gaussian** (normal) pattern, this can be translated to, say, that the chance of this kind of temperature or more extreme (less than or equal to 97.8°F) is only 2.5%, where this chance comes from the probabilities of the Gaussian variate.

When the distribution is not Gaussian, it is difficult to assign a probability to any measurement, but *Z*-scores are still used because of their extremely useful property, namely, that mean = 0 and SD = 1. This comes directly from the way *Z*-scores are defined. Because mean = 0 and SD = 1, this is also called **standardized deviate** or **standardized variate**. The process of subtracting the mean and dividing by the SD is called **standardization of values**.

Whereas the *Z*-score is defined in terms of population mean and population SD, the standardized deviate or standardization of values can be done using the sample mean and sample SD also. If there are 15 subjects in a sample, calculate the mean and SD of these values, subtract the sample mean $\bar{x}$ from each value, divide by the sample SD $s$, and get standardized values = $\frac{x-\bar{x}}{s}$. This is demonstrated in Table Z.2 for serum urea levels observed in 15 subjects in the sample. The sample mean in these data is 34 mg/dL, and the sample SD is 14.21267 mg/dL, but the mean and SD of the standardized values are 0 and 1, respectively. Extreme values do not matter in this case. In our example, one person had a serum urea level of 78 mg/dL, whereas all others were between 15 and 45 mg/dL. This has not affected the mean or SD of the standardized values; neither is a Gaussian pattern required for this process.

A big advantage of standardized values is that they can be compared for entirely different measurements. For example, if one person's standardized value of serum urea level is −0.1407 and his/her standardized value for intelligence quotient (IQ) is +1.7384, it can be easily concluded that the serum urea level of this person is slightly less than the average, while IQ is much above the average. When comparable measurements, such as serum urea and serum creatinine, are available, this type of comparison of standardized values can provide useful insight to the clinician as to what measurement could be the culprit. Precisely for this reason, standardized values are sometimes used in regression to obtain the standardized **regression coefficients** because then, these can be compared across the regressors to find which regressor is contributing more to the variation in response than the others.

**TABLE Z.2:**
**Mean and SD of *Z*-scores for Sample Values**

| | Serum Urea (mg/dL) $x$ | Standardized Values $\frac{x-\bar{x}}{s}$ |
|---|---|---|
| | 32 | −0.1407 |
| | 45 | 0.7740 |
| | 23 | −0.7740 |
| | 27 | −0.4925 |
| | 36 | 0.1407 |
| | 31 | −0.2111 |
| | 29 | −0.3518 |
| | 36 | 0.1407 |
| | 42 | 0.5629 |
| | 78 | 3.0958 |
| | 26 | −0.5629 |
| | 15 | −1.3368 |
| | 27 | −0.4925 |
| | 30 | −0.2814 |
| | 33 | −0.0704 |
| **Sum** | **510** | **0.0000** |
| **Mean ($\bar{x}$)** | **34** | **0.0000** |
| **Sample SD ($s$)** | **14.21267** | **1.0000** |

Sometimes, particularly for highly skewed distributions, such as of weight in children, you may occasionally find that the median is used for calculating *Z*-score in place of the mean. If that is done, the property of mean = 0 and SD = 1 may not hold, and the transformed values cannot be called "standardized." Use of the median is done for pragmatic reasons since the mean in the case of a highly skewed distribution is not a representative value.

## *z*-test

This is the most basic of all statistical tests and is based on the ***Z*-score** of the sample summary. The *Z*-score for individual values is $\frac{x-\mu}{\sigma}$, where $x$ is the value of the measurement, $\mu$ its mean, and $\sigma$ its standard deviation (SD), and the mean of $Z$ is always 0 and variance always 1. Replace $x$ with any sample summary, $\mu$ with its mean, and $\sigma$ with its SD, now called standard error (SE), and get the criterion for the $z$-test for random samples. That is, in its most generalized form,

$$z\text{-test: } z = \frac{\text{sample summary} - \text{its mean}}{\text{its SE}}.$$

The sample summary could be the sample mean, sample median, sample proportion, difference between these two groups, etc. When the underlying distribution of $x$ is **Gaussian** (normal), the distribution of most sample summaries is also Gaussian, and in that case, this $z$ has a Gaussian distribution with mean = 0 and SD = 1. For testing a hypothesis, the value of this $z$ is calculated under the null hypothesis. A large value of $|z|$, say, more than 2, would indicate that the value of the sample summary is improbable (***P*-value** is small) under the null, and thus, the null is rejected. That is, the value of $z$ obtained from the data under the null is checked against a Gaussian table for finding the one-tailed or two-tailed *P*-value depending on whether the alternative is **one-tailed or two-tailed**, and is rejected if the *P*-value is less than the prefixed **level of significance**. This is popularly known as the $z$-test.

If the underlying distribution is different from Gaussian, the **central limit theorem** comes to the rescues for large samples, particularly for mean and proportion, and the test then can still be used under **Gaussian conditions**. Just to remove any confusion, note that the same criterion becomes **Student *t*** under Gaussian conditions when the SE in the denominator is replaced by the *estimated* SE. The $z$-test requires that the "population" SE be used in the denominator, but for many applications, estimated SE is used in place of the population SE in the realization that Student $t$ also becomes Gaussian for a sufficiently large sample. In summary, the $z$-test, say, for a sample mean, is exact for small samples when the underlying distribution is Gaussian and the SE is known and not estimated. In all other cases, it is approximate and requires a large sample. The requirement of a large sample is twice as important for this because of two approximations: (i) for approximating the Student $t$ with Gaussian $z$ and (ii) for using the result of the central limit theorem for non-Gaussian distribution of the sample summary under test. For the first, generally, a sample of size at least 30 is considered adequate, but for the second, a very large sample may be required for some sample summaries, such as odds ratio.

The $z$-test takes a different form depending upon what sample summary is being used for the test. This may require independence of observations, and independence of samples in the case of comparison of two groups, but the equality of variances is not required except for simplifying the calculations. For $z$-tests for different

situations, see the topics **comparison of two or more correlation coefficients**, **comparison of two or more odds ratios**, **comparison of two or more proportions**, **comparison of two or more relative risks**, and **comparison of one-sample mean and proportion with a specified value**. In the last case, a *z*-test is used for proportion and not for the mean (Student *t* is used for the mean), and a *z*-test in all these situations is used for one and two groups but not for more than two groups. For all *t*-tests, such as for comparison of one sample mean with a specified value, comparison of intercepts with a specified value or in two simple linear regressions, comparison of two means, and comparison of a regression coefficient with a specified value or of two regression coefficients, it becomes a *z*-test in the rare case where the population SD is known and not estimated from the sample.
