# Additional Terms

Appear in italics in the text: These terms are mentioned or briefly explained in the text without details.

# Preface

The science of biostatistics has proliferated enormously during the past few decades, and its medical applications seem to have increased exponentially. Our interaction with a large number of medical practitioners and researchers reveals that they are increasingly perplexed over the biostatistical methodology and terminology used in medical literature. Understanding biostatistical concepts is sometimes a challenge for medical professionals because they often lack formal training in this area. Encyclopedias are commonly used as a reference to quickly learn the essentials of a specific topic. We believe that our concise-encyclopedia (ency) will be a useful resource for anyone needing to quickly understand the basics of a particular biostatistical concept with a minimal level of mathematical knowledge. The topics, including alternative phrases, are arranged alphabetically, and the reader can easily locate the topic of interest and understand the meaning of the terms involved, their applicability to health sciences, and their medical interpretation. We have tried to orient the discussion of the topics firmly to the needs and backgrounds of medical and health professionals so that it resonates with them. Like any encyclopedia, this one, too, is not a replacement for a textbook, as the matter is not arranged in a logical sequence. For a regular book in a similar mode, see the fourth edition of *Medical Biostatistics* by Abhaya Indrayan (CRC Press, 2017), which takes you through most of these topics in a logical flow from beginning to end using medical uncertainties as the common theme for navigation.

Our target audience is those medical professionals who want to adhere to an evidence-based approach to medical practice. This requires a good understanding of biostatistical methods for proper interpretation of results reported in scientific articles. These professionals include physicians, surgeons, dentists, pharmacists, nursing professionals, nutritionists, and epidemiologists. Academia, especially graduate students in medical and health sciences, may also find this ency useful as a reference.

We have conceived this encyclopedia as relatively short, hence the term *concise*. It focuses on conceptual knowledge and practical advice in an easy-to-read format rather than mathematical details. This approach hopefully enhances the book's usefulness as a reference for medical and health professionals. Limiting the book to a single volume will also make it more affordable and attractive to individual professionals and not just libraries. Because of the limited size, the explanations provided for various terms in this volume cannot be comprehensive, and some readers may feel that the types of details they need are missing. For some terms, such as *regression* and *analysis of variance*, full chapters in many books and, in fact, full books are available. Our explanation is limited to the essential features, applications, and interpretations we perceive as relevant to medical sciences. However, in this process, we may not have been able to meet the exacting standards of some statisticians.

It is not possible to cover everything in one volume, yet this ency may be quite comprehensive for the target audience. It defines and explains more than 1000 commonly and not-so-commonly used key biostatistical terms and methods, ranging from simple terms such as *mean* and *median* to advanced terms such as *multilevel models* and *generalized estimating equations*. Those health topics that have significant biostatical components are also presented. These include terms relating to community health, and social and mental health.

We have listed alternative terms to make searching easier and also to help our medical colleagues by removing some of the confusion surrounding multiple terms for the same method or topic. We have also tried to explain how they are related, if at all. For example, an independent variable in a regression setup is also called a regressor, an explanatory variable, a predictor, a covariate, a confounder, a concomitant variable, etc., depending upon the context. Similarly, a dependent variable is also called a response, a target, or an outcome variable. We discuss all of them together under one unifying topic, "dependent and independent variables," so that their subtle distinctions can be explained. All the related terms for each topic are listed for completeness but refer the reader to the unifying topic. For these few terms, the length of the entry is considerably increased. On the other hand, a topic that needs to be extensively described with varied applications, such as chi-square, is split into several relatively smaller topics to retain the focus and to keep each topic within a manageable limit. The purpose is to remain short and crisp for the convenience of our medical readers. For some topics, such a split may have hindered providing a correct perspective. Also, we have tried to describe each topic in a self-contained manner for independent reading so that the reader does not have to continually flip through the book, although some cross-referencing for the involved terms seemed unavoidable. Thus, there is some duplication, which was inevitable in this kind of work, although we have tried to minimize this, sometimes by combining two related topics.

Given that the target audience is medical professionals, formulas and mathematical details are limited to high school algebra. Thus, formulas for only those terms that do not require complicated mathematics have been provided. For others, a heuristic approach is adopted to explain and describe the rationale and applications. We are aware that heuristics can generate imprecision and sometimes even errors—thus, imperative care has been taken. Many topics are illustrated with the help of medical examples and figures, including references to contemporary medical literature. The list of references for topics is not comprehensive, though, and is restricted to the most relevant, so that the reader does not feel burdened. Web links have been provided for references wherever we could locate them so that the reader can directly access the referenced material. This could not be done for the referenced books. The date of last access by us is written only for those

websites that are likely to change. For ostensibly permanent websites such as those of journals, the date of last access is not provided. These links provide an indispensable platform for further study and research.

We realized the difficulty in communicating complex mathematical issues in a simple nonmathematical language and accepted this challenge. Efforts all throughout this ency are in simple language that can be appreciated by the target audience, who have less grounding in mathematics. We have not used formal language; instead, the tone is conversational. In the process, though, we may not have been very accurate in explaining a method or a concept. This admittedly is a limitation of this book. But our focus is firmly on medical applications and concerns. For intricate methods, where we have explained only the concept and applications but not the analysis, a reference is provided wherein one can find the required details. Historical briefs, biographical snippets, and photographs of prominent statisticians are added to provide a broader context for the topics covered.

Within each topic, those terms that are explained elsewhere in this volume are in bold when they appear first, particularly when details of that term are likely to help the reader to understand the current topic. There might be some minor variation in the topic title as required for the current text. Other statistical terms appear in italics and are separately listed so that these can also be located. Phrases that we want to emphasize also are in italics. To those of our medical colleagues who are not familiar with statistical notations, we advise that they see the topic "notations" in this ency so that they feel comfortable in reading and understanding this ency. We have tried to follow a uniform system of notations across the topics.

Almost all other encyclopedias are written by several contributing authors and edited by experts. Perhaps ours is the first attempt to prepare an encyclopedia by two authors. This has advantages and disadvantages. The first advantage is uniformity of the level of discussion—when based on contributions by different authors, some topics are discussed at too high a level and others at too low a level, depending on the concerned authors' understanding of the topic. The second advantage is our consistent style. A disadvantage is that this book may not delve as deeply into some topics as individual experts would prefer.

Despite our best care, errors may have occurred. We are sure that the book will be critically examined by the reviewers. Their feedback will help in improving the next edition.

# Acknowledgments

Our sincere thanks to John Whittington for reviewing and revising several sections of this book, which substantially added value to this work.

We are grateful to Ms. Laxmi Raghuvanshi for helping us with many figures in Excel, in checking the calculations, and providing other help from time to time.

## abortion rate/ratio

Abortion *rate* is the number of abortions per 1000 women of reproductive age group, whereas abortion *ratio* is the number of abortions per 1000 live births:

$$\text{Abortion rate in a year x} = \frac{\text{abortions in year x}}{\text{females of reproductive age-group in that year}} * 1000$$

$$\text{Abortion ratio in year x} = \frac{\text{abortions in year x}}{\text{live births in that year}} * 1000$$

The reproductive age group for females varies from population to population, but for comparability, this is considered to be 15–49 years. In the United States, this is calculated per 1000 women aged 15–44 years [1].

Abortion is the termination of a pregnancy before the fetus becomes viable, generally before completing 24 weeks of pregnancy. It could be deliberate to avoid an unplanned birth or due to a medical complication (called *induced*), or spontaneous (called *miscarriage*) mostly due to poor health of the mother or an accident. In developed countries, induced abortions are dominant, whereas in underdeveloped countries, spontaneous losses also could be substantial. Both types of abortions are mostly preventable. Induced abortions in case of life-threatening situations sometime raise a value judgment question regarding whose life is more important to save—mother or child. The abortion rate as well as the abortion ratio can be calculated separately for induced and spontaneous abortions or for the combined number.

According to the Centers for Disease Control (CDC), induced abortions were nearly 14 per 1000 women in the United States in 2011, and the abortion ratio was 239 per 1000 live births [1]. Most of these abortions took place in women in their early 20s. These numbers signify the distinction between the two indicators of **incidence** of abortions besides telling us the magnitude of the "problem."

When the count of stillbirths is also available so that you know total pregnancies, this rate can also be calculated as the percentage of pregnancies. For example, in India, in the year 2012, an estimated 25% of pregnancies resulted in abortions [2]. Some of these are ascribed to avoiding the birth of a female child because of the stigma attached to girls in some sections of Indian society. This may have occurred in China as well, where the one-child policy was enforced and many preferred a boy.

## absolute risk reduction, *see* attributable risk (AR)

## accelerated failure time model, *see also* proportional hazards

The accelerated failure time (AFT) model is used in **survival analysis** for studying the effect of a covariate that either accelerates or decelerates survival or failure. This is an alternative to the popular **proportional hazards** model, which works when the covariate affects the incidence of failure by a fixed multiplicative constant irrespective of time. Note the difference—one is for the covariate, such as an intervention, which affects the quickness with which the outcome occurs, whereas the second is for the covariate that affects the number of outcomes. Hazard ratio is difficult to interpret for a covariate that affects the speed of occurrence. The results of the AFT model may be more relevant as they can be directly translated into expected reduction or prolongation of the time to event. This can provide a useful framework for research, particularly in relation to aging.

The AFT model is a parametric model as it depends on the distribution of the failure time, whereas the proportional hazards model is semiparametric as it does not require distribution of the failure time; the proportionality of hazards alone is enough. AFT utilizes the entire survival curve, whereas the proportional hazards model compares only the mortality rates. For details of the differences between the two, see Patel et al. [1].

In a study on factors associated with time to next attack in neuromyelitis optica in South Korea, an AFT model revealed that the interattack interval naturally (without intervention) increased by 1.31 times as the cumulative number of attacks increased with time but also increased independently 4.26 times in those on rituximab treatment [2]. Note in this case how the number of attacks and the treatment decelerated the time to next attack (time interval increased). In the case of antiretroviral therapy in HIV cases in Cameroon, the AFT model has been used since the survival time rapidly increased after start of the therapy [3].

Under the AFT model, the effect of intervention is to shift the entire survival curve almost uniformly. This can be mathematically expressed as $S_1(ct) = S_0(t)$, where $S_0(t)$ is the survival at time $t$ in the control group and $S_1(ct)$ is the survival at time $ct$ in the intervention group. If the intervention increases the duration of survival, the value of $c$ will exceed 1, and if the intervention decreases the duration of survival, the value of $c$ will be less than 1. This could be understood as the acceleration or deceleration factor. The AFT model helps us in estimating the value of $c$. However, that is valid only when the effect of intervention on the duration of survival is consistent all through one's life. The model can be used only when the survival duration follows a specified distribution. This can be **exponential, Weibull**, or any such distribution. For further details, see Swindell [4].

## acceptable risk

As in common parlance, acceptable risk in health and medicine too is highly contextual and greatly varies from situation to situation and person to person. Nonetheless, for some kind of uniformity and to remove subjectivity, the *acceptable risk* of any intervention can be defined as gains from the intervention outweighing its cost. Each of these can be computed from different perspectives. For example, in public health, a risk is acceptable if the gain to society as a whole outweighs the adverse health impacts and resources required from society to reduce that risk. Assessment of these may require systematic studies and expert opinions. For environment regulations in the United States, a lifetime risk of less than one in a million is considered an acceptable risk of developing cancer from a risk factor, whereas in the United Kingdom, this is the acceptable limit for 1-year risk. This illustrates that acceptable risk varies according to individual and collective perceptions. Generally, it depends on the current norms prevalent in a setup, and these can quickly change. For details of the concept of acceptable risk, see Hunter and Fewtrell [1].

Sometimes, a higher risk than is really acceptable is tolerated by individuals and societies, such as with smoking. Thus, there is a distinction between accepted risk and acceptable risk. Also, determination of acceptable risk could be highly subjective, influenced by local perceptions and culture, as discussed by Hsu [2] for surgical masks as opposed to N95 respirators for prevention of nosocomial Middle East respiratory syndrome coronavirus (MERS-CoV), which has high **case fatality**. Similarly, Park et al. [3] have mentioned acceptable risk in the context of revisional bariatric surgery performed via a laparoscopic approach without really quantifying it.

For statistical decisions, though, the acceptable risks are fairly well defined in terms of probability of **Type I error** and of **Type II error**. These errors delineate the acceptable risk of a false-positive result and a false-negative result when based on appropriate statistical methods of data analysis. However, these, too, depend on the availability of correct data and the use of correct methods.

## acceptance and rejection regions

*Acceptance and rejection regions* are typical statistical terms and are used for the set of values of the **test criterion** in a **test of hypothesis** setup that decides whether to reject or not to reject a **null hypothesis**. The possible values of the test criterion are divided into two mutually exclusive sets: one with very little chance of being consistent with the null hypothesis and the other with a bigger chance. The set of values that have very little chance is termed the *rejection region*, and the other, which is the complement, is called the *acceptance region*.

For example, for the ***z*-test**, a value of $|z| \geq 1.96$ is the rejection region for a **two-sided alternative** at a 5% **level of significance**. Half of this region is in left tail, and the other half is in the right tail of the distribution (Figure A.1a). For **chi-square** at 5 degrees of freedom, the rejection region at a 5% level of significance is $\chi^2 \geq 11.07$ (Figure A.1b). This is a **one-tailed** critical region. Our *z*-test and chi-square test examples illustrate that different tests have different procedures to obtain the acceptance and the rejection regions. You can see that these regions are determined by the level of significance, the sampling distribution of the test criterion, and whether the test is one-tailed or two-tailed.

Technically, a null hypothesis is never accepted (it is just not rejected)—thus, the term *acceptance region* is inappropriate. But this term was commonly used till some time ago. The values in this region are not sufficiently against the null hypothesis. The rejection region is also called the **critical region**, and the value that separates the two regions is called the **critical value**. The critical values in our examples are 1.96 and 11.07, respectively. However, these terms are seldom used in the modern literature since almost all statistical software directly give the exact ***P*-value** corresponding to the value of the test criterion for a given sample—thus, the region or the critical value is not needed. This *P*-value is compared with the prefixed level of significance to come to the conclusion to either reject or not reject the null hypothesis.

## acceptance sampling, *see* lot quality assurance scheme

## accuracy

In the context of a *single* value, accuracy is the nearness to its true value. "Age 26 years, 2 months, and 21 days" is more accurate than just "26 years." In a conventional sphygmomanometer, calibrations are at intervals of 2 mmHg; thus, most blood pressure (BP) measurements

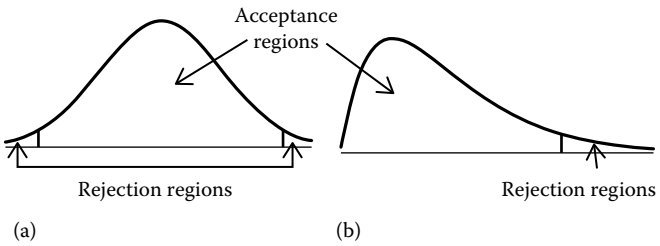

**FIGURE A.1** Acceptance and rejection regions: (a) *z*-test two-tailed; (b) $\chi^2$-test one-tailed.

also have only that kind of accuracy. Therefore, this instrument does not provide very accurate readings. Perhaps better accuracy is not needed for BP values. Only as much accuracy is needed in medical measurements as is required for clinical assessment.

Statistically, more accurate measurement will have less error component. But realize that results cannot be more accurate than the measurements themselves. Although it is customary to state summaries like mean and standard deviation to one more decimal place than are the data, they must be finally interpreted as if they have the same accuracy as the measurements. Intermediary calculations are done to several more decimals so that the final result retains the accuracy of the measurements. Remember that no such calculation can ever add to the accuracy. For ***P*-values** also, the old convention was to say "$P < 0.05$." This is less accurate than something like "$P = 0.045$," which is now commonly done. The more decimal places, the better the accuracy. But in this case, too, having more than three decimals does not help in a statistical assessment of the result. The other statistical example is the use of a **continuity correction**, as for discrete values to continuous values (see **Gaussian probability** as an example). This correction helps in getting more accurate results.

For many medical measurements, accuracy beyond a certain degree does not add to the prediction of occurrence or nonoccurrence of outcomes, but there are instances when a minor variation can cause a substantial ripple effect and a major difference in the outcome. For details, see the topic **butterfly effect**, where an example of cancer is also provided, although in that case, it is not the inaccuracy but the effect of a slight change in the input value.

The term *accuracy* is also used to describe the quality of a method. The accuracy of a method is its ability to reach the true value almost each time. This is evaluated by comparing the values obtained by a method with the known standard values. A more accurate method will provide readings with less error most of the time. For example, Lock and Ronald [1] found the FreeStyle Freedom Life system to be the most accurate method out of the four they compared in meeting the International Organization for Standardization (ISO) standards for blood glucose measurements.

You may find an overlap of usage among the terms *accuracy*, *reliability*, and validity. In scientific literature, this happens because of poor understanding or because of carelessness. For example, Rebel et al. [2] have mixed up the use of the terms *accuracy* and *reliability* while evaluating point-of-care monitoring of blood glucose level. In fact, accuracy is very different from reliability (reliability is the same as precision) and slightly different from validity. Statistical validity of the sample values refers to the average being able to hit the target, whereas accuracy is generally used for single measurements. For further details, see **reliability** and **validity**.

## actuarial method, *see* expectation of life and the life table

## adaptive designs for clinical trials

Adaptive designs allow flexibility to redesign a clinical trial midstream, guided by the interim experience. This can make the trial more efficient by saving time, money, and patients. Suppose that after due consideration of available knowledge, you plan a clinical trial on 1000 subjects in each **arm** with 1-year follow-up. Two months into the trial, you find from **interim analysis** that your anticipations at the planning stage were incorrect and that the trial will give you confirmatory results on efficacy (or a lack of it) in just 6 months (or you need to extend it to 16 months to get an adequate number with the desired end point); or only 700 would suffice (or 1500 would be needed); or that the doses you are trying are too high (or too low) and you need to have a middling dose; or that a concomitant treatment is needed; or that a particular subgroup, such as males of age 70+ years, needs to be excluded. Sometimes, even the baseline information on the enrolled subjects may indicate that modifications in the design are needed. For example, this may tell you that the expected kind of subjects are not being enrolled and that the eligibility criteria need to be changed. In such situations, you would not want to waste resources by sticking to the original plan in the hope of wonders; instead, you would want to adapt the trial to the realities revealed by actual experience.

The need for adaptation arises from the fact that sometimes, all the information needed to plan a near-perfect trial is not available in advance. Besides medical issues such as side effects, biostatistical issues that can affect planning are the variance of the estimate of the **effect size** you wish to consider, expected compliance, and a conjecture of the anticipated effect size itself. When these are not available with a reasonable degree of assurance, you may want to fall back on an adaptive design that allows flexibility. Adaptive designs incorporate practical considerations of possibly not getting the things right first time in the preparation of the design.

Adaptation is planned in advance by anticipating different scenarios that could unfold in the planned trial. Thus, it can handle only limited issues and not those that were unforeseen or ignored. The issues must arise from interim analysis and not from extraneous sources. Changing the features of the trial due to other considerations is not adaptation in the sense we are discussing here. Adaptation is not a substitute for a sloppily planned trial. On the other hand, implicit in all this is that the trial has an immaculate design that has considered all the available information, including what adaptations are to be made in case specific issues are found.

Despite the clear advantages of adaptive trials, they have been rarely used so far. The first difficulty is that the adaptive methodology is still evolving. Secondly, this could involve many features of the design and can be done possibly at several stages of an ongoing trial. It is difficult to visualize in advance where and what adaptations would be required. Thirdly, there is confusion on what all should be considered for adaptation, how to keep **Type I** and **Type II errors** under control despite periodic evaluations, and how to handle logistic problems that arise from adaptation of an ongoing trial. The timing of interim analysis will be stated in the trial's protocol: it will occur at a predefined time, and care is taken that such appraisal does not undermine the integrity and validity of the trial.

When adaptations are done, the analysis becomes computationally complex, for which specially tailored software packages are being developed. Nonetheless, the adaptive strategy is being explored with enthusiasm by drug companies, regulators, and researchers. As experience accumulates, adaptive trials can be better designed and will have wider acceptability. An adaptive trial can quickly move from phase II to phase III since lessons learnt are already incorporated. This can expedite the process of product development. For sure, this strategy can address frustration arising in conventional structured designs when the trial gives negative results and you wish that if something could be done differently, the results would not be so disappointing. Adaptive trials may soon become industry standard as the problems in their implementation are sorted out.

A

Among various adaptations, the biostatistically most relevant is to **reestimate the sample size** on the basis of the actual effect size found at interim stages. You can imagine that the reestimated sample size should only increase and not decrease, although a decision to stop the trial either for efficacy or for futility can be made. That, however, does not mean that the trial is deliberately designed to have a small size. Reestimation requires intricate statistical inputs as this is done to preserve the **level of significance** and the statistical **power**. Such statistical adaptation does not cause many ethical problems; rather, it seems to enhance ethics by keeping a provision to stop the trial early in case convincing evidence of efficacy or of futility (see **stopping rules**).

Interim analysis has the potential to unblind an otherwise blinded trial. Un**blinding** is necessary to assess whether the treatment arm is giving evidence of sufficient efficacy relative to the control arm. Steps are specified at the time of the designing of the trial to determine who will be unblinded (such as the **Data Safety and Monitoring Board**), and how the investigators and the subjects will continue to remain blinded for the trial to go unhindered. The person/team unblinded for interim analysis must be independent of the team of investigators and comprise people who have nothing to gain or lose from the interim analysis. This team should make only indirect statements, such as "the trial will continue for 8 more months" or "will enroll 130 more subjects," so that the integrity of the trial remains intact.

Englert and Kieser [1] have discussed how adaptive designs in phase II cancer clinical trials help in reducing the required number of subjects for coming to a decision. For more details of designs with interim appraisals, see Chow and Chang [2].

## added variable plot

The added variable plot is the plot of **residuals** from a **regression** model that excludes a particular **independent variable** of interest versus the residuals when this particular independent variable is regressed on the remaining variables. Thus, both regressions have the same set of regressors, but the dependent in one case is the actual outcome, and the dependent in the other case is the regressor of interest itself. Consider, for example, regression of $y$ on $x_1, x_2, \ldots, x_{k-1}, x_k, x_{k+1}, \ldots, x_K$ and you are interested in investigating the role of a particular variable $x_k$ as an added variable. The procedure would be to find residuals of regression of $y$ on $x_1, x_2, \ldots, x_{k-1}, x_{k+1}, \ldots, x_K$ (without $x_k$) and the residuals of regression of $x_k$ on the same set of regressors, namely, $x_1, x_2, \ldots, x_{k-1}, x_{k+1}, \ldots, x_K$ (without $x_k$). Plot the first residuals against the second residuals to get an added variable plot. For further details, see Dayal [1].

Thorough study of an added variable plot for patterns might provide useful clues first about any utility of this added variable and second about the functional form of the relationship of the added variable with the outcome, and whether or not there are few influential values. You can decide whether to keep these influential values or to exclude them. Their exclusion may help in achieving better parsimony, and inclusion can give more realistic results.

The information provided by the added variable plot has been found to be more valid than the information provided by the residual plot against this new regressor. This is considered a valuable tool to evaluate all kinds of regressions: ordinary least squares, logistic, and Cox. Statistical software packages generally have a provision to generate added variable plots for all these regressions.

Possibly due to the expertise needed to read a variable added plot, this is rarely used in medical research. We could not find a single medical article in the PubMed database that has used the term "variable added plot." We are still including it here because of its statistical relevance for medical research. An example on this is provided by Chen and Wang [2] in the context of the Cox proportional hazards model.

## additive effect/factors

Suppose you find for your subjects that an increase in **body mass index (BMI)** in men from 32 to 33 kg/m$^2$ is associated with an increase in systolic level of blood pressure (BP) by 3 mmHg on average and that an increase in triglyceride level (TGL) from 150 to 160 mg/dL is associated with 4 mmHg increase in this BP on average. Does this mean that a group of subjects with BMI = 33 kg/m$^2$ and TGL = 160 mg/dL will have an average systolic BP 3 + 4 = 7 mmHg more than the average of group with BMI = 32 kg/m$^2$ and TGL = 150 mg/dL? If yes, the effects of BMI and TGL on systolic BP are called additive. Quite often, these effect sizes do not add up, and the average difference would be either substantially higher or substantially lower. In that case, the factors are said to have an **interaction**. In other words, the absence of interaction indicates that the factors and their effects are additive.

Statistical methods such as **two-way analysis of variance (ANOVA)** and **regression** are relatively simple when the factors are additive. If not, an interaction term also needs to be considered. When you are considering two or more factors together, it is desirable to explore their interaction. Even when factors are additive, results from considering them one at a time can give different results compared to considering them together. For example, results of two one-way ANOVAs are not the same as one two-way ANOVA even when the factors are additive.

The concept of additive effect can be readily extended to the administration of two (or more) drugs. For example, according to Govorov et al. [1], tadalafil and alpha-blocker cotherapy in Russia for lower urinary tract symptoms due to benign prostatic hyperplasia (LUTS/BPH) suggests an additive effect, though such cotherapy is not recommended yet. On the other hand, Iverson et al. [2] found in a small study in the United States that the effect of ingestion of two amino acids (leucine and glycine) on the decrease in glucose response was not additive.

## adjusted effects, *see also* adjusted mean, adjusted odds ratio, adjusted $R^2$

When the effect of an **antecedent** X on **outcome** Y is also affected by another factor Z, the effect obtained after removing the effect of Z is called the Z-adjusted effect of X on Y.

Whenever two or more factors are considered together for their effect on an outcome, their independent effects most likely will be different from their joint effect. The effect of most medical factors depends on what other factors are present. The presence of other factors can be synergistic (enhance the effect) or antagonistic (reduce the effect). For example, the risk of death of a person of age 70 years with kidney disease and diabetes is more than the sum of the risk of death with kidney disease alone and diabetes alone. When both diseases are present, the risk increases steeply. In this case, you can find the effect of diabetes alone after adjusting for the effect of kidney diseases using statistical methods such as **logistic regression**. This will be called the effect of diabetes on the risk of death adjusted for kidney disease. Similarly, you can find the adjusted effect of kidney diseases. Almost any measure of **effect size** can be adjusted for the presence of other factors by suitable statistical methods when the relevant data are available. For example, you can have **adjusted mean**, **adjusted odds ratio**, **adjusted $R^2$**, etc. But be careful in their interpretation. Sometimes, such adjusted effects are interpreted as a net effect or pure effect. This may not be so, since adjustment is done only for those factors that have been included in the analysis. There might be other factors, not included in the analysis, that also might be making a negative or positive contribution. That part is ignored in this kind of statistical adjustment.

## adjusted mean

This is the mean obtained after removing the effect of differential composition of two or more groups so that the means become comparable. Suppose that in a survey of 300 adults, the mean serum folate level (nmol/L) in current, former, and never smokers of different age groups is as given in Table A.1. The age composition of groups is different, and this might affect the mean folate level in different smoking groups. Thus, the mean folate level in current, former, and never smokers is not comparable. They can be made more comparable by proper adjustment for age variation.

The means in column D are calculated with due consideration to the different numbers of subjects in different age groups as is needed for grouped data. This is called the **weighted mean**. For example, the mean serum folate level for current smokers is

$$\frac{6.5\times 80 + 7.0\times 40 + 8.5\times 10}{80+40+10} = 6.8 \text{ nmol/L}.$$

Of the 70 former smokers, 40 are in the age group of 60+ years. This number is only 10 out of 130 in the current smokers. This differential can affect the mean serum folate level because the level depends on age. This mean in column D is unadjusted in the sense that the difference in age distribution is overlooked. The difference in these unadjusted means across smoking status categories is not necessarily real but could be partially due to the difference in their age structure. The effect of age disparity can be removed by calculating the age-adjusted mean. For this, a standard age distribution is required. The age distribution of total subjects (last row) can serve as the standard in this example. When this standard is used on the unadjusted means, the following is obtained:

**TABLE A.1**
**Mean Serum Folate Level (nmol/L) by Age and Smoking Status**

| | Age (Years) | | | Unadjusted Mean for All Adults | Age-Adjusted Mean |
|---|---|---|---|---|---|
| | 20–39 | 40–59 | 60+ | | |
| **Smoking Status** | **A** | **B** | **C** | **D** | **E** |
| Current smokers | 6.5 | 7.0 | 8.5 | 6.8 | 7.1 |
| | (80) | (40) | (10) | (130) | |
| Former smokers | 7.5 | 8.5 | 9.0 | 8.6 | 8.1 |
| | (10) | (20) | (40) | (70) | |
| Never smokers | 7.0 | 8.0 | 9.0 | 7.6 | 7.7 |
| | (50) | (40) | (10) | (100) | |
| **Total** | **6.8** | **7.7** | **8.9** | **7.5** | |
| | **(140)** | **(100)** | **(60)** | **(300)** | |

*Note:* The number of subjects is in parentheses.

The age-adjusted mean serum folate level for current smokers is

$$\frac{6.5\times 140 + 7.0\times 100 + 8.5\times 60}{140+100+60} = 7.1 \text{ nmol/L}.$$

This is obtained by applying the age-specific rates in the group to the standard age structure. This procedure is similar to the procedure used to calculate the directly standardized death rate. Similarly, age-adjusted mean can be calculated for the former smokers and the never smokers. These are given in the last column of Table A.1.

Note that the large difference between the unadjusted means of folate level in current and former smokers decreased considerably in this example after the age adjustment. This implies that much of this difference was due to the differential in the age structure of the subjects in these two categories. This adjustment brought the groups to a common base with respect to age and made them comparable.

The difference between age-adjusted and age-standardized effects is that age adjustment is done for "locally" available age distribution whereas age standardization is done with respect to the standard age structure of the population, which may be extraneous or even imaginary. For example, *age-standardized death rates* across countries can be obtained with respect to an imaginary world standard population, such as the one devised by the World Health Organization [1].

## adjusted odds ratio (adjusted OR), *see also* odds ratio

As the name implies, the odds ratio (OR) is the ratio of the **odds** of the presence of an antecedent in those with a positive outcome to

A

the odds in those with a negative outcome. This ratio needs to be adjusted when the outcome is suspected to be affected by other factors. For example, the presence of oral cancer in any case is affected by whether or not the person consumed smokeless tobacco for a long duration. Let this be the antecedent of interest. But oral cancer can also occur or accelerate by insufficient intake of fruits and vegetables and the presence of leukoplakia. When such concomitant variables, called *covariates*, are ignored altogether, what is obtained is called *unadjusted OR*. But when the analysis is geared to remove the influence of these covariates, adjusted OR is obtained. For example, you may have an unadjusted OR = 12.7 for smokeless tobacco in cases of oral cancer, and after adjustment of the covariates, this may reduce to 8.9. The balance of 3.8 can be attributed to the covariates in the model. Adjusted OR will decrease if the covariates tend to increase the incidence of disease and will increase if the covariates decrease the incidence.

The most common method for finding the adjusted OR is **logistic regression**. In this method, the **logistic coefficients** are the logarithms of respective ORs. This regression can be run with several covariates in the logistic model. Each coefficient provides ln(OR) for that factor, and this is automatically adjusted for the other covariates in the model. In our example, the coefficient of leukoplakia will provide an OR adjusted for the use of smokeless tobacco and insufficient intake of fruits and vegetables, and the coefficient of the use of smokeless tobacco will provide an OR adjusted for insufficient intake of fruits and vegetables and the presence of leukoplakia. The same regression model can provide several adjusted ORs.

Adjusted ORs are often misused. It is incorrect to interpret the adjusted OR as the *net effect* of the antecedent. Sometimes, this is termed the *independent contribution* of the antecedent. This term is also suspect. The adjustment is only for those covariates that are included in your model. There might be other factors that are not present in the model, including those that are unknown but may influence the outcome. Since no adjustment is done for these covariates, adjusted OR does not measure the net effect, or even the independent effect. The best way to understand this is the effect adjusted for the other covariates in the model. In our example, 8.9 is the OR adjusted for intake of fruits and vegetables and the presence of leukoplakia. This is not adjusted for other factors such as family history and exposure to sun, and this is not the net effect either.

Another fallacy commonly occurs in interpreting the adjusted OR when only the **linear effect** of the covariates is considered. Almost invariably, logistic regression is run with linear terms of the covariates. Thus, the adjustment also is for linear effect. If the effect of a covariate has a quadratic, logarithmic, exponential, or any such nonlinear form, that will not be adjusted unless such forms are included in the model.

## adjusted $R^2$, *see also* multiple correlation

In order to understand adjusted $R^2$, first recall $R^2$ itself. This is the square of the **multiple correlation** coefficient, which is defined as the Pearsonian **correlation coefficient** between a variable and the best linear combination of other relevant variables. This is generally obtained between a **dependent variable** $y$ and a combination of **independent variables** $x_1, x_2, \ldots, x_K$ in a multiple linear regression setting. This linear combination is chosen in such a manner that $R^2$ is maximum. The value of $R^2$ is obtained as 1 − SSE/SST, where SSE is the **sum of squares** due to error and SST is the total sum of squares (see **multiple linear regression** to understand these sums of squares). The value of $R^2$ is used to assess how good that linear regression is in explaining or predicting $y$.

One property of $R^2$ is that it improves as more variables are added to the regression. However, adding new variables also results in the loss of **degrees of freedom** (*df's*), and therefore, **statistical significance** does not necessarily improve by adding new regressors—it can even decline. Thus, an adjustment is required for the df's before the value of $R^2$ can be realistically assessed. These df's depend on the number of **regressors** in the model and the sample size. The adjustment is done by dividing the sums of squares by the respective df's. Thus,

$$\text{adjusted } R^2 = 1 - \frac{\text{SSE}/\text{df}_e}{\text{SST}/\text{df}_t},$$

where $\text{df}_e$ is the df for SSE and $\text{df}_t$ is for SST. In terms of the usual $R^2$, this becomes

$$\text{adjusted } R^2 = 1 - \frac{(1-R^2)(n-1)}{n-K-1},$$

where $n$ is the sample size and $K$ is the number of regressors. This adjustment would be substantial if $n$ is small. Since this is adjusted for the number of independent variables, adjusted $R^2$ can also be used to compare two or more regressions with a different number of regressors. For example, in a study on echocardiographic predictors of exercise and mortality in chronic obstructive pulmonary disease in Denmark, lung functions alone (in addition to the baseline variables) provided adjusted $R^2 = 0.475$ for prediction of distance performance in a 6-minute walking test, whereas this became adjusted $R^2 = 0.511$ when echocardiographic variables were also added [1]. The number of regressors in the two models is different—thus, adjusted $R^2$ is the right method to compare the performance of the two models.

A word of caution. Just as with $R^2$, adjusted $R^2$ is also used only for *linear* regressions. If the regression is nonlinear, the corresponding parameter is called the **coefficient of determination** and is denoted by $\eta^2$, as separately explained.

## adjusting for baseline values, *see also* analysis of covariance (ANCOVA)

Baseline adjustment is the adjustment in the results due to a differential baseline in two or more groups. Baseline adjustment is a worthwhile exercise—sometimes an essential requirement—for evaluating any change. This is because change can substantially depend on the baseline values. An effective hematinic regimen may be able to improve hemoglobin level from a baseline of 8–12 mg/dL but would not show similar improvement when the baseline level is already 13 mg/dL. Such a differential response due to a differential baseline is generally anticipated before conducting the study and not afterward. In any case, a rational judgment should be made to decide that the outcome variable for analysis would be the raw values as observed or as the change from baseline. This would mostly depend on the interpretability. In either case, adjustment for baseline should be considered.

Three basic methods are available for baseline adjustment. First is the **stratification** of the subjects by baseline values. This may work when stratification can be done on some objective basis and the sample size is large enough to yield a reasonable size for each stratum. Thus, this should be done before conducting the study. Homogeneity of baseline values within each stratum helps to rule out the effect of baseline. The results should be presented stratum wise in this case. Second is **analysis of covariance (ANCOVA)** as discussed under this topic. You can also include the stratification variable as a covariate if stratification has been done. For ANCOVA, the covariate must be quantitative and should have been suspected to be a variable that has a fairly strong relation with the outcome. Third is a simple analysis of change scores. Change can also be measured in terms of the percentage of the baseline values if that is more appropriate and can be analyzed either by parametric methods that are primarily based on Gaussian distribution such as *t*-test or by nonparametric methods such as the Wilcoxon test when Gaussianity is violated.

ANCOVA generally considers a linear effect of the baseline values, and the tests of hypotheses and confidence intervals require that the distribution of the residuals is Gaussian. When these conditions are met, ANCOVA continues to be the method of choice for baseline adjustment. But this may fail if the change occurs before baseline assessment or if the outcome variable is unreliable or unstable [1]. A good strategy is to analyze data with and without baseline adjustment, and see how adjustment has or has not been helpful.

## adolescent health (epidemiological indicators of)

Epidemiologically, adolescent health is generally measured in terms of the adequacy of physical growth and sexual maturation. Vital changes occur during adolescence that set the basics of adulthood. A spurt in gain in height and weight occurs, and genitals take shape. Pubic hair grows. Menarche occurs, and breasts develop in girls. Variation, as always, remains an integral part of all these developments. Relatively few physical sicknesses occur in this phase of life. Although adolescent health can also be assessed in terms of the parameters that apply to adults, such as smoking and other health behaviors, we restrict our discussion here to the more commonly used epidemiological indicators.

### *Growth in Height and Weight in Adolescence*

Most countries have not developed standards for growth in height and weight during adolescence. The National Center for Health Statistics (NCHS) data, obtained for US children and adolescents [1], are often used for comparison. Maximum growth in median height in 1 year occurs during the 13th year in US boys (7.5 cm) and during the 11th year in girls (7.5 cm). This maximum in British children occurs around the 14th year and the 12th year, respectively [2]. Many children show slower or delayed growth mostly due to genetic and nutritional factors. A child's measurement can be compared with the NCHS **growth chart** or the chart of the child's native country (where available) to assess the progress of growth. The assessment is in terms of the **percentile** achieved.

Preece and Baines [3] have developed models that can be used to evaluate height parameters such as height for age, velocity at start of growth spurt, age at peak height velocity, and peak height velocity. These parameters have special relevance to the adolescent group.

Short stature in adolescent girls that persists into adulthood is associated with increased risk of adverse reproductive outcomes. The risk of low-birth-weight babies, cephalopelvic disproportion, dystocia, and cesarean section increases in short mothers. No specific health risk is known for short-statured boys.

### *Sexual Maturity Rating*

Breast development in females, the appearance of pubic hair in both boys and girls, and the development of male genitalia are graded into stages from 1 to 5, where the first is the preadolescent stage and the last is the fully matured adult stage. One can think of these stages as scores and use them as measures of the extent of pubertal development. This can be related to age to find whether or not development is on course. Clear guidelines on this are not yet available and need to be developed separately for each population depending on the rate of sexual maturation generally seen in healthy adolescents in that population.

## adult health (epidemiological indicators of)

The health of an adult can be measured in several dimensions. The discussion in this biostatistics book is restricted to some epidemiological indicators of general health and excludes particular diseases. Nonetheless, physiological functions such as of the kidney, liver, lung, and heart can be measured to assess health at an individual level.

Among epidemiological indicators of adult health, the most prominent is **obesity**. As described under that topic, this can be measured by body mass index, waist–hip ratio, skinfold thickness, and several other indicators. Second is smoking. For comprehensively measuring this, see the **Indrayan smoking index**, which includes not just cigarette-years but also age at the start of smoking; intermittent smoking; smoking of other products such as cigars, pipes, and *bidi*; years since cessation by ex-smokers; etc. Different aspects of **quality of life** are measured in social, mental, and physical health domains. Several other such measures can be devised to meet specific objectives.

## adult literacy rate, *see* education indicators

## adverse effects and adverse patient outcomes

Adverse effects of medical interventions are those effects of an intervention that are detrimental to the health of the person who gets the intervention. These effects could be transient or long term.

A

These may also be called **side effects**. The intervention could be advice, a drug, surgery, a device, or any such maneuver. No intervention is completely free of side effects—thus, the convention is to refer to relatively serious side effects as adverse effects. This makes it subjective, and no widely acceptable definition is available for severity. However, there is some consensus regarding when a side effect can be called rare and when it is common. This is as follows:

Very common: ≥1/10
Common: ≥1/100 and <1/10
Uncommon: ≥1/1000 and <1/100
Rare: ≥1/10,000 and <1/1000
Very rare: <1/10,000

Adverse effects are gradually gaining prominence, perhaps even more than efficacy, as awareness is increasing. Patients do not want to end up with some other ailment while undergoing treatment of their disease. They also want to be fully warned of the adverse effects up front so that an informed decision can be made to go ahead with the treatment or not, or to look for an alternative strategy. For this reason, the pharmaceutical and medical device companies are now more sensitive to such effects of their product. Regulatory agencies also seek data on adverse effects from the companies who want license to produce and market such products.

Although phase III trials (see **phases of clinical trials**) are designed to gather the data on adverse effects, the follow-up cannot be very long in this phase. Some adverse effects show up after sustained use of the drug for chronic diseases such as hypertension and diabetes that need almost lifelong treatment. Some adverse effects show up long after the treatment is discontinued. Thus, **postmarketing surveillance** (phase IV trial) is considered the most dependable methodology to discover such effects. There are many instances when a drug or a treatment strategy is retracted when such adverse effects are reported. After years of intake of aspirin as a preventive medication for minimizing the chance of heart attacks, the Food and Drug Administration (FDA) of the United States now concludes that the data do not support the use of aspirin as a preventive medication by people who have not had a heart attack, stroke, or cardiovascular problems [1]. In such people, the benefit has not been established, but risks—such as dangerous bleeding into the brain or stomach—are still present. You can see how adverse effects can remain unnoticed for years when millions have adopted the drug in good faith.

Another related term is *adverse patient outcomes*. Here, the focus is on the outcome instead of the intermediary events. Instead of being improved, if the health of a patient deteriorates or experiences adverse effects after the intervention, this is called adverse patient outcome. This can occur either because of inadequate care in a health facility or due to inappropriate intervention. Lapses such as late or missed medication can also cause adverse patient outcomes. Nosocomial and urinary tract infections in inpatients and complaints from patients are commonly used criteria for classifying them as adverse patient outcomes. The magnitude of such outcomes is a potent tool for measuring the quality of services and of interventions. Statistically, this is used as an index for **quality control** in a health setup. Sometimes, adverse patient outcomes form a basis for insurance claims or any such compensation to the patient.

Beside categorization into care- and intervention-related categories, adverse effects may also be classified as perceived or reported; preventable or nonpreventable; temporary or permanent; and also minor, major, or grave. For quality control purposes, preventable adverse outcomes are important. Two major sources attributed to such adverse outcomes are poor nursing services and toxic effects of drugs. For nurses, this could be due to either heavy workload [2] or inadequate training [3]. This source obviously applies to a hospital setup only, whereas toxic effects of drugs will mostly occur in a domiciliary setup.

## affinity, *see also* measures of dissimilarity and similarity

In statistics, affinity is the closeness of one set of values with another set. The term is generally used for groups rather than individuals. Similarity seems a more appropriate term for individual values. However, affinity between groups depends on similarity of individual values belonging to different groups.

Conventional similarity measures are applicable to quantitative values. The value 12 is closer to the value 14 than the value 8. This is easily seen in a univariate case such as this but not as obvious in a **multivariate** situation. Consider aspartate aminotransferase (AST) units per liter, alanine aminotransferase (ALT) units per liter, and total bilirubin (mg/dL) in persons suspected to have liver disease. Let these values in three persons be (22, 35, 3.2), (20, 38, 2.8), and (25, 27, 3.2). In such a multivariate setup, which two subjects have more similarity with regard to these values? Or, which of the other two persons has more similarity with the first person with respect to these parameters? See **measures of dissimilarity and similarity** in this volume, which can be used to assess similarity between individuals in different groups. Some of these can be used for assessing affinity in groups in a multivariate setup.

For affinity in groups with qualitative values, separate measures are available for binary categories and for polytomous categories. This is measured by associations as described under the topics **association between dichotomous characteristics** and **association between polytomous characteristics**.

Affinity measures are needed for **cluster analysis** and used in some other statistical setups also. But the term is frequently used in the medical context as well with varied meaning. Affinity of chromatography columns is commonly assessed for, say, binding of drugs. Galli et al. [1] discuss the affinity of endocrine active substances and their metabolites toward the ligand binding domain of the androgen receptor in three distantly related species, namely, human, rat, and zebrafish. This needs quite complex mathematics. Chaudhury et al. [2] talk about B-cell affinity maturation, which explains enhanced antibody cross-reactivity induced by a malaria vaccine. These illustrate the varied uses of the term in medical literature.

## age–period–cohort analysis

Age–period–cohort analysis is used to segregate the effect of age, period, and cohort on an outcome in a **time series** setup where observations at different ages are available for people born over a long period of time. Age, the calendar date of the study (called *period*), and the year of birth (called *cohort*) all can have an independent effect on health parameters. For example, people born in 1930 may have had different health problems at the age of 65 years than those born in 1960. This can happen because the nutrition pattern may have changed in these 40 years; people may have become more conscious about exercise, life may have become more stressful, etc. In other words, **birth cohort** itself may have an independent effect. The age effect is already well known—health problems at the age of 65 years are different than, say, at the age of 30 years. *Period* is the term used for the calendar year of the end point. For those born in 1930, age 65 years is reached in 1995, and for those born in 1960, this period is the year 2025. Results may differ just because the period differs. This can happen due to factors such as changes in the inclusion criteria, different **sampling techniques**, and migration in surveys at different points in time. Those aged 65 years in 2025 may be exposed to much better connectivity, and this could have revolutionized their attitude and care compared to those aged 65 in 1995.

In this setup, the change in values at the end point relative to the starting point contains the effect of age, period, and cohort. The statistical problem is to find the independent effect of each of these factors. The challenge arises due to the fact that period = cohort + age. Given any two, the third can be exactly obtained. Because of this rather perfect **collinearity**, the usual **regression** techniques fail, and all three cannot be simultaneously estimated within the usual regression setup. A method called **partial least squares** is generally used in this setup. This method extracts components of independent variables that have the highest covariance with the dependent variable. For example, Jiang et al. [1] studied trends in body mass index (BMI) in males and females of different ages in Ireland by measuring them in the years 1998, 2002, and 2007. They found the first extracted component $w_1$ = 0.029 * age + 0.039 * period − 0.026 * cohort for males. This shows that men born later had lower BMI than those born earlier (cohort effect = −0.026 units per year as per the coefficient in this component), older men had higher BMI than younger men at the time of examination (+0.029 units per year), and the period effect at +0.039 units per year in these subjects was the highest among these three [1]. The last shows that, possibly, the survey methods at different points in time were different, and that also contributed to the decrease in BMI over this period.

Another example of the cohort effect is as follows. Recently, a controversy erupted over a cardiovascular risk model in the US population of age 40–79 years. It was found to overestimate the risk by almost twice as much as it should in some cases. It appears that the problem arose because the cohorts underlying the model are over a generation old, with enrollment years beginning in the late 1980s and early 1990s. Major population changes have occurred in the past two decades. People now smoke less, and awareness about the harms of high cholesterol has increased. Thus, the risk one generation ago is unlikely to represent the risk of contemporary 40- to 79-year olds [2]. This is in addition to the fact that those who were 40 years old at that time are 70 years old now (although they continue to be in the age bracket of 40–79 years) and have different risk due to aging and longer exposure to the risk factors.

In place of partial least squares, the **mixed effects models** can also be used for age–period–cohort analysis [3]. The method is too intricate for this book for medical professionals.

## age-specific death rates, *see* death rates

## agglomerative methods, *see* hierarchical clustering

## agreement assessment (overall), *see also* Bland–Altman method of agreement

When a measurement is taken by two methods, at two times, at two sites, by two observers, etc., on the same set of subjects, the assessment of agreement between these measurements can be useful in many situations. For example, new instruments are invented and new methods are discovered that measure anatomical and physiological parameters with less inconvenience and at a lower cost. We do want to assess how much they agree with the existing method. Acceptance of any new method depends on a convincing demonstration that it is nearly as good as the established method, although the established method may also be in error.

Irrespective of what is being measured, it is highly unlikely that the new method would give exactly the same reading in each case as the old method even if they are equivalent. Some differences would necessarily arise. How do you decide that the new method is interchangeable with the old? The problem is described as one of agreement. This is different from evaluating which method is better. The assessment of "better" is done with reference to a gold standard. Assessment of agreement does not require any such standard.

The term *agreement* is used in several different contexts. The following discussion is mostly restricted to a setup where a pair of observations ($x$, $y$) is obtained by measuring the same characteristic on the same subject by two different methods, by two different observers, by two different laboratories, at two anatomical sites, etc. Later, we briefly describe a method for assessing agreement when the measurements are different, such as body mass index (BMI) and skinfold thickness for assessing obesity.

The measurement could be qualitative or quantitative. The method of assessing agreement in these two setups is different.

A

## Agreement in Quantitative Measurements

The problem of agreement in quantitative measurement can arise in at least five different types of situations: (i) comparison of self-reported values with the instrument-measured values, for example, urine frequency and bladder capacity by patient questionnaire and frequency–volume chart; (ii) comparison of measurements at two different sites, for example, paracetamol concentration in saliva and that in serum; (iii) comparison of two methods, for example, bolus and infusion methods of estimating hepatic blood flow in patients with liver disease; (iv) comparison of two observers, for example, duration of electroconvulsive fits reported by two psychiatrists on the same group of patients, or of two laboratories when, for example, aliquots of the same sample are sent to two different laboratories for analysis; (v) **intraobserver consistency** in evaluating reliability of the method or of the observer, for example, measurement of anterior chamber depth of an eye segment two times by the same observer using the same method. In the first four cases, the objective is to find whether a simple, safe, less expensive procedure can replace an existing procedure. In the last case, it is an evaluation of the reliability of the method.

The statistical problem in all these cases is to check whether or not a $y = x$ type of relationship exists in *individual* subjects. This looks like a regression setup $y = a + bx$ with $a = 0$ and $b = 1$, but that really is not so. The difference is that, in regression, the relationship is between $x$ and the average of $y$. In an agreement setup, the concern is with individual values and not with averages. Nor should agreement be confused with high correlation. Correlation would be nearly 1 even if there is a systematic bias and nearly the same difference occurs in every subject. The following example illustrates the distinction between $y = x$ regression and agreement.

The following are hemoglobin (Hb) values reported by two laboratories for the same blood samples:

| | |
|---|---|
| Lab 1 ($x$) | 11.3 12.0 13.9 12.8 11.3 12.0 13.9 12.8 |
| Lab 2 ($y$) | 11.5 12.4 14.2 13.2 11.1 11.6 13.6 12.4 |

$$\bar{x} = 12.5 \quad \bar{y} = 12.5 \quad r = 0.945$$

$$\hat{y} = x \text{ , i.e., } b = 1 \quad \text{and} \quad a = 0$$

The two laboratories have the same mean for these eight samples and a very high correlation (0.945). The **intercept** $a$ is 0, and **slope** $b$ is 1.00. Thus, the regression is $y = x$. Yet there is no agreement in any of the subjects. The difference or error ranges from 0.2 to 0.4 g/dL. This is substantial for Hb level in the context of the present-day technology. Thus, equality of means, a high degree of correlation, and regression $y = x$ are not enough to conclude agreement. Special methods are required.

If you notice carefully, the first four values of $x$ in this example are the same as the last four values. The first four values of $y$ are higher and the last four values are lower by same margin. Thus, for each $x$, $\bar{y} = x$, giving rise to the regression $\hat{y} = x$. In this particular case, the correlation coefficient also is nearly 1.

## Approaches for Measuring Quantitative Agreement

The conventional method for measuring agreement in quantitative measurements is the popular **Bland–Altman method** [1], also called the limits of disagreement approach. The other approach is **intraclass correlation** [2]. Both of these are described in this volume under the respective terms. Indrayan [3] has compared these two approaches and listed their merits and demerits. Alternative methods are as follows.

The limits of disagreement approach of Bland and Altman is based on the average difference and has the same limitation as applicable to all averages. For example, this approach does not work if the bias or error is proportional. Fasting blood glucose level varies from 60 to 300 mg/dL or more. Five percent of 60 is 3 and of 300 is 15. The limits of disagreement approach considers them different and ignores that both are 5% and proportionately the same. Also, if one difference is 10 and the other is 2, not necessarily proportional, the limits of disagreement approach generally considers the average. Individual differences tend to be overlooked as outliers. This ignores the fact that a few unusually large differences distort the average and are not properly accounted for except by disproportional inflation of the standard deviation (SD).

To account for small and big individual differences as well as proportional bias, it may be prudent to set up a clinical limit that can be tolerated for individual differences without affecting the management of the condition. Such limits are required anyway for the limits of agreement approach also, albeit for the average. These clinical limits of indifference can be absolute or in terms of percentage. If not more than a prespecified, say, 4% of individual differences are beyond these limits in a large sample, you can be safe in assuming adequate agreement. This does not require any calculation of mean and SD. You may want to add a condition, such as that none of the differences should be more than two times the limit of indifference. Any big difference, howsoever isolated, raises alarm. A plot of $y$ versus $x$ can track that the differences are systematic or random.

As an example, consider the following data on fasting blood sugar level in 10 blood samples.

| | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| Method 1 ($x$) | 86 | 172 | 75 | 244 | 97 | 218 | 132 | 168 | 118 | 130 |
| Method 2 ($y$) | 90 | 180 | 73 | 256 | 97 | 228 | 138 | 172 | 116 | 132 |
| $d = x - y$ | –4 | –8 | +2 | –12 | 0 | –10 | –6 | –4 | +2 | –2 |
| 5% of $x$ | 4.30 | 8.60 | 3.75 | 12.20 | 4.85 | 10.90 | 6.60 | 8.40 | 5.90 | 6.50 |

Suppose method 1 is the current standard, although this can also be in error. Method 2 is desperately cheap and gives instant results. For example, method 1 could be the usual venous blood–based estimation of glucose level, and method 2, based on capillary blood. Suppose also that clinicians are willing to accept 5% error in view of distinct advantages of method 2. Note that this indifference is in percentage and not an absolute value.

None of the differences exceed the clinical limit of indifference in this sample. Thus, method 2 can be considered in agreement with method 1, although a larger sample is required to be confident. However, most differences are negative, indicating that method 1 generally provides lower values. The average difference is 4.2 mg/dL in absolute terms and nearly 3% of $y$ in relative terms. This suggests the correction factor for bias. If you decide to subtract 3% of the level obtained by method 2, you can get very close to the value obtained by method 1 in most cases.

Now forget about 5% tolerance, and note that some differences are small and some are quite large in this example. Since the SD of the differences $s_d = 2.80$ in this case, the Bland and Altman limits of disagreement are

$$-4.2 \pm 2 \times 2.80, \quad \text{or} \quad -9.8 \quad \text{to} \quad +1.4.$$

These limits may look too wide and beyond clinical tolerance, particularly on the negative side. These limits do not allow larger error for larger values that proportionate considerations would allow. Also, these are based on the average and do not adequately consider individual differences. If 1 out of 10 values shows a big difference, this can distort the mean, inflate the SD and provide unrealistic limits of disagreement. The alternative approach just suggested can be geared to allow not more than 5% individual differences beyond the tolerance limit, and you can impose an additional condition that none should exceed by, say, 10% of the base value. Since it is based on individual differences and not the average, this alternative approach may be more appealing too.

Another modification of the Bland–Altman method is in comparison of two entirely different measurements. For example, you might be interested in finding out whether assessing obesity in individuals by BMI and skinfold thickness gives the same result or not. If they give the same result, BMI is much simpler. These two measurements are on entirely different scales, and the usual Bland–Altman method is not applicable. However, both these can be converted to ***z*-score** or ***T*-score** for each person. Once this is done, both are on the same scale and can be compared. Now you can use the Bland–Altman method on these converted scores and assess agreement as usual.

### *Agreement in Qualitative Measurements*

Assessment of optical disk characteristics by two or more observers, results of Lyme disease serological testing by two or more laboratories, and comparison of x-ray images with Doppler images are examples of the problem of qualitative agreement. The objective is to find the extent of agreement between two or more methods, observers, laboratories, etc. In some cases, for example, in a comparison of two laboratories, agreement has the same interpretation as **reproducibility**. In the case of comparison of observers, it is termed **interrater reliability**. In all these cases, only one group of subjects is assessed twice. Thus, this is a matched pairs setup.

For simplicity, for the time being, consider only the presence or absence of a characteristic assessed by two observers in the same group of subjects. An example is the presence or absence of a lesion in x-rays read by two observers. Suppose the observations are as given in Table A.2.

The two observers agree on a total of (29 + 11 =) 40 cases in this example. This is the sum of the frequencies in the leading diagonal cells. In the other 20 cases, the observers do not agree. Apparently, the agreement = 40/60 = 66.7%. But part of this agreement is due to chance, which might happen if both are dumb observers and randomly allocate subjects to present and absent categories. This chance agreement is measured by the cell frequencies expected in the diagonal when the observers' ratings are independent of one another. These expected frequencies are obtained by multiplying the respective marginal totals and dividing by the grand total, as obtained for calculating the **chi-square**.

**TABLE A.2**
**Presence or Absence of a Lesion Assessed by Two Radiologists in X-Rays of 60 Suspected Cases**

| | Observer 1 | | |
|---|---|---|---|
| **Observer 2** | **Present** | **Absent** | **Total** |
| Present | 29 | 7 | **36** |
| Absent | 13 | 11 | **24** |
| **Total** | **42** | **18** | **60** |

For the data in Table A.2, the chance-expected frequencies are $36 \times 42/60 = 25.2$ and $24 \times 18/60 = 7.2$ in the two diagonal cells. The total of these two is 32.4. Agreement on so many cases is expected by chance alone. Thus, agreement in excess of chance is in only 40 – 32.4 = 7.6 cases. The maximum possible excess is 60 – 32.4 = 27.6. A popular measure of agreement is the ratio of the observed excess to the maximum possible excess, in this case, 7.6/27.6 = 0.275 or 27.5%. Thus, the two observers in this case do not really agree much on rating of x-rays for the presence or absence of lesion. Most of their agreement is due to chance.

The method just described is for 2 × 2 tables. A general method for assessing quantitative agreement is **Cohen kappa**. This can be used when each measurement is categorized into more than two categories. In the case of ordinal categories, it also raises the possibility of near agreement, such as one method rating an object as excellent and the other rating it as good. They do not exactly match but are close. For this, one can use weighted kappa, as discussed under Cohen kappa or the **Bangdiwala *B***-statistic [4]. There are several other measures of **association between dichotomy characteristics**, as separately discussed. These include the Jaccard coefficient and Yule *Q*. These actually are for association in dichotomy categories but can be construed to measure agreement as well.

## agreement charts

These charts graphically depict the extent of **agreement** between two **ordinal** measures. This applies when the same attribute is assessed by two methods, two observers, two sites, etc. on *n* different subjects by using an ordinal scale, and the objective is to depict the extent of concordance. The corresponding numerical measure is **Cohen kappa**. This chart serves as a good complement to the value of kappa but cannot replace it.

Table A.3 contains data on diagnoses of the same 69 suspected cases of multiple sclerosis by two independent neurologists. The diagnosis is in four ordinal categories from "certain" to "no." The agreement between the neurologists is clear for the cases in the diagonal, i.e., 5, 11, 3, and 14. These are shown by dark rectangles in Figure A.2. This would be called an agreement chart even when the shades of gray are absent. Such a chart without shades of gray can be drawn for nominal categories also. Shades of gray can be explained as follows for ordinal categories.

For ordinal categories as in Table A.3, we can go a step further, realizing that there is some degree of agreement between contiguous

A

**TABLE A.3**
**Assessment of Multiple Sclerosis in 69 Cases by Two Neurologists**

| Multiple Sclerosis Diagnosis | | Winnipeg Neurologist | | | | Total |
|---|---|---|---|---|---|---|
| | | Certain | Probable | Possible | No | |
| New Orleans neurologist | Certain | 5 | 3 | 0 | 0 | **8** |
| | Probable | 3 | 11 | 4 | 0 | **18** |
| | Possible | 2 | 13 | 3 | 4 | **22** |
| | No | 1 | 2 | 4 | 14 | **21** |
| **Total** | | **11** | **29** | **11** | **18** | **69** |

*Source:* Bangdiwala SI, Shankar V. *BMC Med Res Methodol* 2013 Jul 29;13:97. http://www.biomedcentral.com/content/pdf/1471-2288-13-97.pdf.

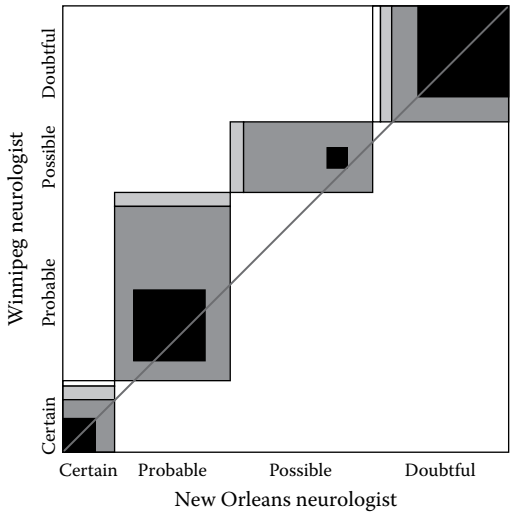

**FIGURE A.2** Agreement chart for comparing multiple sclerosis diagnosis by two neurologists. (From Bangdiwala SI, Shankar V. *BMC Med Res Methodol* 2013 Jul 29;13:97. http://www.biomedcentral.com/content/pdf/1471-2288-13-97.pdf.)

categories and less agreement between distant categories. This means that if one observer calls it "probable" and the other "possible," there is some agreement compared with if one says "probable" and the other says "no." This can be termed *partial agreement* of different degrees and can be shown by progressively declining shades of gray as in Figure A.2. The areas are proportional to the numbers in different cells of Table A.3.

The actual procedure for an agreement chart is to draw $K$ rectangles of dimensions proportional to the respective row and column totals at the diagonal position from the lower left to the upper right inside an $n \times n$ square, where $K$ is the number of categories and $n$ is the total number of subjects. Then these rectangles are filled up with black in the proportion of the complete agreement and shades of gray for partial agreement of different degrees. These charts can be directly obtained through some statistical software packages, such as SAS.

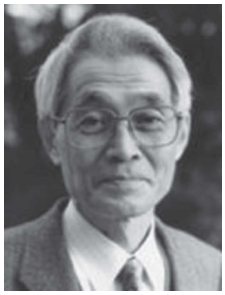
## AIC, *see* Akaike information criterion (AIC) and general AIC (GAIC)

## Akaike information criterion (AIC) and general AIC (GAIC)

The Akaike information criterion (AIC) is used to select one of many potential **models** such that the chosen model is relatively simple yet is a good fit to the data. A paper on this criterion was first published by Hirotugu Akaike in 1974 [1], but it became popular after its English generalization appeared in 2002 [2]. One of its early applications is in evaluating pharmacokinetic equations [3].



Hirotugu Akaike

AIC is based on the method of **maximum likelihood**. This method provides those estimates of the parameters of a model that make the observed sample values most likely. For computational convenience, log-likelihood is maximized in place of the likelihood itself. Logarithms tend to linearize the likelihood function in most cases. Since likelihood is a probability between 0 and 1, log-likelihood will always be negative. Thus, instead of log-likelihood, $-2\ln L$ is used, where $L$ is the notation for likelihood. This not only makes it positive but also is easy to handle as the distribution of $-2\ln L$ is known (chi-square) for many situations. Because of the minus sign in this, those estimates are chosen in a model that minimizes $-2\ln L$. This is the same as maximizing $L$.

In the case of multiparameter models such as **regression**, it is known that the larger the number of independent variables, the better the fit. In this case, the regression coefficient of each independent variable is a parameter. However, an increased number of parameters also makes the model more complex, less parsimonious, and more difficult to adopt in practice. Thus, the aim is to choose a model that has a minimum number of parameters, yet the likelihood

remains relatively high. To balance the number of parameters and the likelihood, the number of parameters is used as a *penalty* on the likelihood. This gives rise to the AIC, defined as

$$\text{AIC} = -2\ln L + 2K,$$

where $K$ is the number of free parameters. This $K$ is similar to the *degrees of freedom* in other setups. Note that AIC penalizes likelihood for a higher number of parameters. The parameter estimates obtained by this method are called **penalized likelihood** estimates. This method obtains those estimates that minimize AIC. This is an approach in between goodness of fit and simplicity where parsimony is balanced with good predictivity. The following comments may be helpful in application of AIC to real-life situations.

- To answer the question "From which model have our observed values most likely come?", calculate AIC for all potential models and select the one with minimum AIC. Statistical packages are available that do this calculation for you.
- AIC is asymptotic, i.e., it works well only for large $n$.
- AIC is mostly used for regressions or models depicting trend. This is considered an improvement over **stepwise methods** since some aspects of stepwise methods are subjective.

The penalty in AIC is $2K$. In some situations, a higher number of parameters severely compromises parsimony. In those situations, you can incorporate a higher penalty for the number of parameters. When this is done, this is called generalized AIC (GAIC). In general, you can have

$$\text{GAIC}(p) = -2\ln L + pK.$$

For example, in the case of the **Box–Cox power exponential (BCPE) method** of finding centile curves for the growth of children, $p = 3$ is preferred. In the usual AIC, $p = 2$.

## aleatory uncertainties, *see also* epistemic uncertainties

Aleatoricism is the incorporation of chance into the process of creation. The word derives from Latin word *alea*, the rolling of dice. Aleatory uncertainties can be understood as those arising from factors internal to the system. They are inherent, unpredictable, and stochastic in nature. For further details, see Indrayan [1]. The other type of uncertainty is epistemic, which arises from limitation of knowledge. The details of **epistemic uncertainties** are separately given. We can divide them into the following categories for effective control.

- Biological—nonmodifiable (age, gender, heredity or genetic makeup, birth order, height, etc.)
- Biological—modifiable (anthropological, physiological, biochemical parameters)
- Socioeconomic factors (income, education, and occupation) that can affect personal hygiene, nutrition, and self-esteem
- Cultural, behavioral, and psychological (mental status, family system, faith in prayers, sexual practices, addictions, personality traits, tension–anxiety–stress, etc.)
- Observers, instruments, and laboratories, i.e., avoidable variation in measurements
- Environmental (climate, dust, mosquitoes, flies, pollution, sanitation, water supply, infection load, quality and quantity of health facilities, family and societal support, communication, traffic, laws and their enforcement, etc.)
- Multifactorial (lifestyle, hygiene, nutrition, knowledge–attitude–practices, susceptibility, utilization of health services, etc.; importantly, **sampling errors/fluctuations**)

One important feature of aleatory uncertainties is that they are **empirical** and can be evaluated by **probability**. The second aspect of aleatory uncertainty, particularly in medical research, is its control. This is achieved by developing a design that can provide evidence largely free of aleatory variation encumbrances. Since the sources of aleatory uncertainties are known, an appropriate design can indeed be developed. **Uncertainty analysis** is one of the tools that help to delineate aleatory uncertainties by providing intervals within which the results are likely to lie under varying conditions.

## algorithm (statistical)

An algorithm is a set of systematic rules for accomplishing a particular objective. The diagnostic algorithm, for example, is to elicit signs and symptoms, order and assess laboratory and radiological investigations, place all the information in the context of the patient concerned, and evaluate the probabilities of various competing diagnoses. In biostatistics, the term is generally used for the specifics of a step-by-step procedure to be followed in a statistical method. Many times, they refer to the computer coding for various calculations. If this is your interest, you may want to see Weihs et al. [1] for statistical algorithms in freely available R packages.

In the case of **stepwise regression**, for example, the algorithm could either be forward selection, backward elimination, stepwise, or best subset. Each of these has steps of what to do. In **classification and regression trees**, the tree algorithm, as the name suggests, devises split nodes that generate branches by using if-then rules. **Path analysis** provides an algorithm for decomposing effect into direct and indirect within the postulated model. For **cluster analysis**, two broad categories of algorithms are hierarchical agglomerative and hierarchical divisive. For **reestimation of sample size** in case of **adaptive trials**, many algorithms are available, such as those devised by **O'Brien–Fleming** and **Lan–deMets**. A recent development is statistical algorithms for monitoring gene expression (see, for example, Ref. [2]). There are many other statistical algorithms that can be cited.

## allocation of subjects, *see also* random allocation

The term *allocation of subjects* is generally used in the context of **clinical trials** where the trialist has to decide which person or patient will receive which "treatment." These treatments could be a **placebo**, an existing standard, or a new regimen under trial and its variations such as different dosages or different routes of administration. Subjects receiving a particular treatment form a group. Thus, allocation of subjects is done to various groups with some specific objectives in mind.

The method followed for allocation of subjects to different groups has significant bearing on the results. If mostly severe cases or mostly old-age cases happen to receive the new treatment, the trial may unnecessarily provide evidence against the **efficacy** of the treatment. Thus, a preset and well-thought-out method is followed for allocation of the subjects. This method is explicitly stated in the **protocol** itself as part of the design of the trial much before the trial begins.

The most popular method and perhaps the most appropriate is **random allocation**. This gives an equal chance to the eligible subjects of being allocated to any of the groups under trial. Thus, many unknown or unaccounted-for factors that can influence the results tend to equalize among the groups, and this helps in getting unbiased results. Subjective allocation, such as alternating between the groups, is not considered random even if the investigator justifies it by saying that he/she allocated without any bias. It is necessary that a scientifically accepted method of random allocation be adopted.

Random allocation can be done in various ways, such as simple, **block, cluster, and stratified randomization**. Sometimes due to exigencies, **quasi-random allocation** is done. In addition, the allocation is, many times, concealed from the participants, resulting in **blinding**, so that unbiased responses can be elicited. The term *participants* in blinding refers to not only the subjects but also the assessors and possibly the data analysts, who can also be biased.

## alternative hypothesis, *see* null and alternative hypotheses

## alpha error, *see* level of significance

## alpha-spending function, *see also* Lan–deMets procedure

In some medical studies, particularly in a **clinical trial** setup, the data are sometimes periodically examined in an ongoing trial as per the predetermined scheme to assess if it is worth continuing or it is better to stop. Stopping can be either because sufficient evidence of the efficacy of the regimen under test has already emerged or because the interim data convincingly indicate that the regimen lacks the required efficacy—thus, it is futile to continue. When such **interim analyses** are done, each analysis commits its own **Type I error** of wrongly rejecting a **null hypothesis**. Thus, the total Type I error, also called alpha error, can exceed its stipulated limit. For keeping it under control, each comparison at interim stages is done at a much smaller level. In other words, a small portion of the available alpha error is spent at each stage of analysis. The rule that sets the limit of alpha error at each interim analysis is called the alpha-spending function. This function tells us how much alpha error can be allowed at the first interim analysis, how much at the second interim analysis, etc.

Among popular alpha-spending functions are the **O'Brien–Fleming procedure** and **Lan–deMets procedure**. These are described as separate topics. The alpha-spending function is flexible, and its details and those of the interim analysis proposed to be used should be fully specified with complete justification in the **protocol** itself so that no subjectivity creeps in at a later stage.

## analysis of covariance (ANCOVA)

This is a method of adjusting the effect of a covariate on a quantitative outcome while preserving the effect of the real factors under study. You may be aware that in both **regression** and **analysis of variance (ANOVA)**, the dependent variable is quantitative. However, in the case of regression, the independents too are quantitative, whereas in the case of ANOVA, they are qualitative. What should one do if the independent set contains both quantitative and qualitative factors and the dependent set continues to be quantitative as before? The answer is analysis of covariance (ANCOVA). You can see that ANCOVA sits between regression and ANOVA. The primary purpose of ANCOVA is to adjust the results for covariates that can affect the results—thus providing unbiased results for the effect of the main variables under study. This method is commonly used also for **adjusting for baseline** imbalances. ANCOVA is a generalized procedure and is mathematically intricate even when only the linear effect is considered. As for other mathematically intricate topics, we are explaining only the underlying principles and their application, and not the formulas.

Consider determinants of body mass index (BMI) of adults of aged 20–49 years. This is the dependent variable $y$ in this setup and is calculated exactly as weight/height.[2] Among several determinants of BMI that can be considered, the important ones are gender (male or female); physical activity (none, mild, moderate, or heavy); and fat and carbohydrate intake (g/day). Note that these variables affect each other, and any conclusion based on any one variable in isolation may be misleading. Thus, all the variables should be considered together. If the primary interest is in knowing the relationship between BMI and physical activity and gender, it needs to be adjusted for the accompanying differentials in dietary intake. In this situation, dietary intake of fat and carbohydrate are the covariates. This adjustment is done by ANCOVA. It is similar to ANOVA of BMI on gender and physical activity on **residuals** after removing the effect of dietary differentials. Adjusted analysis can give very different results from unadjusted analysis. The result also depends on what and how many covariates are included in the analysis.

For running ANCOVA, the quantitative covariates remain as they are, but the qualitative covariates are assigned values (0, 1) through the **indicator variable**. In the BMI example, suppose $x_1$ is the fat intake and $x_2$ the carbohydrate intake. For sex, the indicator variable could be $x_3$, with $x_3 = 0$ for males and $x_3 = 1$ for females. For physical activity, since there are four categories, the indicator variables can be defined as follows:

For no physical activity: $x_4 = 0$, $x_5 = 0$, $x_6 = 0$
For mild physical activity: $x_4 = 1$, $x_5 = 0$, $x_6 = 0$
For moderate physical activity: $x_4 = 0$, $x_5 = 1$, $x_6 = 0$
For heavy physical activity: $x_4 = 0$, $x_5 = 0$, $x_6 = 1$

The number of indicator variables is one less than the number of categories. But this takes care of all the categories, and no category is left out in the cold. Now a regression is run with $x_1, x_2$, $x_3$, $x_4$, $x_5$, and $x_6$ as the regressors. The corresponding **regression coefficients** measure the contribution of each variable and each category, and this contribution is now adjusted for the other variables included in the model. Note the following:

- All covariates must be prespecified in the trial **protocol**. If an unanticipated covariate appears at a later stage, the statistical and clinical reasons to include this in ANCOVA should be explicitly documented. Previous experience may also suggest the functional form of the role of these covariates in explaining or predicting the outcome. As much as possible, this form should also be specified in the protocol. Also think of interactions. The number of covariates should be small for clarity and should be chosen with care. A large number of covariates tends to complicate the inference besides, of course, requiring a large sample. This is more so when interactions are also included. Similarly, a large number of cross-classifications in the case of categorical covariates can cause problems even when the covariates are not many. In this case, examine whether some categories can be collapsed without sacrificing the utility of results. Computationally, a large number of categories does not cause problems when an adequate sample size is available.
- The method becomes complex when, for example, the interest is in the effect of $x_1$ and $x_3$ on $y$ keeping $x_2$, $x_4$, $x_5$, and $x_6$ fixed. This can also be stated as the effect of $x_1$ and $x_3$ on $y$ after eliminating the effect of $x_2$, $x_4$, $x_5$, and $x_6$—in our example, the effect of fat intake and sex on BMI in people with the same carbohydrate intake and same the physical activity. Typically, covariates are quantitative, but in this case, physical activity is qualitative. The method of **general linear models** allows this also, and statistical packages do all the required calculations once the design command is properly specified. For example, Murphy et al. [1] studied the association between domestic physical activity and leanness controlled for age, gender, socioeconomic status, and smoking status using ANCOVA.
- Just as in regression and ANOVA, ANCOVA also is generally restricted to a linear effect and requires Gaussian distribution of residuals for the confidence interval and test of significance of the estimates of the parameters. Linearity is not in the restricted sense but in the wider sense where the square, cube, logarithm, etc., of independent variables are permissible but not of parameters.
- You can see that ANCOVA, as just explained, is another statistical method to reduce the specter of uncertainty. It adjusts the comparison across groups for imbalances in the covariates and enhances the precision by accounting for these imbalances. To check the validity of ANCOVA, homogeneity of slopes and absence of **interaction** between covariates and qualitative variables are tested. Thus, do ANCOVA with abundant caution. ANCOVA can be extended to include interaction between covariates and qualitative variables (that is, varying slopes) although this requires much more statistical expertise both for running the statistical package as well as for interpreting the output.

## analysis of variance (ANOVA), *see also* one-way ANOVA, two-way ANOVA, repeated measures ANOVA

Analysis of variance (ANOVA) is a method for testing the significance of the difference in means in three or more groups, analogous to the **Student *t*-test** for two independent groups. The method grew out of Ronald Fisher's investigations at the Rothamsted Research Centre of the effect of fertilizers on crop yield in the 1920s. This has now been extended to a large number of other complex problems such as multifactor setup, repeated measures, fixed and random effects, and regression setup. All these are discussed in this volume under the respective topics.

The method remains conceptually simple but becomes mathematically complex. As always in this book, we avoid complex mathematical expressions and concentrate on explanations that may help in understanding the basic concepts, in being more judicious in choosing an appropriate method for a particular set of data, in realizing the limitations of the methods, and in interpreting the results properly.

The Student *t*-test is valid for almost any underlying distribution if $n$ is large but requires a **Gaussian** pattern if $n$ is small. A similar condition also applies to the ANOVA method of comparison of means in three or more groups. The test criterion now used is called $F$. As in the case of the Student $t$, this test also requires that the outcome variable be quantitative and the variance in different groups be nearly the same. This property is called **homoscedasticity**. The third, and most important, prerequisite for validity of $F$ is independence of observations. Serial measurements, taken over a period of time on the same unit, generally lack independence because a measurement depends on its value on the previous occasions. A different set of methods, called hierarchical or **repeated measures** and akin to a paired $t$, is generally applied for analyzing such data. But the dependence of measurements at different anatomical sites, such as electrical activity at different sites of, brain is more difficult to handle and may require **multivariate methods**.

Some kind of **random sampling** is required, as always for statistical methods, for validity of conclusions from the ***F*-test**. The usual ANOVA considers groups on a **nominal scale** with no order or quantitative implications. This implies that if your groups are like cases with mild disease, moderate disease, a serious form of disease, and critical cases, usual ANOVA would ignore this gradient in the groups. Further analysis or an alternative method such as **scoring** would be needed if you want to study the effect of this gradient on the outcome.

The name *analysis of variance* comes from the fact that the total variance in the subjects in all the groups combined is partitioned into components arising from different sources such as within-groups variance and between-groups variance. Between-groups variance is the systematic variation occurring due to group differentials. For example, ANOVA may reveal that 60% variation in P3 amplitude in

A

**TABLE A.4**
**ANOVA Table for a Two-Way ANOVA for Effect of BMI and WHR Categories on Triglyceride Level in 100 Subjects**

| Source | Sum of Squares | df | Mean Square | *F* | *P*-Value |
|---|---|---|---|---|---|
| Between BMI categories | 2369.334 | 3 | 789.778 | 4.079 | 0.009 |
| Between WHR categories | 3417.571 | 2 | 1708.786 | 8.826 | 0.000 |
| Interaction BMI * WHR | 872.474 | 6 | 145.412 | 0.751 | 0.610 |
| Error | 17037.355 | 88 | 193.606 | | |
| **Corrected Total** | **30412.960** | **99** | | | |

healthy adults is due to genetic differentials, 10% due to age differentials, and the remaining 30% due to other factors. Such a residual left after the extraction of the factor effects of interest is considered a random component arising due to intrinsic biologic variability between individuals and the unaccounted-for factors. This is the within-groups variance. If genuine group differentials are present, then the between-groups variance should be substantially large relative to the within-groups variance. Thus, the ratio of these two components of variance can be used as a criterion to find whether the group means are different. This is what the *F*-test does. The numerator of the variance is the sum of squares. The within-groups sum of squares has other names also, such as **error sum of squares** and *residual sum of squares*.

The results of ANOVA are presented in what is called an *ANOVA table* (for an example, see Table A.4), which contains various sums of squares, their respective degrees of freedom (df's), mean squares, the values of *F*, and their statistical significance in terms of *P*-value. Sum of squares has various types such as Type I, Type II, and Type III, as explained under **sum of squares**. Table A.4 shows results of a two-way ANOVA for triglyceride level as affected by body mass index (BMI) and waist–hip ratio (WHR) in a random sample of 100 subjects. Such a table can be easily obtained by using almost any statistical software package. Mean square is obtained by dividing the sum of squares by the respective df, and under the conventional setup, *F* is obtained by dividing each mean square by mean square due to error (MSE). The *P*-value comes from the *F* distribution under the null hypothesis of equality of means.

The ANOVA method in actual applications depends on the design. For example, a **one-way ANOVA** is used for comparing means in three or more groups without considering any other factor. A **two-way ANOVA** is used when the subjects are simultaneously divided by two factors, such as patients divided by sex and severity of disease. In Table A.4, these are divided by BMI and WHR categories. Repeated measures ANOVA is used when the same subjects are assessed on the same medical parameters on two or more occasions, such as pain score before the anesthesia for a surgery and at 30 s, 1 min, and 2 min after the anesthesia. Finding the sum of squares due to each regressor and the residual in a **regression** setup is also called ANOVA. There are several other applications of the ANOVA method. For further details of the ANOVA method, see Doncaster and Davey [1].

## analysis (statistical)

Many people wonder what this so-called statistical analysis is all about. Analysis literally means breaking down a complex entity into smaller components so that it can be properly understood, comprehended, and examined. The term *statistical analysis* is applied mostly to data whose micro and macro features are studied through statistical methods. For example, you may be interested in sieving signals from noise in the data and arrive at a result that has credibility. The term *data analysis* is used every day for statistical analysis, but there is a subtle distinction. Statistical analysis necessarily has an inference component that requires that some conclusion be made regarding the population as a whole from which the data have been extracted. Data analysis may or may not have this component. Data analysis may help draw a conclusion regarding the data on hand without any extrapolation to the "population."

All statistical methods help in the statistical analysis of data. Different methods are used for different purposes depending on the objective of the study. It could be exploratory, descriptive, or inferential. The objective of **exploratory analysis** is to examine the data with regard to their adequacy for inferential purposes. This includes, among others, studying the **validity** of the data, assessment of missing values, and identifying the outliers. **Descriptive analysis** is mostly in terms of tabulation and graphs. These help in summarizing the data, finding the pattern in the data, and identifying the right methods of further analysis. The core statistical analysis is inferential, which includes finding the strength and form of relationships or trends, confidence intervals, and the tests of hypotheses, for the parameters of interest. Steps taken before the availability of data, such as designs of the study, framing of the forms for recording, and collection of data, are also statistical but not part of statistical analysis.

To give you some examples of core statistical analyses, regression *analysis* is done to find the best-suited relationship between a dependent variable and a set of regressors, cluster *analysis* is done to discover affinity structure in the data, survival *analysis* is done to find survival patterns and contributory factors, *analysis* of covariance is done to find the effect of factors and covariates, discriminant *analysis* is done to find the best function that separates groups from one another, etc.

Statistical analysis is recognized as an important ingredient in any empirical science that depends on observed values and not theorems. Medicine and health are particularly vulnerable because of high interindividual and intraindividual variations. This is aggravated by the need to be exact in conclusions regarding such vital aspects of life.

## analytical studies

Two broad types of data-based studies are descriptive and analytical. The objective of **descriptive studies** is to find the health status of a group of subjects without worrying about the reasons or contributory factors. These are enumerative in nature since the objective mostly is to give counts and percentages in different segments of the subjects. They are context specific as they relate intimately to the locale and the characteristics of the population. Census and sample surveys are examples of descriptive studies. On the other hand, there are relatively small-scale studies with the objective to discover antecedent–outcome types of relationships. These are called analytical studies as they have cause–effect overtones and the effect of each contributory factor is sought to be delineated. They have wider implications for similar subjects in other populations. They have at least one factor that can be considered antecedent and another factor that can be considered outcome. One precedes the other, although the sequence may not be clear to begin with. Analytical studies try

to answer the *why* and *how* of a phenomenon. Investigations on the association between two or more factors also come under this category, but the effort generally is to estimate the exact contribution of each antecedent to the outcome. Analytical studies are statistically much more challenging than descriptive studies.

Analytical studies almost invariably have a comparison group, although this can arise from within. Sometimes, the values before an intervention serve as the comparison group.

As described for **designs of medical studies**, analytical studies are basically of two types—observational and experimental. Observational studies are on the natural course of events without human intervention, and the data are examined regarding what might have caused or contributed to a particular outcome. These could be retrospective (e.g., case–control), prospective (e.g., cohort), or cross-sectional. See the topic **observational studies** for details. On the other hand, a basic feature of experimental studies is intentional human intervention to see its effect on the outcome. As per the details given for **experimental studies**, these could be laboratory experiments, clinical trials, or field trials. **Clinical trials** are the most glaring example of medical experiments and most challenging among the analytical studies in health and medicine.

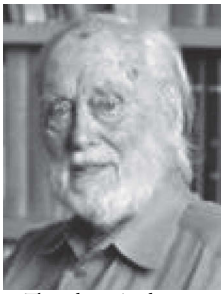
## Anderson–Darling test

The Anderson–Darling (A-D) test can be used to check whether sample values fit well in to a specified statistical **distribution**. They proposed this test in 1952 [1]. Although the test can be used for any distribution, its most common application is to check whether the observed values could have come from a **Gaussian distribution**. For correct implementation of many statistical procedures such as ANOVA and regression, fulfillment of the requirement of Gaussianity must be checked, particularly for obtaining valid confidence intervals and for correct testing of hypothesis results. For checking Gaussianity, the A-D test can be used for $n$ as low as 8. If the test gives a statistically significant ***P*-value**, you cannot assume that the values have come from a Gaussian distribution.



Theodore Anderson

The A-D test is a modification of the popular nonparametric **Kolmogorov–Smirnov (K-S) test** and uses the weighted sum of the squares of the differences between the **cumulative frequencies** based on the hypothesized and the observed cumulative frequencies. The K-S test, in its usual form, requires a large sample, whereas the A-D test does not require a large sample. However, the A-D test is parametric as its $P$-value depends on the distribution under test. If the distribution under test is Gaussian, then the $P$-value is different compared to if the distribution under test is, for example, a Weibull distribution. Because of mathematical intricacies, we are not giving the details of the calculations required for an A-D test. This test is widely available in statistical packages, and you would not have much problem in using this test for your data when needed.

If you are interested in a non-Gaussian application of the A-D test, see the work of MacKenzie [2], who used it for checking the Poisson distribution of intersuicide duration in Cornell and the Massachusetts Institute of Technology (MIT).

## ANOVA, *see* analysis of variance (ANOVA)

## antagonism, *see* interaction

## antecedent factors

An antecedent is a factor that precedes an outcome and is suspected to have contributed in shaping the outcome. This could be an exposure, such as sexual intercourse with a subject suffering from a sexually transmitted disease, or could be a risk factor, such as short stature for age at puberty. The other names for antecedent are *cause*, *predisposing factor*, and *determinant*. In a regression setup, they are called regressors, predictors, or independent variables. Much of **empirical** research in medical sciences is directed toward finding the cause of a particular outcome. While cause attribution is difficult in an empirical setup, antecedent–outcome relationships are relatively easy to study. For **analytical studies**, this relationship is a defining feature.

In a gestational age–birth weight setup, gestational age is clearly an antecedent. A woman's nutrition level, body mass index, smoking, age, parity, previous history, and heredity may also be examined as antecedents for birth weight. But what about unconventional factors such as blood group and the month of conception? If a researcher has reasons to suspect that these also may have some role in determining birth weight, these also can be examined as antecedents. Thus, an antecedent is not necessarily a cause but can be any factor that may have been directly or indirectly instrumental or believed to be affecting an outcome. In this case, the study investigates **association** in place of cause.

In some situations, the distinction between an outcome and an antecedent is blurred. Smoking can lead to depression, and depression can lead to smoking. Gender and blood group are genetically determined simultaneously, and neither is antecedent to the other. Anxiety can cause disease, and vice versa. Also, the same factor can be an antecedent in one setup and an outcome in another setup. Excessive alcohol intake is an antecedent for liver diseases but is an outcome of peer pressure or depression. What is clear to you as an antecedent may not be clear to others. Thus, the **protocol** of the study must specify all the antecedents along with the method for their measurement. In any case, this specification is needed to provide exactitude to the research.

A large number of antecedents can be identified for an outcome, but ethics, feasibility, and parsimony require that only a few relevant ones be included in the study. The general advice is to prefer those that are directly influencing the outcome or those that are suspected

A

to make a prominent contribution. However, in the present era when such kind of obvious factors have already been fully investigated, those making an indirect contribution and those that are obscure can also be investigated. Sometimes, unsuspected antecedents are investigated for fun in the hope of an unexpected result. Note that only the known or suspected factors, even speculative, can be investigated, but those in the **epistemic** domain can never be investigated—and those may be more important. Thus, all medical studies have limited implications.

It is not necessary that the value of antecedent factors is already known in a study and that of outcome elicited. In **retrospective studies** such as **case–control**, the antecedent is elicited, and outcome is already known. Thus, the antecedent is a response in this setup. In **cross-sectional studies**, both antecedent and outcome are elicited simultaneously. However, in prospective studies, the antecedent is known, and the outcome appears during the follow-up.

## APACHE score

An acronym for *acute physiology and chronic health evaluation*, the APACHE score is used to assess the criticality of patients admitted to the intensive care unit (ICU). In a medical care setup, caregivers, patients, and their families all are keen to know how severe the condition is. This helps in taking appropriate steps and to forward a reasonable prognosis. Among many severity scoring systems for critical conditions, APACHE scores are the most commonly used and deserve some understanding. The basic premise in these scores is that the worst physiological derangement noted during the first 24 h after admission in an ICU more or less determines the chance of hospital survival. These derangements define organ insufficiency. This implies, though, that treatment and care are not of much consequence as they are nearly the same in hospitals across the United States, where this scoring system evolved. In other setups, care may be a strong determinant, and this is not part of the APACHE score.

William Knaus

APACHE I was proposed in 1981 by Knaus et al. [1] and was found to be surprisingly accurate in predicting mortality in patients in a variety of ICUs. An exception noted later was patients requiring a coronary bypass graft, where the physiological derangement was high but mortality was low. APACHE I considered 34 physiological measurements that are routinely collected in most US hospitals. Thus, no extra efforts were required. Each of these measurements was assigned points according to the severity of derangement. For example, a serum pH value of either <7.15 or ≥7.70 has +4 points as both are considered equally grave, whereas a normal value between 7.33 and 7.49 has 0 points as this is no derangement [2]. A slightly higher pH value between 7.50 and 7.59 was assigned +1 point, but on the lower side, a value between 7.15 and 7.32 was assigned +2 points as this is considered relatively more harmful. The sum of such points over the 34 measurements is the APACHE score. The higher the score, the greater the chance of death. However, this version was found too complex for adoption.

APACHE II [2] is the simplified version of APACHE I and includes only 12 physiological measurements. But it added points for age (ranging from 0 for age <45 years to 6 for age ≥75 years) and previous history (5 points for nonoperative or postoperative emergency patients and 2 points for elective postoperative patients in the past). The maximum possible score is 71, although in practice, none exceeds 55. A score of 40 or more has been seen to be strongly associated with hospital death. These scores were woven into a **logistic regression** with mortality as the outcome using data from a large number of ICUs across the United States. The equation derived is

$$\ln\left(\frac{R}{1-R}\right) = -3.517 + (0.146 * \text{APACHE-II score}) + (0.603, \text{only if postoperative surgery}) + (\text{diagnostic category weight}),$$

where $R$ is the predicted risk of death and diagnostic category weight was separately derived for each of 50 disease groups. For example, this weight for asthma/allergies is −2.108 and for cardiogenic shock is +0.393. A negative weight implies that the risk of mortality is less, and positive weight implies that the risk is greater. These weights have been described by Knaus et al. [2].

Subsequently, APACHE III appeared between 1991 and 2002 in several different versions. This included 17 physiological variables, adjusted for location and length of stay before ICU admission, and used splines for statistical modeling. The last version of APACHE III covered 96 disease groups. APACHE IV appeared in 2006 and included 116 disease groups. This revised the prediction equation, used five new predictors, extended splines, and made prior length of stay continuous in terms of minutes and not just in integer days. The details of APACHE IV have been described by Zimmerman and Kramer [3].

In short, APACHE III and IV are more complex and only marginally increase the predictive accuracy over APACHE II. Thus, many still prefer APACHE II. The percentage of ICU patients correctly classified into survive/death by APACHE II was observed as 85.5% in US hospitals, and the **area under the ROC curve** was 0.863 [2].

This scoring system is applicable to critical cases wherein survival is known not to exceed 80%. If somebody naive uses this percentage as predictivity for survival without using any scoring system, he/she would be right in about 80% of cases. Since the predictivity of APACHE II is about 85%, this adds just about 5% to the accuracy of prediction. ICU admission itself requires screening that reasonably predicts the chance of survival without using the APACHE score. Note that correct prediction is not as high as the hype around this scoring system. Moreover, not many studies are available that can give guidance regarding the use of APACHE in developing countries, where ICU care and mortality could be very different. Not many realize its limitations.

APACHE scoring is useful in many other setups. You can legitimately compare severity of cases admitted in the ICU of one hospital with that in another hospital, or in two or more groups, such as severity in people with different occupations. Similarly, if a regimen is effective in 72% of cases with an APACHE II score between 20 and 24, and another is effective in 78% with the same score, you are confident of a 6% difference in efficacy in such cases. Also, if the average APACHE II score in critical cases admitted

in a hospital during 2005–2009 is 17 and the average rises to 21 in cases admitted during 2010–2014, it would be legitimate to say that the cases admitted later are more severe. The actual utility of APACHE scores lies in this kind of comparison rather than in predicting survival.

## Apgar score

The Apgar score is just about the first test a newborn undergoes immediately after birth. A newborn is evaluated on appearance, pulse, grimace, activity, and respiration. The first letters of these make up the term *APGAR*, but it was first proposed by Virginia Apgar in 1952 [1].

Virginia Apgar

Appearance is evaluated by skin color, pulse by heart rate, grimace by reflexes, activity by muscle tone, and respiration by breathing effort. Each of these is assigned a score of 0, 1, or 2 at 1 min after birth and again 5 min after birth to see if there is any improvement. The sum of these scores is called the Apgar score at 1 and 5 min, respectively. The maximum is 10 for an absolutely healthy child, although that would be rare, and 0 for a dead child. A healthy child will have a score of 7 or more. A low score (say, <4) is regarded as an indication of poor prognosis and a need for immediate special care of the child, such as resuscitation.

Li et al. [2] investigated the relevance of Apgar score in the United States after 50 years of use in the context of steep advancements in care and technology, and report that it has continuing value for predicting neonatal and postneonatal adverse outcomes in term as well as preterm infants. They also found that this is applicable to twins and in various race/ethnic groups as well. The Apgar score is not so appropriate for long-term prediction of the health of a child [3], although Naeser et al. [4] found in a co-twin control study in Denmark that a high Apgar score was a risk factor for atopic dermatitis. The authors called this a novel finding.

**Scoring systems** come under the domain of biostatistics. For example, the **APACHE score** is based on **logistic regression**. But Apgar is an example of a simple scoring system as a sum of five individual scores and serves the purpose well.

## area diagram

This diagram represents the data in terms of areas. One such illustration is Figure A.3a. It shows the distribution by cholesterol level of subjects of different body mass index (BMI) values in a hypertension clinic. But the BMI levels are stacked over one another. This is an area diagram as the sequential addition of the percentages gives the cumulative distribution. Not merely stacking but also the sequence of stacking must have a physical meaning in such an area diagram. In this example, the area below the second polygon depicts the cholesterol level distribution of those who have BMI < 30 kg/m$^2$, and the area below the top line is the cholesterol level distribution of all the subjects with any BMI. The figure also shows that more obese subjects commonly have

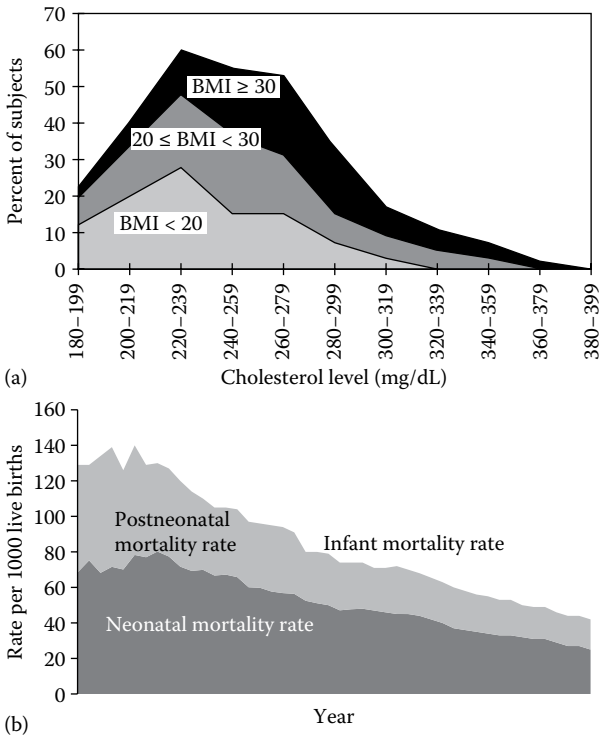

**FIGURE A.3** (a) An area diagram for cholesterol levels in different body mass index (BMI) categories. (b) An area diagram showing trend of neonatal, postneonatal, and infant mortality rate in a developing country.

A

higher cholesterol levels, and the distribution changes shape from one BMI category to another.

Figure A.3b is a different type of area diagram. This shows the trend of **neonatal mortality rate** (NMR) and postneonatal mortality rates (PNMR) in a developing country over a period of 40 years. But the top line also has a physical meaning since that depicts the trend of **infant mortality rate** (IMR). This is possible in this case since NMR + PNMR = IMR, and all are computed per 1000 live births.

## area sampling

As the name implies, in area sampling, geographical areas are sampled, and all eligible persons or units of interest in the selected areas are included in the sample.

Sometimes, particularly in large-scale field studies, it is convenient to sample geographical areas instead of individuals or families. This happens when maps with appropriate divisions are available but the **sampling frame** of the actual **units** of investigation is not. In some areas, households migrate from one place to another, new households spring up quickly, and no updated records are available. Even when the full listing is available, area sampling is easy to execute when a map is available (Figure A.4).

In area sampling, the **sampling unit** is specified in advance depending on what spatial divisions are available or applicable to the study. For example, you can have census blocks or villages as your sampling unit if the map has a demarcation for these areas. If a district has 2500 census blocks, select as many as decided on, and everybody in those selected census blocks will be in your sample. If the unit of inquiry is an old person of age 65 or above, visit every house in the selected areas and locate persons of this age.

Area sampling is a variation of **cluster sampling** where, also, people contiguous in some sense are selected. As in the case of cluster sampling, area sampling is most efficient when units within selected areas are diverse. This helps in achieving representation of a cross-section of the population. But it is likely that units within an area are similar since they belong to the same area. In that case, a large number of areas are selected so that some areas with different kind of people are also included. The sample size may steeply increase, but the cost may still be low since traveling cost and travelling time are drastically reduced.

In most situations, the areas are selected randomly. For this, the areas are numbered, and selection can be done with the help of random numbers. However, as in all random sampling, particularly for small sample size, not all types of areas may be represented. In Figure A.3, northeast areas are not represented. If it is expected, for example, that people living in one type of area are different from others, use **stratified random sampling** with different types of areas as strata. This will ensure that all kinds of people are included in the sample.

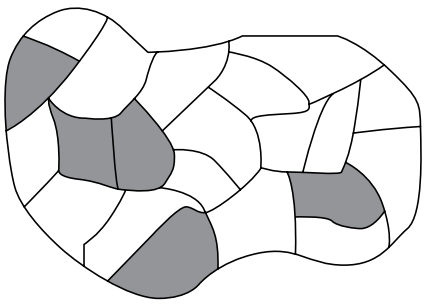

**FIGURE A.4** Selection of five areas from a town.

## area under the concentration curve (AUC curve)

In pharmacokinetic studies, drug concentration in the system is measured at different points in time, and a curve is obtained (Figure A.5a). This is called the *concentration curve*. The objective is to find the pattern and extent of **bioavailability** of the drug over a period of time. This is the total amount of the drug reaching the body. Whereas the pattern is obtained by the shape of the curve, the extent of bioavailability is obtained by what is called the area under the concentration curve (AUC curve). This has special significance when the concentration is obtained at varying time intervals. In the case of regular time intervals, AUC is conceptually similar to the mean or sum of all the values. In Figure A.5a, the concentration rapidly increases till 180 min and then gradually starts to decline. Figure A.5b compares AUC for two regimens.

AUC is also used in animal experiments and clinical trials when the response is studied at different points in time. The response could be intensity of pain after analgesia, physical stress during exercise, efficacy of a regimen over time, or any other such measure. Many times, concentration is measured in logarithmic units because concentration is mostly multiplicative.

AUC can be obtained for each person under study, but the convention is to draw it for averages over the subjects. This is valid so long as the values across persons are homogeneous. If one person shows a widely different trend from another, the average conceals this variation. Such an individual-specific response may have clinical implications that are lost in averages.

The method generally followed for calculating the area under the curve is called the *trapezoid rule*. The total area is divided into small trapezoids (Figure A.5a). The area of each trapezoid can be calculated easily, e.g., area of trapezoid ABCD = (AB + CD)/2 * BC. Sum the areas of all the trapezoids and get the area under the curve. The last point is joined with concentration 0 for this purpose if the period of observation does not extend to the

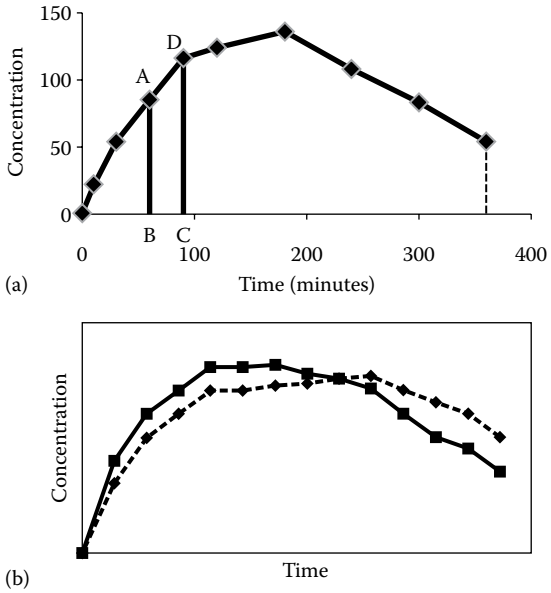

**FIGURE A.5** (a) Area under the concentration curve. (b) Markedly different curves with the same area.

time when concentration of the drug falls to zero (undetectable) levels. Thus, this will be the area truncated at the last time point. For example, Gaudreault et al. [1] evaluated truncated area under the curve as a measure of the relative extent of bioavailability. Many statistical packages plot this kind of curve and calculate the area under the curve once the concentrations at different points in time are entered.

A difficulty with AUC is that it has limited physical meaning. When used in isolation, it may fail to provide an adequate assessment of the trend, even on average, because it is neither specific nor sensitive to the changes in the patterns. In the case of comparison, curves with markedly different trends can give the same area (Figure A.5b). For this reason, AUC is not a valid measure of **bioequivalence**. Also, as the time passes, some patients drop out or are cured—thus, the average response at different points in time is based on different values of $n$. This is forgotten while studying AUC.

The AUC curve can give valid results when the average response in one group is better than that in the other at almost every time point. If they crisscross, then the conclusion can be very wrong. In this case, the investigator may have to be more specific on what exactly he/she is looking for. Merely stating a trend or pattern does not help. Depending on what is most relevant for the objective of the study, particularly in **pharmacokinetic** studies, it could be the time taken to reach the peak ($T_{max}$), the time taken to return to the initial level, the peak level attained ($C_{max}$), the response level after a specific time gap, **half-life**, etc. In many situations, the AUC needs to be considered in conjunction with other parameters such as $T_{max}$ and $C_{max}$ for a valid conclusion. In a study on treatment efficacy, the interest may be in the value at the end relative to the initial value. If the study is on effectiveness of an analgesic, the interest may be in $T_{max}$, $C_{max}$, and possibly time to reach to some specified critical level. No matter what parameter is used, it should always be decided beforehand on the basis of clinical utility and not after inspecting the data. AUC is considered a comprehensive measure of performance, but further insight is obtained by $T_{max}$, $C_{max}$, etc.

The AUC curve is different from the area under the **receiver operating characteristic (ROC) curve**. The term *area under the curve* is also used in the context of probabilities in a distribution. For one such use, see **Gaussian distribution**.

## Armitage–Doll model

The Armitage–Doll model seeks to statistically explain the onset of epithelial carcinoma as a multistage process in humans, triggered by exposure to carcinogenic substances and undergoing several successive qualitatively different cellular changes (such as mutations) over time. This model was first proposed by Armitage and Doll in 1954 [1].

The Armitage–Doll model explains the rapid rise in incidence and hence mortality due to some cancers over age and also the long latent period before a tumor develops after the exposure. The model states that

$$\text{hazard of cancer at time } t\text{: } h(t) = \alpha t^{K-1},$$

where $K$ is the number of stages of cellular changes required for cancer to appear and $\alpha$ is a constant. $K$ and $\alpha$ will change from cancer to cancer. The model is easier to understand if log transformation is used, since then,

$$\log h(t) = \log\alpha + (K-1)\log t.$$

This is a linear relationship between the log of hazard and the log of time that is an outcome of **Weibull distribution** of the time for appearance of cancer. The value of $K$ for many cancers is between 5 and 7, suggesting that cancer development requires 5–7 cellular changes [2]. The model mimics a two-stage model for, say, breast cancer, with exponential proliferation of aberrant cells. But it fails to account for the steep fall in cancer incidence after the age of 80 years [3]. The model has been recently applied to pancreatic cancer data that found that this cancer possibly takes about 17 years and requires a series of five mutations for cells to become malignant [4].

## arms of a trial

Various groups receiving different regimens in a **clinical trial** are called arms of a trial. A clinical trial generally will have two arms—a test arm and a control arm—but a test also can have more than one arm if two or more regimens are under investigation. In this case, this becomes a **multiarm trial**. A test arm can also be called a treatment arm if the regimen is for treatment of a disease or an experimental arm if it is an experiment.

A clinical trial necessarily contains a group on whom the regimen is tried to find its **efficacy** and side effects. By itself, this group may provide an estimate of the efficacy but would not provide any comparison. Many researchers use the preintervention status of the subjects for comparison. This could provide an estimate of the change brought about by the intervention if nothing else has changed between the initial and final measurements. Part of this effect could be due to the **placebo** and **Hawthorne effects**. You cannot say how much of it is due to pure psychological effect and how much is due to the regimen. Thus, a **control group** is also investigated, who receive a placebo. A group receiving the existing regimen can also serve as

A

a control. The purpose of the control arm is to serve as a comparator so that the effect can be meaningfully interpreted. These different groups in a trial form arms of the trial.

## association and its degree

Association has the same statistical meaning as in day-to-day language. Two characteristics are said to be associated when change in one is accompanied by some change in the other in the long run. However, this is not necessarily causal—that is, the effect in every case is not necessary. Association between two characteristics can occur because of the presence of other conducive factors. If glaucoma occurs more commonly in females in some population, sex and occurrence of glaucoma are associated in that population. This can be due to anemia in relatively more females than males or for some other reason. Being female is not the cause of glaucoma. This is just *association*, which is relatively a much milder term than cause.

When no association exists, you can say that the characteristics are statistically **independent**. This, in effect, means that the chance of occurrence of one does not affect the chance of occurrence of the other. The occurrence of glaucoma in one woman does not alter the chance of occurrence in another woman unless, possibly, they belong to the same family. Statistically, the term *association* is used primarily for **qualitative** characteristics rather than **quantitative** characteristics. The corresponding term for quantities is **correlation**.

The **chi-square test** is the method of choice to find whether two characteristics are associated or not. This is a large-sample test and can be used both for **dichotomous** and **polytomous categories**. A **statistically significant** chi-square only says that an association is present but does not say how much. Some associations are strong, and some are weak. For assessing the degree, methods for **association between dichotomous characteristics** are different from the methods for **association between polytomous characteristics**. See these topics for details. For example, you can find an association between occupation and site of cancer in cancer patients. Since these categories are on a **nominal scale**, the sign of association, negative or positive, depends on the order in which they are stated in a **contingency table**. However, an **association between ordinal characteristics** can be factually negative—as one becomes higher, the other becomes lower. The association between age groups (young, middle, and old) and physical health (poor, fair, good, and excellent) among adults is generally negative in the sense that as age increases, physical health decreases. When one characteristic is qualitative and the other quantitative, you can explore whether a **coefficient of determination** can be used to measure the degree of association.

Whereas **experimental studies** and **clinical trials** are aimed at cause–effect relationships, **observational studies**, such as prospective, retrospective, and cross-sectional, are expected to provide evidence only of association and not of cause–effect. Cause–effect is concluded when several other stringent criteria are met, as mentioned under **cause–effect relationship**.

## association between dichotomous characteristics (degree of)

When one characteristic of the subjects tends to change with another characteristic, this is called an association between these two characteristics. The most common situation for investigation of an association in the case of **qualitative variables** is that of dichotomy. The bivariate binary observations in this case are generally summarized in the form of a 2 × 2 table of the type given in Table A.5.

**TABLE A.5**
**Cross-Classification of Subjects by Two Binary Variables**

| | Variable 1 | |
|---|---|---|
| **Variable 2** | **Present** | **Absent** |
| Present | $a$ | $b$ |
| Absent | $c$ | $d$ |

It is customary in the case of qualitative variables to use the term *association* in preference to *correlation*. The most widely used measure of the strength of association in such a setup is either **relative risk (RR)** or **odds ratio (OR)**, depending on whether the design is **prospective** or **retrospective/cross-sectional**. If variable 1 is the **outcome** and variable 2 is the **antecedent** in Table A.5, these are calculated as follows.

$$\text{RR} = \frac{a/(a+b)}{c/(c+d)} \quad \text{and} \quad \text{OR} = \frac{ad}{bc}.$$

In some situations, ln(RR) and ln(OR) are preferred because of the linearizing property of the logarithm in this case. This transformation also assigns a negative or positive sign to the relationship as appropriate, making the interpretation easy.

Consider the cross-sectional data in Table A.6 on gender and blindness in patients coming to a cataract clinic where the definition of blindness is visual acuity (VA) < 1/60 in at least one eye. What is the degree of association between gender and blindness in these data?

The answer lies in the OR. Since females have a higher rate of blindness in this case, it is better to compute OR in females relative to males. This will somewhat reverse the notations and is given by

$$\text{OR} = \frac{110 \times 419}{101 \times 370} = 1.23.$$

As far as these data are concerned, females with blindness in at least one eye are 1.23 times as likely to have a cataract as males, or the odds are nearly 5:4. This, in a way, measures the degree of association as well. A higher value of OR indicates stronger association.

The conventional measures of association for 2 × 2 tables are the following dichotomy coefficients:

$$\text{Positive matching dichotomy coefficient: } S_1 = \frac{a}{a+b+c+d}.$$

This is the proportion of pairs with both values present.

**TABLE A.6**
**Gender and Blindness in Patients Coming to a Cataract Clinic**

| Gender | Blind | Not Blind | Total |
|---|---|---|---|
| Male | 101 | 419 | **520** |
| Female | 110 | 370 | **480** |
| **Person** | **211** | **789** | **1000** |

$$\text{Jaccard dichotomy coefficient: } S_2 = \frac{a}{a+b+c}.$$

This is the proportion of pairs with both values present given that at least one occurs. This is not symmetric to the presence and absence of disease.

$$\text{Simple matching dichotomy coefficient: } S_3 = \frac{a+d}{a+b+c+d}.$$

This is the proportion of pairs where the values of both variables agree.

$$\text{Anderberg dichotomy coefficient: } S_4 = \frac{a}{a+2(b+c)}.$$

This is basically the same as $S_2$ but is standardized for all possible patterns of agreement and disagreement.

$$\text{Tanimoto dichotomy coefficient: } S_5 = \frac{a+b}{a+2(b+c)+d}.$$

This is $S_3$ standardized for all patterns of agreement and disagreement.

It is not easy to choose one among these. They will most likely give different results. You may have to carefully examine the data and the objective of the relationship that you want to measure. For example, $S_2$ and $S_4$ are appropriate when the absence of an attribute in both variables ($d$ in Table A.5) does not convey any useful information.

Another popular measure of degree of association for dichotomous categories is

$$\text{Yule } Q: = \frac{ad-bc}{ad+bc}.$$

In terms of OR, this is $Q$ = (OR − 1)/(OR + 1). This lies between −1 and +1 and can be interpreted like a **correlation coefficient** for assessing the strength of relationship.

**Association between polytomous characteristics** and **association between ordinal characteristics** are discussed separately.

## association between ordinal characteristics (degree of)

Association between two characteristics is the tendency of change in one characteristic of subjects to be accompanied by change in the other characteristic. Most common is the **association between dichotomous characteristics**, which is presented separately. Now consider two characteristics on an **ordinal scale**, such as severity of disease and obesity. One may have $R = 4$ categories, and the other, $C = 3$ categories. The interest is in measuring the strength of association between these two ordinal characteristics. The data can be arranged in an $R \times C$ table.

The association is high if the higher category of one is more frequently seen with the higher category of the other. The association between severity of disease and obesity is high if more severe cases are obese. This is called **concordance**. If less severe cases are mostly obese, this is discordance. However, in this case, you need to consider all possible pairs of pairs. If one pair is $(x_1, y_1)$ and the other pair is $(x_2, y_2)$, they are concordant if $x_1 < x_2$ and $y_1 < y_2$ or if $x_1 > x_2$ and $y_1 > y_2$, and disconcordant if $x_1 < x_2$ but $y_1 > y_2$ or if $x_1 > x_2$ but $y_1 < y_2$. Also, pairs are tied for $x$ if $x_1 = x_2$ irrespective of $y$, and tied for $y$ if $y_1 = y_2$ irrespective of $x$. In ordinal data, ties are quite common. For $n$ subjects, there are a total of $n(n-1)/2$ pairs since the pair $[(x_1, y_1), (x_2, y_2)]$ is considered same as $[(x_2, y_2), (x_1, y_1)]$. For a $3 \times 2$ table (Table A.7), this can be explained as follows.

Total number of persons $a + b + c + d + e + f = n$
Total number of pairs of pair = $n(n-1)/2 = T$
Concordant pairs of subjects = $a(e + f) + bf = P$
Discordant pairs of subjects = $c(d + e) + bd = Q$
Pairs tied on characteristic 1 ($x$) alone = $ad + be + cf = X_0$
Pairs tied on characteristic 2 ($y$) alone = $a(b + c) + bc + d(e + f) + ef = Y_0$
Pairs tied on both $x$ and $y$ = $a(a-1)/2 + b(b-1)/2 + c(c-1)/2 + d(d-1)/2 + e(e-1)/2 + f(f-1)/2 = (XY)_0$

$(XY)_0$ does not contribute to the measure of association, and these are ignored except for calculating the total number of pairs.

Now, various measures of ordinal association can be defined as follows. You may find varying definitions in the literature.

$$\text{Kendall Tau-a: } \tau_a = \frac{P-Q}{n(n-1)/2}.$$

This is the surplus of concordant pairs over discordant pairs as a proportion of the total pairs. If the agreement in pairs is perfect, $Q = 0$, and tau-a = 1, assuming no ties. If all are discordant pairs, $P = 0$ and tau-a = −1. Thus, this ranges from −1 to +1. If ties are present, this modifies to

$$\text{Kendall Tau-b: } \tau_b = \frac{P-Q}{\sqrt{(P+Q+X_0)(P+Q+Y_0)}}.$$

The denominator is now partially adjusted for ties, and $P$ and $Q$ will also be automatically adjusted by definition. Tau-b works well for square tables where the number of categories for one characteristic is the same as for the other characteristics (i.e., $R = C$). Tau-b = +1 if the table is diagonal and Tau-b = −1 if all diagonal elements are zero. If the table is not square, the corresponding adjustment for the size is

$$\text{Kendall Tau-c: } \tau_c = \frac{2(P-Q)R}{n(n-1)(R-1)},$$

where $R$ is the smaller of number of rows and number of columns. This is also called *Stuart Tau-c*.

**TABLE A.7**
**Cross-Classification of Persons with Two Ordinal Characteristics**

| | Characteristic 1 ($x$) | | |
|---|---|---|---|
| **Characteristic 2 ($y$)** | **Low** | **Medium** | **High** |
| Low | $a$ | $b$ | $c$ |
| High | $d$ | $e$ | $f$ |

A

Beside these variations of tau, there are two other popular measures of ordinal association.

$$\text{Goodman–Kruskal gamma: } \gamma = \frac{P-Q}{P+Q}.$$

This completely excludes ties from the numerator as well as from the denominator. This also ranges from −1 to +1. If the number of discordant pairs is the same as concordant pairs, $\gamma = 0$.

All these measures are symmetric in the sense that it does not matter which characteristic is in the rows and which is in the columns (or, in other words, there is no distinction between antecedent and outcome). Both are treated the same way. For a directional hypothesis such that *x* predicts *y* (or *x* is the antecedent and *y* is the outcome), use

$$\text{Somer } d = \frac{P-Q}{P+Q+Y_0},$$

where $Y_0$ is the number of pairs tied for *y*. Note that only the pairs tied for *x* are excluded from the denominator.

Suppose Table A.8 is obtained regarding smoking and drinking in cancer cases.

For this table,

$n = 51$ and $T = 51 \times 50/2 = 1275$
Concordant pairs $P = 35(2 + 3) + 4 \times 3 = 187$
Discordant pairs $Q = 1(6 + 2) + 4 \times 6 = 32$
Tied on *x* (smoking) $X_0 = 35 \times 6 + 4 \times 2 + 1 \times 3 = 221$
Tied on *y* (drinking) $Y_0 = 35(4 + 1) + 4 \times 1 + 6(2 + 3) + 2 \times 3 = 215$
Tied on both *x* and *y* $(XY)_0 = ½ (35 \times 34 + 4 \times 3 + 1 \times 0 + 6 \times 5 + 2 \times 1 + 3 \times 2) = 620$

These numbers give

$$\text{Tau-a} = \frac{187-32}{1275} = 0.12$$

$$\text{Tau-b} = \frac{187-32}{\sqrt{(187+32+221)(187+32+215)}} = 0.35$$

$$\text{Tau-c} = \frac{2\times(187-32)\times 2}{51\times 50\times 1} = 0.24$$

**TABLE A.8**
**Smoking and Drinking in Cancer Cases**

| | | Smoking | | |
|---|---|---|---|---|
| **Drinking** | **Nonsmokers** | **<3.5 Pack/ Week** | **≥3.5 Pack/ Week** | **Total** |
| Nondrinkers | 35 | 4 | 1 | **40** |
| Drinkers | 6 | 2 | 3 | **11** |
| **Total** | **41** | **6** | **4** | **51** |

$$\text{Goodman–Kruskal } \gamma = \frac{187-32}{187+32} = 0.71$$

$$\text{Somer } d = \frac{187-32}{187+32+215} = 0.36$$

Note how widely different values are obtained by different measures for the same data. For this reason, many workers do not rely much on these measures.

## association between polytomous characteristics (degree of)

Association is the tendency of two characteristics of subjects moving together at least in some subjects. The change in one relative to the other may be small or large. **Association between dichotomous categories** of the two characteristics and **association between ordinal characteristics** are discussed separately. This section is on association between two **polytomous** characteristics.

Consider classification of disabled persons by type of disability and the degree of disability (Table A.9). The type of disability is in five categories, and the degree of disability, in three categories. If **odds ratio (OR)** is used as a measure of association in this example, you need to compute OR for each pair of degree-of-disability categories—i.e., OR of category 1 versus category 2, of category 1 versus category 3, and of category 2 versus category 3—for each type of disability. Such multiple ORs may be useful in some cases but can be confusing in many cases. Moreover, a measure of overall association will not be available.

An alternative is to compute the usual **chi-square** $\chi^2 = \Sigma(O - E)^2/E$ and use this as a measure of association. It is true that a higher degree of association will yield a higher value of chi-square, but the value of chi-square also depends heavily on the sample size *n*. It increases without bound as *n* increases. To counter this, the following measure is proposed:

$$\text{Phi coefficient}: \phi = \sqrt{\chi^2/n},$$

where the square root is taken to offset the effect of squares in chi-square. Note that the concept of negative association is not relevant in the case of polytomous **nominal categories** except for the order in which they are stated—and this order has no meaning for nominal

**TABLE A.9**
**Type of Disability and Its Degree in 1000 Disabled Persons**

| | Degree of Disability | | | |
|---|---|---|---|---|
| **Type of Disability** | **Mild** | **Moderate** | **Severe** | **Total** |
| Visual | 19 | 69 | 22 | **110** |
| Locomotor | 39 | 142 | 29 | **210** |
| Hearing | 46 | 325 | 89 | **460** |
| Mental | 21 | 98 | 51 | **170** |
| Other | 7 | 3 | 20 | **50** |
| **Total** | **132** | **657** | **211** | **1000** |

categories. The phi coefficient can exceed unity. Also, $\phi$ depends on the size of the table. A modification of this measure is

$$\text{Tschuprow coefficient } T = \sqrt{\frac{\phi^2}{\sqrt{(R-1)(C-1)}}},$$

where $R$ and $C$ are the number of rows and number of columns, respectively, in the contingency table. This takes care of the size of the table. Another modification is

$$\text{Contingency coefficient: } C = \frac{\sqrt{\chi^2}}{\sqrt{\chi^2 + n}}.$$

This cannot exceed unity but could also never be one, even when the association is perfect. The value of $\chi^2$, and hence of $\phi$ and of $C$, can be severely affected by the cutoff points of categories when they are for a variable on a **metric scale**. Different cutoff points may give different values.

The most popular of such chi-square-based measures is the Cramer *V*.

$$\text{Cramer } V = \sqrt{\frac{\chi^2}{n * \min(R-1, C-1)}}.$$

This provides a good measure for tables of any size, and ranges between 0 and 1. For 2 × 2 tables, $V = \phi$. Cramer *V* is especially suitable for a square contingency table (i.e., when number of rows $R$ = number of columns $C$).

The value of $\chi^2$ for the data in Table A.9 is 37.14. If the **cell frequencies** are proportionately decreased to one-fifth, rounded off to the nearest integer, so as to have a total of 200, you get $\chi^2 = 7.39$. The large difference between this value of $\chi^2$ for $n = 200$ and the previous value for $n = 1000$ illustrates that $\chi^2$ is heavily dependent on $n$. A proportionate decrease (or increase) in cell frequencies does not affect the degree of association but affects the value of $\chi^2$. For these data,

(a) For $n = 1000$, as in Table A.9, $\chi^2 = 37.14$, $\phi = 0.19$, $C = 0.19$, and $V = 0.14$.
(b) For $n = 200$ (proportionate cell frequencies), $\chi^2 = 7.39$, $\phi = 0.19$, $C = 0.19$, and $V = 0.14$.

Note that $\phi$, $C$, and $V$ for the two $n$'s are the same, while the value of $\chi^2$ is very different. In this example, the values of $\phi$ and $C$ seem equal for each of the two $n$'s because of the rounding off, but this generally will not be the case.

A major objection to the measures $\phi$, $T$, $C$, and $V$ is that they lack underlying substantive meaning. A measure of the degree of relationship in polytomous categories with a useful interpretation is **proportional reduction in error (PRE)**, as explained separately. The primary purpose of PRE is to measure the utility of one characteristic in predicting the other.

## association in prospective, retrospective, and cross-sectional studies, *see also* chi-square test for 2 × 2 tables

Antecedents and outcomes are defining features of all analytical studies, including prospective, retrospective, and cross-sectional studies. This section is restricted to two characteristics: one **antecedent** and the other **outcome**, both being **dichotomous**. The results in this setup are easily described by a 2 × 2 contingency table, as shown in Table A.10. The notation in this table is as follows: $O_{rc}$ is the observed frequency in the $(r, c)$th cell ($r = 1, 2$; $c = 1, 2$), and inside parentheses in each cell in the table are the corresponding probabilities. The dot in the subscript is for the corresponding total. This is shown as though the relationship between antecedent and outcome is under study, and we presume this in this section, but these can be relaxed to include any two dichotomous categories. This is also known as a *fourfold table*. **Prospective, retrospective, and cross-sectional studies** provide three different situations for such a table, as described next.

**TABLE A.10**
**General Structure of a 2 × 2 Contingency Table**

| Variable 2 (Outcome) | Variable 1 (Antecedent) | | |
|---|---|---|---|
| | **Present** | **Absent** | **Total** |
| Present | $O_{11}$ ($\pi_{11}$) | $O_{12}$ ($\pi_{12}$) | $\boldsymbol{O_{1\bullet}}$ **(**$\boldsymbol{\pi_{1\bullet}}$**)** |
| Absent | $O_{21}$ ($\pi_{21}$) | $O_{22}$ ($\pi_{22}$) | $\boldsymbol{O_{2\bullet}}$ **(**$\boldsymbol{\pi_{2\bullet}}$**)** |
| **Total** | $\boldsymbol{O_{\bullet 1}}$ **(**$\boldsymbol{\pi_{\bullet 1}}$**)** | $\boldsymbol{O_{\bullet 2}}$ **(**$\boldsymbol{\pi_{\bullet 2}}$**)** | $\boldsymbol{n}$ |

### *Structure in a Prospective Study*

Because the investigation is from antecedent to outcome in a prospective study, the column totals $O_{\bullet 1}$ and $O_{\bullet 2}$ are fixed in advance. They can also be denoted by $n_1$ and $n_2$, respectively. These are the numbers of exposed and nonexposed subjects followed up for appearance of outcome. The row totals $O_{1\bullet}$ and $O_{2\bullet}$ become known only after the investigation is over. In terms of notations in Table A.10, the relevant **null hypothesis** in this case is $H_0$: $\pi_{11} = \pi_{12}$. This states that the incidence rate in the two groups is the same. In this case, $\pi_{11} + \pi_{21} = 1$ and $\pi_{12} + \pi_{22} = 1$. Thus, $H_0$ is equivalent to $\pi_{21} = \pi_{22}$.

### *Structure in a Retrospective Study*

The direction of the investigation in a retrospective study is from outcome to antecedent. Thus, the row totals $O_{1\bullet}$ and $O_{2\bullet}$, say with and without disease, are fixed in advance, and the column totals $O_{\bullet 1}$ and $O_{\bullet 2}$ are obtained through the study. The fixed row totals can also be denoted by $n_1$ and $n_2$. The null hypothesis now is that the rate of presence of antecedent in those with a positive outcome is the same as in those with a negative outcome, i.e., $H_0$: $\pi_{11} = \pi_{21}$. In this case, $\pi_{11} + \pi_{12} = 1$ and $\pi_{21} + \pi_{22} = 1$. The $H_0$ implies $\pi_{12} = \pi_{22}$ also.

### *Structure in a Cross-Sectional Study*

In this case, $n$ subjects are simultaneously cross-classified by the antecedent and outcome. Neither the column totals nor the row totals are fixed in advance, and both become known only after study of the subjects is over. In this case, $\pi_{11} + \pi_{12} + \pi_{21} + \pi_{22} = 1$. According to the multiplicative **law of probabilities**, the antecedent and outcome are independent if and only if $H_0$: $\pi_{rc} = \pi^*_{r\bullet}\, \pi_{\bullet c}$ ($r, c = 1, 2$) holds, where $\pi_{r\bullet} = \pi_{r1} + \pi_{r2}$ and $\pi_{\bullet c} = \pi_{1c} + \pi_{2c}$.

The $H_0$ in the prospective and retrospective setup is called *hypothesis of homogeneity* (column homogeneity and row homogeneity, respectively), and the $H_0$ in the cross-sectional setup is called *hypothesis of independence*. All these situations can be viewed as subjects divided by two qualitative characteristics with the objective to investigate if one characteristic has any association with the

A

other—whether one is occurring more commonly with the other than expected by chance. These hypotheses are tested by **chi-square test for 2 × 2 tables**. See that topic for details.

## assumptions (statistical)

Assumptions actually are *requirements* for a method to be valid. All statistical methods are valid under some conditions. For example, the **Student *t*-test** requires that the observations follow a **Gaussian distribution**, and the ANOVA ***F*-test** requires **homoscedasticity** across groups plus some other conditions. These are examples of requirements for the validity of a method but are statistically called assumptions. The term *assumptions* has come to stay, although the term *requirements* is a better description.

Different statistical methods have different requirements, but perhaps the most common is that individuals are randomly selected and are **independent**, and the values follow a Gaussian pattern. Among others are homoscedasticity, linearity, lack of **multicollinearity**, etc., depending upon which statistical method is being used.

All statistical methods require **random sampling** in case a sample is taken. This is the reason that random sampling is so pervasive in statistical texts. This helps in working with probabilities—the backbone of statistical science. Independence is violated when two or more observations belong to the same person or to an identifiable affinity group. Many physiological parameters and pathologies are shared among members of the same family, and children in the same class share a teaching environment. Variables concerned with these will not be independent. Generally, however, my blood pressure (BP) level is hardly affected by what the BP of my neighbor is if we do not have the same lifestyle. Thus, these are practically independent. Gaussianity of observations can be easily checked (see **Gaussianity, how to check**) for quantitative data, but realize that symmetry and single mode are no guarantee that the observations follow a Gaussian distribution. There might be deviation in **kurtosis** as examined under the **Box–Cox power exponential (BCPE) method**. In many cases with large samples, Gaussianity is not a strict requirement, because of the **central limit theorem**. This applies to sample means and several other measures. Those statistical methods that work reasonably well in situations where assumptions are mildly violated are called **robust** methods.

The user should be familiar with the validity conditions of the method he/she is using and is expected to satisfy himself/herself that these conditions are nearly fulfilled, if not fully fulfilled. Results based on invalid methods would also be invalid. In case the conditions are not satisfied, alternative approaches such as **nonparametric** methods are adopted. These are valid under milder conditions but generally have less statistical **power**.

## asymptotic relative efficiency, *see* relative efficiency of estimators

## asymptotic regression, *see* regression (types of)

## attack rate

The extent of morbidity in a group of people can be measured in several ways. In the case of acute conditions, particularly infections, it is easier to talk in terms of attacks than **incidence**. The same person can have two or three attacks of diarrhea or of cold in 1 year. Some noncommunicable conditions such as angina and asthma also have the same feature. Thus, the emphasis here is on disease spells rather than on affected persons.

$$\text{Attack rate} = \frac{\text{new spells during a specified time interval}}{\text{total population at risk during the same interval}} * 100.$$

This is commonly used when the exposure is for a limited period, such as during an epidemic, but can be used otherwise too. This can also be calculated per *person-year*.

You can also calculate secondary attack rate (SAR) based on new spells among those who were exposed.

$$\text{Secondary attack (SAR)} = \frac{\text{new spells within the range of incubation period among those exposed to primary cases}}{\text{subjects exposed to the primary cases that can spread the disease}} * 100.$$

For this rate, the denominator and the numerator are restricted to the susceptible contacts. This rate is generally used for diseases such as measles and chickenpox that are infective for only a short period. SAR measures the intensity of the spread of infection or risk among the susceptible contacts after exposure to an infective case. When the primary case, also called the **proband**, is infective for a long period, as in tuberculosis, the duration of exposure becomes important. SAR then is computed per 100 person-weeks, person-months, or person-years of exposure.

SAR is a useful measure not only for infectious diseases but also for diseases of unknown etiology, such as Hodgkin disease, to find out whether it is communicable. SAR is also useful in evaluating the effectiveness of control measures such as isolation and immunization.

SAR can be used in other contexts as well. As an example, consider the risk of diabetes in nondiabetic siblings of children diagnosed with type 1 diabetes. Steck et al. [1] analyzed the family history of 1586 patients in Colorado with type 1 diabetes diagnosed before 16 years of age and interviewed during 1999–2002. Probands are those who were initially affected, and secondary cases are those who appeared later in the family of probands. SAR by age 20 years in siblings was 4.4%, but it was significantly higher in siblings of probands diagnosed under age 7 years than in those diagnosed later. In the parents, too, the SAR by age 40 years was higher when the proband was diagnosed at less than 7 years of age.

This example illustrates the use of the concept of SAR in a very different context. It is not related to the repeated episodes yet delineates the communicability. Such usage is not uncommon, and it is nice to be familiar with different contexts in which a term can be used.

## attenuated correlation

Attenuated correlation is the underestimation of the correlation coefficient due to random measurement errors. This applies to those measurements that cannot be made with sufficient **accuracy**. You should be able to anticipate this error in your investigation. Behavioral variables are glaring examples of variables that can hardly be measured accurately; medical measurements such as blood pressure and pulse

rate are also known to contain errors when measured, particularly when measured by human beings. In the laboratory, the quality of reagents and chemicals can affect accuracy. A lower value of a correlation than expected is an appropriate situation where you can suspect attenuated correlation. The Pearson **correlation coefficient** can be disattenuated as follows:

$$\text{Disattenuated correlation between } x \text{ and } y = \frac{\text{observed } r_{xy}}{\sqrt{\text{Rel}(x)*\text{Rel}(y)}},$$

where $r_{xy}$ is the correlation coefficient, and Rel($x$) and Rel($y$) are **reliabilities** of the observed values of $x$ and $y$. Reliabilities depend on measurement error. If the observed correlation is 0.7 and the reliability of $x$ and $y$ are 0.8 each, the actual correlation is $0.7/\sqrt{(0.8*0.8)} = 0.875$. This correction may not work well when reliability drops below 0.70. Reliability of observed values should be measured using a valid procedure. Mostly, **Cronbach alpha** is used for this purpose. If you have an opportunity to find the errors ($e_x$ and $e_y$) by comparing with standard values or otherwise, you can find reliability as follows:

$$\text{Rel}(x) = \frac{\text{var}(x) - \text{var}(e_x)}{\text{var}(x)},$$

where var is the sample variance. And similarly for $y$.

Similar adjustment can also be suggested for partial correlation, regression coefficient, and multiple correlation [1]. However, note the following for a disattenuated correlation:

- This can exceed 1.0. In that case, the value is considered equal to 1.0.
- This is not suitable for finding the confidence interval and hypothesis testing, since its **sampling distribution** is not known.
- This is not a substitute for accurate measurements. It should be used only when accurate measurements are not possible or are exceedingly difficult or costly.
- The difference between disattenuated and attenuated correlation provides a good assessment of the magnitude of measurement errors.

An application of a disattenuated correlation is seen in a microarray cross-platform study by Archer et al. [2]. The authors considered microarray gene expression in two platforms as $x$ and $y$. Fluorescent intensities for scanned microarray images were used as surrogates for true gene expression values. These surrogates obviously have errors. They noted that correlation attenuation for C3B arrays across platforms was 0.386, which happened to be more than half of the variability attributed to measurement error, and the disattenuated correlations are much higher. This suggested that the cross-platform correlations reported in previous studies without this correction were underestimates. The authors concluded that it is essential to evaluate intraplatform reproducibility while estimating a cross-platform correlation.

## attributable fraction, *see* attributable risk (AR) fraction

## attributable risk (AR), *see also* attributable risk (AR) fraction, population attributable risk, and population attributable fraction

Attributable risk (AR), also known as *absolute risk difference*, is the difference in the **risk** among the exposed and the nonexposed subjects. If the risk of lung cancer among those smoking for 10 years is 7.6% and in nonsmokers of the same age-gender is 1.2%, the risk attributable to smoking is the difference, i.e., 6.4%. This can also be understood as the *risk difference* and is also called **absolute risk reduction**. For AR to be valid, it is necessary that the groups are similar with respect to all factors except the risk factor under review, i.e., no other factor is present to alter the risk. For studying any risk, information on outcome is obtained for any given risk. This implies that this should be a **prospective study**. Risk can be any exposure or any other **antecedent**.

The method of calculating AR is different for independent samples than for matched pairs.

### *AR in Independent Samples*

For independent samples, the method can be explained with the help of the notations in Table A.11. In this table, *a, b, c, d*, and $O_1$., $O_2$. are the observed cell frequencies, and $\pi$'s are the corresponding probabilities. Sample size is $n_1$ for those with the antecedent and $n_2$ for those without the antecedent.

In terms of probabilities in Table A.11, for independent samples,

$$\text{AR} = \pi_{11} - \pi_{12},$$

provided $\pi_{11} + \pi_{21} = 1$ and $\pi_{12} + \pi_{22} = 1$. This is estimated as

$$\text{AR} = \frac{a}{n_1} - \frac{b}{n_2} = p_1 - p_2.$$

Since AR is the difference between risks in two groups, the confidence interval (CI) for large $n$ can be obtained by the usual method for

**TABLE A.11**
**Structure of a Study for Attributable Risk: Independent Samples**

| | Antecedent | | |
|---|---|---|---|
| **Outcome** | **Present** | **Absent** | **Total** |
| Present | $a$ ($\pi_{11}$) | $b$ ($\pi_{12}$) | $\boldsymbol{O_1.}$ ($\boldsymbol{\pi_1.}$) |
| Absent | $c$ ($\pi_{21}$) | $d$ ($\pi_{22}$) | $\boldsymbol{O_2.}$ ($\boldsymbol{\pi_2.}$) |
| **Total** | $\boldsymbol{n_1}$**(1)** | $\boldsymbol{n_2}$**(1)** | |

A

**TABLE A.12**
**Comparison of Relative Risk (RR) and Attributable Risk (AR) of Death Due to Lung Cancer and Cardiovascular Diseases in Heavy Smokers among British Male Physicians**

| | Annual Death Rate/1000 | | | |
|---|---|---|---|---|
| **Cause of Death** | **Nonsmokers** | **Heavy Smokers** | **RR** | **AR** |
| Lung cancer | 0.07 | 2.27 | 32.43 | 2.20 |
| Cardiovascular disease | 7.32 | 9.93 | 1.36 | 2.61 |

CI for difference in proportions. The test of hypothesis $H_0$: AR = 0 is equivalent to $H_0$: $\pi_{11} = \pi_{12}$ as well as to $H_0$: RR = 1, where RR stands for relative risk. These can be tested by chi-square test or the *z*-test. These procedures are equivalent for large *n*. The hypothesis that AR is a specified quantity $\pi_0$ can also be tested by the ***z*-test**, as explained for proportions.

RR and AR can sometimes lead to very different conclusions. Consider the data in Table A.12, which are from the famous Doll and Hill study of British doctors. It compared the mortality from lung cancer and cardiovascular disease in nonsmokers and heavy smokers (>25 cigarettes per day) from 1951 to 1961.

The RR for lung cancer was high, i.e., 32.43. This indicates a very strong **association** of lung cancer deaths with heavy smoking and underscores the importance of smoking in the etiology of lung cancer. The association of cardiovascular disease death with heavy smoking was mild, only 1.36. But the AR in the two cases was nearly the same. During 1951–1961, elimination of heavy smoking among British male doctors would have reduced the cause-specific mortality for lung cancer almost as much in absolute terms as for cardiovascular disease.

Also note that the risk of death by lung cancer in nonsmokers is low—only 0.07 per 1000—causing RR to appear so high. This is one of the limitations of RR. Against this, the cardiovascular disease mortality is high even among nonsmokers, so that the RR is not so high.

Since AR and RR are functions of $p_1$ and $p_2$ only, $p_1$ and $p_2$ can be uniquely determined when AR and RR are known. Simple algebra yields

$$p_1 = \frac{AR \times RR}{RR - 1} \quad \text{and} \quad p_2 = \frac{AR}{RR - 1}.$$

### *AR in Matched Pairs*

**Matched pairs** is a setup where the same group of people are assessed twice, such as before and after an intervention. Two separate groups where individuals are one-to-one matched for the characteristics that can affect the outcome, except the antecedent under study, are also considered matched pairs. With a dichotomous antecedent and outcome, the data in matched pairs would appear as in Table A.13.

AR in the case of matched pairs (large *n*) is estimated as

$$\text{AR}_\text{M} = \frac{|b - c|}{n},$$

**TABLE A.13**
**Matched Pairs with Dichotomous Antecedent and Dichotomous Outcome: Prospective Study**

| | Partner 1: Antecedent Not Present (Not Exposed or Control) | | |
|---|---|---|---|
| **Partner 2: Antecedent Present (Exposed or Experiment)** | **Positive Outcome (Disease+)** | **Negative Outcome (Disease−)** | **Total** |
| Positive outcome (disease+) | *a* | *b* | ***a + b*** |
| Negative outcome (disease−) | *c* | *d* | ***c + d*** |
| **Total** | ***a + c*** | ***b + d*** | ***n = a + b + c + d*** |

where *b*, *c*, and *n* are the same as in Table A.13. For matched pairs, the hypothesis $H_0$: $\text{AR}_\text{M} = 0$ can be checked by the **McNemar test** when *n* is large. For CI, however, **standard error (SE)** is needed. For matched pairs, it is given by

$$\text{SE}(\text{AR}_\text{M}) = \sqrt{\frac{(b+c)n - (b-c)^2}{n^3}}.$$

Thus,

$$95\%\ \text{CI for AR}_\text{M}\text{: AR}_\text{M} \pm 1.96 * \text{SE}(\text{AR}_\text{M}).$$

These formulas are the same as for a difference in proportions in a matched pairs setup.

For the data on the common cold in Table A.14, $\text{AR}_\text{M} = (15 - 5)/50 = 0.20$. Thus, the therapy seems to increase the 1-week relief rate by 20%. At least, this is the finding from these 50 pairs. Also,

$$\text{SE}(\text{AR}_\text{M}) = \sqrt{\frac{(15+5)50 - (15-5)^2}{50^3}} = 0.08485.$$

Thus, the 95% CI for $\text{AR}_\text{M}$ is

$$(0.20 - 1.96 \times 0.08485,\ 0.20 + 1.96 \times 0.08485)$$

or

$$(0.03,\ 0.37).$$

**TABLE A.14**
**Trial for Therapy for Common Cold: Matched Pairs**

| | Without Therapy (Control Group) | | |
|---|---|---|---|
| **With Therapy (Experimental Group)** | **Relieved within 1 Week** | **Not Relieved within 1 Week** | **Total** |
| Relieved within 1 week | 22 | 15 | **37** |
| Not relieved within 1 week | 5 | 8 | **13** |
| **Total** | **27** | **23** | **50** |

The AR is 20% in this sample, but the CI says that the actual AR in the corresponding population could be as low as 3% or as high as 37%.

Since the CI does not contain 0, $H_0$: AR = 0 can be rejected at the 5% level. If the McNemar test with continuity correction is used for this hypothesis, then

$$\chi^2_M = \frac{\left(|15-5|-1\right)^2}{15+5} = 4.05.$$

This is more than the critical value 3.841 of chi-square at 1 df at a 5% level of significance. Thus, $H_0$: AR = 0 is rejected by this method also. The excess relief with the therapy is statistically significant.

Note the following regarding RR and AR:

- Risk in a statistical sense does not necessarily refer to an adverse outcome. In the data in Table A.14, the risk is for relief within 1 week, which is a positive feature. The term *protective effect* is used for such a factor.
- This section assumes large *n*, but the **binomial** methods can be used to find CI and to test $H_0$ on RR or AR when *n* is small.
- All the RR-related parameters can be estimated from retrospective or case–control studies by replacing RR with OR as an approximation under certain condition, as explained under the term **odds ratio**. This obviates the need to carry out expensive prospective studies. However, *AR does not have this feature.*
- Another advantage with RR opposed to AR is that RR often comes close to multiplying individual RRs when two independent factors act jointly in concert. This does not happen with AR.
- The same AR, such as a difference of 4% between 60% and 64%, has an entirely different implication than same difference, say, between 2% and 6%.
- RR generally represents the magnitude of the association and provides information that can be used in making a judgment on causality. Once a causality inference is drawn, AR assumes importance in delineating the public health importance of the exposure.
- Many times, AR gives more valid information to health managers than RR. This happens particularly when the disease is rare. Suppose oral cancer has a risk of 0.0002 in non-tobacco-chewing persons but has a risk of 0.015 in those who chewed tobacco for 10 years of more. Thus, RR = 0.015/0.0002 = 75, whereas AR = 0.015 − 0.0002 = 0.0148 (less than 1.5% only). Changing habits of tobacco chewing in this setup will not make much of a difference in the overall incidence of oral cancer, RR = 75 notwithstanding. This is all the more true if only a small percentage, such as 2%, of the population chews tobacco.

## attributable risk (AR) fraction, *see also* population attributable risk and population attributable fraction

Attributable risk (AR) measures the expected reduction in risk if the exposure factor is eliminated. A slight modification of AR is the AR fraction. This is the AR calculated as a proportion of the incidence in the exposed group, i.e.,

$$\text{AR fraction} = \frac{\pi_{11} - \pi_{12}}{\pi_{11}} = \left(1 - \frac{1}{\text{RR}}\right),$$

where $\pi_{11}$ is the risk in the exposed group and $\pi_{12}$ is the risk in the unexposed group. The numerator in this expression is the AR. In the alternative expression, RR is the relative risk. In short, the AR fraction is called the **attributable fraction**. It is the proportion contributed by the exposure to the elevated risk—thus, it measures the extent of preventability of the disease from eliminating a particular factor. This is also called a **prevented fraction** because this delineates the preventable incidence when the exposure is eliminated. Another name for the same quantity is **etiologic fraction**. When multiplied by 100, this becomes the AR percent. For example, if hypertension is responsible for 30% of the risk of myocardial infarction among adult males in your area, then AR fraction = 0.30. If you want to see this in action, see, for example, the work of Cosgrove et al. [1], who found after a systematic review of literature that only 20% of cases of type 2 diabetes can be attributed to depression in people.

Note that the AR fraction can be very high even when the AR is low. Suppose the risk of low birth weight in a developed country is 0.06 (6%). Of this 0.06, let 0.04 be due to poor nutrition of mothers. Then the AR fraction of low birth weight due to poor nutrition is 67%. Eliminating poor nutrition is expected to reduce the risk of low birth weight by 67%—from 6% to 4%—but 2% risk will remain.

1. Cosgrove MP, Sargeant LA, Griffin SJ. Does depression increase the risk of developing type 2 diabetes? *Occup Med (Lond)* 2008 Jan;58(1):7–14. http://occmed.oxfordjournals.org/content/58/1/7.long

## attributes

*Attribute* is the statistical name for any characteristic of the unit or subject of the study. The convention is to restrict this term to **qualitative** characteristics measured on **nominal** or **ordinal scales**. Thus, sex, disease, nature of diet, exercise, smoking, type of treatment, etc. are attributes, but creatinine level, hemoglobin level, blood pressure, etc. are not. The latter are on a **metric scale** but can be converted into attributes, such as hemoglobin level converted to no anemia, mild anemia, and severe anemia.

A response on each attribute can be divided into at least two categories—with attribute and without attribute. This is **dichotomous**. You can have **polytomous categories** of an attribute such as blood group, which can be one of O, A, B, and AB. These are **mutually exclusive and exhaustive categories** since each person has to have just one blood group and no other blood group is possible in the same person. However, an attribute such as a symptom may not have mutually exclusive and exhaustive categories. One person can have two or more symptoms, and a subject may have a symptom other than those listed. Observations for an attribute are in terms of the number of subjects (**frequencies**) who fall into different categories of an attribute. If two or more attributes are studied together, the observations are in terms of the number of subjects in cross-classification.

Frequencies in mutually exclusive and exhaustive categories of one or more attributes give rise to what is called a **contingency table**. A basic statistical method for studying association or a pattern in responses of one or more attributes in contingency tables is **chi-square**. But other methods such as **logistic regression** and

A

**log-linear models** are also used for studying attributes when the situation so demands.

In the context of **factor analysis**, where the objective is to discover inherent natural structure among variables, the observed variables are considered **surface attributes**, and the actual underlying factors, *internal attributes*. Factor analysis determines the number and nature of the underlying internal attributes, and the pattern of their influence on surface attributes.

## AUC, *see* area under the concentration curve (AUC curve)

## autocorrelation

Autocorrelation (also called **serial correlation**) is the ordinary **correlation** of values with their preceding values. Correlation of $x_t$ at time $t$ with its value $x_{t-k}$ at time $(t - k)$ is called autocorrelation of lag $k$. If there are $n$ time points so that there are a total of $n$ values, and if $k = 3$, autocorrelation of **lag** 3 will be obtained as the usual correlation between $(x_4, x_5, \ldots, x_n)$ and $(x_1, x_2, \ldots, x_{n-3})$. When a product–moment correlation coefficient is used, for sample values, this is given by

$$\text{autocorrelation of lag } k\text{: } r_k = \frac{\Sigma(x_t - \bar{x})(x_{t-k} - \bar{x})}{\sqrt{\Sigma(x_t - \bar{x})^2}\sqrt{\Sigma(x_{t-k} - \bar{x})^2}}.$$

The usual correlation requires two different series of values, but autocorrelation does not require two series. This is the correlation with its own past values. Inherent in the concept of autocorrelation is a **time series** setup where the subjects or units are measured serially at a large number of different points in time. For example, if a man is checking his prostate-specific antigen level at 3-month intervals, the value in June will depend to a great extent on what it was in March. Death rate due to kidney diseases in a country in 2015 will depend on what it was in previous years. They are autocorrelated. This correlation may remain even when the time factor is properly accounted for because other factors such as population characteristics may also change over this period but are not accounted for.

Beware that the correlation is not necessarily with immediate preceding values but can have what is called **lag** of more than 1. This lag is also called *periodicity*. For example, diseases such as dengue fever have a seasonal pattern since dengue fever depends on *aegypti* mosquito density, which rises in the rainy season in dengue-prone areas. When monthly data are available, it may be more useful to examine the correlation of incidence in a month with the value in the corresponding month a year ago—that is a lag of 12 months. The periodicity of this disease is 12 months. Autocorrelation is a tool to find repeating patterns. The absence of autocorrelation of any lag is an indication of randomness. That is, the observations, despite being in time series, can be considered random in the sense of being independent of time.

In the case of *stationary time series*, the variance of $x_t$ at time $t$ is the same as the variance of $x_{t-k}$ at another point in time $(t - k)$. Thus, the two values in the denominator in the calculation of autocorrelation should be nearly the same in this case, particularly when the time series is sufficiently long. This will make the formula simple, and some books do give this simple formula.

When the lag is not easily identifiable from extraneous considerations, the autocorrelation function, also called **correlogram**, can provide an answer. This plots the autocorrelation of various lags versus lag (Figure A.6) and is also called a correlogram. In Figure A.6, the autocorrelation of lag 2 is high, and autocorrelations of all other lags are small, indicating that the periodicity is 2. The autocorrelation is declining as the lag increases—meaning thereby that the values are related more to the recent past and not so much to the distant past.

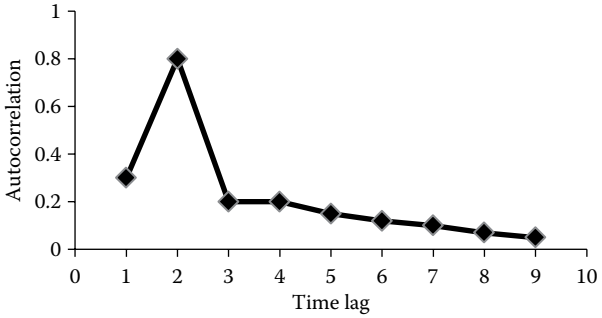

**FIGURE A.6** Autocorrelation function (correlogram).

The presence of autocorrelation violates independence, which is a requirement for many statistical methods. In effect, this tends to reduce the number of variables actually available for modeling since some values can be reasonably predicted by others. Thus, it is customary to check for autocorrelation before such methods are used. The most popular statistical method for this check is the **Durbin–Watson test**. When a change in value from the previous occasion has sensible meaning, this can be a strategy worth trying to find if these differences are uncorrelated. In that case, there is no need to worry about autocorrelation.

In the case of **regression**, for example, a snakily trend or any other nonrandom pattern of **residuals** is an indication that autocorrelation is present. A spurious trend and underestimation of uncertainties may occur when autocorrelation is present but ignored. For this reason, a whole set of separate methods are used for time series analysis with methods such as **autoregressive moving average (ARMA) models**. Similarly, **repeated measures ANOVA** is a method for serial measurements that is distinct from the usual **ANOVA**. Sometimes, **multivariate methods** are used that consider autocorrelated observations as one set.

Awaya and Nishimura [1] have provided a good example of how autocorrelation can be useful. They found that short-term changes in the number of Kawasaki disease cases in Japan have a significant positive correlation (they called it cross-correlation) with pollen releases 9–10 months ago. This suggests first that Kawasaki disease development follows pollen release and second that the lapsed period is somewhere around 9–10 months. The disease could also be the cumulative effect of pollen exposure for elapsed months.

## autoregressive models, *see* autoregressive moving average (ARMA) models

## autoregressive moving average (ARMA) models

Autoregressive moving average (ARMA) models are tools for analysis of the form and extent of the effect of previous values on the

current values in a sufficiently long **time series**. Generally, observations for not less than 50 time points are needed to use this model, and it is desirable to have more than 100. The ARMA model combines two methods—autoregression and moving averages.

### *Autoregression*

It is natural to expect in a time series setup that the observed values will have some kind of correlation with previous values—called **autocorrelation**. A step further is the form of this relationship—called **regression**. Autoregression is the regression on previous values. An elementary form of autoregression is $x_t = a_0 + a_1 x_{t-1} + e_t$, where, as you can see, the model presumes that the value $x_t$ at time $t$ is mostly determined linearly by the value $x_{t-1}$ at time $(t - 1)$. In this equation, $a_0$ is the **intercept**, $a_1$ is the **regression coefficient**, and $e_t$ is the error term. This equation is based on time **lag** 1, but you may want to investigate dependence on values with some other lag. In that case, $x_{t-1}$ is replaced by $x_{t-K}$ for lag $K$. This model can be generalized to say that the value at time $t$ depends on values on all the $K$ previous occasions. This can also be generalized to include nonlinear terms. For linear terms, the model becomes

$$\text{autoregressive model of order } K, \text{ AR}(K):$$
$$x_t = \alpha_0 + \alpha_1 x_{t-1} + \alpha_2 x_{t-2} + \ldots + \alpha_K x_{t-K} + \varepsilon_t,$$

where $\varepsilon_t$ are the errors that are independent with each other and with $x$'s, and have fixed variance $\sigma^2$.

The first step in building up an autoregressive model is to identify the lag. This must be much less than the length of the series. You may have extraneous knowledge leading you to believe that a value is mostly determined by only the previous value, in which case the lag is 1; that it is mostly determined by the corresponding value 12 months ago, as in the case of a seasonal trend; or any such plausible reason for any other lag. If there are no a priori reasons for any particular lag, the lag can be statistically identified by plotting the autocorrelation function. Autocorrelation can be significant for two or more lags. In Figure A.6, under the topic **autocorrelation**, it is possible that the autocorrelation of lag 1 is also high in addition to the autocorrelation of lag 2. In that case, the autoregressive model just mentioned can legitimately have $K = 2$.

The next step after identifying the lag is to estimate the regression coefficients of the autoregressive model. These are the parameters of the model. The estimation can be done by the **least squares method** or by using what are called Yule–Walker equations, but the Burg method is considered better [1]. These are mathematically complex procedures that we are not discussing in this volume, but the names are provided so that you can make a judicious choice while running a software package. Keep in mind, though, that higher $K$ makes the model complex, although it may provide a good fit. Parsimony cannot be sacrificed for minor gain; choose the least $K$ that still provides a reasonably good fit. A model with the fewest **parameters** yet adequately describing the data is preferred.

Autoregressive models can be useful in many **longitudinal studies**, particularly when the time points are equally spaced. Once the values are found to be dependent on the previous values (significant autoregression), it can be argued that the same trend will continue, and future values can be partially predicted by the current and previous values. For example, autoregressive models reveal that cognitive declines precede and predict physical decline in Alzheimer disease [2]. In this application, there are two series—cognitive functions and physical functions—but the basic premise is the same, and autoregressive models were used.

### *ARMA Models*

As separately discussed, **moving averages** are the averages of the first $M$ values (from 1 to $M$) out of a total $n$ ($M \ll n$), then the next $M$ values (from 2 to $M + 1$), then the next $M$ values (from 3 to $M + 2$), etc. When calculated for an appropriate period $M$, called order $M$, moving averages can considerably smoothen the time trend by averaging out short-term fluctuations. Thus, moving averages serve two purposes—they help first in detecting a trend and second in recognizing a change in trend.

The moving average (MA) model in this context is defined in terms of the errors because it is already adjusted for the mean, and it is expressed as

$$\text{moving average model of order } M:$$
$$\text{MA}(M)\ x_t = \beta_0 + \beta_1 \varepsilon_{t-1} + \beta_2 \varepsilon_{t-2} + \ldots + \beta_M \varepsilon_{t-M}.$$

Obviously, $M$ has to be much less than the length of the series denoted by $n$. When AR and MA models are combined, we get the following:

$$\text{ARMA model of order } (K, M): x_t = \Sigma_{k=1}^{K} \alpha_k x_{t-k} + \Sigma_{m=1}^{M} \beta_m \varepsilon_{t-m} + \varepsilon_t.$$

This ARMA model has come to be regarded as the most basic tool to model a time series. Through a complex process as described by Box et al. [3], some parts of which have been mentioned earlier, the parameters of this model are estimated, and the model is used for forecasting. Sometimes $\log x_t$ is modeled in place of $x_t$ itself, particularly when the variance increases as the values increase, since the log-transformation stabilizes the variance in this case.

As in the case of any model, an important step in ARMA is to validate the model. For this, the first step is to check the biological plausibility so that it looks justified. It should be able to serve the purpose for which it is built and should be feasible to adopt. The second step is to examine this statistically: not only should the model-generated values be close to the sample values, but also, the residuals should be random. Estimated parameters should also be statistically significant.

A step further is autoregressive integrated moving average (ARIMA) models. A moving average is integrated when the terms of the series are "differenced" to make it stationary by removing seasonality. For details, see Box et al. [3].

## average deviation, *see* variation (measures of)

## average linkage method of clustering, *see also* cluster analysis

Average linkage is one of the several methods of **hierarchical** agglomerative clustering. Clustering is the process of putting similar

A

units in one group and dissimilar ones in another distinct groups. In the hierarchical agglomerative process, the two most similar units are put into one group at the first stage. This group is now considered as one entity. Now the distance of this entity from other units is compared with the other distances between various pairs of units. Again, the closest are joined together. This hierarchical agglomerative process goes on in stages, reducing the number of entities by one each time. This is a bottom-up approach. The process is continued until all units are clustered together as one big entity, although it can be stopped midway when the desired kind of clusters are obtained. Note that subsequent clusters completely contain previously formed clusters in this method.

It may not be immediately clear how to compute the distance between two entities containing, say, $I$ and $J$ units, respectively. Several methods are available, such as **single linkage, complete linkage**, and **centroid**. Different methods can give different results. Jain et al. [1] and several others have studied the relative merits and demerits of some of these methods. No specific guideline can be given, but the method of average linkage has been found to perform better in many situations in the sense that the clusters obtained by this method are more compact within and fairly distinct from one another.

The average linkage method uses the average of the distances between units belonging to different entities as the measure of distance between two entities. This is also called the unweighted pair-group method using arithmetic averages **(UPGMA) method of clustering**. Consider entity A comprising $I$ units ($a_1$, $a_2$, …, $a_I$) and entity B comprising $J$ units ($b_1$, $b_2$, …, $b_J$). Then

average linkage method:

$$\text{distance between entity A and entity B } d_{AB} = \frac{1}{I \times J}\Sigma_i \Sigma_j (d_{ij}),$$

where $d_{ij}$ is the distance between $a_i$ and $b_j$. In other words, find all the distances between units of the first entity and units of the second entity, and take the average. In Figure A.7, entity A has 17 units, and entity B has 6 units. Some distances between these units are shown but not all. The average of all these distances is the distance between entity A and entity B under this method. If entity A has $I$ = 5 units and entity B has $J$ = 4 units, this would be the average of 5 × 4 = 20 distances. This method can be modified to include distances between pairs belonging to the same entity also. That is, if entity A has $I$ = 5 units and entity B has $J$ = 4 units, the distances between pairs of all these 9 entities are considered. These will be 9 × 8/2 = 36 distances, and the average of these 36 distances will be considered as the distance between entity A and entity B. This modification is called *average linkage within groups*.

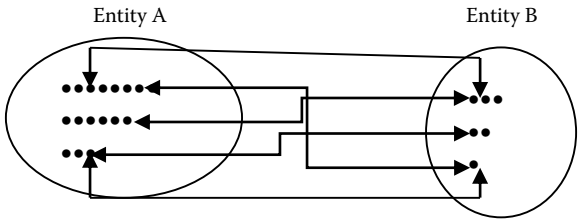

**FIGURE A.7** Average linkage distance between entity A and entity B is the average of distances between units.

The distance between units can be obtained by different methods, but the most popular is the square of the **Euclidean distance**. This is defined as $d_{ij} = (a_i - b_j)^2$ when $a_i$ and $b_j$ are univariate, and as $d_{ij} = \Sigma(a_i - b_j)^2$ when $a_i$ and $b_j$ are multivariate quantities (the sum is over elements of the multivariate quantity). For further details, see Everitt et al. [2].

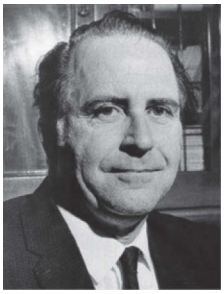
# B

## backward elimination, *see* stepwise methods

## Balaam design, *see also* crossover design

The Balaam design, first proposed by Leslie Balaam in 1968 [1], is a type of higher-order two-period **crossover design** for comparison of regimen A with regimen B in which subjects are randomly allocated to one of four sequences: AA, AB, BA, or BB. Sequence AA means that the subjects in this group receive regimen A in period 1 followed by regimen A again in period 2. Sequence AB means regimen A followed by regimen B, etc. Thus, all subjects receive a regimen two times. It has features of both parallel design and crossover design. The advantage of the Balaam design as opposed to the simple (AB/BA) crossover design is that it works when the effect of a treatment in the first period could be different from its effect in period 2. Most commonly, this happens when a carryover effect is present. Although still desirable, the washout period is less crucial in this design. However, the requirement of subjects in a Balaam design is twice that in the conventional AB/BA crossover design because now we have AA and BB groups as well.



Leslie Balaam
(Courtesy of the University of Sydney Archives.)

Berlin et al. [2] used a Balaam design for comparing the efficacy of a steroid nasal spray with an antihistaminic nasal spray in the treatment of perennial allergic rhinitis. Each of these nasal sprays was compared with placebo—thus, these in fact are two separate trials. The **difference-in-differences approach** was used to compare the two modes of treatment. Described here are essential features of one of these trials that would illustrate the use of the Balaam design.

Twenty patients with perennial allergic rhinitis were randomly allocated to four groups of five patients each. These groups received (i) a steroid nasal spray followed by a steroid nasal spray, (ii) a steroid nasal spray followed by placebo, (iii) placebo followed by a steroid nasal spray, and (iv) placebo followed by placebo, respectively. This completes the Balaam design for this trial. The crossover was done in the middle of the eighth week. Among the outcomes were severity of congestion, daytime sleepiness, and sleep. Each was scored on a scale of 0 to 4. The mean difference in these scores between the drug and the placebo was estimated.

The same process was followed for an antihistaminic spray on another group of 24 patients, and the mean difference in scores between spray and placebo were obtained. This difference was compared with the difference found with the steroid spray. The conclusion they reached is that the steroid spray was more effective than the antihistaminic spray in cases of perennial allergic rhinitis.

For the method of analysis of data from the Balaam design, see Jones and Kenward [3]. The method generally assumes that the carryover effect is determined by the first treatment irrespective of what the second treatment is. This may not hold true with some treatments.

## balanced and unbalanced designs

One of the important specifications in the **design of a study** is the sample size in different groups under study. If the number of subjects in each group is the same, the design is called balanced—if not, then it is an unbalanced design.

Consider a hypothetical example of a drug for improving hematocrit level in girls of age 10–12 years, 13–15 years, and 16–18 years in a developing country where this measure is generally low in this segment of the population. The sample size could be 30 in each group in a **one-way** setup. Since the number of subjects is the same in each group, this is a balanced design.

Sometimes, the situation demands an unbalanced design, such as illustrated in Table B.1. A study was undertaken by Wang et al. [1] on the effect of maternal smoking on birth weight in the United States. For our example, we vary this study somewhat and assume that some women, who were otherwise habitual smokers, gave up smoking off and on but not completely during pregnancy. Nonsmokers are excluded in this example. Suppose that such women were asked

**TABLE B.1**
**Average Birth Weight (kg) of Children Born to Women with Different Amounts and Durations of Smoking**

| Duration of Smoking in Pregnancy | Amount of Smoking | | | |
|---|---|---|---|---|
| | Mild | Moderate | Heavy | All |
| <18 weeks | 3.45 ($n$ = 15) | 3.42 ($n$ = 12) | 3.43 ($n$ = 7) | **3.44 ($n$ = 34)** |
| 18–31 weeks | 3.38 ($n$ = 8) | 3.40 ($n$ = 10) | 3.39 ($n$ = 6) | **3.39 ($n$ = 24)** |
| 32+ weeks | 3.35 ($n$ = 25) | 3.30 ($n$ = 23) | 3.18 ($n$ = 29) | **3.25 ($n$ = 17)** |
| **All** | **3.41 ($n$ = 28)** | **3.40 ($n$ = 25)** | **3.32 ($n$ = 22)** | **3.38 ($n$ = 75)** |

*Note:* Entries are average birth weight in kilograms.

at the time of their last antenatal visit just before birth about the duration of smoking (factor 1) and the amount of smoking (factor 2). Thus, this is a **two-way design**. At the end of the pregnancy, the researcher categorized duration of smoking as <18 weeks, 18–31 weeks, or ≥32 weeks. These are the three levels of factor 1. The amount of smoking was categorized as mild (1–9 cigarettes per day), moderate (10–19 cigarettes per day), or heavy (20+ cigarettes per day). Only days when there was at least some smoking are included in this calculation, and the amount of smoking is the average per smoking day. These are the three levels of factor 2. The **outcome** of interest (**response variable**) was birth weight of the children born to these women.

In Table B.1, there are, for instance, 15 women who smoked an average of 1–9 cigarettes per day for a total of less than 18 weeks during the entire pregnancy. The average birth weight of their babies was 3.45 kg. There are 8 women who smoked an average of 1–9 cigarettes per day for a total of 18–31 weeks, and the average birth weight of their babies was 3.38 kg, and so on. Because of unequal numbers in different groups, this design is unbalanced.

Analysis of data from an unbalanced design is more complicated than that from a balanced design for a number of reasons. Firstly, the computations are more complex, although that is not a limitation, as the software takes care of this easily. Secondly, an unbalanced design requires more careful consideration of the validity assumptions such as **homoscedasticity**, particularly when the group sizes are not large. Thirdly, the **power** of the study for detecting a specified difference is largest when the total number of subjects is equally divided among groups. Fourthly, the reason for unequal numbers may have to be explained. Thus, use an unbalanced design only when there is full justification for doing so.

## Bangdiwala *B*, *see also* Cohen kappa

The Bangdiwala *B*-statistic is a measure of qualitative agreement between two independent raters, two observers, two methods, etc., when the same subjects are classified into the same *K* categories. The problem is frequent in health and medicine: for example, when two radiologists interpret the same x-ray as being definitely negative, probably negative, probably positive, or definitely positive for a particular lesion. **Cohen kappa** also has the same function, but it adjusts for chance agreement by frequencies, whereas Bangdiwala *B* adjusts for chance agreement by areas measured by marginal totals. This was proposed by Shrikant Bangdiwala in 1985 [1].

Shrikant Bangdiwala

**TABLE B.2**
**Assessment of Intrathecal Synthesis by Two Laboratories**

| | Laboratory 1 | | | |
|---|---|---|---|---|
| **Laboratory 2** | **Positive** | **Doubtful** | **Negative** | **Total** |
| Positive | 36 | 5 | 3 | **44** |
| Doubtful | 7 | 12 | 6 | **25** |
| Negative | 1 | 4 | 55 | **60** |
| **Total** | **44** | **21** | **64** | **129** |

$$\text{Bangdiwala } B = \frac{\Sigma O_{kk}^2}{\Sigma(O_{k\bullet}O_{\bullet k})},\ k = 1,2,\ldots,K;$$

where $O_{kk}$ is the cell frequency in the $k$th row and $k$th column (diagonal element), $O_{k\bullet}$ is the marginal total in the $k$th row, and $O_{\bullet k}$ is the marginal total in the $k$th column.

Cohen kappa is much more commonly used, but its value ranges from $-a/(1-a)$ to 1, where $a$ is the agreement expected by chance. The value of the *B*-statistic ranges from 0 for no agreement to 1 for perfect agreement, which makes *B* more easily interpretable.

Consider $n$ subjects or units divided into $K$ categories by two methods, for example, $n = 129$ suspected cases of multiple sclerosis assessed for intrathecal synthesis by two laboratories as positive, doubtful, or negative ($K = 3$ categories). For such data in Table B.2,

$$B = \frac{36^2 + 12^2 + 55^2}{44\times 44 + 25\times 21 + 60\times 64} = 4465/6301 = 0.71.$$

Cohen kappa for the same data is $\kappa = 0.68$. There is hardly any difference for these data, but 0.71 on a scale of 0 to 1 can be appreciated better than 0.68 on a scale of −0.61 to 1. The value −0.61 is the value of Cohen kappa for these data when there is no agreement. Munoz and Bangdiwala [2] have provided a comparison of Cohen kappa and Bangdiwala *B*, and highlighted how *B* can also be represented graphically (see **agreement charts**).

## bar diagrams

The bar diagram is probably the most common form of visual representation of data and is indeed very versatile. If the data are **mean**, **rate**, or **ratio**, the bar may be the most appropriate diagram. It is especially suitable for categories on a **nominal** or **ordinal scale**, although it can be drawn for **metric categories** as well. The bar diagram is more suited to disjointed categories, but that is not a prerequisite. For example, age-specific fertility rate in age groups 15–19, 20–24, 25–29, etc. can be shown by a bar diagram despite age categories being contiguous. This is because the value to be depicted is a rate. Had this value been the number of subjects in each age group, the diagram would have been a **histogram**.

In a bar diagram, groups are represented on one axis, and the values in those groups, on the second axis. The length of the bar is proportional to the value in that group. The width of the bar is such that the bar diagram does not look awkward, but it has no meaning.

Generally, a suitable gap is kept between the bars. The width of the bars and the space between consecutive bars is usually kept the same unless one particular category is to be highlighted.

Figure B.1a represents the percentage distribution of palpable breast lumps by histopathological diagnosis in different age groups. This is called a *divided-bar diagram*. According to these data, as age advances, the relative incidence of carcinoma increases. If the total number of women with palpable breast lumps was highest in the age group 45–49 years, these bars would not show this information, since each bar represents the total cases in the respective age groups as 100%. If the number of cases of age 30–34 years is 20 and that of age 35–39 years is 80, both will have the same height in this type of diagram. The comparison in this graph is of percentages with different diagnoses across various age groups.

Figure B.1b is a *multiple-bar diagram* showing the mean and **standard deviation** (SD) of some lung function parameters in male workers in factories with different pollutants. Both between- and within-factory comparisons can be made with the help of this diagram.

The bars do not have to be vertical. Sometimes, horizontal bars give a better representation. In fact, some call diagrams with vertical bars *column diagrams* and those with horizontal bars *bar diagrams*. Figure B.1c is one such diagram with horizontal bars, simultaneously showing two pieces of information for some magisterial districts in South Africa [1]. One horizontal axis measures the number of cervical smears per 1000 women, and the other, the ratio of malignant to suspicious smears. Note how a bar diagram can quickly become complex.

Sometimes, it is difficult to properly interpret a bar diagram in the literature because the information provided is incomplete or the diagram is not properly drawn. Whenever feasible, each bar should be accompanied by the value it represents. For example, if a bar shows that 42% of cases reporting pain in the knees have arthritis, mention "42%" at the top of the bar or inside the bar so that the reader can immediately understand. The bar diagrams in Figure B.1 have this deficiency.

A special bar diagram used in demography is the **population pyramid**. This shows the number or percentage of males and females in different age groups in a population. Another is the **epidemic curve**, which shows the number of new cases arising in a population at different points in time. See these topics for details.

## Barnard test

It is customary to use the **Fisher exact test** for detecting any **association** in a **2 × 2 table** with small frequencies. This test assumes fixed marginal totals—both row totals as well as column totals. This restriction is valid for a situation where, for example, you have six persons with disease and six without disease, and the test is built up in a manner that it is constrained to give six positive (some may be without disease) and six negative (some may be with disease) results. Note that this is an unnatural restriction and would rarely

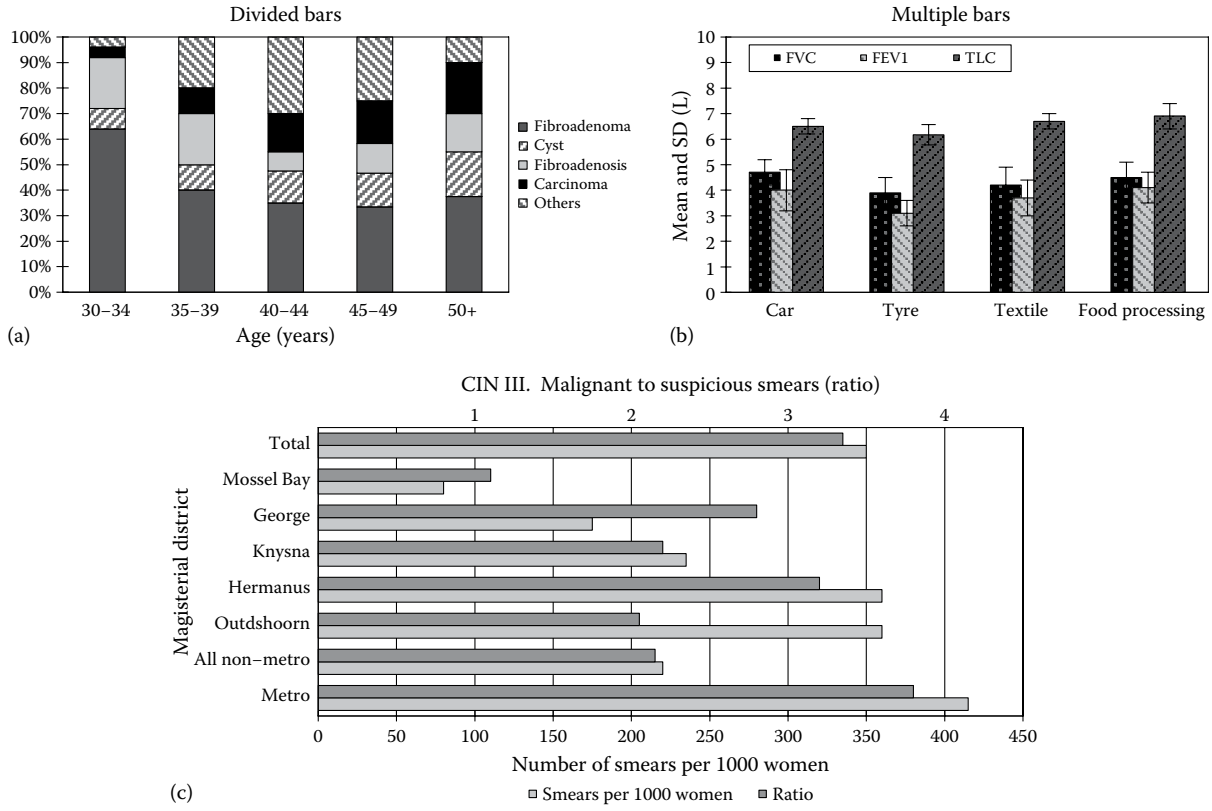

**FIGURE B.1** Different types of bar diagrams: (a) Palpable breast lump by histopathological diagnosis in different age groups; (b) mean and SD of lung functions in male workers in different types of factories; (c) ratio of malignant to suspicious smears and their screening incidence by magisterial district, Western Cape, South Africa. (From Bailie R, Bourne D. *Int J Epidemiol* 1996;25:46–52. http://ije.oxfordjournals.org/content/25/1/46.long.)

B

**TABLE B.3**
**Distribution of Diabetic and Nondiabetic Subjects by Obesity**

| | Diabetics | Nondiabetics | Total |
|---|---|---|---|
| Obese | 10 | 5 | **15** |
| Nonobese | 2 | 4 | **6** |
| **Total** | **12** | **9** | **21** |

hold in practical situations. This restriction makes the test overly conservative (i.e., fails to reject the **null hypothesis** when it should). To overcome this problem, another test, called the Barnard test [1], has been proposed, which requires fixed margins on one side and not both sides. This would be the case when two populations are being sampled as naturally occurs in a **case–control study** and in a **prospective study**. George Barnard proposed this in 1945, to the chagrin of Fisher. This test is more powerful but computationally difficult and is not popular yet. For a comparison between the Fisher exact test and the Barnard test, see Mehta and Senchaudhari [2]. They have shown that the *P*-value for the same data is 0.0641 by Fisher exact test and only 0.0341 by Barnard test. At a significance level of 0.05, the Fisher test does not reject the null, but the Barnard test does. This illustrates that the Barnard test is more powerful in detecting a difference.

George Barnard

The Barnard test uses the product of two **binomials** in place of the hypergeometric used by Fisher. Consider a sample of 12 diabetics and 9 nondiabetic subjects. Suppose 10 of 12 and 5 of 9, respectively, are obese. This could be written as a 2 × 2 table (Table B.3).

Note in this case that the column totals are fixed but not the row totals. Under the null hypothesis that the prevalence of obesity is the same $\pi$ in the two groups, the probability of this configuration by the product of two binomials (product **law of probability** can be used in this case since the two groups are independent) is

$$[^{12}C_{10}\,\pi^{10}(1-\pi)^{(12-10)}]*[^{9}C_{5}\pi^{5}(1-\pi)^{(9-5)}].$$

A similar probability can be obtained for all the configurations adverse to the null and favorable to the alternative hypothesis. The sum of all these probabilities will be the *P*-value for the Barnard test.

## Bartlett test

**Homoscedasticity** is the equality of variances in different groups. This requirement should be reasonably satisfied for **analysis of variance (ANOVA)** and some other parametric procedures. This can be checked graphically by the **box plot** for different groups. The conventional statistical test for checking homoscedasticity is the Bartlett test. This was proposed by Maurice Bartlett in 1937 [1].

Maurice Bartlett

The Bartlett test compares the weighted **arithmetic mean** of the sample variances with their weighted **geometric mean**. The geometric mean has the property that it is always less than the arithmetic mean and is equal only when all the values are equal. A large difference between the arithmetic mean and the geometric mean indicates that the values are different. A function of these two types of means is used as the **test criterion**, which follows an approximate **chi-square distribution** for large $n$ when the underlying distribution is Gaussian. The **degrees of freedom** are $K - 1$, where $K$ is the number of groups. The test should not be statistically significant for assuming homoscedasticity. The approximation is unsatisfactory if sample size in many of the $K$ groups is less than 5.

The validity of this test is heavily dependent on the distribution of the underlying **variable** being Gaussian and requires a large **sample size**. For this reason, many software packages now use the **Levene test**. The Levene test is based on the median and thus is more robust to any departure from Gaussianity.

Besides **ANOVA**, the Bartlett test can be used in a variety of other situations where equality of variances is a requirement. Its multivariate analog is available [2] for use with **Hotelling $T^2$** and **multivariate ANOVA** setups to test homogeneity of **dispersion matrices** across groups. This version of the test also requires **multivariate Gaussianity** of the data.

One of the requirements of a successful **principal components** analysis and **factor analysis** is that the **correlations** are sufficiently high among variables. Another Bartlett test [3] can be used to test the null hypothesis that the correlation matrix is proportionate to an identity. An identity matrix is the one in which the diagonal elements are unity (the correlation of a variable with itself is always 1) and the off-diagonal elements are zero (no correlation between variables). This is called the Bartlett test for **sphericity**. Such a test should reject the null hypothesis (say, $P < 0.05$) for factor analysis to be a useful procedure.

## baseline, *see also* baseline equivalence, baseline hazard/risk

Baseline refers to the status of the subjects of a study before exposure to a potentially hazardous or beneficial maneuver. Postexposure values are compared with baseline values for assessing whether the exposure made any difference. When preexposure values are not available for a group, values in another group without exposure can play the role of baseline. In this case, for a valid comparison, the exposed and unexposed groups are chosen such that they are similar at baseline, particularly with regard to the factors that can influence the outcome. This is called *baseline matching*. This is one of the methods used to achieve **baseline equivalence**.

In **paired samples**, the change from preexposure to postexposure is the typical outcome of interest. Since baseline (pre) values can affect the amount of change, the percent change is sometimes calculated. This works well provided that the percent change is independent of the baseline. This limitation tends to be overlooked, and this can lead to spurious results, as illustrated in the following example.

Given here are hypothetical data on the rise or fall in hemoglobin (Hb) levels in a random sample of eight adolescent girls after iron supplementation for 2 weeks.

Rise in Hb level (g/dL): 0.4 0.7 −0.9 0.3 0.1 0.5 0.9 0.2

A one-sample ***t*-test** reveals that this rise, on average (mean rise = 0.275 g/dL), is not statistically **significant**. Although the rise in this example is calculated over the baseline values, a rise of 0.3 over, for example, 8.7 g/dL is considered the same in this example as the same rise over, say, 13.7 g/dL. In this sense, the rise does not consider the actual Hb level in the subjects before the start of the supplementation. Now examine the situation when the baseline levels are also considered. The following are the corresponding Hb levels (g/dL) of these eight girls before supplementation:

Baseline Hb level (g/dL): 10.1 8.5 13.8 9.7 12.4 9.0 8.6 12.1

This indicates that the girls with the higher baseline levels of Hb showed a smaller rise. In fact, a girl with an Hb level of 13.8 g/dL showed a fall. The relationship can be examined by running a **simple linear regression** of rise on the baseline level. This regression equation is

$$\text{rise} = 2.85 - 0.244\ (\text{baseline Hb}).$$

This shows that the rise, on average, is higher when the baseline values are lower and becomes negative in this case when the baseline Hb level exceeds 11.7 g/dL. Since a fall can be ruled out in the case of iron supplementation except for extraneous reasons, it might be concluded that iron supplementation in such girls is possibly not useful when Hb level is already 11.7 g/dL or higher. The lesson from this example is that consideration of baseline values can be important for valid inference.

Baseline is important in some other contexts as well. In the case of population studies, baseline information can be obtained by what is called **health situation analysis**. Baseline information on enrolled subjects in a clinical trial may indicate that the design needs to be modified with respect to doses, sample size, duration of follow-up, type of subjects (say, age 70+ to be excluded), etc. In a prospective study, some subjects generally drop out during the course of the investigation. Since baseline information on them would be available in this case, that can be used for adjustment of results.

It is usually preferable to undertake an **analysis of covariance (ANCOVA)** of the postintervention values with baseline values as a **covariate** rather than undertaking an analysis of changes from baseline. ANCOVA would adjust results for differentials at the baseline. For a convincing example, see Vickers [1].

## baseline equivalence, *see also* baseline

The term *baseline equivalence* is generally used in the context of case–control studies, medical experiments, and clinical trials. It refers to the fact that the subjects in different treatment groups to start with are similar, and more or less ensures that any difference observed subsequently between groups can be legitimately ascribed to the exposure or intervention.

In a case–control setup, generally, the subjects with disease and controls without disease are compared with respect to past exposure. These two groups should be equivalent for all characteristics except the exposures under study. This is referred to as baseline matching.

Baseline equivalence is usually easily achieved in medical experiments because of the nature of the material. For example, an experiment on the shape of red blood cells at various ionic strengths will usually fulfill the baseline equivalence requirement because various groups of cells (including those in the control group) typically come from the same stock. It is because of this equivalence and standardized laboratory conditions that the experiments are able to provide compelling evidence of the presence or absence of a cause–effect type of relationship.

In a clinical trial setup, the difference in outcome between the test group and the control group can be legitimately ascribed to the intervention when the participants with and without intervention are equivalent to begin with. **Randomization** is a very potent tool to achieve such equivalence. This works well for trials on a large number of participants but can occasionally fail for small samples. If a trial on a large enough sample cannot be conducted, alternate strategies are as follows:

- Identify pairs of participants matched for baseline characteristics and **randomly allocate** one of each pair to the two **arms** (test and control) of the trial. However, this approach is applicable only if a group of subjects is readily available for randomization so that matched pairs can be selected. In practice, that is rarely the case as the subjects are generally recruited and randomized one at a time.
- Adopt **stratified randomization** to ensure that the subjects with similar baseline characteristics are randomized in nearly equal numbers to treatment groups.
- Use **minimization**, which determines allocation to treatment groups at the time of randomization of each individual subject by considering the baseline characteristics of all previously randomized subjects and the one now to be randomized. The minimization process then allocates the subject with nearly 100% probability to the treatment group, which results in the best baseline equivalence between the treatment groups.

It is quite common to use statistical tests to compare groups with respect to baseline characteristics to confirm baseline equivalence.

However, if allocation to groups has been at random, this is not usually appropriate or technically valid. Such tests determine the probability that observed between-group differences in baseline characteristics could have arisen by random allocation to the groups, so they are not really appropriate when it is already known that allocation was at random.

## baseline hazard/risk

**Hazard** is the instantaneous rate of an outcome at a particular point in time. This presumes that the outcome depends on time, for example, the hazard of death at age 70 years. While the hazard will vary with time, in most situations, it will also depend on other factors as well. For example, the hazard of death of a person at age 70 years when the person is male, was diagnosed with leukemia 2 years ago, and is thin is different from the hazard of death of a person who is female and thin with no other risk factor. Baseline hazard is the hazard in the absence of any risk factor. In this example, the hazard of death at age 70 years for a person who has no other risk factor is the baseline hazard for this age.

The most pronounced application of the baseline hazard is in the **Cox model**. This is given by

$$h(t) = h_0(t)*\exp(b_1x_1 + b_2x_2 + \ldots + b_Kx_K),$$

where $h(t)$ is the hazard of the outcome such as death at time $t$ and $h_0(t)$ is the baseline hazard at this time when all $x$'s are 0. These $x$'s are the risk factors, as explained in the preceding paragraph. In the context of the Cox model, they are called *covariates*. Note that $h_0(t)$ represents the effect of time alone without the covariates. The binary outcome in this is not necessarily survive/die and could be any end point reached or not reached. Interpretation of the baseline hazard $h_0(t)$ remains the same.

Another similar term is *baseline risk*. This has a slightly different interpretation. This is the risk in an unexposed group at a defined end point. Note that **risk** is obtained for the terminal event, whereas hazard can be computed for any point in time during the interregnum.

Baseline risk can play an important role in the interpretation of **relative risk** (RR). For example, if the 10-year risk of death with leukemia is 0.99, and with anemia, only 0.02, then the RR of death with leukemia is nearly (0.99/0/02 ≈) 50. On the other hand, if the comparison is with breast cancer cases, where the 10-year risk of death may be 0.60, then the RR is only 0.99/0.60 = 1.65. This is as high as it can get in this situation because no risk can exceed 1 (see the numerator of this RR). The value of RR is greatly influenced by the risk in the control group. Also, 1 out 2 is 50%, and 50 out of 100 is also 50%. Underlying numbers are important. These two aspects are many times forgotten while interpreting the value of RR.

## bathtub curve/distribution

A bathtub curve has a shape similar to that of a bathtub, with high values at two extremes and low values in the middle. It is difficult to imagine a medical situation where values at both the extremes are nearly equal to give it an exact bathtub shape, but some medical situations approximate this pattern. The plot of the risk of death in human beings over age is shaped nearly like a bathtub (Figure B.2a). The risk of death is relatively high in the earliest years of life, decreasing fairly soon to a minimum, remaining low for a substantial part of life, and then starting to climb again sometime around age 50 years, when people start to die rapidly as they grow older. Thus, it has three distinct phases—decreasing risk, nearly a constant risk, and steeply increasing risk.

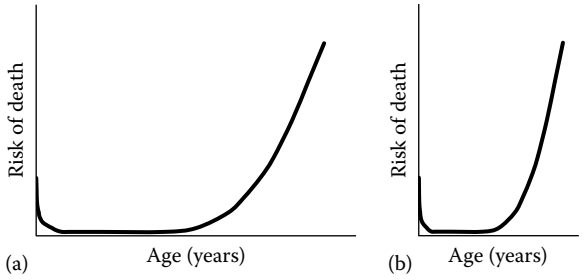

**FIGURE B.2** Bathtub curve for risk of death over age (a) with normal $x$-axis and (b) with shrunken $x$-axis.

The risk of many diseases or risk of death is high for unusually low values of most medical parameters as well as for exceedingly high values of these parameters. For example, low body mass index (BMI) is also harmful, although possibly not as much as very high BMI, while persons with values between, say, 20 and 27 kg/m$^2$ have low risk. Similarly, the risk of failure of, say, a kidney transplantation is high in the initial few days or weeks. If that period passes, the risk is low for quite some time but steeply increases after a few years as age advances. All these situations yield a bathtub-shaped curve.

If the $x$-axis (age in Figure B.2a) is shrunk, the same curve may look like a **J-shaped curve**. Figure B.2b is based on exactly the same data, but the $x$-axis is shrunk, giving it a J-shape. If the risk at the beginning of life is almost as high as at the end, this may look like a **U-shaped curve** with a shrunk $x$-axis, and like an actual bathtub for an expanded $x$-axis, the difference being that the flat part in the U-shaped curve in the middle is practically nonexistent or small, whereas this region is substantial in the bathtub curve.

Note that the examples we have provided are for the bathtub curve and not for bathtub distribution. This becomes a **distribution** when the $y$-axis is frequency or percentage of subjects in place of risk or rate. In the case of deaths over age, if you plot the number of deaths in a general population over age, you will have a bathtub shape to a point, say, up to the age 85 years, but after that, since the population is small, the *number of deaths* is also small. This gives rise to what we call a **smoke-pipe distribution**.

## Bayesian confidence interval, *see* Bayesian inference

## Bayesian inference, *see also* Bayes rule

Bayesian inference is a method to derive new knowledge on the basis of some kind of objective collation of the existing evidence. This looks like an elegant way to evolve but has stumbling blocks. Some believe that Bayes, who was associated with a church, devised his rule as an attempt to prove the existence of God [1]. We describe the Bayes methodology in the context of statistical inference.

Among the various ways in which the statistical inference approach can be divided, one is based on how the inferences are derived. One approach is called Bayesian, and the other is classical, called the *frequentist approach*. For example, when we find a **confidence interval (CI)**, the inference is based on what *repeated* CIs with similar samples will reveal. This is a frequentist approach, pioneered by Ronald Fisher, considered by many as the father of statistics. A 95% CI, when computed for, say, 200 random samples of the same size from the same population, is likely to contain the true value of the parameter 190 (95%) times. The value of the parameter is considered fixed. In contrast, in a Bayesian CI, the parameter value

is considered to have a **distribution**. This is called the prior distribution since it is based on prestudy knowledge. The sample values are used to "update" this *prior distribution* using the **Bayes rule**, and this updated distribution is called the *posterior distribution*. The CI is then based on this posterior distribution. In the case of testing of a hypothesis, Bayesian procedure is to compute the probability of the value of the parameter specified in the null hypothesis given in the sample values. In terms of **conditional probability**, this can be written as $P(\theta|x)$, where $\theta$ is the parameter, $x$ is the sample, and $P$ stands for probability. On the other hand, in a frequentist approach, our inference is based on $P(x|\theta)$.

Note that the Bayes rule is central to the Bayesian inference. This rule helps to convert one **conditional probability** $P(x|\theta)$ into its inverse $P(\theta|x)$ but requires knowledge of $P(\theta)$ and $P(x)$. These probabilities depend on the distribution of $\theta$ and the distribution of $x$. While the distribution of the sample values $x$ is easy to handle, the difficulty arises in postulating a prior distribution of $\theta$. This assumes that we know some properties of the parameter on the basis of which $P(\theta)$ can be postulated. For example, we may postulate on the basis of the previous experience that the chance of the next person in a renal clinic having a failed kidney is 1 in 15—that is, the clinic has been receiving, on average, 1 out of 15 cases with a failed kidney. This is our prior belief. If all of the next few cases turn out to have a failed kidney, our belief alters, reflecting the posterior probability. Such probabilities are commonly used in clinical practice. When a patient goes to a clinic with certain complaints, you mentally evaluate his/her chances of being affected by a particular disease on the basis of clinical findings. When the results of medical tests or radiological images are available, that belief may alter.

Kim and Kim [2] used a Bayesian inference approach in the empirical prediction of genomic susceptibilities for multiple cancer classes. They examined four prediction models and used their combined prediction of the susceptibility for each test individual using a Bayes approach.

## Bayes rule, *see also* Bayesian inference

The basic premise of Bayes is to change our mind as new evidence emerges. Thomas Bayes described this rule in the 1740s, but it was Laplace who described it independently in 1774 and gave it a modern mathematical form [1]. The rule can be understood easily in terms of the basic concepts of **probabilities**.

Thomas Bayes

The Bayes rule has widespread applications, but this section is restricted to its prominent use in medical sciences. Medical knowledge sometimes is such as to provide probabilities of the form $P$(complaints|disease), which is the probability of complaints for a given disease, whereas the probabilities actually required in diagnostic process are the probability of disease given the complaints, namely, $P$(disease|complaints). Both of these are conditional probabilities. One is the inverse of the other in the sense that the first is the probability of complaints conditioned on disease being known, and the second is the probability of disease conditioned on complaints being known. The Bayes rule is a tool that helps in finding such **inverse probabilities**.

For simplicity and for generalizability, denote the set of complaints by $C$ and the particular disease by $D$. When some additional information is available, $P(D|C)$ can be obtained from $P(C|D)$ by using the Bayes rule. For this conversion, two additional probabilities are required. The first is $P(D)$. This is the **prior probability** of the disease in the absence of any information and is the same as the prevalence of the disease in the subjects under investigation. This may be derived from, for example, the records of the health facility where this is to be applied or may be available from a survey. The second is $P(C)$. This is the **relative frequency** of the complaints in similar patients. Special efforts may be required to compute $P(C)$, but it is worth the effort given the difficulty in obtaining $P(D|C)$ directly. As it turns out, $P(C)$ can often be easily computed by an alternative method, given later in this section. Once these probabilities are available, the required inverse probability $P(D|C)$ can be computed from

$$\text{Bayes rule: } P(D \mid C) = \frac{P(C \mid D)P(D)}{P(C)}.$$

This gives the **posterior probability** after the complaints are known. The probabilities $P(C|D)$, $P(D)$, and $P(C)$ may be available in a research setup, but for everyday practice, an educated guess may have to be made on the basis of knowledge and experience, as just mentioned.

The Bayes rule is more useful when it is known that the set of complaints $C$ can occur only in $K$ **mutually exclusive and exhaustive categories**. If the group of complaints (abdominal pain, vomiting, and constipation) are considered to occur only in abdominal tuberculosis (abdTb) ($D_1$), amebiasis ($D_2$), and hepatitis ($D_3$) and no other disease, and if the diseases do not really overlap, then we have $K = 3$ mutually exclusive and exhaustive categories of $C$. If that is so, we can find the probability of abdTb given those complaints by using the following:

$$\text{Bayes rule (slightly expanded version): } P(D_1 \mid C) = \frac{P(C \mid D_1)P(D_1)}{P(C \mid D_1)P(D_1) + P(C \mid D_2)P(D_2) + P(C \mid D_3)P(D_3)}.$$

This version obviates the need to know $P(C)$—the relative frequency of complaints in this example, which could be difficult to obtain in many cases. The following example illustrates its use and also the caution required in interpreting an inverse probability.

Suppose only 1 in 2000 male adults in an area suffers from a coronary disease for which a screening tool is the electrocardiogram (ECG). When a person actually has the disease, suppose ECG is so good that it is positive 98% of the time, and it is also positive just 1% of the time in those who do not have the disease. What is the probability that an ECG-positive person actually has the disease?

Let $D_1$ = {person has the disease}, $D_2$ = {person does not have the disease}, and $C$ = {positive ECG}. Then, the preceding paragraph says that $P(D_1) = 1/2000 = 0.0005$, $P(D_2) = 1 - 0.0005 = 0.9995$, $P(C|D_1) = 0.98$, and $P(C|D_2) = 0.01$. Use the following to find $P(D_1|C)$.

Since $D_1$ and $D_2$ are mutually exclusive ($K = 2$ in this case), an expanded version of the Bayes rule gives

$$P(D_1 \mid C) = \frac{0.98 \times 0.0005}{0.98 \times 0.0005 + 0.01 \times 0.9995} = 0.047.$$

If the values are really as in this example, a very small $P(D_1|C)$ indicates that a positive ECG does not provide any clue to the disease. This may seem paradoxical in view of the 98% positivity of the ECG in coronary cases. The difficulty is in it being positive in 1% of the subjects without the disease. And this group is very large: 1999 out of 2000 in this screening exercise. Thus, most positive results arise from errors rather than from diseased cases. A tool with a much smaller error rate is required to be effective in such a situation.

In clinics, however, an ECG will be done only for those who are otherwise suspected to have a coronary problem. And in them, $P(D_1)$ would be high. $P(C|D_1)$ would also be high. Thus, $P(D_1|C)$ would be much higher in a clinic setup than the one obtained earlier in a screening example. ECG will not be a waste of resources in this setup.

## before–after design/study

In an experimental setup, when a separate group of units receives a control regimen, this is called a **parallel control** group. Some experiments are undertaken without a parallel control group. For example, a study measuring tail-flick latency in mice exposed to heat before and after administration of an analgesic does not have a parallel control group. Such a design is called a before–after design, and the experiment is called a before–after study. Since there is no parallel control group in this setup, this is sometimes referred to as an *uncontrolled design*, although this is rather misleading since each subject serves as its own control. Many call this a **quasi-experimental design** because of the lack of random allocation to a test and comparison group.

Instead of incorporating a separate control group, it is indeed sometimes prudent to assess the outcome before and after the intervention in the same unit. In a bacterial colony, the bacteria could be counted initially, provided a specific favorable environment such as sucrose in the medium, and counted again after specified time. This is a before–after experiment and the simplest form of a **repeated measures design**. In a **clinical trial**, one can measure oxidative stress enzyme levels (e.g., superoxide dismutase) in Parkinson disease, introduce an intervention to reduce this stress, and measure again. A parallel control group is not necessary in this setup, although some experiments may have a parallel group as well for observing the trend in them also after placebo.

Before–after experiments have smaller variability than parallel-group designs because the subjects for before–after measurements are the same. Such experiments also require fewer subjects to detect the same effect as compared with parallel control experiments.

A major problem with the before–after design is that it assumes that nothing except the intervention is changing the outcome. But the observed effect could be at least partially due to psychological factors that operate in a **placebo** group. There might also be some natural changes over time. The **Hawthorne effect** may also be working. Extremely low values at prestage could become slightly high, and extremely high values, slightly low because of the effect of **regression to the mean**. All these are inextricably mixed, and it is impossible with this type of design to separate the intervention effect from other effects. Lipsey and Wilson [1] identified 45 reviews on behavioral treatments that separately reported the pooled estimate for controlled and uncontrolled studies and found the observed effect for uncontrolled studies to be greater than that from studies with parallel controls. This explains why a before–after design is typically used when parallel controls are not feasible and randomization is difficult.

The analysis of data from a before–after study is generally done by considering the difference between *post-* and *pre-*values. Since both these values are subject to sampling fluctuation and measurement errors, the differences are kind of doubly exposed to these "ills." The better approach is to use pre-values as covariates and do an **analysis of covariance**. If a parallel control group is also subjected to before–after measurements, a commonsense approach to arrive at the causative relationship is the **difference-in-differences** method. The before–after difference in the test group is compared with the before–after difference in the control group. If this difference in differences is statistically significant, you can safely conclude that the test regimen has some effect. Realize, though, that this method also is approximate due to problems of double errors with the differences. One can hope that in the case of a difference in differences, these errors cancel out between the groups.

## Beherens–Fisher problem, *see* Welch test

## bell-shaped distribution, *see* Gaussian distribution

## Berkson bias

This bias occurs when a conclusion is drawn from a special group of subjects that do not represent the target population. Berkson bias is common in case–control studies in a hospital setting where the controls also are from the hospital and these controls show overrepresentation (or underrepresentation) of the risk factor under study. Overrepresentation can happen since hospital controls will usually have some disease and this disease may also be related to the risk factor under study.

Consider a simple example of smoking as a risk factor for lung cancer. If this study is done in a hospital setting using a case–control design, you might take patients with diseases other than cancer from the same hospital as controls. However, these patients may also have a preponderance of smokers, as smoking can have manifestations other than lung cancer; for example, they may have asthma. Despite being noncancer patients, asthma patients are not proper controls for studying smoking as a risk factor. Controls should be chosen such

that they have the same prevalence of the risk factor (in our example, smoking) as in the general population. Even cases of fracture may not be appropriate controls, since it is possible that smokers get more fractures than nonsmokers.

Joseph Berkson

The concept of Berkson bias was first introduced by Joseph Berkson in 1946 [1]. Details are available in Westreich [2].

Hernández-Díaz et al. [3] have discussed the paradox that among low-birth-weight (LBW) babies in the United States, infant mortality rate (IMR) was lower for children born to smokers compared with the children born to nonsmokers. This was not due to a beneficial effect of maternal smoking but possibly because LBW babies born to nonsmokers had other debilitating conditions such as birth defects that caused LBW and higher mortality. Another example is provided by Peroutka et al. [4], who concluded that certain migraine comorbidities reported in the literature may have resulted from Berkson bias as opposed to a shared pathophysiological variation in the C3 gene. These examples illustrate that Berkson bias is an important phenomenon and cannot be overlooked by studies that investigate cause and effect or etiology using hospital patients.

## best subset method of choosing predictors

As the name implies, the best subset method is choosing a subset of predictors out of all possible subsets that best predicts or explains the outcome. The criterion for "best" is defined before the procedure begins—this could be highest **coefficient of determination**, highest **statistical significance**, least **misclassifications**, most convincing biological plausibility, or any other such criterion.

In a multivariable situation such as in **regression** and **discriminant function**, it is customary to start with a large number of possible predictors. Using all of them is one possibility, but that tends to make the model too complex for adoption. The estimates of the regression coefficients also become less efficient. Various statistical methods are used to select a few that are more relevant or significant. Suppose there are $K$ predictors ($x_1$, $x_2$, …, $x_K$) to begin with, and the outcome variable is $y$. Under the best subset method, the relationship of $y$ with each $x_k$, of $y$ with pairs $x_k$ and $x_{k*}$, of $y$ with each triplet of $x$'s, etc. are examined. That is, all possible combinations are tried. With $K$ predictors, this will amount to a total of $2^K$ combinations. If $K = 4$, there will be a total of $2^4 = 16$ combinations. This number will rise steeply as the number of candidate predictors increases. Fortunately, statistical packages can easily handle these calculations, and the subset of predictors that provide the best prediction can be identified.

In a **multiple linear regression** setup, for which the best subset method is commonly used, only the linear combinations are examined. However, it is possible to have, for example, $x_2 = x_1^2$ or $x_3 = x_1 * x_2$, or any such function, so long as they do not introduce **multicollinearity**. All other requirements such as **independence**, **Gaussianity**, and **homoscedasticity** must also be fulfilled.

## beta distribution

The beta distribution is a **distribution** with varying shapes depending on the value of its parameters (Figure B.3). This distribution has two **parameters** in the same way that the Gaussian distribution has two parameters. One is generally denoted by α and the other by β, although these are not universally accepted notations (**Gaussian distribution** has universally accepted notations for its parameters, namely, μ and σ). In the case of Gaussian distribution, μ denotes mean, and σ denotes standard deviation, but this is not so for α and β for beta distribution. But they also determine the shape of the distribution. Figure B.3 shows the shape of this distribution for different values of α and β. For example, the distribution is just a flat line (see **uniform distribution**) for α = 1 and β = 1 and is right skewed for α = 2 and β = 6 but an extreme shape for α = 2 and β = 0.1. It has a symmetric shape when α = β.

Because of the wide and varied shapes available for different values of α and β within the beta distribution, this distribution is sometimes used to model health outcomes. For example, in an interesting paper, Kalmijn et al. [1] used beta distribution to model the distribution of happiness score among respondents. They measured happiness on a scale of 0 to 10. Among its statistical usage is in exact **confidence interval** for a probability π in a **binomial** case, which is obtained by using a beta distribution.

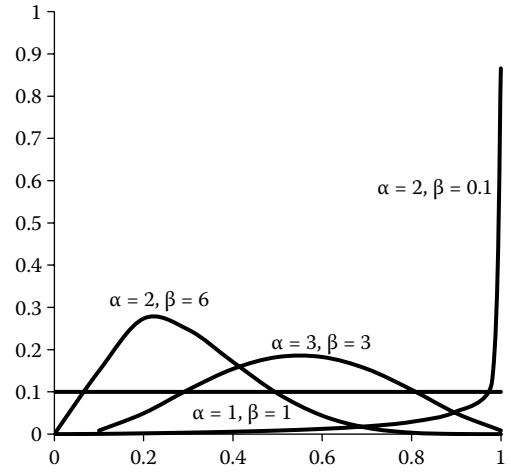

**FIGURE B.3** Shape of beta distribution for different values of the parameters α, β.

While trying to fit a beta distribution to a data set, the first step would be to **normalize** the values $y$ by using the transformation $x = (y - A)/(A - B)$, where (A, B) is the possible range of $y$ values. The possible range can be wider than the range you actually observed in your sample. These can be ignored. After normalization, all values of $x$ will be between 0 and 1. The next step is to calculate the mean and variance of your $x$ values. The estimates of $\alpha$ and $\beta$ are obtained by solving the equations

$$\text{mean} = \frac{\alpha}{\alpha+\beta} \text{ and } \text{variance} = \frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}.$$

These equations can be solved easily for $\alpha$ and $\beta$ by using some high school algebra. Use the estimated values of $\alpha$ and $\beta$ to get the distribution with the help of appropriate software.

## beta error, *see* Type II error

## biased estimate, *see* unbiased estimate

## biased sample

A sample is considered **unbiased** when it truly represents the features of the target population. If it does not, it is a biased sample. This is a frequent source of error in statistical conclusions. This can happen even when the selection is **random** or even when **random allocation** is made in experimental studies. A large sample tends to magnify this bias rather than control it. The following types of subjects can provide a biased sample in medical studies.

### *Survivors*

Consider the relationship of lung functions with age after the age of 50 years. It is well known that lung functions decline because of biological degeneration in old age, but the gradient differs from population to population. How does one find the exact effect of age in a particular population? Those with poor lung functions are likely to be in poor health and thus have less longevity. They may not be available in old age. Any estimation based on survivors is bound to be biased. It may not be easy to find the correct gradient in this case. Perhaps a more valid picture is obtained if lung function parameters of those dying at varying ages are available in records and are used for adjustment, but such data are not usually available. In the absence of such adjustment, lung functions among survivors are not a true reflection of the age-based gradient. The actual gradient could be a sharper decline. Similarly, a study based only on hospital cases will exclude those who die before admission. Serious cases, those residing in remote areas, and those who are too poor to afford hospitalization tend to be excluded. Similar bias occurs in a variety of other situations where the study is on prevalent cases rather than on incident cases.

The same sort of caution is required in some serial procedures in medicine. In some cancers, surgery is undertaken when radiotherapy fails and the patient remains operable at the conclusion of radiotherapy. Patients not responding to radiotherapy are not necessarily uniform in their grade of malignancy or age, nor in their resolve to fight the disease. Thus, additional caution is required at the time of drawing conclusions in such cases.

### *Volunteers*

Early **phases of clinical trials** are often undertaken on volunteers. They self-select themselves as the subjects. Volunteers tend to be very different from the general class of subjects. Many of them are either hopeless terminal cases or people with exceptional courage, either of which could affect the response. The results, thus, are not applicable to the general class of patients. Nevertheless, volunteer studies have a definite place in phase I trials as they do provide important clues on the toxicity of the regimen under test, the dose level that can be tolerated, and the potential for further testing of the modality.

Even for nonvolunteers, medical ethics requires that the subject's consent be taken for participation in a study. Real consent, after fully explaining the underlying uncertainties, is difficult to obtain without an inducement. Again, the subjects self-select themselves by providing or refusing consent, and some bias is likely. Some of this is eliminated by random allocation. This is feasible for **clinical trials** but not, for example, for cross-sectional **surveys**. Even in clinical trials, the generalizability suffers due to self-selection of subjects because of informed consent. Conclusions based on such studies can be fallacious for the general class of patients, although such subjects do provide evidence of efficacy of the regimen. Not many professionals appreciate this limitation imposed by consent-based selection, and they wonder later why their results cannot be reproduced in practical situations.

Similar problems, although of less severity, arise with surveys based on mailed questionnaires, subjects listed in a telephone directory, and Internet users. None of these sources are adequate for an unbiased sample of the general population. Because of the high nonresponse rate in many such surveys, the results are rarely valid even for the restricted class they represent.

The solution in all these cases is proper adjustment of the results, although this is not straightforward. The adjustment can be done only when relevant information is available on at least some subjects who are truly representative of the target population. In the absence of this, the alternative is to use the results only for the restricted population that these subjects represent. The third approach is to interpret the results as indicative of what *might* be occurring in the total population. In the case of nonresponse by some subjects after inclusion, you would most likely have their basic information, such as their demographics. If so, identify the type of subjects who dropped out, and use this information to adjust the results.

### *Clinic Subjects*

Clinic and hospital subjects also form a biased sample, as they tend to have a more severe form of disease and, in some countries, include mostly those who can afford these services. Mild cases tend to ignore their condition or self-treat themselves. An interesting example is migraine, which was once believed to be more common in the intelligent professional class [1]. An epidemiological study on a random sample could not substantiate such a relationship when the role of **confounding factors** was eliminated. Those in the more intelligent professional class perhaps seek medical assistance in the early phases of the disease and with greater frequency than their nonprofessional counterparts. Despite such a limitation, clinic-based studies do give important information on the presenting symptoms, their correspondence with laboratory and radiological findings, response

to various therapeutic procedures, prognostic features, etc. But the results are seldom applicable to the types of cases that do not show up in clinics. It is sometimes believed that consecutive cases coming to a clinic would be free from bias. While such cases could be true representatives of clinic subjects, the general bias in all clinic-based subjects still remains.

A similar bias occurs when the sample is restricted to people in employment. Such persons are healthier than the general population. For this reason, results based on employed people cannot be generalized to the other segments of the population.

A **nonrandom sample** tends to be biased anyway, but **random samples** can also be biased. For example, **systematic random sampling** can yield a biased sample if periodicity or trend is hidden in the subjects from 1 to *N*. As in the case of **simple random sampling**, by chance, this method can fail to give adequate representation to some specific groups of interest, particularly when the sample size is small A random sample, irrespective of the method used, tends to be unbiased when it is large. It is often mistakenly thought that random sampling necessarily produces a representative sample. Although that becomes increasingly likely as the sample size increases, the very nature of a random process implies that anything is equally likely—thus, even a very large random sample can be theoretically nonrepresentative.

## bias in literature review

Many medical studies depend on what published literature says. Few realize that the literature itself could be biased—**publication bias** is prominent and well acknowledged. In addition, the list of references provided at the end of most research articles can also be biased. Researchers have a natural tendency to quote only that part of the literature that tends to support their findings—perhaps even at the cost of the credibility of the study. This is done to create an impression that their research is more persuasive. The next researcher then also tends to review the same literature and thus gets the same biased view. The opposite or indifferent view tends to be ignored or overlooked unless that also is a dominant view and is easily traceable. This bias can be avoided by including those articles that challenge your thesis. Research must remain a relentless search for truth instead of advancing a particular view. Thus, all views must be represented in the review of literature. Recent literature, as opposed to old literature, is likely to be more representative of the current knowledge.

Second is the language bias that could result in a biased review of literature. This occurs because the literature in languages other than that of the researcher is rarely included in the review. This literature can provide a new perspective but is mostly ignored.

Third, bias can occur when the literature search by the authors is based on certain specific terms. This search will find only a particular type of literature, and the search may therefore not be comprehensive or representative, something that is often unintentional. To avoid this bias, the search terms should be chosen such that divergent findings can be represented. The assistance of a specialist librarian experienced in literature search may be beneficial.

In **meta-analysis**, it is a regular practice to filter out articles that do not meet specified criteria. This is necessary also so that only credible and relevant articles are picked up. This would occur, for example, when articles following a particular methodology are included and others excluded. There is a distinct risk in this process that some articles with variant findings are not included. If so, the meta-analysis can give biased findings.

## bias in medical studies and their minimization, *see also* bias (statistical)

The results of a medical study become clouded when some bias is detected after the results are available. Therefore, it is important that all sources of bias are considered while conducting a study and all efforts are made to avoid or control them.

### *List of Biases in Medical Studies*

Since bias can occur at every step of research (planning, execution, analysis, and reporting), a large number of sources of bias exist in a medical research setup. The following list describes the most common and most important. These are not **mutually exclusive**. In fact, the overlap is substantial. Also, some of the biases in this list are collections of biases of a similar type. If all these are stated separately, the list may become unmanageable. Biases are described in brief here in the order in which studies are done, i.e., planning, execution, analysis, and reporting.

1. *Bias in concepts:* This bias occurs when there is a lack of clarity about the concepts to be used in the proposed study. Lack of clarity gives an opportunity to the investigators to use subjective interpretation that can vary from person to person. This bias can also occur when the logic used is faulty: sometimes, the premise of the logic itself can be incorrect. For example, it is generally believed that lower values of body mass index and blood pressure are better for health. In fact, very low values of these are also associated with increased morbidity and mortality. Ignoring stress as a factor in causation of a disease such as diabetes just because stress is so difficult to measure also comes under this kind of bias.
2. *Definition bias:* The subjects and medical condition under study should be sharply defined so that there is no room for ambiguity. For example, a study on tuberculosis cases should specify that these are be sputum positive, Mantoux positive, radiologically established, or some combination. A blurred definition is open to subjective interpretation, and this can affect the **validity** of the study.
3. *Bias in design:* This bias occurs when the **case** group and the **control** group are not equivalent at **baseline** and differentials in prognostic factors are not properly accounted for at the time of analysis. Design bias also depends on the structure of the study. For example, an **ecological study** has more chance of bias in results than a double-blind **randomized controlled trial** (see **bias pyramid**). **Random allocation** and large sample size tend to minimize this type of bias.
4. *Bias in the selection of subjects:* The subjects included in a study may not truly represent the target population. This can happen when the sample is not randomly selected or when the sample size is too small. In both these instances, the sample may fail to represent the entire spectrum of subjects in the target population. Studies on volunteers and clinic subjects always have this kind of bias. Indrayan [1] has discussed this at length. Selection bias can also occur because the serious cases have already died and are

not available with the same frequency as the mild cases (also called **survival bias**). For example, Bidzan et al. [2] had an initial group of 158 older patients with mild cognitive impairment, but conclusions were drawn on 52 who were available at follow-up 5 years later. This is obviously biased. A similar bias can occur in selection of cases with diseases that have highly variable incubation periods, such as AIDS. (See also *length bias*.). Bias due to self-selection or volunteers is obvious since those not consenting are excluded.

5. *Bias due to concomitant medication or concurrent disease:* Selected patients may suffer from another apparently unrelated condition, but their response might differ either because of the condition itself or because of medication given concurrently for that condition. This can be controlled by appropriate restrictions on concurrent disease in the **inclusion and exclusion criteria** and by strict restriction of concurrent medications where feasible.
6. *Instruction bias:* When there are no instructions or when unclear instructions are prepared for conducting a study, the investigators use discretion, and this can vary from person to person and from time to time. Modern clinical trial protocols and associated guidelines usually give very clear and detailed instructions regarding trial conduct.
7. *Length bias:* C**ase–control studies** are generally based on prevalent cases rather than incident cases. **Prevalence** is dominated by those who survive for a longer duration. And these patients may be qualitatively different from those who die early. Thus, the sample would include disproportionately more of those who are healthier and survive longer. The conclusions cannot be generalized to those who died earlier. The disease profile can also differ since there would be more cases in whom disease progression is slow. Those suffering from an aggressive form of the disease would be missed because of the rapid progression of the disease and early death.
8. *Bias in detection of cases:* Error can occur in diagnostic or screening criteria. For example, in a prostate cancer detection study, if prostate biopsies are not performed on men with normal results after screening, the true **sensitivity** and **specificity** of the test cannot be determined. Also, a laboratory investigation done properly in a hospital setting is less prone to error in the detection of cases compared to one carried out in a field setting. Detection bias also occurs when cases with mild disease do not report or are difficult to detect. If this is inadvertent, the results would be biased without anybody knowing that such a bias was present.
9. *Lead-time bias:* Not all cases are detected at the same stage of the disease. With regard to cancers, some may be detected by screening before they are clinically apparent, for example, by Pap smear, whereas some may not be detected until clinical manifestation of the disease starts appearing. In some cases, detection occurs when the disease is already at an advanced stage. But the follow-up is generally from the time of detection. This difference in "lead time" can cause systematic error in the results. These issues can be partly addressed by strictly defining inclusion criteria in terms of stage of disease at detection and/or by stratifying subjects according to the stage of disease at detection.
10. *Bias due to confounder:* This bias occurs when **confounders** are not dealt with adequately. If that happens, any difference or **association** cannot be fully ascribed to the **antecedent factors** under study. For this, identify the confounders after a thorough review of the literature and devise a strategy to deal with them.
11. *Bias due to epistemic factors:* Efforts can be made to control only those factors that are known. But there may be many unknown factors that could affect the results. These **epistemic** factors can bias the results in very unpredictable ways. There is nothing specific that can be done for the unknown factors, but randomization and adequate sample size seem helpful for minimizing this type of bias.
12. *Contamination in controls:* Control subjects are generally those that receive placebo or regular therapy. If these subjects are in their homes, it is difficult to know if they have received some other therapy that can affect their status as controls. In the prostate cancer detection project reported by Concato et al. [3], the control subjects are those who were under routine care. But some of these may have been screened outside the study and treated. Thus, their survival rate would not be sufficiently "pure" to be compared with the survival of those who were screened by the test procedures. In a field situation, contamination in a control group can occur if the control group is in close proximity to an unblinded test group and learns from the experience of the latter. In another situation, a neighboring area may not be the test area of the research, but some other program may be going on there that has a spillover effect on the control area.
13. *Berkson bias:* Comparison of hospital cases with hospital controls can be biased if exposure increases the chance of admission. This can lead to an overrepresentation of subjects with that exposure. Cases of injury in motor vehicle accidents can suffer from this kind of bias. See also **Berkson bias**.
14. *Bias in ascertainment or assessment:* This bias occurs in unblended studies when unknowingly or deliberately, the investigators are more thorough with cases than with controls. A similar problem can also occur when subjects belonging to a particular social group have records but others have to depend on recall. Sometimes, this is also called *information bias.*
15. *Interviewer bias or observer bias:* Interviewer bias occurs when one is able to elicit better responses from one group of patients (say, those who are better educated) relative to another (such as illiterates). Observer bias occurs when the observer unwittingly (or even intentionally) exercises more care about one type of response or measurement than others, for instance, those supporting a particular hypothesis versus those opposing the hypothesis. Observer bias can also occur if, for example, the observer is not fully alert when listening to Korotkoff sounds while measuring blood pressure or not able to properly rotate the endoscope to get an all-around view of, say, the duodenum in a suspected case of peptic ulcer.
16. *Instrument bias:* This occurs when the measuring instrument is not properly calibrated. For example, a weighing machine that does not show zero when resting will give an inaccurate measurement of weight. Another kind of instrument bias occurs when a device does not provide a complete picture of the target organ, thereby giving false or incomplete information. For example, an endoscope

might not reach the site of interest. Another example is **Likert scale** assessment, where +3 may be a more frequent response on a scale of −5 to +5 than +8 on a scale of 0 to 10, although both are same. A third kind of instrument bias occurs when an instrument is considered the **gold standard** because this is acknowledged as the best while forgetting that the best may still be imperfect. Errors can occur even with this "gold." Fourth is when **predictivity** of an instrument is used in a new setup without considering that different prevalence in this new setup would affect the predictivity.

17. *Hawthorne effect:* When subjects know that they are being observed or being investigated, they often alter their behavior and response. In fact, this is the basis for including a **placebo** group in a trial. The usual responses of subjects are not the same as when they are under a scanner. Such effects should not cause the results of a trial to be biased in favor of one treatment, as both the groups are under observation. See also **Hawthorne effect**.
18. *Recall bias:* There are two types of recall bias. One arises from better recall of recent events than those that occurred a long time ago. Also, serious episodes are easier to recall than mild episodes. The second type of recall bias occurs when cases suffering from a disease are able to recall events much more easily than healthy controls. A thorough probing can possibly help to reduce this bias.
19. *Response bias:* Cases with serious illness are likely to give more correct responses regarding history and current ailments compared with controls. This is not just because of recall but also because patients with serious illness tend to keep meticulous records. Some patients, such as those suffering from sexually transmitted diseases (STDs), may intentionally suppress sexual history and other information because of the stigma attached to these diseases. Injury history may be distorted to avoid legal consequences. If the subjects are able to exchange notes, their responses to questions might alter and, in some cases, might even become nearly uniform. An unexpected illness, death in the family, or any such drastic event may produce an extreme response. Response bias can also be regarded as a type of *information bias*.
20. *Bias due to protocol violation:* It is not uncommon in a clinical trial that some subjects do not receive the full intervention or the correct intervention, or some ineligible subjects are randomly allocated in error. This occurs when the study **protocol** is not faithfully followed, something that can bias the results.
21. *Repeat testing bias:* In a pretest–posttest situation, the subjects tend to remember some of the previous questions, and they may no longer commit previous errors in the posttest—thus doing better for reasons other than the intervention. The observer may acquire expertise to elicit the correct response on the second or third occasion. Conversely, fatigue may set in with repeat testing, which could alter the response. Moreover, many biological measurements have a strong tendency toward the mean (see **regression to the mean**): extremely high scorers tend to score lower in subsequent testing, and extremely low scorers tend to do better in a subsequent test, whereas midrange scores remain similar.
22. *Clustering bias:* This is related to repeat testing bias. When the subjects belong to an affinity group, they tend to give a similar response. For example, people in one profession, people living close together, family members, etc. are such affinity groups. When members of such groups are study subjects by design, use **design effect** to minimize the effect of clustering. If clustering occurs by chance, you may not even know that it is there, and the results would be biased.
23. *Midcourse bias:* Sometimes, after enrollment, subjects have to be excluded if they develop an unrelated condition such as an injury, or become so seriously ill that their continuation in the trial is no longer in their interest. If a new facility such as a health center is started or closed for the population being observed for a study, the response may alter. If two independent trials are going on in the same population, one may contaminate the other. An unexpected event such as a disease outbreak can alter the response of even those who are not affected.
24. *Self-improvement effect:* Many diseases are self-limiting. Improvement over time occurs irrespective of the intervention, and it may be partially or fully incorrectly ascribed to the intervention. Diseases such as arthritis and asthma have natural periods of remission that may look like the effect of therapy. The use of proper controls and random allocation may address this source of bias.
25. *Bias due to digit preference:* It is well known that most people have a special love for the digits 0 and 5. Measurements are more frequently recorded ending with these digits. A person aged 69 or 71 is likely to report his/her age as 70 years. Another manifestation of digit preference is in forming intervals for quantitative data. Blood glucose level categories would be commonly chosen as 70–79, 80–89, 90–99, etc., and not 64–71, 72–79, etc. If the digit 0 is preferred, 88, 89, 90, 91, and 92 can be recorded as 90. Thus, intervals such as 88–92, 93–97, and 98–102, may be better to ameliorate the effect of digit preference rather than the conventional 85–89, 90–94, 95–99, etc. See also **digit preference**.
26. *Bias due to nonresponse:* In most medical studies, particularly those requiring follow-up, some subjects refuse to cooperate, suffer an injury, die, or become untraceable. Nonrespondents have two types of effects on the results. First, they are generally different from those who respond, and their exclusion can lead to biased results. Second, nonresponse reduces the sample size and can result in substantial differences between the numbers in different groups, both of which can decrease the **power** of the study to detect specified differences or **associations**.
27. *Attrition bias:* The pattern of nonresponse can differ between subgroups in the sense that in one subgroup, more severe cases drop out, whereas in another group, mostly mild cases drop out. In a rheumatoid arthritis databank study, attrition during follow-up was high in patients of young age, who were less educated, and were non-whites [4]. Everything possible should be done to convince the subjects to respond.
28. *Bias in handling outliers:* No objective rule can define a value as an outlier other than that the value must be far away from the mainstream values. If the duration of hospital stay after a particular surgery is mostly between 6 and 10 days, some researchers would call 18 days an outlier and may exclude it on the suspicion of it being an incorrect recording or transcription, and some would consider it correct and include it in their calculation. In view of this subjective and essentially arbitrary definition of an outlier,

many would not exclude any extreme value, howsoever different it might be. Thus, the results would vary depending on a researcher's approach to detecting and handling outliers. Generally speaking, you should not exclude a suspected outlier from analysis unless there is convincing reason to label it as an outlier. When an analysis with such exclusions is performed, an analysis without any exclusions should also be normally performed.

29. *Recording bias:* At least two types of errors can occur in recording data. The first arises due to the inability to properly decipher the writing on case sheets, particularly since physicians are notorious for illegible writing. This can happen particularly with similar-looking digits such as 1 and 7, and 3 and 5. Thus, the entry of data may be in error. The second arises due to the carelessness of the investigator. A diastolic level of 87 can be wrongly recorded as 78, or a code 4 entered as 6 when remembered incorrectly. Some errors may also be typographical since wrongly pressing adjacent keys on the keyboard is not uncommon. Errors can also occur when data are manually transcribed from one document to another.
30. *Bias in analysis:* See **bias (statistical)**.
31. *Bias due to competing cofactors:* Some factors influence results **synergistic**ally or **antagonistic**ally when relevant cofactors are present. If this is not properly taken into account, the effect of an intervention can be underestimated or overestimated. It is therefore important to identify as many such factors as possible and take them into account during analysis.
32. *Prevalence–incidence bias:* This occurs when effects of risk factors on prevalence could be a function of the duration of the disease and can be mistaken for effects on disease occurrence when not properly accounted for.
33. *Interpretation bias:* This arises from the tendency among some researchers to interpret the results in favor of a particular hypothesis, ignoring the opposite evidence. This would be mostly unintentional but can also be intentional in rare cases.
34. *Reporting bias:* Researchers may have conscious or subconscious preconceptions and expectations of results, and this may result in writing reports that are not really consistent with the data available. For example, it is easy to suppress contradictory evidence by not talking about it.
35. *Bias in presentation of results:* Scales in graphs can be chosen such that a small change looks like a big change or vice versa [1]. Also, the researcher may merely state the inconvenient findings that contradict the main conclusion but not highlight them in the same way as done with the findings that support the main conclusion.

For more details, see Delgado-Rodriguez and Llorca [5].

### *Steps for Minimizing Bias in Medical Studies*

The purpose of describing various types of biases in so much detail is to create awareness of the need to avoid or at least minimize them. Everything possible should be done to keep them under control so that you do not have to give an explanation such as "hand of God" in a soccer game. In the context of a medical study, bias in results and conclusions is a function of the study design and its implementation. The following steps can be suggested to minimize bias in the results in a research setup. Not all steps apply to all the situations. Adopt the ones that apply to your setup. Details of some of these steps are given by Indrayan [1].

1. Develop an unbiased scientific temperament by realizing that you are in the occupation of a relentless search for truth.
2. Specify the problem and the objectives to the minutest detail.
3. Assess the validity of the identified **target population** and the groups to be included in the study in the context of objectives and the methodology. The inclusion and exclusion criteria should be precisely worded to address this problem.
4. Assess the validity of antecedents and outcomes for providing the correct answer to your questions.
5. Beware of epistemic **uncertainties** arising from the limitation of scientific knowledge. The use of double-blind randomized controlled trials goes a long way toward minimize this bias.
6. Evaluate the **reliability** and **validity** of the measurements required to assess the antecedents and outcomes, as well as of the other tools you plan to deploy.
7. Where appropriate, consider undertaking a **pilot study** and pretest the tools. Make changes as needed.
8. Try to identify all possible confounding factors and other sources of bias, and develop an appropriate design that can take care of most of these biases, if not all.
9. Choose a representative sample, preferably by a random method as and when possible.
10. Choose an adequate size of the sample in each group.
11. Rigorously train yourself and your coworkers in making correct assessments prior to the beginning of a study.
12. Use **matching**, **blinding**, **masking**, and **random allocation** as needed.
13. Monitor each stage of research, including periodic checking of data.
14. Make determined efforts to minimize nonresponse and partial response.
15. Double-check the data and rectify errors in recording, entries, etc.
16. Analyze the data with proper statistical methods. Use **standardized** or **adjusted rates** where needed, perform **stratified analysis**, or use **mathematical models** such as **regression** to take care of those confounders that could not be ruled out by design.
17. Interpret the results in an objective manner, based only on the evidence at hand.
18. Report only the **evidence-based** results, enthusiastically but dispassionately.
19. Exercise extreme care in drafting the report and keep comments or opinions clearly separate from evidence-based results.

Bias and other aspects of design can be very adequately taken care of if you imagine yourself presenting the results a couple of years hence to a critical but friendly audience [6]. Consider what your colleagues would question or advise at that time, and their reaction when you conclude that the results are significant or if you conclude that the results are not significant: Might there be alternative explanations of the results? Are there any confounding factors that have been missed? Or could **chance** or **sampling error** be an explanation? Such considerations will help you to develop a proper design and to conduct the study in a conscientious manner. A word of caution in the end. Do not try to control or eliminate all the sources of bias at the time of planning. This may affect the proper execution of the study and practical utility of results. Control the effect of some sources at the time of analysis. Others that remain can be acknowledged as limitations of the study. This is appreciated much more than the claim of completely unbiased results.

## bias in publications, *see* publication bias

## bias pyramid, *see* evidence (levels of)

## bias (statistical), *see also* biased sample, unbiased estimator

Statistical bias occurs when an inappropriate statistical procedure is used. This could be in the calculation of sample size, sampling (see **biased sample**), statistical estimation (see **unbiased estimate**), model building, or any other method of statistical analysis. If an inappropriate method is used, the results may not reflect the true state of affairs and can lead to wrong conclusions.

Amongst many types of statistical bias, some are described elsewhere in this volume, as indicated in bold in the previous paragraph. What follows is a description of two other types of statistical bias.

1. *Bias in analysis:* This again can be of two types. The first occurs when gearing the analysis to support a particular **hypothesis**. When comparing *pre-* and *post*-values, for example, hemoglobin (Hb) levels before and after weekly supplementation of iron, the average increase may be so small that it will not be detected by a comparison of the means. But it may be detected when evaluated as a proportion of subjects with levels <10 g/dL before and after iron supplementation. This will happen when the rise in Hb level is small in many subjects but crosses the threshold of 10 g/dL. The second bias in analysis can arise due to differential interpretation of ***P*-values**. When $P = 0.055$, one researcher may refuse to say that it is significant at a 0.05 level, and another may say that it is marginally significant. Some researchers may change the **level of significance** from 5% to 10% after having seen the results, although the level of significance should be decided prior to the analysis.
2. *Bias due to lack of power:* **Statistical tests** are almost invariably used to check the **significance** of differences or **associations**. The statistical **power** of these tests to detect a specified difference or association depends to a large extent on the number of subjects included in the study and the variability of the data. If the study is conducted on a small sample, even a big difference cannot be detected, leading to a false-negative conclusion. When conducted on an appropriate number of subjects, the conclusion can change.

## bidirectional dependence

Two variables $x$ and $y$ are considered to be bidirectionally dependent when $y$ depends on $x$ and $x$ depends on $y$—for example, health depends on exercise, and exercise depends on health. The general statistical setup is that one or more variables are **dependent** on one or more **independent variables**. Statistical analysis of data in this setup is relatively easy since independent variables can be considered fixed in most situations, such as in **regression**. However, rarely, the dependence is bidirectional. Data with bidirectional dependence are not easy to analyze. For example, this may require a *two-stage regression* procedure. The details are too complex to be described in this book. Those interested may refer to Faries et al. [1].

1. Faries D, Leon AC, Haro JM, Obenchain RL. *Analysis of Observational Health Care Data Using SAS*. SAS Publishing, 2010.

## bihistogram

*Bihistogram* is the term used for a figure that has two **histograms** placed opposite to one another for comparison. Sometimes, they can be placed side by side also. Figure B.4 is a bihistogram where histograms for diastolic levels of blood pressure (BP) for hypertensive persons and controls are compared.

Histograms show the distribution of a quantitative variable whose values are divided into categories. For example, in Figure B.4, the diastolic BP categories (in mmHg) could be 70–74, 75–79, 80–84, etc. In the case of nonobese persons, the values start from 70 mmHg in this bihistogram, whereas they start from 85 mmHg for obese people. The peak (highest frequency) for obese people is at 100–104 mmHg but is at 85–89 mmHg for nonobese persons. The comparison shows that the two distributions are nearly the same except that there is a shift of nearly 15 mmHg for the obese group. Thus, the bihistogram provides an effective comparison of the distribution in the two groups.

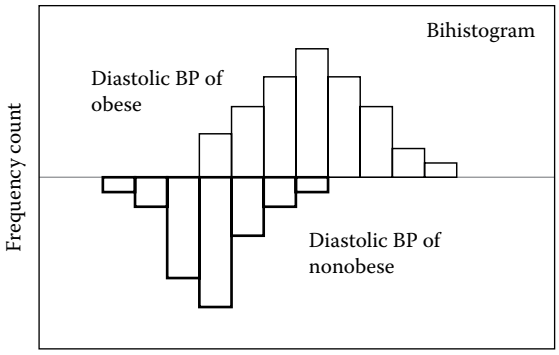

**FIGURE B.4** Bihistogram of diastolic BP in obese and nonobese subjects.

## bikini syndrome, *see* confidence intervals (the concept of)

B

## bimodal distribution

**Mode** is the most common value in a set of data—a definition that assumes that only one value can be the most common. Sometimes, you can have two or more modes. Consider the following data on duration of immobility in days in cases of acute polymyositis of the back in 38 women.

| | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 7 | 5 | 9 | 7 | 36 | 4 | 6 | 7 | 5 | 8 | 3 | 6 | 5 |
| 7 | 8 | 10 | 7 | 14 | 10 | 9 | 4 | 6 | 11 | 9 | 6 | 5 |
| 8 | 8 | 6 | 7 | 5 | 5 | 12 | 3 | 5 | 9 | 10 | 7 | |

Mode = 5 days and 7 days, occurring in 7 patients each

A distribution containing two modes such as in this example is called a bimodal distribution. In this example, the maximum frequencies are equal, but that is not a requirement for a distribution to be bimodal. Mode essentially means a peak in a distribution. You can have many peaks in one distribution—and thus many modes. When you plot a **frequency curve**, the values around the mode have less frequency, and the peak stands out. The age distribution of Hodgkin disease and leukemia is bimodal with one (smaller) peak around 20 years and the other (bigger) peak at around 60 years. Figure B.5 describes a similar bimodal distribution of Crohn disease. A bimodal distribution can also arise with a mixture of two separate distributions, such as of height when men and women are mixed. In a figure in the topic **normal range of medical parameters**, diseased and healthy cases are mixed, giving rise to two modes—one for healthy subjects and the other for nonhealthy subjects.

Sometimes, sample values appear to have two or more modes due to **sampling fluctuations** rather than an actual bimodal distribution. In most situations, a biological explanation will be available, as in the example we have cited. When there are two modes and they have unequal peaks as in Figure B.5, the value with a higher mode is called a *major mode*, and the other, a *minor mode*. When two or more modes are really present, mean and median may not be adequately representative of the **central value**. Such a distribution is not **Gaussian** (normal), and many statistical tests such as **Student *t*** and **ANOVA** *F* may fail. Instead, **nonparametric methods** should be used for data values that have bimodal distribution. Most bimodal, and for that matter, multimodal, distributions can be considered a mixture of two or more unimodal distributions as just described and can be analyzed accordingly.

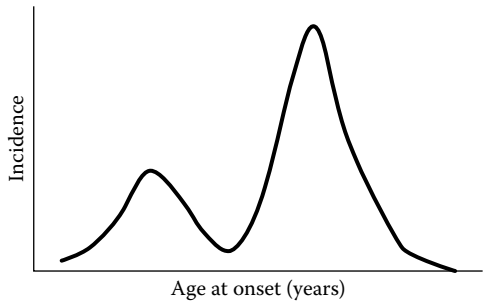

**FIGURE B.5** Age distribution of onset of Crohn disease: a bimodal distribution.

## binary dependent/outcome/predictor/response/variable

When the assessment of a characteristic is in terms of only two categories, such as yes/no, present/absent, or favorable/unfavorable, these are called **dichotomous categories.** The corresponding variable is called a binary variable. Recording gender as male or female is an obvious example. You can have a binary predictor or a binary **independent variable** such as in a **regression models**, or you can have a binary outcome, response, or **dependent variable**. The occurrence of malaria dependent partly on the density of female anopheles mosquitoes in an area and the diagnosis of primary biliary cirrhosis dependent on elevated serum alkaline phosphatase levels are examples in which the dependent variable (presence or absence of disease) is binary. In the context of outcome, such as cured/not cured, this is also called a **quantal response**. A **continuous variable** can also be made binary, such as with diastolic blood pressure <90 mmHg or ≥90 mmHg, although this amounts to loss of information.

A binary outcome in *n* independent trials (such as *n* subjects) leads to **binomial distribution**. In all such dichotomous situations, the binary variable *y* is given a value of 0 for a negative response or 1 for a positive response, with no other possibilities. The probability of a positive response is $P(y = 1)$ and is denoted by $\pi$ for population. This is estimated by the corresponding proportion in the sample, denoted by *p*.

**Logistic regression** is the most appropriate statistical method for binary response when the objective is to predict the response with a set of predictors or to explain it with a set of independent variables. In this case, the dependent variable is actually the proportion or probability of subjects with a positive response. Even though the **Cox model** is for **hazard**, the dependent variable in this case is also binary, such as survived/dead. **Discriminant functions** can also be used for binary outcomes. The concept of **number needed to treat (NNT)** is especially useful for comparing two treatment regimens with a binary response.

In the case of assessment of subjects on two binary variables, the results can be studied using a $2 \times 2$ table. This can be analyzed in a variety of ways, as mentioned under **two-by-two table**. There could be a $2 \times K$ table, where one variable is binary and the other has *K* categories. An example is distribution of male and female cases of glaucoma by blood group. Such tables are generally analyzed by using a **chi-square** test.

## binomial distribution/probability

The binomial distribution arises for "successes" in binary outcomes when (i) there are *n* independent trials (occurrence in one does not affect the outcome in any other trial) and (ii) the probability of success remains the same for each trial. For example, if 20 males of age 60 years and above are randomly selected, the number of males with an enlarged prostate out of 20 will have a binomial distribution. In this case, "success" is having an enlarged prostate, and *n* is 60. Note that a person with an enlarged prostate in the sample does not affect the chance of any other person in the sample of having or not having an enlarged prostate. The outcome in different persons is independent. Also, if all the persons in the sample are from the same milieu, the chance of one with an enlarged prostate is the same as that of anyone else in the sample.

A prominent application of binomial distribution is illustrated in the following example. Consider the 5-year survival among patients with cervical cancer. There is no noncancer or any other group for comparison. Two kinds of statistical questions can arise in this case.

(i) If the proportion surviving for 5 years among patients with cervical cancer is known to be 30%, what is the chance that at least 6 will survive for at least 5 years in a random sample of 10 patients? (ii) If the number surviving in a random sample of 20 patients is only 4, how likely is that the survival rate in the long run could be 30%? These two questions are, in fact, two ways of looking at the same statistical issue. The answer to these questions is obtained by the binomial distribution, as described next.

### *Binomial Distribution*

For simplicity, let us call the event of interest a success. Denote its probability by $\pi$. In the preceding example, the event of interest is survival for 5 years, and $\pi = 0.3$. It can be shown by the multiplication **law of probability** that the probability of $x$ successes in $n$ independent trials is given by

$$\text{binomial distribution: } P(x) = {}^{n}C_{x}\pi^{x}(1-\pi)^{n-x},$$

where ${}^{n}Cx = \dfrac{n!}{x!(n-x)!}$ and $x! = x(x-1)(x-2)\ldots 3.2.1$ (for example, ${}^{5}\mathrm{C}_{3} = \dfrac{5!}{3!(5-3)!} = \dfrac{5\times 4\times 3!}{3!\times(2\times 1)} = 10$), and $\pi$ is the probability of success in one trial. In our example, a trial corresponds to one patient. Patients behave independently in the sense that the survival of one patient does not affect the chance of survival of another. Also, the chance of survival for each patient should be the same. This would be so when the patients are homogeneous with respect to prognostic factors. When these conditions are fulfilled, this distribution can be used to answer the two questions earlier posed.

### *Binomial Probability*

In question (i) above, $n = 10$, and $\pi = 0.3$. The success in this case is survival. You need to find $P(x \geq 6)$. Because not more than 10 successes are possible in 10 patients and the successes are **mutually exclusive**, by addition law of probability,

$$\begin{aligned} P(x \geq 6) &= P(x=6) + \mathrm{P}(x=7) + \ldots + P(x=10) \\ &= {}^{10}C_{6}(0.3)^{6}(0.7)^{4} + {}^{10}C_{7}(0.3)^{7}(0.7)^{3} + \ldots + {}^{10}C_{10}(0.3)^{10}(0.7)^{0} \end{aligned}$$

and, from the equation mentioned earlier,

$$= 0.0368 + 0.0090 + 0.0014 + 0.0001 + 0.0000 = 0.047.$$

Thus, the chance that at least 6 will survive for 5 years in a sample of 10 patients is only 4.7%, which may seem surprisingly low.

Question (ii) is more appropriately answered by obtaining the probability of $x = 4$ or a more extreme value, i.e., $P(x \leq 4)$. Because of mutually exclusive values of $x$, for $\pi = 0.3$ and $n = 20$,

$$\begin{aligned} P(x \leq 4) &= P(x=0) + P(x=1) + P(x=2) + P(x=3) + P(x=4) \\ &= {}^{20}\mathrm{C}_{0}(0.3)^{0}(0.7)^{20} + {}^{20}\mathrm{C}_{1}(0.3)^{1}(0.7)^{19} + {}^{20}\mathrm{C}_{2}(0.3)^{2}(0.7)^{18} \\ &\quad + {}^{20}\mathrm{C}_{3}(0.3)^{3}(0.7)^{17} + {}^{20}\mathrm{C}_{4}(0.3)^{4}(0.7)^{16} \\ &= 0.0008 + 0.0068 + 0.0278 + 0.0716 + 0.1304 = 0.238. \end{aligned}$$

This probability is fairly high. Thus, it is not unlikely (probability is 0.238) that the survival rate in the long run is 30%.

Suppose for some reason that the interest is in finding the probability of at least two survivals out of $n = 10$. In notation, this is $P(x \geq 2)$. Calculating all the probabilities for $x = 2, 3, \ldots, 10$ by hand would take a lot of time and effort. In this situation, use the fact that $P(x \geq 2) = 1 - P(x \leq 1)$. Now this is to be computed only for $x = 0$ and $x = 1$. Similarly, for example, $P(x \leq 8) = 1 - P(x \geq 9)$.

### *Large* n*: Gaussian (Normal) Approximation to Binomial*

The calculation of the binomial probability can become complex and time consuming when $n$ is large and when it is to be computed for several different values of $x$. When the **Gaussian conditions** are satisfied, which is likely when $n$ is large, the binomial distribution can be approximated by a **Gaussian distribution**. This approximation arises from the **central limit theorem** as the binomial $x$ also is a summation type of variable—this time, the sum of 1's and 0's for success and failure, respectively. For Gaussian approximation of a binomial, the following are needed:

$$\text{mean of a binomial variable } x = n\pi, \text{ and } \mathrm{SD} = \sqrt{n\pi(1-\pi)}.$$

Thus, for large $n$,

$$z = \frac{x - n\pi}{\sqrt{n\pi(1-\pi)}}$$

is a standard Gaussian variate. When $n$ is large, this can be used to answer the same types of questions as posed earlier. This is illustrated in examples given as follows.

If the proportion surviving for at least 3 years among cases of cancer of the cervix is 60%, what is the chance that at least 40 will survive for 3 or more years in a random sample of 50 such patients?

For $n = 50$ and $\pi = 0.60$, mean number of survivors, $n\pi = 50 \times 0.60 = 30$, and

$$\mathrm{SD} = \sqrt{n\pi(1-\pi)} = \sqrt{50\times 0.60\times 0.40} = 3.464.$$

Since $n\pi \geq 8$ and $n(1-\pi) \geq 8$ also, the Gaussian conditions are satisfied, and we can use Gaussian approximation. With **continuity correction**, $P(x \geq 40) = P(x \geq 39.5)$. Thus,

$$\begin{aligned} P(x \geq 40) &= P\left(\frac{x - \text{mean}}{\mathrm{SD}} \geq \frac{39.5 - 30}{3.464}\right) \\ &= P(z \geq 2.74) \\ &= 0.0031 \text{ from Gaussian distribution} \end{aligned}$$

This low probability indicates that there is practically no chance that 40 or more patients will survive for at least 3 years in a sample of 50 when the survival rate is 60%. This might seem unbelievable, but it is true.

The probability just calculated is the approximate probability based on a Gaussian distribution. The exact binomial probability by binomial distribution for $x \geq 40$, when $n = 50$ and $\pi = 0.60$, is 0.0008.

## bioassays, *see also* parallel-line assays, slope-ratio assays, quantal assays

Assays are investigative procedures used for assessing the presence, amount, or activity of a substance. Most such assays are

B

based on chemical reactions between the test substance, the analyte, and various test reagents, where the outcome of the test is measured by several different methods. *Bioassays*, short for "biological assays," use the effect of the analyte on a living organism (animal, plant, bacteria, in vivo) or living tissues (e.g. cells, in vitro).

Conventional assays are experiments where we intentionally do something at different intensities to see what the effect is and compare it with the effect of a standard intervention at similar intensities. The effect of an intervention is technically called the response. In the case of assays, we apply the same intervention at different intensities in the hope that the response will be higher for the increased intensity. Many bioassays study such **dose–response relationships**. This particularly applies to poisons such as insecticides and pesticides. The larger the dose, the more insects will die. In this case, the response is death. In general, the response could be any other outcome. In the case of carcinogens, for example, an increased dose means a greater chance of cancer. The primary objective of assays is to estimate the **relative potency** of the test intervention compared with the standard intervention for achieving a particular outcome. Many times, the test preparation is a dilution or concentration of the standard preparation, leading to what is called *dilution assays*.

Statistically, there are basically two types of bioassays. **Quantal assay** is the term used when the response is binary, such as survive/die, relieved/not relieved, and cholesterol level high/within normal limits. These are particularly useful for estimating **median effective dose ($ED_{50}$)** or median lethal dose ($LD_{50}$) as the case may be. This is the dose at which 50% of the experimental units respond. The others are quantitative assays where the response is quantitative, such as time taken to respond, cholesterol level itself, and pain score. Death is a quantal response, but the time elapsed before death is quantitative. When the comparison is with a standard preparation, an assay with a quantitative response is called a quantitative assay.

Quantitative assays generally are parallel line or slope ratios depending on the pattern of response in the test preparation group and the standard preparation group. The basic setup in **parallel-line assays** is that the response in the test and the standard preparation differs by a fixed amount at each dose of the drug. In **slope-ratio assays**, the response is the same for both test and standard preparation at some baseline but increases (or decreases) at a faster rate for one preparation than the other as the dose increases. However, the trend in both should be linear. In slope-ratio assays, the estimate of the relative potency is given by the ratio of the slopes, hence the name. Quite often, the dose and the response are transformed, such as by logarithm to achieve linearity in the relationship. Such transformed dose and response are respectively called *dose metameter* and *response metameter*. When such transformations are used, the interpretation of the estimate of parameters such as relative potency needs special care. See the topic **logarithmic scale**.

Statistical methods for analyzing bioassays were initially described by Emmens [1] in his book published in 1948 but are generally attributed to Finney [2] because of his comprehensive book on this subject. See **parallel-line assays**, **slope-ratio assays**, and **quantal assays** for some details about analysis of data from different types of bioassays.

2. Finney DJ. *Statistical Method in Biological Assay*. Charles Griffin and Company, 1952.

## bioavailability, *see also* half-life of medications, area under the concentration curve

*Bioavailability* is the term used for the rate and extent to which an external substance is available at its intended organ or site in a biological system at different points in time after its administration. In the vast majority of cases, the concentration in bloodstream is measured in place of the site or organ, although exceptionally, concentration in other tissues or body fluids may be examined. This, in a way, measures the absorption or the concentration of the substance as a surrogate to its therapeutic potency. Bioavailability can be studied either in terms of amount, say in micrograms (or percentage of the amount ingested, such as 35%) or in terms of rate per unit of time, such as micrograms per hour. This can also be measured as micrograms per kilogram of body weight.

Bioavailability is considered an important pharmacological property of a substance and is assessed through **pharmacokinetic studies**, most commonly in phase I of a drug trial. This also is used to establish or refute bioequivalence of two substances (generic versus brand), two formulations (tablet versus capsule), two routes of administration (oral versus injectable), etc. As explained for **bioequivalence**, this equivalence is concluded when the bioavailability of the substances are same at different points in time. Bioequivalence has become a big issue since the 1980s, when generic drugs started competing with brand-name drugs, claiming that these provide the same response. Bioavailability is the anchor for bioequivalence studies.

Among various parameters used for assessing bioavailability, the most common is the plot of concentration versus time, called the concentration curve. The **area under the concentration curve (AUC curve)** provides a good measure of overall bioavailability of the drug, although there are deficiencies also with this measure, as explained under that topic. Among other important pharmacokinetic parameters used to assess bioavailability are **half-life**, maximum (peak) concentration ($C_{max}$), and time after administration to reach the peak value ($T_{max}$). See the topic **bioequivalence** in case you are interested to know more.

Usually, a **crossover design** is used to conduct comparative bioavailability studies. This means that a random half of the subjects receive the AB sequence, and the other half, the BA sequence. Each subject gets a washout period for the substance to exit the system either through metabolizing or through excretion. In case a carryover effect remains, one can think of other designs, such as the **Balaam design**, where the sequences administered are AA, AB, BA, and BB.

A large number of bioavailability studies are available in the literature. For example, Salem and Kuratko [1] compared bioavailability of two active substances in krill and fish oil, and also discussed some difficulties in such a comparison. Gaudreault et al. [2] evaluated the truncated area under the curve as a measure of the relative extent of bioavailability. This area is different from the area under the receiver operating characteristic (ROC) curve.

2. Gaudreault J, Potvin D, Lavigne J, Lalonde RL. Truncated area under the curve as a measure of relative extent of bioavailability: Evaluation using experimental data and Monte Carlo simulations. *Pharm Res* 1998;15:1621–9. http://link.springer.com/article/10.1023/A%3A1011971620661#page-1

## bioequivalence, *see also* bioavailability, area under the concentration curve

In the context of treatment regimens, equivalence has two distinct dimensions—therapeutic equivalence and bioequivalence. Only the end point at a particular time point is considered for therapeutic equivalence, whereas bioequivalence considers the entire course of the regimen. When the course of the disease or the improvement pattern over a period of time is the same for two regimens, they are considered bioequivalent. **Bioavailability** is the main consideration that decides bioequivalence. Bioequivalence implies therapeutic equivalence, but the reverse is obviously not necessarily true.

Bioequivalence may be relevant in situations where the course of the disease or the mechanism working behind is important. A diuretic may be as effective in controlling blood pressure as a beta-blocker, but their mechanisms for reaching the same end point are different. In this case, they are therapeutically equivalent but not bioequivalent. In some specific patients, diuretics may be more effective than beta-blockers, and for that, the mechanism is important. Then the interest would be in bioequivalence. When the presentation (color, packaging, size, etc.) or mode of administration (daily/weekly, once a day/twice a day) or ingestion (oral/injectable, etc.) of a regimen is changed, the interest could be in either bioequivalence or therapeutic equivalence.

Bioequivalence requires **pharmacokinetic studies**, and the comparison may be in terms of peak concentration ($C_{max}$), time to reach its peak ($T_{max}$), **half-life**, **area under the concentration curve (AUC curve)**, etc. Regulatory agencies mostly consider only the AUC curve and $C_{max}$—$C_{max}$ being used as a measure of rate of delivery. $T_{max}$ is considered when there are specific claims of rapid delivery. The difficulty is that the area under the curve has limited physical meaning. When used in isolation, it may fail to provide an adequate assessment of the difference in trend, even on average, because it is neither specific nor sensitive to changes in patterns. Curves with markedly different trends can give the same area [see Figure A.5 in the topic **area under the concentration curve (AUC curve)**]. Also, as time passes, some patients drop out or get cured—thus, average response at different points in time is based on different $n$. This is ignored while studying AUC.

In a statistical test for bioequivalence of two pharmaceutical preparations, if the difference in concentration or any such parameter is less than a specified clinically unimportant margin, you can conclude that the groups are essentially equivalent even if the difference is statistically significant. Generally, the rule of 80/125 is followed for equivalence, which means that the difference between the two regimens should not exceed the 20% limit. Note that 20% of 125 is 25, which takes it back to 100, and 20% of 100 is 20, which reduces it to 80. This applies to confidence interval (CI). For example, the 90% CI for the ratio of these parameters should be between 0.80 and 1.25. Also note that most bioequivalence parameters are multiplicative instead of additive—thus, many times, log transformation is used. Thus, they are typically compared in their logarithmic form. This applies to concentration but does not apply to time-based parameters such as $T_{max}$ and half-life, since time is not multiplicative. For sample size and other details, see **equivalence tests**.

Let us reemphasize that a distinction should also be made between bioequivalence at the individual patient level and the average bioequivalence in groups of patients. If the two regimens under comparison produce different responses in individuals, this is ignored in average bioequivalence, whereas in individual bioequivalence, this interaction is an important consideration. Average bioequivalence would imply that either of these regimens can be prescribed to *newly* incoming patients. Individual bioequivalence would mean that the *existing* patient can be switched from one regimen to the other in the midst of the ongoing treatment. For example, drug switchability or interchangeability can be from brand name to generic while the patient is still under treatment, say for cost considerations.

Bioequivalence studies can be done on healthy subjects as well as for some regimens using the **crossover** strategy. In the case of drugs with a very long half-life, a parallel-group design may be used. Bioequivalence studies necessarily use a **repeated measures design**, because only then can the pharmacokinetics and the course of disease be studied. For statistical details of bioequivalence, consult Patterson and James [1].

## bioinformatics

Bioinformatics can be crudely understood as computer-based information system applications to biology. Most relevant of these for us are applications to health and disease in humans. Medical marvels, riding on bioinformatics, are poised to take center stage in our health care. The *Star Trek* fantasy of a doctor scanning the body with a handheld machine to get the particulars of a patient's condition looks to be within reach. Indrayan [1] visualized a pocket health monitor two decades ago, and now, there is a talk of a real scenario where your smartphone can turn into a personal doctor [2].

Bioinformatics is a rapidly evolving science facilitated by expanded computer efficiency. Computer technology has made it feasible to study the structure and characteristics of billions of molecules in various biological organisms, including human beings. The human genome itself is estimated to have 3 billion base pairs [3]. Bioinformatics is the science that tries to systematically organize the information about these billions of items so that useful information with regard to health and disease can be extracted. This also helps in identifying drugs that can be specifically targeted, relying on genomic sequencing.

A statistical component in bioinformatics is within- and between-subjects variations, which exist in all biological systems. Subjects tend to behave differently at different points in time, and different subjects have different profiles. This variation generates uncertainty, which can be studied only by statistical methods.

## biostatistics

Biostatistics comprises statistical methods that are used to manage some crucial aspects of uncertainties in the field of medicine and health, and the statistical methods in this are those that help to derive meaning from data by considering the underlying uncertainties and variations.

Medicine involves close interactions with the patient, and a large number of steps are usually taken before arriving at a treatment regimen. The patient's history is taken; measurements such as weight, blood pressure, and heart rate are recorded; physical examination is carried out; and a range of investigations are undertaken. In the course of these steps, a patient sometimes encounters many observers and many instruments. Variations among them contribute their share to the uncertainties seen in clinical practice. The assessment of diagnosis, treatment, and prognosis can all go wrong. **Medical uncertainties** are profound, and it is important to delineate them and contain their effect on our health care decisions.

Uncertainties are not something that doctors are necessarily used to handling. Sometimes, even communicating and understanding risks can be difficult. The role of **statistics** is precisely this. Statistics can be regarded as the *science of management of uncertainties in an empirical setup*—a tool to measure them and minimize their impact on decisions. A basic feature of statistical methods is that they enable us to draw conclusions about the whole from the study of a part—a sample. This provides a framework within which to think critically about evidence, and to understand and appreciate the concepts of risks and probability.

Another aspect is of errors in the data and missing values. Statistical methods also help in detecting and handling these aberrations that give rise to statistical lies [1], which statistics is notorious for.

Uncertainties are prominent in practically all medical situations and need to be properly managed. Management in any sphere is a complex process, more so if it concerns phenomena such as uncertainties. Management of uncertainty requires a science that understands randomness, instability, and variation. Biostatistics is the subject that deals specifically with these aspects. Although the *bio* part of *biostatistics* should stand for all biological sciences, it has become convention to apply the term *biostatistics* to statistical applications in only medical and health sciences.

Since the uncertainties are glaring, one wonders how medicine has been successful, sometimes very successful, in giving succor to mankind. The silver lining is that a trend can still be detected among these variations, and following this trend yields results within clinical tolerance in most cases. The term *clinical tolerance* signifies that the medical intervention may not necessarily restore the body system to its homeostatic level but tends to bring it closer to that level so that the patient feels better, almost cured. Also note the emphasis on "most cases." Positive results are not obtained in all cases, nor is this expected. But a large percentage of cases respond to medical intervention. Thus, the scenario is doubly probabilistic and underscores the prominent role of biostatistics in medical decision making.

Many clinicians deal with these uncertainties in their own subjective ways, and some are very successful. But most are not as skillful. To restore a semblance of science, methods are needed to measure these uncertainties, to evaluate their impact, and of course to keep their impact under control. Such a need is more conspicuous in a research setup than in everyday practice. All these aspects are primarily attributed to the domain of biostatistics. Biostatistical methods not only contribute to probabilistic thinking but also encourage critical and logical thinking. This helps to judge the believability of something that nobody has witnessed.

Biostatistical methods are becoming more complex by the day just as almost all other sciences. Many medical professionals find it difficult to catch up, and many consider biostatistics an unnecessary intrusion into their clinical acumen. But biostatistics seems to have firmly entrenched itself in medical research, if not in clinical practice, which gives the analogy to a joke that it is a wife that you cannot live with and cannot do without either. Another popular quote that says that biostatistics is used more for support than illumination just as a streetlight pole is for drunkard also illustrates how biostatistics is treated by some medical researchers. Biostatistics consultation should start at the beginning of a project. Consulting after the project is over, when the reviewers have found fault, is like a postmortem that can diagnose the cause of death but cannot revive the project.

Distinguish biostatistics from medical **data mining**, which relates to the existing data. Hospitals these days keep an electronic record of all patients they manage, particularly those admitted. You may collate these data, tabulate them, present them in graphs and diagrams, etc. This also is a perfectly valid statistical activity, although it has no chance element. After examining such data for thousands of patients, for example, undergoing gastrointestinal (GI) surgery, you may reach a conclusion that women of age 50–59 years are the ones who more commonly chose elective GI surgery in that hospital compared with any other age-sex groups. This may have some implication for the policy of the hospital, but this conclusion cannot be generalized to other hospitals, although one can surmise that this is so for other hospitals also catering to a similar population. Statistical inference such as estimation and test of hypothesis cannot be used in data mining unless this is considered as a **random sample** from a hypothetical hyperpopulation of patients coming to that hospital. If that assumption is made, you are back to the fold of biostatistics.

## biplot

A biplot is a specific type of graphical display of **multivariate** data. Although two or three variables are easy to depict, depiction of a larger number is difficult. How can mean plasma glucose level (both fasting and postprandial), weight, and blood pressure (systolic and diastolic) be shown for two groups of subjects in the same figure? Several types of biplots have been proposed that can show four or even five variables simultaneously. However, the methods are complex, and the figure so obtained can be difficult to interpret. One such biplot is shown in Figure B.6 for stroke patients. You will appreciate that such a figure, as of now, does not seem to serve the purpose of better perception and adequate cognition that a figure is supposed to serve. For further details of biplots, see Gabriel and Odoroff [1].

## birth and death registration

Almost all countries around the world require that each birth and death be registered with the local registrar. Generally, the local authority such as a municipality is assigned the function to register such events and issue a birth or death certificate as the case may be. This is called the **civil registration system**. Although some countries now have an online system for registering births and deaths through hospitals, many still require manual registrations. For example, in India, an act provides that each birth and death must be reported to the local registrar within 21 days.

A *birth certificate* will generally contain information on the place of birth, sex, age of the mother, and sometimes other details

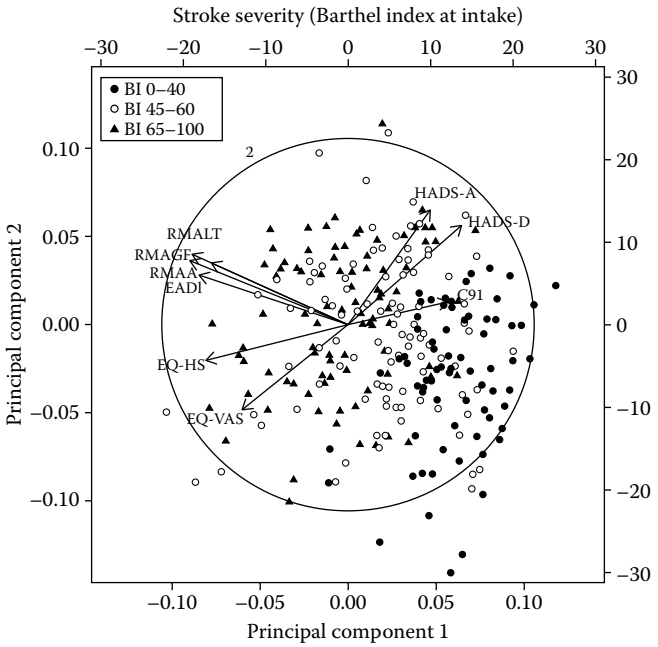

**FIGURE B.6** Biplot without CSI and with projected HADS-A and HADS-D vectors. BI—Barthel index; CSI—Caregiver Strain Index; EQ-HS—EuroQol health state; EQ-VAS—EuroQol visual analogue scale; HADS-A—Hospital Anxiety and Depression Scale–Anxiety; HADS-D—Hospital Anxiety and Depression Scale–Depression; RMAGF, RMALT, and RMAA—Rivermead Motor Assessment gross function–leg, trunk, and arm. (From De Wit L, Molas M, Dejaeger E, De Weerdt W, Feys H, Jenni W, Lincoln N, Putman K, Schupp W, Lesaffre E. The use of a biplot in studying outcomes after stroke. Neurorehabil Neural Repair 2009 Oct;23(8):825–30. http://www.ncbi.nlm.nih.gov/pubmed/19498014.)

(e.g., occupation) of the mother and/or father. A *death certificate* carries information on age, sex, place of death, and, most importantly, the **cause of death**. The cause should be medically certified. The recorded causes should ideally follow the **International Classification of Diseases (ICD)** system so that they are uniformly understood across the world, although this often does not happen. The World Health Organization (WHO) recommends that the causes be divided into immediate, underlying, and contributory.

Birth certificates provide a legal framework not just for health benefits but also for, say, school admission, juvenile justice, child labor, inheritance, etc. Similarly, death certificates also help in inheritance, property disputes, etc. Cause of death is particularly useful for targeted interventions against causes that are alarming or preventable, thus helping to reduce premature mortality.

In countries where a complete listing of the population is available, birth and death registrations can be used to instantly update records. These records can also be analyzed to ascertain whether more births or deaths are occurring, at what age of women in the case of birth, at what age in the case of death and with what cause, etc. Since age and cause of death are important indicators of health status and health requirements, birth and death registration serves a very useful statistical purpose.

A civil registration system may not able to capture all births and deaths, particularly in developing countries. The cause of death may or may not be medically certified. Such countries therefore try to collect data from other sources to fulfill their requirement for planning and evaluation of their health programs.

## birth cohort

A birth cohort is a group of people born in a certain specified period and who are periodically followed up for their health parameters since birth, sometimes from pregnancy. Thus, a birth cohort study is a **prospective study** with no randomization of the exposure. The objective of the follow-up is to keep complete track of various health events since birth and to study their relationship with one another and with other environmental and behavioral factors. Birth cohort studies are believed to be a reliable source for generating **cause–effect relationships** since information on many **antecedents** and **confounders** is available that can be taken into account when deriving net relationships with the outcomes. This can help policy makers.

A birth cohort can be chosen to be representative of births in a defined area. Follow-up frequency and period of follow-up is decided beforehand, and the outcome of interest is specified. Covariates under study are chosen and confounders identified. If the outcome of interest is rare, the cohort size obviously should be large so that enough events occur in the follow-up period for drawing a reliable conclusion.

When followed up until adulthood, birth cohorts provide a unique opportunity to study the impact of early life events, such as birth weight and childhood obesity, on subsequent adverse health events. There has been a considerable interest in such studies ever since the Barker hypothesis [1] was put forward. A large range of hypotheses can be investigated by birth cohort studies.

Birth cohort studies are not simple to implement, because they involve huge cost and efforts for long-term follow-up. In addition, such cohorts may be truncated because of migration, noncooperation, and occasional deaths. More challenging is the need to deal with time-related changes—new technology, new knowledge, and new methods could easily make earlier observations obsolete, and environmental, social, and physical changes could severely affect the results even if time-dependent covariate analysis is done. Birth cohort studies may not provide breakthrough results during the early phase, and this can cause frustration and despondence. Despite such problems, there has been a marked increase in birth cohort studies because of their inherent value in providing a comprehensive picture of events in real time.

With digitization of records since birth, these kinds of studies have become easy in many countries. When complete records are available, historical birth cohorts can be analyzed for events since birth. In one such study in Australia, Srinivasjois et al. [1] observed that those born at a shorter gestational age remain more vulnerable to subsequent hospitalization for a variety of causes up until 18 years of age compared with full-term infants. Magnusson et al. [2] studied the diet of a birth cohort at the age of 8 years in Sweden for development of allergic rhinitis and nonallergic rhinitis in the next 8 years, and concluded that regular consumption of oily fish and dietary long-chain n-3 polyunsaturated fatty acids (PUFAs) in childhood might decrease the risk of rhinitis. For a 20-year follow-up of a birth cohort in Australia for clinical cardiovascular risk during young adulthood in offspring of hypertensive pregnancies, see Davis et al. [3].

A good account of birth cohort studies has been provided by Lawlor et al. [4].

## birth–death process, *see* stochastic processes

## birth order

Are you the first child born to your mother? Then your birth order is 1. As the name implies, the birth order of the eldest child is 1, that of the next is 2, etc., counting only the live births. Stillbirths and other pregnancy terminations such as abortions are excluded. Deaths occurring after birth do not alter the birth order of siblings.

Birth order can affect health in a variety of ways. The first child initially enjoys all the attention and resources, whereas the second and subsequent births generally get divided attention and divided resources. The effect of birth order on psychological development, intellectual capabilities, and personality traits is well known, but it affects physical health as well. Birth order affects the hemoglobin level of the woman, which can affect the birth weight, which in turn can affect a large number of health conditions. For example, birth order has been found to be associated with cardiovascular risk factors in young adulthood in Sweden [1] and posttraumatic stress disorder in the United Kingdom [2].

Birth order can have significance in many epidemiological studies. It is seen to affect height in Swedish men [3] and suicide rate in Norway [4]. Statistically, isolation of the effect of birth order is not always straightforward, because the outcome may have a multifactorial etiology. For example, Turner et al. [5] found a V-shaped effect of birth order on autism in multiplex families in the United States, where middle births are at high risk, and a linear effect in simplex families, where the risk increases with each additional birth. It is therefore necessary to exercise care when studying birth order as an antecedent for an outcome.

## birth rate, *see* fertility indicators

## birth weight ratio

This is defined as

$$\text{BWR} = \frac{\text{birth weight ratio:}\quad \text{actual birth weight}}{\text{expected birth weight for gestational age and gender}}.$$

This measures how a child's weight at birth is different from what is expected for his/her gestational age and gender. A statistical relationship (third-degree polynomial) is available to find the expected weight for gestational age and gender [1]. More crudely, the median birth weight for a specific gestational age can be used as the expected weight in the denominator.

The BWR has special significance for developing countries such as Bangladesh, where many premature births take place. The BWR is used as an index of small-for-gestational-age (SGA) births relating to children who could not grow normally during pregnancy and require special care. Generally accepted categorization of the BWR is as follows:

| | |
|---|---|
| Normal: | $\text{BWR} \geq 0.90$ |
| Mild SGA: | $0.75 \leq \text{BWR} < 0.90$ |
| Severe SGA: | $\text{BWR} < 0.75$ |

SGA is valuable in predicting several health outcomes, particularly during infancy. For example, Voskamp et al. [2] found in a nationwide study in the Netherlands that the BWR has better discriminating power than birth weight percentile for perinatal deaths. SGA can affect growth and development. It has been found to affect height but not age at menarche in Korea [3].

## biserial correlation, *see* point-biserial correlation

## bivariate distributions

When two variables are considered together, this is called a bivariate setup. The **joint distribution** of the variables $x$ and $y$ is the pattern they jointly follow. This helps us to know the probability that the two

variables together take given values. For example, the joint distribution of albumin and globulin levels will indicate the chance that a random person has, say, albumin between 4 and 5 g/dL and globulin between 7 and 8 g/dL. This also indicates the distribution of each variable over all possible values of the other, called the **marginal distribution**. This can also tell us the distribution of one variable for specific values of the other, called the **conditional distribution**. Further explanation is as follows.

Simultaneous study of two variables helps to explore or determine the extent and nature of the relationship between them. For example, we all know how age and height are intimately related in children, and that the relationship is **nonlinear**. In this case, both variables are **continuous**, but one or both of them can be **discrete**. Blood group (O, A, B, AB) distributions in different races (e.g., Aryan, Caucasian, Black, and Mongoloid) is an example where both variables are discrete. At the extreme of this is a **binary** bivariate setup, such as the relationship between **antecedent** present/absent and **outcome** present/absent (see **two-by-two tables**).

The number of subjects with different values of the two variables together gives shape to a bivariate distribution. An example of bivariate distribution of systolic and diastolic level of blood pressure (BP) in women of age 40–44 years is in Table B.4. Values of diastolic and systolic levels are given in intervals for convenience, but that is not necessary. Note, for example, that women with diastolic BP of 60–64 mmHg most frequently have systolic BP between 120 and 129 mmHg (**mode** = 120–129 mmHg), whereas those with diastolic BP of 70–74 mmHg have modal systolic level = 130–139 mmHg. These findings come from conditional distribution of systolic BP for diastolic BP between 60 and 64 mmHg and conditional distribution of systolic BP for diastolic BP between 70 and 74 mmHg, respectively. Similarly, there is a distribution of diastolic level for each interval of systolic level. This is the essential feature of a bivariate distribution.

The distribution of all women by diastolic level is in the last column of Table B.4. This is the marginal distribution of diastolic level. Similarly, the last row is the marginal distribution of systolic level in these 600 women. In many applications, the term *marginal* is ignored, and the distribution among total subjects is simply called the **distribution** of the concerned variable.

As mentioned earlier, we can have a bivariate distribution when one or both variables are discrete. Distribution of birth weight of boys born at different birth orders will be a bivariate distribution where one variable (birth order) is discrete and the other (birth weight) is continuous. In this case, the distribution of all boys (irrespective of birth order) is the (marginal) distribution of birth weight in these newborns.

The concept of joint distribution, conditional distribution, and marginal distribution can be extended to a multivariate setup when the number of variables is three or more.

## bivariate Gaussian distribution

A bivariate Gaussian distribution, better known as bivariate normal distribution, is a special type of **bivariate distribution** that follows a bell-type shape (Figure B.7a). This figure has three axes. In the context of the systolic and diastolic BP example in Table B.4 (but with ungrouped data), the bottom two axes depict systolic ($x$) and diastolic levels ($y$), and the vertical axis depicts the number of subjects. Note the symmetry of this shape and equal standard deviations (SDs) of $x$ and $y$ in Figure B.7a. In this case, you will see the same shape no matter which side the plot is viewed from. The frequency is highest (peak of the distribution) when $x$ and $y$ values are at the middle of their ranges, and the decline of frequencies on either side of these values follows the same pattern. The peak is such that **kurtosis** is 0.

For contrasting with other bivariate distributions, see Figure B.7b, which is for data in Table B.4 with BP groups intact. Since this is based on sample values, the shape is not smooth, and there are bumps and corners. This does not look like a bivariate Gaussian distribution, as the distribution has a longer tail on one side than the other side. Also, it can be seen that the variability of the systolic level is higher relative to that of the diastolic level. When this occurs in a bivariate Gaussian distribution, the shape is not exactly symmetrical, as in Figure B.7c, where the length of the bell at the base is more than its width because of unequal SDs. The shape depends not only on SDs but also on the **correlation** between $x$ and $y$.

## black-box approach

Using computer programs without properly understanding the underlying procedure is sometimes called a black-box approach. Users generally know what goes in and what comes out of a computer package, but few understand what happens in between. This

**TABLE B.4**
**Bivariate Distribution of Systolic and Diastolic Level of Blood Pressure (BP) in 600 Healthy Females of Age 40–44 Years**

| | Systolic BP (mmHg) | | | | | | | Total (Marginal distribution of diastolic BP) |
|---|---|---|---|---|---|---|---|---|
| **Diastolic BP (mmHg)** | **100–109** | **110–119** | **120–129** | **130–139** | **140–149** | **150–159** | **160–169** | |
| 60–64 | 1 | 2 | 5 | 2 | 2 | 0 | 0 | **12** |
| 65–69 | 4 | 8 | 12 | 4 | 1 | 0 | 0 | **29** |
| 70–74 | 1 | 7 | 18 | 33 | 12 | 8 | 2 | **81** |
| 75–79 | 3 | 12 | 15 | 58 | 22 | 18 | 4 | **132** |
| 80–84 | 2 | 23 | 20 | 45 | 71 | 32 | 7 | **200** |
| 85–89 | 0 | 2 | 5 | 15 | 54 | 26 | 5 | **107** |
| 90–94 | 0 | 0 | 1 | 3 | 6 | 20 | 9 | **39** |
| **Total (marginal distribution of systolic BP)** | **11** | **54** | **76** | **160** | **168** | **104** | **27** | **600** |

*Note:* Shaded-in row is the conditional distribution of systolic level when the diastolic level is between 60 and 64 mmHg; shaded-in column is the conditional distribution of the diastolic level when the systolic level is between 110 and 119 mmHg.

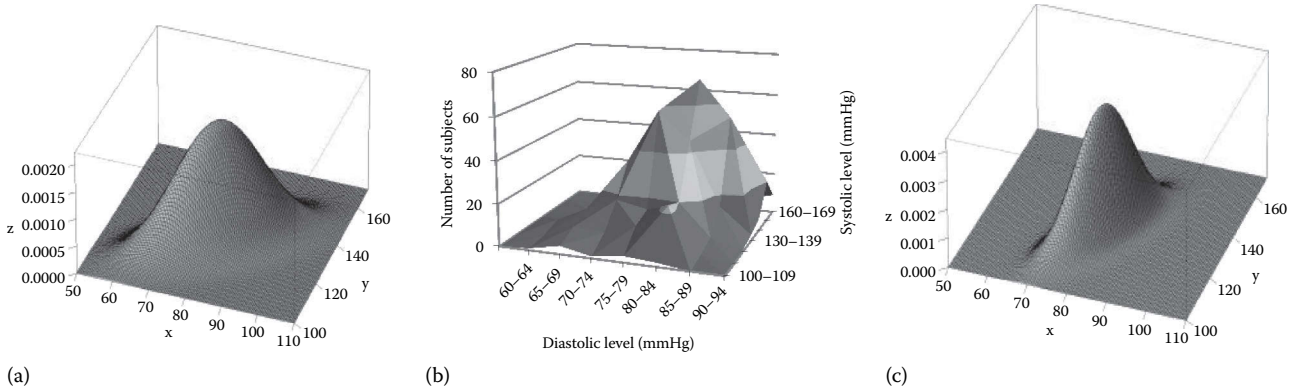

**FIGURE B.7** (a) Bivariate Gaussian distribution with equal standard deviation of $x$ and $y$; (b) bivariate distribution of data in Table B.4 and (c) bivariate Gaussian distribution with unequal standard deviations.

approach is frequently used for computational problems in biostatistics by those who find it difficult to spend time to understand the procedure, or when they possibly lack expertise.

As statistical methods are becoming increasingly complex by the day, use of a black-box approach is inevitably increasing. Many health professionals and some statisticians find the intricate mathematics behind these methods too complex to understand, and resort immediately to the use of computer software to get a solution to their problems. Most statistical software packages are not yet intelligent enough to check the underlying assumptions and appropriateness of the method for the problem at hand. Even if software packages are intelligent for the specified method, users sometimes are not fully aware of how to use them. Further difficulties arise in proper interpretation of the computer output, particularly since statistical software tends to give large output as a default. Some researchers use this output in their report without full appreciation of the implications. It is difficult to ascertain from the finished report whether or not the results and conclusions are based on proper reading of the computer output. Thus, some research reports remain of doubtful value.

A black-box approach can be used for any calculation for which a computer package is available, but it is frequently used for **predictive models**, particularly in **data mining**. Kuhn and Johnson [1] have given an example of a model to "[i]dentify patients who will be admitted to a hospital within the next year, using historical data," to illustrate how challenging unfolding a black-box algorithm could be.

1. Kuhn M, Johnson K. Who's afraid of the big black box? Statisticians' vital role in big data and predictive modeling. *Significance* July 2014;11(3);35–7. http://onlinelibrary.wiley.com/doi/10.1111/j.1740-9713.2014.00753.x/abstract

## Bland–Altman method of agreement, *see also* agreement assessment (overall)

The Bland–Altman method is the most widely used method of assessing **agreement** between the same quantitative measurement taken on the same subjects by two methods, two sites, two observers, etc. The paper describing this was originally published in a statistical journal (*The Statistician*) in 1983 [1], and it was repeated in a revised form for a medical audience in *The Lancet* [2] in 1986 with a reverse sequence of authorship. From then on, this paper has become one of the most cited in medical literature.

Martin Bland

The Bland–Altman method of agreement is for finding whether the two measurements taken on the same subjects agree or not. Thus, this investigates the presence or otherwise of an $x = y$ relationship for each individual. If the two measurements agree, all points will fall on an $x = y$ line. This is different from regression since regression is for averages. For details, see **agreement assessment (overall)**. Some other methods of assessing agreement are discussed under that topic.

The two measurements will rarely agree completely. Differences will arise, and the question is whether the differences are within the tolerance range or not. In the Bland–Altman method, the differences $d = (x - y)$ in the values obtained by the two methods or observers under comparison are examined. If these differences are randomly distributed around 0 and none of the differences is large, the agreement is considered good. The method was initially devised for measurements where neither of the two is a gold standard. This method considers $x$ to be as good or as bad as $y$—it is symmetric. Modifications have now appeared that allow it to be used when the comparison is with the gold [3].

A graphical approach for the setup in which both measurements can be in error is to plot $d$ versus $(x + y)/2$. This has become known as the *Bland–Altman plot*. A flat line around 0 is indicative of good agreement. Depending upon which is labeled $x$ and which $y$, an upward trend indicates that $x$ is generally more than $y$, and a downward trend, that $y$ is more than $x$. If $x$ is a gold standard against which $y$ values are to be assessed for agreement, plot $(y - x)$ versus $x$ [3].

A commonsense approach is to consider agreement as reasonably good if, say, 95% of these differences fall within the prespecified clinically tolerable range and the other 5% are also not too far. Statistically, note that when the two methods or two observers are actually measuring the same variable, then the difference $d$ is mostly the measurement error. Such errors are known to follow a **Gaussian** (normal) **distribution** irrespective of the distribution of the original measurements. Thus, the distribution of $d$ in most cases would be Gaussian even when the

distribution of $x$ or of $y$ or both is far from Gaussian. Then the limits $\bar{d} \pm 1.96 s_d$ are likely to cover differences in nearly 95% of subjects, where $s_d$ is the standard deviation (SD) of the differences. The literature describes them as the **limits of agreement**, but they are actually *limits of disagreement* because they delineate the extent of disagreement. If these limits are within clinical tolerance in the sense that a difference of that magnitude does not alter the management of the subjects, then one method could be replaced by the other. The mean difference $\bar{d}$ is the **bias** between the two sets of measurements, and $s_d$ measures the magnitude of random error. For further details, see Bland and Altman [2]. They also discuss how error in estimating $\bar{d} \pm 1.96 s_d$ can affect the limits and how to calculate limits of disagreement in the case of **repeated measures**.

The Bland–Altman approach has its limitations. Suppose a method consistently gives a level 0.5 mg/dL higher than the other method. The **correlation coefficient** between these two methods would be a perfect 1.0. Correlation fails to detect systematic bias. This well-known artifact incidentally also highlights the limitation of the limits-of-disagreement approach. The difference between measurements by two methods is always +0.5 mg/dL—thus, the SD of difference is 0. The limits of disagreement in this case are (+0.5, +0.5). This, in fact, is just one value and not limits. A naive argument could be that these "limits" are within clinical tolerance and thus, the agreement is good. To detect this kind of fallacy, plot the differences against the mean of paired values. This trend can immediately reveal this kind of systematic bias. Secondly, the method considers absolute difference and does not work well when the difference between two measurements under investigation is in proportion to the values—a larger difference for large values. For this setup, Indrayan [4] has proposed a modification (see **agreement assessment**), although the Bland–Altman method can also be used after taking logarithms.

As an example, consider the following data of Chawla et al. [5] on systolic blood pressure (BP) readings derived from the plethysmographic waveform of a pulse oximeter, which could be useful in a pulseless disease such as Takayasu syndrome. The readings were obtained (i) at the disappearance of the waveform on the pulse oximeter on gradual inflation of the cuff and (ii) at the reappearance on gradual deflation. In addition, BP was measured in a conventional manner by monitoring the Korotkoff sounds. The study was done on 100 healthy volunteers. The readings at disappearance of the waveform were observed to be generally higher, and at reappearance, generally lower. Thus, the average (AVRG) of the two is considered a suitable value for investigating the agreement with the Korotkoff readings. The results are in Table B.5. The scatter and the line of equality are shown in Figure B.8.

**TABLE B.5**
**Results of Agreement Analysis of AVRG with Korotkoff Method of Measuring Systolic Level of Blood Pressure in Healthy Subjects**

| | AVRG | | Korotkoff |
|---|---|---|---|
| Mean systolic BP (mmHg) | 115.1 | | 115.5 |
| SD (mmHg) | 13.4 | | 13.2 |
| Mean difference (mmHg) | | −0.4 | |
| *P*-value for paired *t* | | >0.50 | |
| Correlation coefficient ($r$) | | 0.87 | |
| SD of difference, $s_d$ (mmHg) | | 6.7 | |
| Limits of disagreement (mmHg) | | (−13.5,12.7) | |
| **Intraclass correlation coefficient** ($r_I$) | | 0.87 | |

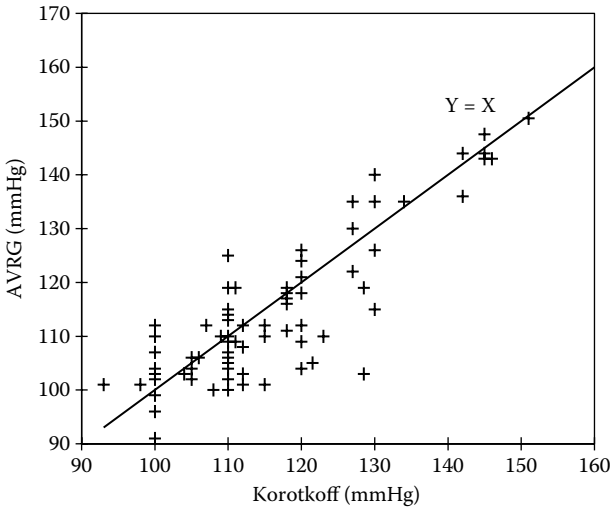

**FIGURE B.8** Scatter of the pulse oximeter and Korotkoff readings (AVRG = average of readings at disappearance and reappearance of a waveform).

Despite the means being nearly equal and the correlation coefficient high, the limits of disagreement show that a difference of nearly 13 mmHg can arise between the two readings on either side (average of pulse oximetry readings can give either less or more than the Korotkoff readings). These limits are further subject to sampling fluctuation [2], and the actual difference in individual cases can be higher. It is for the clinician to decide whether a difference of such magnitude is tolerable. If it is, then the agreement can be considered good, and pulse oximetry readings can be used as a substitute for Korotkoff readings; otherwise, they should not be regarded as interchangeable. Thus, the final decision is clinical rather than statistical when this procedure is used.

## blinding, masking, and concealment of allocation

Blinding in health and medicine is withholding information from those involved. This can be used in a variety of research setups, such as blinded reviews of the articles submitted for publication so the reviewers do not know who has conducted the study and where, and can provide their unbiased view. In case–control studies, for example, blinding the observers, where feasible, can help in obtaining unbiased data. The purpose is to look fair to those who are being assessed and to provide unbiased data as much as possible. Our concern in this section is with blinding in a clinical trial setup, where

fairness and unbiased data have special significance. Related topics of masking and concealment of allocation are also discussed in this section.

In a **clinical trial** setup, sometimes, the exposure or the accompanying baseline information and sometimes the outcome are not correctly assessed. This can occur due to bias of the observer or of the recording clerk, who may classify a subject into a particular category of interest supporting one's individual hypothesis. Observer **bias** can also occur if the subjects with disease are evaluated more intensively and more carefully than those without disease. In addition, there is a tendency for the subjects to respond differently depending on whether they are in the treatment group or in the control group. They may show some psychological effect when actually, none is present, or they may conceal a real effect. They may want to switch from one group to another depending upon which group is showing better results. This can disturb the trial. To control all these biases, three precautions are taken. The first is called blinding of the subjects and the assessors, the second is called masking of the regimen, and the third is concealment of allocation. These are closely related but different procedures, although often confused with one another.

Blinding is not revealing to those involved in the trial which subject is receiving the test regimen and which the control regimen. Thus, this term refers to the subjects and the assessors and not the regimen. The corresponding term for making the regimen apparently indistinguishable is called masking. Concealment of allocation means that the person doing the allocation does not know what the next allocation is going to be. This is also described in this entry. Masking and concealment of allocation are needed for effective blinding. The details are as follows.

## *Single, Double, and Triple Blinding*

Trials with no blinding are called **open trials** or *open-label trials*. In this type of trial, everybody knows who is receiving which treatment. Experience suggests that unblinded trials are more likely to falsely show a benefit of the active regimen than blinded trials. Some subjects may show improvement or deterioration unrelated to the true effect of the treatment if they know to which group they belong. Participants in the control group may feel discriminated against if the allocation is open. Also, patients who know that they are receiving a new regimen may either exhibit increased anxiety or have favorable expectations. In addition, subjects are more likely to seek adjunct intervention in an open trial and more likely to dropout. If the treating clinician is aware of the upcoming allocation, he/she could exclude patients he/she considers unsuitable for that treatment or include patients considered especially suitable. This can introduce bias. During the course of the trial, a clinician who knows the group assignment, is more likely to administer cointervention and more likely to adjust dose. All these potential sources of bias can be avoided if subjects and the observers are blinded.

*Single blinding* refers to subjects not told about the treatment allocation. This eliminates the possibility of participants psychologically changing their response when they know that they are in a particular group. Blinding works as an insulation against such biases as the subjects are generally more committed when told in advance that they can get any of the regimens under trial and give consent to participate. Single blinding occurs automatically if the subjects are unconscious or anesthetized when a treatment is given or a procedure undertaken, such as using or implanting a device, or changing the policy of intensive care. The term *single blinding* can also be used when the assessors are blinded but not the subjects. When this is done, this is specified upfront, or else the usual single blinding is assumed, where the subjects are blinded and not the assessors. Although any single blinding is far from ideal, it may be unavoidable if some features or effects of treatments are apparent to trial personnel and observers but not to the subjects, or vice versa.

If the assessor knows what treatment a particular subject is receiving, this may affect the way the questions are asked, investigations done, or interpretations made. Thus, it is desirable that the assessor also is kept blind. This removes possible bias of the physicians or nurses involved in patient assessment—or at least mitigates any subconscious influence on the outcome assessment. Unblinded assessments can also be unbiased when done by credible people, but blinding improves the confidence in the results without much additional cost. When observers, assessors, and other study-related personal are blinded, in addition to the subjects, this is called *double blinding*. Such a precaution is an important criterion for validity of the results of a trial. A double-blind **randomized controlled trial** is considered a gold standard for assessing the **efficacy** and safety of a new regimen or any other intervention.

Sometimes, even the data analyst has preconceptions, expectations, and prejudices. He/she might be interested in particular findings and can gear the analysis and interpretation accordingly. Most such biases at the data management stage occur in the coding of adverse events when manually done or in the interpretation of handwriting when the case sheets are handwritten. If the data analyst is aware of the treatment allocation, he/she could be selective in whether to seek clarification when something is not clear and may impose his/her own interpretation. To avoid this, the analyst can also be kept blind about the codes. The codes are broken only after the data analysis is complete. This makes the trial *triple blind*. However, make sure blinding the data analyst is not jeopardizing the analysis and presentation. Ii is better to specify in advance what analysis would be done and what tables would be prepared.

In a blinded trial, other than during the phase of analysis, treatment allocations should not be available to anyone, even in the form of treatment A and treatment B. It is also important that nobody involved in the trial knows which patients are receiving the same treatment. Blinding can be implemented by involving a third party who keeps the record that a subject has received treatment or control. Rigid coding systems, such as code X for the treatment and code Y for the placebo, should be avoided because breaking the code for one patient breaks it for the rest of the trial. This can easily happen in a medical care setup, where laboratory investigations or side effects can identify that a subject has received the active regimen or placebo.

Details of how blinding is actually intended to be implemented should be fully specified in the protocol, and how it was actually implemented should be stated when reporting a trial. Merely stating that blinding was done is not enough. In fact, such details should be given in the protocol itself.

## *Difficulties in Blinding*

Blinding can be difficult and sometimes not achievable. One problem is masking, as described later in this section, and the second problem is its feasibility. For assessing outcomes such as quality of life, readmissions, and falls after hip surgery, blinding is just not possible if one maneuver is keeping patients in the hospital for a specified number of days, and the other is early discharge and home rehabilitation. In most surgical interventions, the control has to be another kind of surgery and not a placebo. A sham surgery may be unethical many times because it exposes a patient to surgical risks. In either case, it is extremely difficult to enforce blinding in a surgical trial. The patient can be kept blind after proper consent, but the surgeon definitely

knows. However, a mechanism can possibly be developed wherein all assessments subsequent to the operations are done by another surgeon who does not know and cannot decipher whether the patient belongs to the test surgery or the control surgery group.

If the effects of one of the treatments are such as to be apparent (e.g., marked facial flushing after taking a drug or developing different symptoms after different types of surgery), it is almost impossible to maintain the blindness. A similar problem arises if, for example, two different durations of hospitalizations are being compared.

Blinding is rarely feasible in studies requiring long follow-up. At some stage, something happens that can break the code. It is very difficult to enforce blinding in field trials also except in some typical situations. Special efforts may be needed. For example, Lwegaba [1] reports a single-blinded field trial on educational material for tobacco prevention. The trial was conducted on school students, and the schools were distantly located so that contact between students did not occur and the blinding could be maintained.

Some trials keep a provision of **interim appraisals**. This has the potential to unblind an otherwise blinded trial. Unblinding is necessary to assess whether the treatment arm is giving sufficient evidence of efficacy or of futility relative to the control or for sample reestimation. Efforts are made that this unblinding remain confined to an unconcerned group, such as the Data Safety and Monitoring Board, and does not extend to the participants and the assessors, and the blinding for them remains in effect till such time that the trial is completed.

Morality issues are attached to blinding because the information is withheld from the participants, on the one hand, who would be keen to know what they are getting in case an unusual side effect appears or unusual recovery occurs, and on the other hand, from the doctor, who may not be able to take remedial measures if anything happens to the detriment of the participant. Nonetheless, this is considered acceptable so long as the subjects are fully informed about blindness and they provide consent. Also, breaking the code must be axiomatic if the care providers consider it necessary in the interest of the patients.

There are logistical problems in ensuring that the blinding remains effective. We have already mentioned side effects that can easily indicate which subject is on an active drug and who on placebo. Masking the regimens to at least look similar, as discussed in a subsequent paragraph, is a challenge in many practical situations. A substantial improvement in some patients and not others may also give indication as to who is in which group.

For more details of blinding, see any good book on clinical trials, such as that by Friedman et al. [2].

## Masking

The term *blinding* applies to the human beings involved in a project, and *masking*, to the regimens and the procedures. An obvious prerequisite for maintaining blinding is that the treatments must not be distinguishable. Regimens and procedures in a trial must be disguised to look similar to the subjects and to the assessors as much as possible. This can be easily illustrated for drugs where the active drug under trial and the placebo should be exactly alike in appearance (color, size, weight, packaging, smell, etc.) and possibly in taste. Note that the treating physician would know the treatment because he/she is giving the treatment unless the masking of the regimen is done and the regimen, such as tablets, are in envelopes for administration. For masking, both the regimens have to be administered equally often. If one is once a day and the other twice a day, the former has to be given a placebo a second time each day to look like a similar treatment. This looks easy in this example, but consider one regimen requiring six tablets a day and the other just two. You can have four placebos, but the subjects may find six too cumbersome to swallow and may decide to take three. All these may be placebos. This may be difficult to track. Thus, masking is not always easy. Consider beforehand what is feasible. A classic example is two anesthetic agents, one of which is to be given at 30 mL and the other at 60 mL. Dilution in this case is not advisable. For masking in this situation, a placebo (say, saline) of 60 mL to the first group and 30 mL to the other groups of the same appearance is given. The order is randomized. This might look strange, as both the groups are getting placebo. This becomes necessary in this case to mask the regimen. This is called the *double dummy technique*.

In the case of hospitalized patients, the two groups should undergo the same rituals in terms of diet, laboratory and radiological investigations, transfer from intensive care to routine care, etc. The term used for such procedures is *sham* (just like in *sham surgery*), whereas the equivalent term for drugs is *placebo*. This is applicable to the single-blind (subject is blind) setup since in a double-blind trial, no one knows the allocation, and all will inevitably be treated identically.

## Concealment of Allocation

Allocation concealment is when the person allocating the treatments in a clinical trial does not know what treatment the *next* person is going to get. The allocation of the subjects to the treatments under trial is generally done with the help of opaque sealed envelopes that contain the allocation. They are opened only after the subject's name and other identification is written on the envelope so that the treatment cannot be changed. Concealment means that the envelopes are in random sequence and the serial on the envelope is not able to reveal what treatment it contains. A third party keeps all the records of the random sequence. This prevents bias of the allocating person in choosing which subject will get what treatment. Using a pharmacy as the third party is common for concealment of allocation in the case of drug trials.

Do not confuse concealment of allocation with **blinding**. Concealment seeks to protect the sequence of the assignment, whereas blindness is not knowing who is getting what. The question of sequence before actual allocation does not come in the case of blinding, but it comes in the case of concealment of allocation. Concealment is always feasible, but blinding is not always feasible. Blinding protects the sequence *after* allocation and is a safeguard for response and ascertainment bias, which occur after the treatment is administered. When the allocation is not concealed, even random assignment can be subverted. This could lead to selective withdrawals before the treatment starts. Details and an example of how all this was implemented in a trial on misoprostol are given by Piaggio et al. [3], although they seem to have mixed up **masking** with blinding.

## block, cluster, and stratified randomization, and minimization, *see also* random allocation

B

**Randomization** is random allocation of subjects to the arms of a trial. This is done primarily to achieve **baseline equivalence** of the groups under trial. Beside simple individual randomization, this can be done by the method of block randomization, cluster randomization, and stratified randomization in certain specific situations or by using more complex techniques such as minimization and adaptive randomization.

### *Block Randomization*

Block randomization is one of the most common methods of randomization. This requires that subjects are divided into $M$ blocks of size $2n/M$ each, where $n$ is the stipulated size of each of the two groups. In the case of more than two groups, the block size must be a multiple of the number of groups. For two groups, the block size can be 4 or 6 or 8, but not 5 or 7. If you have enrolled a total of 80 subjects, you can make 20 blocks of 4 subjects each. Within each block, allocate two subjects at random to group 1 and the other two to group 2. Thus, you can have one of the following allocations.

(1,1,2,2), (1,2,1,2), (1,2,2,1), (2,2,1,1), (2,1,1,2), (2,1,2,1).

One of these blocks is chosen at random for the first four subjects and allocated to group 1 or group 2 accordingly. Then proceed to the second block of four subjects, and so on until all subjects are randomized. This method is called block randomization.

An advantage of block randomization is the possibility of one group becoming full before the other is ruled out. But the difficulty is that you know that the fourth subject after the first three going to groups 1,1,2 must go to group 2. Thus, blinding is difficult. For this, several random block sizes are advocated that are concealed from the investigators.

### *Cluster Randomization*

In place of randomization of individual subjects, it is sometimes convenient to randomize groups. This is also used when randomization of individuals is not feasible. For example, you may want to assign residents of an entire village to a particular mosquito control strategy for malaria and another village to another strategy. The data are still collected at an individual level. This is called cluster randomization.

Individual randomization is advocated in a setup where the response of an individual is independent of that of another individual, whether belonging to the same village, family, or any other cluster. For example, kidney transplant patients in a hospital may be undergoing a similar preoperative and postoperative protocol, as opposed to the patients in another hospital, and the responses of patients within each hospital will be correlated with one another. In this case, individual randomization will not work, and cluster randomization can provide more reliable results. However, cluster randomization does not have the same statistical efficiency as individual randomization has. It has low statistical power due to a clustering effect. The sample size has to be larger to compensate for this loss. This may not be a big problem, because chunks of subjects are selected in each cluster so that a few clusters may give a big sample of individuals. The problem of statistical analysis of a cluster-randomized trial is more challenging as this becomes complicated because the **clustering effect** has to be eliminated.

In cluster randomization, generally, only a small number of clusters are randomized. This may still give a large number of individuals, but subjects within each cluster are likely to have similar baseline characteristics that affect the response. Few clusters implies an increased chance of imbalance in the test and the control group. Both groups should be thoroughly examined for baseline equivalence; otherwise, the researchers should keep track of the imbalances at the time of statistical analysis to ensure that this does not affect the results.

### *Stratified Randomization*

Stratified randomization seeks to ensure that the subjects with important covariates are rationally distributed amongst the groups—thereby reducing the possibility of baseline imbalance. This can also be done for anticipated imbalance in the responses. If your study is on a wonder dose that controls blood sugar level for 1 month, and if you know that the effect could be different in males of age <50 years compared to females of age ≥50 years, you may want to divide the enrolled subjects as <50M, ≥50M, <50F, and ≥50F, so that each of these strata is adequately represented, and then divide them equally into group 1 receiving the test drug and group 2 receiving the control regimen. Such stratification is useful when the effect is expected to vary across strata and helps in better interpretation. Some groups may be of special interest and need to be overrepresented. This stratification will not only help to ensure an adequate number of subjects in each stratum but also help in finding which specific group benefits most from the regimen. This conclusion will have as much reliability as afforded by the sample size in each stratum.

Since many medical responses are sex specific, sex-stratified randomization is common. Golomb et al. [1] used this to study statin effect on aggression in the United States. Buhule et al. [2] observed that stratified randomization by obesity, age group, and census region controls better for batch effects in 450K methylation analysis in the United States.

Nonetheless, stratified randomization is not practical if there are many relevant covariates even if a large sample is available. Thus, it is restricted to the most important or strongly related covariates.

### *Minimization*

Minimization uses a computer-based process to determine randomized allocation to treatment groups in real time at the time of randomization of each individual subject by considering baseline characteristics of all previously randomized subjects and the one to be randomized. This process tends to allocate the subject to the group that results in the best baseline equivalence between the groups, while usually, at the same time, also considering equality of allocations to each treatment. Pure minimization is deterministic, which can predict in advance the group to be allocated, but in the method we are discussing, a chance element is introduced. A system that generates this process can be quite complicated. For details, see Saghaei [3].

### *Adaptive Randomization*

Adaptive randomization uses a similar computer-based randomization system as does minimization, but rather than just determining random allocation to treatment in order to maximize baseline equivalence or equality of size of treatment groups, it dynamically adjusts the ratio of allocation to treatment groups in light of emerging efficacy results. This technique may, for example, be used to reduce the number of subjects exposed to an ineffective treatment (such as placebo) should the emerging results show a large difference between groups. Thall and Nguyen [4] have discussed this type of randomization for improving utility-based dose finding with bivariate ordinal outcomes.

## BMI, *see* body mass index

## body mass index, *see also* obesity (measures of)

**Obesity** has been found to be associated with risk of diseases such as hypertension, atherosclerosis, gallbladder disease, and diabetes. It is now standard practice in clinics to assess obesity and give advice accordingly. Ideally, it should be assessed by the amount of fat present in the body, but that is difficult to determine. Weight relative to height is considered a good surrogate. The following indicator is commonly used:

$$\text{body mass index: BMI} = \frac{\text{weight in kilograms}}{(\text{height in meters})^2}$$

Adolphe Quetelet

The name *body mass index* was given by Keys et al. in 1972 [2], although the original name for this index is **Quetelet index** after the Belgian scientist Adolphe Quetelet, who first suggested it in 1832 [3]. The unit of BMI is kg/m$^2$. A World Health Organization (WHO) expert committee [4] has given a nomogram that computes BMI for a given height and weight. Another nomogram is in Figure B.9. This reads the value of BMI for a given height and weight and also tells whether this is low, normal, high, or extremely high.

BMI has the same basic form as the general **ponderal index**. The exponent of the denominator of the ponderal index is 3.0 in the case of infants but progressively declines as age advances. It finally settles down to 2.0 for adults. Thus, we have height$^3$ in the denominator for infants and height$^2$ in the denominator for adults.

Statistically, persons with higher BMI tend to exhibit greater variability in BMI than those with lower BMI. Thus, care is needed in using methods (such as **ANOVA**) that require **homogeneity of variances**.

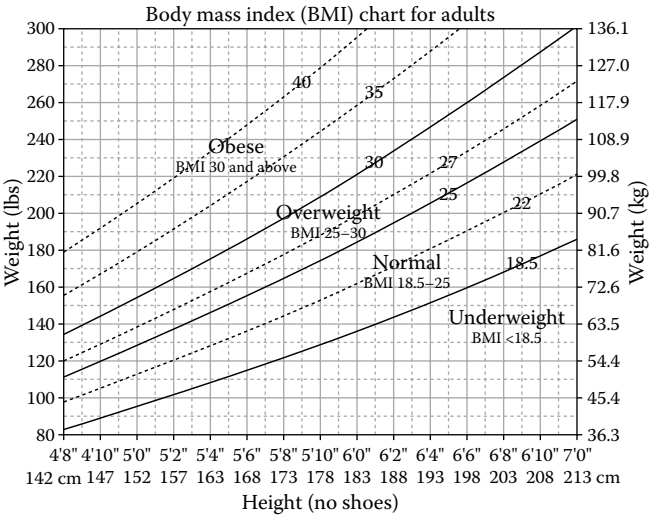

**FIGURE B.9** A nomogram for BMI from height and weight of adults. (From Vertex42. BMI Chart (Body Mass Index). http://www.vertex42.com/ExcelTemplates/bmi-chart.html.)

In the case of self-reporting, it has been observed that people tend to report less weight but greater height. This can make a substantial difference in the value of BMI. Thus, be careful in using BMI based on self-reported height and weight.

BMI is mainly determined by heredity, physical activity, and carbohydrate intake. It is considered age-sex independent in adults, and nearly the same thresholds can be used for females as for males without much error, although it tends to be slightly less in females. However, it is lower in children. For adults, generally, a person with BMI < 16kg/m$^2$ is usually categorized as severely underweight, 16–18.5 as thin, 18.5–25 as normal, 25–30 as overweight, 30–35 as obese, and 35+ as morbidly obese. These categories can vary depending on the context. Individuals with a large body frame and muscle mass, such as athletes, may be wrongly classified as obese. For Asian adults, the WHO has given lower thresholds [5].

Recent evidence suggests that BMI < 16 kg/m$^2$ in adults is more of a risk for early mortality than BMI > 25 kg/m$^2$. A disaggregated analysis by Welch et al. [6] has indicated that BMI = 26 or 27 has nearly the same risk as BMI = 25 kg/m$^2$—thus, these values are no longer considered to indicate overweight. This shows that care must be taken in interpreting BMIs.

BMI has been found to have an association with many health conditions. Besides the usual heart-related parameters, it has also been found to be negatively associated with ovarian cancer risk—for increasing quartiles of BMI, the odds ratio exhibited a decreasing trend [7]. Children with low birth weight but with rapid increase in BMI after the age of 1 year have been found to be at greater risk of coronary heart disease later in life, particularly male children [8]. Obese women can have a longer duration of labor in childbirth.

In US boys, BMI is least (median, 15.3 kg/m$^2$) at age 6 years, and in girls, at age 5 years (median, 15.2 kg/m$^2$). This rises to 23.0 kg/m$^2$ at age 20 years in boys and to 21.7 kg/m$^2$ in girls at this age [9]. Thus, BMI is not age independent in children. For internationally applicable cutoffs for well-to-do children, see Cole et al. [10]. Anderson et al. [11] have given a number of nomograms that more effectively take account of variables referred to previously, such as age-specific and gender-specific height and weight.

## Bonferroni procedure/test, *see also* multiple comparisons

Sometimes, several statistical tests are done on the same data, and a combined conclusion is drawn. If each test is undertaken at, say, a 5% **level of significance**, the total probability of **Type I error** in all tests together is markedly increased. In other words, the more such tests are done, the more likely that at least some will produce a significant result just by chance when no real effect is present. This situation specifically arises in analyses of variance where the means of several groups are compared with each other, termed **multiple comparisons**. Many methods have been proposed to ensure that the probability of **Type I error** does not exceed the predetermined level, and the Bonferroni procedure is one of them.

Bonferroni is the simplest method to ensure that the total probability $\alpha$ of a Type I error does not exceed the desired level in case of multiple comparisons. Under this procedure, a difference is considered **significant** only if the corresponding ***P*-value** is less than $\alpha/H$, where $H$ is the number of comparisons. If there are four groups and *all* pair-wise comparisons are required, then $H = 6$. Then a difference would be considered significant at the 5% level if $P < 0.05/6$, that is, if $P < 0.0083$ for that difference.

The Bonferroni procedure is conservative in the sense that the actual total probability of Type I error will be much less than $\alpha$. This means that there is an additional chance that some differences are actually significant but pronounced not significant. As explained under **tests of hypotheses (philosophy of)**, this is not a major limitation in an empirical sense for any statistical test. The advantage of the Bonferroni procedure is that $H$ can be only as much as the number of comparisons of interest. If there are four groups and the interest is only in comparing group 1 with group 2, 2 with 3, and 3 with 4 (and not, for example, in comparing group l with group 3), then $H = 3$. A small $H$ improves the efficiency of this procedure.

If there are many **predictors**, as in a **regression** setup, an alpha level of 0.05 for each individual predictor may be too high because all tests are based on the same data. Exercise caution and see if you would like to use a Bonferroni type of procedure to adjust the **significance level** in such cases.

## box-and-whiskers plot

As a part of exploratory data analysis, the box-and-whiskers plot was first suggested by John Tukey in 1977 [1]. This is also called a *box plot*. A box is made around the value of the **median** with two divisions. The lower end of the box represents the first **quartile** $Q_1$, and the upper end, the third quartile $Q_3$ (Figure B.10). The height of the box, thus, is the **interquartile range** (IQR), covering the middle 50% of the values. The larger the height of this box, the greater the spread of the values. The width of the box is arbitrary. Vertical lines are drawn from the lower end of the box ($Q_1$) to the "minimum value," and from the upper end of the box ($Q_3$) to the "maximum value." These look like whiskers. Values more than three interquartile distances away from the median are considered clear outliers and marked with an asterisk, and values more than 1.5 × IQR (called *inner fence*) but less than 3.0 × IQR (called *outer fence*) are considered mild outliers and marked by 0. The minimum and maximum values used to draw whiskers exclude these mild and clear outliers. Note that a single graph shows so many values The diagram can be drawn vertically or horizontally.

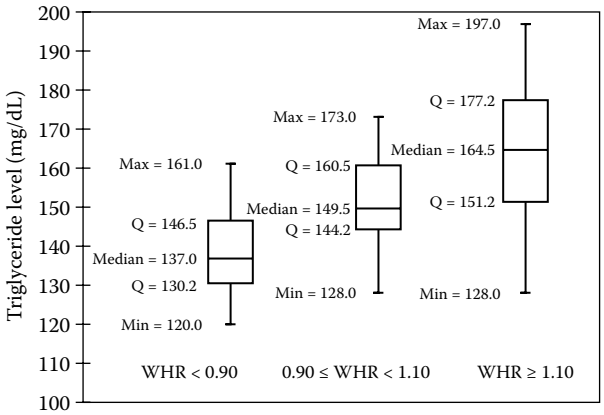

**FIGURE B.10** Box-and-whiskers plots for the data of three WHR groups.

Box-and-whiskers plots for the triglyceride levels (TGLs) in different waist–hip ratio (WHR) categories for hypothetical data are shown in Figure B.10. The values of median, $Q_1$, and $Q_3$ as well as the minimum and maximum values are also shown. In this case, there are no outliers. The figure on the whole displays the location of the median and the dispersion of the data as well as the skewness. The plot for three WHR groups in Figure B.10 shows that the dispersion of TGL is fairly spread out (big box) and is symmetric when WHR ≥ 1.1 but relatively compact (short box) and very skewed (the distance between the median and $Q_1$ is very different from the distance between the median and $Q_3$) when 0.9 ≤ WHR < 1.1. Rising box-and-whiskers plots in this figure also show that TGL rises as WHR increases.

## Box–Cox power exponential (BCPE) method, *see also* LMS method

Lambda-mu-sigma (**LMS**) of Cole and Green [1] and the Box–Cox power exponential (BCPE) of Rigby and Stasinopoulos [2] are popular methods to obtain smoothened centile curves. These are commonly used to obtain percentile curves for various growth parameters in children, such as by the World Health Organization (WHO) Multicentre Growth Reference Study Group [3], and growth reference curves for school-aged children and adolescents [4]. The application extends to any setup where centiles are estimated for different time points. For example, these methods have been used to obtain reference values of differences between TW3-C radius, ulna and short bone (RUS) and TW3-C carpal bone ages of children in China [5]; to obtain centile charts for placental weight for singleton deliveries in Aberdeen, United Kingdom [6]; and for normal values of aortic dimensions, distensibility, and pulse wave velocity in children and young adults in Germany [7].

A main feature of these plots is that percentiles appear to follow a smooth curve over age. Two major statistical issues are involved when plotting these curves. The first is to correctly find different percentiles at each age, and the second is to achieve smoothness of the percentile curves over age. Note that the first problem is to obtain various percentiles at age 1 year, at 2 years, at 3 years, etc. The second problem is to ensure that each of these percentiles forms a smooth curve when plotted versus age. These involve the following problems.

Experience suggests that the **distribution** of many medical measurements is not **Gaussian** (normal) but, rather, tends to be **skewed** and with disturbed **kurtosis**. The LMS method is primarily for correcting skewness, and it does not handle kurtosis, whereas the BCPE method handles both skewness and kurtosis. To understand the BCPE method, it is necessary to first understand the LMS method.

Let $y$ denote the measurement under consideration, such as weight and arm circumference. Consider a distribution of $y$ that has either positive or negative kurtosis. In this case LMS-adjusted $z_{LMS}$ will not give you the correct $z$-score. Additional adjustment is needed for kurtosis. This adjustment is not in terms of changing the transformation but in terms of considering that the distribution of $z_{LMS}$ is not **standard normal** but, rather, another complex distribution called the BCPE distribution. This is where BCPE comes in. Besides LMS ($\lambda$, $\mu$, $\sigma$; see **LMS method**), this distribution has another parameter, denoted by $\tau$. However, the skewness parameter $\lambda$ under the LMS method is now denoted by $\nu$ since $\lambda$ would be the notation for **Box–Cox power transformation** of the $x$ variable.

The notation $x$ is for a variable such as age in the case of weight, while $y$ is the notation for weight in this case. Weight centiles are required for each value of $x$. BCPE distribution reduces to LMS when $\tau = 2$. Thus, the LMS method is a special case of the BCPE method. You might as well use the BCPE method straightaway. This will give $\tau \approx 2$ if the kurtosis is already 0. The values of $\mu$, $\sigma$, $\nu$, and $\tau$ are estimated with the help of special software in a manner wherein the transformed $z$ has a standard Gaussian distribution. The BCPE method is also called the **LMSP method**, where P stands for *power*. The $p$th percentile for BCPE distribution is obtained by using an inverse function, but it does not have an explicit expression of the type that exists for the LMS method. Software help will be required. The software generally used for this purpose is the *Generalized Additive Model for Location, Scale, and Shape* (GAMLSS) developed by Stasinopolous and Rigby [8]. This software is available at http://www.gamlss.org. Indrayan [9] has provided full details of this method in a nonmathematical language.

## Box–Cox power transformations, *see also* power transformations

This is a family of transformations, at their simplest of the form $z = y^{\lambda}$, which are used to reduce asymmetry in data. Many commonly used transformations such as logarithm and square root are specific cases of the Box–Cox power transformation.

B

A square-root transformation ($z = y^{0.5}$) tends to correct mild positive skewness because this transformation shrinks values (when values are >1), but importantly, higher values shrink more than lower values. This is because $\sqrt{(4)} = 2$ (reduces to one-half) and $\sqrt{(25)} = 5$ (reduces to one-fifth). Thus, the right tail shrinks faster toward the mean than does the left tail. On the other hand, if the distribution is negatively skewed with a longer left tail, the transformation $y^{2.0}$ will do just the reverse. It will stretch the right tail much more than the left tail—thereby tending to correct left skewness. Both these transformations are of the type $y^{\lambda}$. The value of power $\lambda$ depends on the type of skewness and the extent of skewness. This is called **power transformation** and is a potent tool to correct skewness. This is the initial form of the Box–Cox power transformation [1] and can be extended.

Extension of this approach involves normalization of the values prior to the transformation. To achieve this, divide each $y$ by its **central value** $\mu$ and calculate $y/\mu$, and the power transformation is applied to these values. This central value could be the mean or median or any other value. You may be aware that the mean is not a good representative central value in the case of a skewed distribution—thus, other options remain for exploration. For example, if the weight of 4-year-old girls has mode = 13.6 kg, we may divide each weight by this value. Then values less than 13.6 would become less than 1.0, and values more than 13.6 would become more than 1.0. When square-root transformation is applied to these transformed values, for example, $\sqrt{(0.2)} = 0.447$ (increases by a factor of more than 2) and $\sqrt{(0.9)} = 0.949$ (increases very slightly). The effect is that the left tail of the distribution stretches where the transformed values are less than 1.0. On the positive side of the mode, for example, $\sqrt{(1.4)} = 1.18$ (reduces by 0.22) and $\sqrt{(2.4)} = 1.55$ (reduces by 0.85)—that is, the values on the positive side shrink, but larger values shrink more, thus correcting right skewness. Similarly, square transformation (or any power more than 1.0) tends to correct left skewness. The advantage of using $y/\mu$ is that it transforms the values to less than 1 on one side and more than 1 on the other side of $\mu$, and then transformation makes more sense. Note that square-root transformation is $(y/\mu)^{0.5}$ and square transformation is $(y/\mu)^2$. In general, the power transformation is $(y/\mu)^{\lambda}$, and the value of $\lambda$ depends on the type of skewness and extent of skewness as before. $\lambda < 1$ is for correcting right skewness and $\lambda > 1$ for left skewness. $\lambda = 1$ is no correction. If the distribution is already Gaussian, no correction is required, and then $\lambda = 1$.

Considering this, an extended form of power transformation is the following:

$$z_{\text{LMS}} = \frac{1}{\sigma_L \lambda}\left[\left(\frac{y}{\mu}\right)^{\lambda} - 1\right] \text{ for } y, \mu, \sigma_L, \text{ and } \lambda > 0,$$

where $\sigma_L$ is as explained shortly. This is the advanced form of the Box–Cox power transformation. The original measurements, such as weight in our example, may have any skewed distribution with a single mode; the distribution of $z_{\text{LMS}}$ with this transformation will be standard normal; and this will give the correct ***z*-score** for calculating the **percentiles** provided that the kurtosis is already 0. Note the involvement of lambda ($\lambda$), mu ($\mu$), and sigma ($\sigma_L$), making it an **LMS method**. Instead of lambda, mu, and sigma, it is customary to use L, M, and S.

The rationale of $(y/\mu)^{\lambda}$ is already explained, and $\sigma_L$ is in the denominator just as in $z = (y - \mu)/\sigma$. But in LMS, $\sigma_l$ is the **coefficient of variation** $\sigma/\mu$. Note that when $\sigma_L = \sigma/\mu$ and $\lambda = 1$, $z_{\text{LMS}}$ in the aforementioned equation reduces the usual $z$-score, namely, $(y - \text{mean})/\text{SD}$. This reinforces that $\lambda = 1$ means no correction for skewness.

For $\lambda = 0$, $z_{\text{LMS}}$ in this equation becomes 0/0 and is replaced by its mathematical equivalent, $[(1/\sigma_L)^*\ln(y/\mu)]$. In this case, this becomes **log transformation**. For such a transformation, negative values of $\lambda$ are ruled out, and negative values of $y$ or $\mu$ are also excluded since these can make $y/\mu$ negative, whose root (such as square root) does not exist. All medical parameters of the type we are discussing have positive values. For example, weight can never be negative. When the values are negative, for example, for a change from pretreatment to posttreatment or a difference between, say, right and left measurements, this transformation would work only after adding slightly more than the minimum difference so that all values are more than 0. If minimum difference is –3, add 3.1 to all the differences and then use this transformation.

Indrayan [2] has provided an easy nonmathematical explanation of this method.

## Box *M* test

In the case of **repeated measures ANOVA** and **multivariate ANOVA (MANOVA)**, among other things, you need to confirm homogeneity of covariance matrices (also called the **dispersion matrix**) across groups when there are two or more groups, particularly when the sample sizes are different in different groups. To check homogeneity, the Box *M* test [1] is used. The basic requirement for a Box *M* test is **multivariate Gaussian** (normal) **distribution** of the values under consideration. The sample size in each group should be large (say >20), and the number of groups should not be too many (≤5). It appears that this test is rarely used in medical literature.

George Box

The Box *M* test is naturally based on the sample dispersion matrices and the pooled dispersion matrix under the null hypothesis. A statistical software package will do this easily and convert this to an *F*-test for the final result. When significant (say, $P < 0.05$), this might indicate that the dispersion matrices are unequal but also could be due to the fact that distributions are not Gaussian. One way to get around this problem in the case of large samples is to equalize the sample sizes in different groups by, say, randomly dropping some observations with a larger sample. The requirement of homogeneity of dispersions is not that great for equal sample sizes. But the better method for checking the homogeneity of dispersion matrices is the multivariate analog of the **Levene test**. This test works better, as this is based on the median. If the dispersions are not homogeneous, use a **Pillai trace** in place of the **Wilk lambda** for testing equality of means in a multivariate setup.

## Box–Pierce and Ljung–Box *Q* test

The Box–Pierce and Ljung–Box tests are two versions of the same test, which is used to check that a series of values have any autocorrelation. If you are not conversant on the concept of **autocorrelation**, see this topic in this volume. As an example, in a monthly series of values with seasonal fluctuations (such as cases of dengue fever each month), the values in the month of September in different years are likely to be correlated. Hence, in a monthly series, this has autocorrelation of lag 12.

For the Box–Pierce and Ljung–Box tests, you have to decide the lag of autocorrelation you suspect and would like to check. This will be based on your knowledge about the series, such as lag 12 for seasonal variations.

If you decide lag $K = 5$, all autocorrelations of lag $K \le 5$ will be checked by this test. Denote these autocorrelations by $r_k$ ($k = 1, 2, 3, 4, 5$). In general, $k = 1, 2, \ldots, K$. Now,

$$\text{Box–Pierce test: } Q = n\sum_k r_k^2 ,$$

where the sum is over $k = 1, 2, \ldots, K$, and $n$ is the total number of values in the series. This criterion is treated as a **chi-square** test with $K$ degrees of freedom (df's). If not significant at the specified level of significance, all autocorrelations of lag $K \le 5$ can be considered not significant. This is taken to provide evidence that the series is random. This test was first proposed in 1978 [1].

The Box–Pierce test is a simplified version of

$$\text{Ljung–Box test: } Q = n(n+2)\sum_k \frac{r_k^2}{n-K} .$$

This also is checked with chi-square with $K$ df's [2].

## Breslow–Day test

Sometimes, data are collected or broken into different **strata**. For example, you may have a history of hypertension (yes/no) for people with and without glaucoma, and this is divided by age (<40 years, 40–59, 60–79, and 80+) and sex (M/F). This will make a total of eight strata. Suppose you have the **odds ratio** (OR) of hypertension for each strata, but you are also interested in **pooled odds ratio** for all strata combined. This pooling is done after proper adjustment of strata sizes. However, the pooling is not valid if one or more ORs is very different from the others. They must be homogenous. For example, this homogeneity is required for the **Mantel–Haenszal test**. The Breslow–Day test is used to test the **homogeneity** of ORs across strata. Since OR is a measure of association, this test can also be used to check whether association between factors A and B is homogenous at different levels of factor C. The criterion used for this test has an approximate chi-square distribution with $(K - 1)$ degrees of freedom (df's), where $K$ is the number of strata. This is when each stratum has a $2 \times 2$ table. If the order of the contingency tables is higher, **log-linear models** can be explored.

Most statistical software will provide the result of the Breslow–Day test. This is based on a complex calculation requiring pooled OR by the Mantel–Haenszel method. For the Breslow–Day test to be valid, the sample size should be relatively large in each stratum, and at least 80% of the expected cell counts should be greater than 5. Note that this is a stricter sample size requirement than the requirement for the Mantel–Haenszel test itself, where this requirement applies to the overall sample size and not for each stratum. Tarone [1] derived an adjustment factor that is subtracted from the Breslow–Day statistic, resulting in an asymptotically chi-squared statistic and relaxing the stricter sample size requirement. This correction is also available in most statistical software. For further details of the Breslow–Day test, see Breslow and Day [2].

Woo et al. [3] used the Breslow–Day test to determine whether hypercholesterolemia and apolipoprotein E polymorphisms affect the risk of intracerebral hemorrhage by statin use. Ko et al. [4] used this test to study ALPK1 genetic regulation and risk in relation to gout.

## Breslow test

A commonly used test for comparing survival pattern in two groups, say under different treatment regimens, is the **log-rank test**. This test gives the same importance to different time points even when one time point has more subjects than the others. Sometimes, time points with a higher number of subjects may need to be given more weight since those may have better **reliability**. In that case, another method, such as the Breslow test [1], can be used for comparing survival curves. This is also known as the *Gehan–Breslow test* and **generalized Wilcoxon test**. For details, see Hosmer et al. [2].

Norman Breslow

B

Since the Breslow test gives more weight to the time points with a higher number of subjects, initial time points where the number of subjects at risk is higher tend to determine the statistical significance. As time passes, subjects die or drop out, and the numbers become smaller. In practice, the difference between survival at initial stages in the two groups under comparison probably would be negligible, and it is only at later stages that differences would become pronounced. In this situation, the Breslow test may lead to incorrect conclusions. As a middle path between the log-rank and Breslow tests, some prefer the **Tarone–Ware test** [3], which gives weight proportional to $\sqrt{n_t}$, where $n_t$ is the number at risk at time point $t$.

## Broca index

The Broca index is probably the simplest measure of excess or insufficient weight in otherwise healthy adults. According to this index, normal weight in kilograms is height in centimeters minus 100.

Broca index for normal weight (kg) = height (cm) − 100.

If a person's height is 172 cm, his/her normal weight should be 72 kg. This can be considered a formula for calculating *ideal weight* in adults. You can see that this is fairly simplistic but works reasonably well for both men and women for general assessment. A suggested modification for women is to subtract 105 from height in cm instead of 100. However, the Broca index may be too simple and not appropriate for specialized applications such as medication dosing.

Paul Broca
(Archives Serge NICOLAS, Paris Descartes University, with permission.)

The formula was first proposed by a French surgeon, Paul Broca, and appears in *Memoires d'anthropologie*, Paris, 1871.

## Brown–Forsythe test

The Brown–Forsythe test is an alternative to the usual ANOVA $F$-test when the requirement of homogeneity of variances is not satisfied.

The most commonly used test for comparing means of three or more groups is the ANOVA ***F*-test**. The requirements for the validity of this test are, among others, that the underlying distribution of the variable under consideration is **Gaussian** (normal) and that the variances in different groups are **homogeneous**. Having equal sample sizes in different groups is an additional help. However, the $F$-test is **robust** in the sense that it works reasonably well for minor violation of these requirements. The requirement of Gaussianity can be further relaxed when the sample size is large because of the **central limit theorem**.

Except when the data are highly skewed or when most group sizes are less than 10, the **Welch test** performs well for testing equality of means in situations of unequal variances and unequal $n$'s. Group sizes between 6 and 10 are your call. When group sizes are really small such as $n < 6$ for most groups, and you have unequal $n$'s and unequal variances, the Brown–Forsythe test [1] is used. This test uses the median in its calculation instead of the mean—thus, it is less sensitive to departures from assumptions. The mathematical procedure for both is complex. The names are given so that you can make an appropriate choice while running a statistical package.

There is another test with the same name but used for testing homogeneity of variances [2] in situations where the **Levene test** is not valid.

## bubble charts

A bubble chart is an extension of a **scatter diagram** where a third dimension is added that signifies size in some sense. A scatter diagram is a plot of points $y$ versus $x$, where both are quantitative but can be either positive or negative or zero. In a bubble chart, these points become bubbles of the size in the third dimension—thus, size cannot be negative. A bubble chart is more effective when the size can be interpreted as an outcome of $x$ and $y$. However, the bubbles do not give a good indication of the actual value represented by each bubble.

Consider the percentage of deaths due to cancer at different ages in the years 1970–2010 in a particular country. In Figure B.11, age at death is on the $y$-axis and year on the $x$-axis. The percentage of death is represented by the size of the bubble. The figure shows that

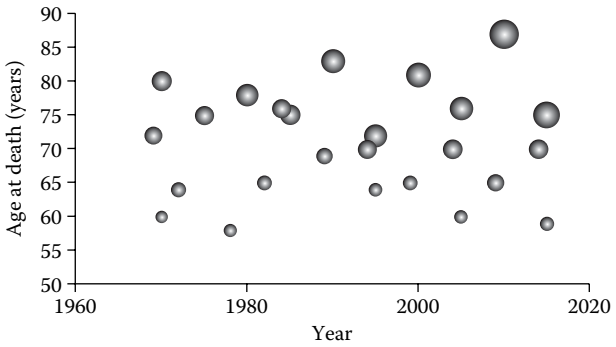

**FIGURE B.11** Percentage of deaths due to cancer in a country at different ages from 55 to 90 years in the years 1970–2015.

the percentage of deaths due to cancer has increased in this country not just as age is increasing but also as time has progressed. The increase in percentage of deaths due to cancer is more pronounced in recent years than in previous years.

More dimensions can be added, although that will make the chart more complex and difficult to understand. For example, you can have hollow bubbles for males and solid ones for females so that the trend in both the sexes can be studied. Further dimensions can be represented by different colors of bubbles. Each of the bubbles can even be a pie diagram to show percentages due to various causes. For an actual example of the use of a bubble chart, see the work of Chien et al. [1], who advocate bubble charts to enhance adherence to quality-of-care guidelines for colorectal cancer patients.

## burden of disease, *see also* disability-adjusted life years (DALYs)

Although initially coined for a specific measure of ill health in a population, *burden of disease* is now a generic term for how severely a specific population is affected by one or a group of diseases. An easy and possibly most commonly used measure of burden of a particular disease is the **age-specific** and overall **mortality** from that disease. For example, according to the recent **global burden of disease** study [1], noncommunicable diseases (NCDs) account for more than two-thirds of all deaths across the world, and they have increased over the 40 years from 1970 to 2010. This can be interpreted as the burden of NCDs in the world. One can also say that nearly 80% of the total burden of all diseases is borne by low- and middle-income countries [2]. Next, burden can be assessed in terms of morbidity caused by the disease. This can be assessed in terms of **incidence** and **prevalence**. Duration and severity of sickness can also be included in this assessment. The higher the morbidity, the greater is the burden. Although the scenario is changing, developing countries have greater burden from communicable diseases than from NCDs. The situation in the developed world is the reverse.

Perhaps the most appropriate use of the term is when the impacts of both mortality and morbidity are combined. This was initiated by the World Bank in the early 1990s for almost all countries of the world and is called global burden of disease (GBD) [3]. This was put forward in a report jointly produced by Harvard University and the World Health Organization (WHO) [4]. The metric used to measure the burden of disease in this report is **disability-adjusted life years** (DALYs) lost due to a particular disease or a group of diseases. This metric combines different indicators of morbidity as well as mortality, takes into account the age of the affected person, and discounts future years lost to the present in case of death. The latter two adjustments proved controversial and have now been removed in the latest report, this time by the Institute of Health Metrics and Evaluation, called GBD 2010. This also changed from an incidence perspective to prevalence perspective, i.e., the morbidity is assessed on the basis of its existence instead of its new appearance. **Disability weights** have been revised, generally downward, and more disease conditions have been added.

The GBD 2010 is the most comprehensive study of its kind, producing comparative metrics for 291 different causes of premature death and disability across 187 countries, 20 age groups, and both sexes for three time periods: 1990, 2005, and 2010. The study also estimated 67 potentially preventable causes of ill health, or risk factors, such as smoking, high blood pressure, and household air pollution [1]. In addition, the WHO has released their estimates for the year 2012. According to these estimates, age-standardized DALYs lost in Afghanistan was 68,970 per 100,000 population in 2012 compared with, for example, 17,696 DALYs lost in Australia [5]. Note the big difference.

The burden of diseases in almost all countries of the world is steadily but surely declining, with the contribution of NCDs increasing and that of other diseases declining. The increase of NCDs is mostly due to ageing of populations across the world and partly contributed to by a more adverse lifestyle. Communicable diseases are declining due to control measures such as immunizations and improvement in environmental conditions. The contribution of accidents and traumas seems to be fairly stable over time and across countries.

### *Salient Features of the Burden-of-Disease Methodology*

The burden-of-disease methodology is intricate and cannot be fully described here. For a complete methodology for computing burden of disease by the WHO, see Ref. [6]. For details of the metric used to assess burden of disease, see the topic **disability-adjusted life years (DALYs)**. Other salient features that can help in the understanding the essentials are as follows.

The burden-of-disease methodology divides all causes of mortality and morbidity into three broad groups: group 1 (communicable, maternal, perinatal, and nutritional conditions); group 2 (NCDs); and group 3 (injuries). Each of these is divided into groups and subgroups. For example, skin diseases are subdivided into psoriasis, acne, eczema, scabies, urticaria, etc. These are all mutually exclusive and exhaustive categories so that there is no duplication and nothing is left out. Age-sex-specific morbidity (including severity) and mortality data on all these conditions are obtained from national health statistics, surveys, research studies, etc., and they are systematically compiled and collated to provide national estimates. Many times, models are developed that can provide reasonable estimates on the basis of **surrogates**. Separate efforts are made to estimate the disability weights for each severity condition of each disease. For countries with little or no data, data from neighboring countries with similar conditions are extrapolated. Special attention is paid to the **epidemiological consistency** of various estimates and their **validity**. These estimates are used to calculate the DALYs lost as estimates of the burden of disease in each country for each condition of ill health in different age-sex groups. Despite huge efforts involved, there is always uncertainty, and **uncertainty intervals** are also computed. This is clearly an enormous exercise, but the good news is that the burden of disease is estimated with tremendous success by a large team of professionals. Subnational efforts are made by the respective countries.

B

## butterfly effect

An enormous effect on the outcome resulting from very minor changes in input values is called the butterfly effect. This can happen due to a ripple effect of chain reactions as in the chaos theory. For example, Dorn [1] has mentioned the following: "Regulated microRNA expression levels, as during a tissue stress response, induce small changes in initial conditions that are sequentially amplified through secondary and higher-order interactions, producing a systemic ripple effect that ultimately invokes disproportionately large (and frequently unanticipated) phenotypes."

The term *butterfly effect* is believed to have been first used by Lorenz in the context of weather forecasting when he observed tremendous changes in the forecast when the input was 0.506 instead of the more accurate figure of 0.506127 [2]. Lorenz's own paper [3] was presented in a conference with no reference to these values, but he is credited to have coined this term. In biostatistics, this can happen in modeling when a slight variation in the value of one input variable substantially changes the expected outcome. This can happen when the variable has high power or is an exponent. For example, $x^8 = 1{,}280{,}631$ for $x = 5.80$ and 1,298,402 for $x = 5.81$—a difference of 0.01 in the value of $x$, which is not even 0.2% of $x$, has made a difference of 17,771, which is nearly 1.4%, 7 times of 0.2%. Similarly, $2^x = 65{,}536$ for $x = 16$ but $2^x = 131{,}072$ for $x = 17$, i.e., if $x$ is increased by 1, $2^x$ becomes double. Figure B.12 illustrates this for cancer. A small difference in the initial value has changed the entire course of the disease. During carcinogenesis, a minor change in one host cell out of millions can have a cascading effect with serious consequences in the course of time [2].

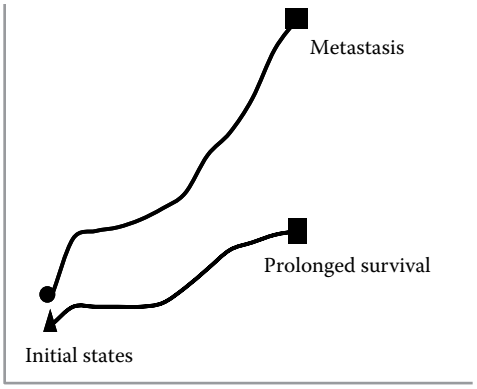

**FIGURE B.12** Butterfly effect in cancer.

A similar issue can arise when a model involves a small proportional difference between two large numbers. If, for example, a calculation involves $d = (x - y)$, if $x$ is 10,010 and $y$ is 10,000, then $d$ will be 10. However, if $y$ decreased by just 1%, to 9900, then $d$ would increase to 110, a massive increase of 1100%. Because of a possible butterfly effect, statistical models involving functions such as powers and exponents, or small proportional differences between large numbers, need special care. In particular, the input value should be fairly accurate to give correct answers.

# C

## calibration

Calibration is the process of adjusting the setting of a tool according to a defined standard so that the readings provided by this tool have increased validity, i.e., they can be believed to be correct. This process is intimately related to quality control; it increases the confidence in the performance of the tool. A new tool must always be calibrated anyway, but an old tool also is calibrated when it is suspected to have "rusted" due to repeated use, misuse, or long nonuse. This clearly applies to laboratory and clinical instruments such as a biochemical analyzer and a sphygmomanometer. A questionnaire, say for assessing quality of life, also needs calibration when translated to another language so that it provides the same response as the original standard would in the identical setting.

For statistical measurements, calibration is the process of adjusting $x$ against a standard $y$. Simply stated, the first stage involves measuring both $x$ and $y$ for a sample of $n$ subjects and using these to develop a relationship between $x$ and $y$. In the second stage, this relationship is exploited to predict $y$ for other subjects by using the observed $x$. Thus, the standard values along with the observed values must be available from the first stage. Statisticians prefer that this relation be a **regression** equation, but not of $y$ on $x$ as usually done but of $x$ on $y$. This is because $y$ is standard and known in this setup. The most elementary regression of $x$ on $y$ is $x = a + by$, where $a$ and $b$ are estimated as in **simple linear regression**. Once this equation is obtained to your satisfaction in the sense that the **residuals** are negligible and randomly distributed around zero, then

$$\text{the calibrated value of } x = \frac{\text{observed value of } x - a}{b}.$$

This is an inverse of the regression equation and is frequently called an *inverse regression*. In a complex form, the regression equation may involve terms such as square, reciprocal, and logarithm. The inverse relationship in that case would not be linear but a curve, called the *calibration curve*.

Mossavar-Rahmani et al. [1] describe calibration of a food frequency questionnaire reporting energy intake using water and urinary nitrogen as biomarkers of objective measures of total energy expenditure. The latter was the standard they used. The statistical method they used is much more complex than just described, but the example illustrates a situation where calibration can be useful. Food frequency questionnaire is known to provide flawed estimates of energy intake, and the reporting can be calibrated to give a more correct estimate of the energy intake.

The method can be extended to calibration between two tools, both of which can be in error [2]. Neither is standard, but both can be standardized to give the same value for the same subjects. The objective in this setup is to increase the likelihood that both tools give the same or nearly the same readings.

## canonical correlation

Canonical correlation is the correlation between one set of variables and another set of variables. Thus, this is a **multivariate** method. For example, you may have wondered if liver and kidney functions have any correlation, and if yes, how much. In this case, one set is liver function tests, say, levels of albumin, bilirubin, prothrombin time, aspartate transaminase, and alkaline phosphatase, and the second set comprises kidney function tests such as serum creatinine, creatinine clearance, blood urea nitrogen, and glomerular filtration rate. In this example, liver function is a five-measurement entity and kidney function is a four-measurement entity. How do you find the correlation between sets of measurements? The answer is canonical correlation.

The ordinary (Pearsonian) **correlation coefficient** assesses the degree of (linear) correlation between two measurements, and the **multiple correlation** coefficient assesses the degree of correlation between one measurement and a set of two or more measurements. Multiple correlation, in fact, is between one variable and the linear combination of the set of other variables. As an extension, the canonical correlation is between the linear combination of one set of variables and the linear combination of the other set of variables. Consider a set of $J$ variables $(x_1, x_2, \ldots, x_J)$ and a second set of $K$ variables $(y_1, y_2, \ldots, y_K)$. Then the canonical correlation is the correlation between $t_1 = a_1x_1 + a_2x_2 + \ldots + a_Jx_J$ and $t_2 = b_1y_1 + b_2y_2 + \ldots + b_Ky_K$. This was first proposed by Harold Hotelling in 1936 [1].

As in multiple correlations, these linear combinations are chosen in a manner that the correlation between these combinations is maximum. In our example, this means the correlation between a linear combination of the five liver function values and a linear combination of four kidney function values is the canonical correlation where linear combinations are those that maximize the correlation. If this correlation is more than, say, 0.7, you can say that liver and kidney functions are closely related, and if this is less than, say, 0.3, you can say that these functions have weak relation. Remember though, as in all Pearsonian correlations, that these are for linear relationships. Quadratic or other kinds of nonlinear relations are not properly assessed by this correlation. It suffers from the same deficiencies as listed for **correlation**.

C

An example of the use of a canonical correlation is between scores of the 11 subscales of the pattern element scale (PES) and 6 cognition scores in dementia patients in China [2]. The authors reported this to be 0.507 and statistically significant ($P < 0.001$). They concluded that PES, which is a relatively brief tool, is helpful in discriminating pattern elements in dementia. This conclusion is a bit too farfetched but illustrates how canonical correlation can be used.

The linear combinations $t_1$ and $t_2$ that provide maximum correlation are called *canonical variates*. These variates can be used as univariate entities and analyzed as usual for inference. However, they may lack substantive biologic meaning. Though extension is seldom done, canonical correlation does not stop with a single relationship between the sets of variables. You can find other pairs of canonical variates that are independent of the previous pairs, but they will provide lower correlation. For further details, see Ref. [3].

## capture–recapture method

Capture–recapture is a simple method to estimate the total size of a population by a particular kind of **resampling**. The methodology was originally devised for obtaining counts of animals in a closed area. Consider a sample of 48 deer ($n_1 = 48$) that are captured, marked, and then released back to their area for mixing up with other animals. They mix with other deer. Subsequently, a second sample of 35 deer ($n_2 = 35$) is captured from the same area. If 16 ($m = 16$) of them are found to have the mark, an estimate of the total number of deer is obtained by inflating by a factor of 35/16. Thus, an estimate of the total count $N$ is $48 \times 35/16 = 105$. A statistically better (**unbiased**) estimate in the long run is obtained when 1 is added to each of these numbers and finally 1 is subtracted. Thus,

$$\text{capture} - \text{recapture estimate } N = \frac{(n_1+1)(n_2+1)}{m+1} - 1.$$

where $n_1$ is the size of the first sample and $n_2$ of the second sample, and $m$ is the number of cases found to appear in both the samples. Note that it requires only basic arithmetic. For our example, this gives $N = (49 \times 36/17) - 1 = 102$, which may be more realistic than the value 105 arrived earlier.

The capture–recapture methodology was first applied for estimating the size of the human population in the 1940s [1]. But there is evidence that Laplace first used essentially the same method to estimate the population of France. This publication appeared in 1783. He used the count of newborn babies and population/births ratio of certain areas to come up with an estimate of the population [2].

The capture–recapture method allows us to estimate the size of the population not just where direct census is impossible or impractical but also at a much cheaper cost of census even if possible. This helps to estimate the total number of cases when their incomplete count is available from two or more *independent* sources. In health and medicine, these sources could be hospital records, physicians in private practice, death certificates, or any other such list of cases. The count of duplicate cases, which appear in more than one list, can help to substantially improve the estimate of the total cases. Hook and Regal [3] argued that the capture–recapture methodology can improve prevalence estimates even for apparently exhaustive surveys. It can also be used to estimate the size of hidden population such as the number of drug users in a district.

The methodology was adopted by McCarty et al. [4] to assess the prevalence of childhood diabetes in Madrid, Spain. A population-based registry identified 432 cases through hospital inpatient records. Another source was the Spanish Diabetes Association, which recorded 138 cases. It was found on matching that 119 cases were common to the two sources. Thus, an estimate of the total number of cases of childhood diabetes is

$$\frac{(432+1)(138+1)}{119+1} - 1 = 501.$$

The results can be converted to prevalence rates as shown in Table C.1.

The cases in either source are undercounts, but the duplicates helped to come up with an estimate of the total cases as well as an improved prevalence rate. This also helps to de-emphasize the need for all registers to be complete.

Note the following for capture–recapture methodology:

- The methodology assumes that there are no intermediary additions or deletions. If there are any, the estimate may have to be revised accordingly.
- It is necessary that the captured subjects "move around freely" and are homogeneously mixed when "released." The two sources should be independent of one another. This is not fulfilled in a situation where, for example, some cases seen by the first source tend to be referred to the second. In such cases, the capture–recapture estimate may be too low. In the case of cancer deaths, if the two sources are death certificates and hospital discharge records, more severe cases are more likely to appear in both the lists—they are not independent.
- Like all estimates, the estimate of the total count by the capture–recapture methodology is subject to sampling fluctuation. Methods are available to find the standard error of this estimate and to construct a 95% confidence interval. If interested, see the work of Laporte et al. [5]. For further reading, see Krebs [6].

**TABLE C.1**
**Capture–Recapture Estimate of Childhood Diabetes in Madrid**

| | Hospital Records | Diabetes Association | Common | Capture–Recapture Estimate |
|---|---|---|---|---|
| Number of cases | 432 | 138 | 119 | 501 |
| Prevalence rate per 100,000 population (total population 4.4 million) | 9.8 | 3.1 | – | 11.4 |
| Extent of undercount (as percent of the last column) | 14% | 72% | – | 0% |

## cartogram

A cartogram is a map that depicts the size of various areas in proportion to the magnitude of the problem in hand. A cartogram of 35 ECG leads is used in precordial mapping for diagnosis of combined myocardial ventricular hypertrophy. The concern in this volume is mostly with statistical mapping and not medical mapping as for ECG. Sometimes it is convenient to show the area of a city or a country in proportion to the population or the number of cases occurring in that city or country. The actual boundaries are approximated, although efforts are made to retain the shape. An example of such a cartogram is Figure C.1, which shows the number of persons living with AIDS in 2007 in each state of the United States [1]. Note how Florida is oversized and Washington state is drastically undersized.

Lovett et al. [2] have discussed cartogram as a health service quality improvement tool in London, and Kotviski and Barbola Ide [3] have prepared one for incidence of scorpion stings in the city of Ponta Grossa in Paraná State of Brazil.

## case–control studies, *see* retrospective studies

## case-fatality rate

The case-fatality rate (CFR) is the rate at which affected persons die. In terms of percentage, this can be stated as

$$\text{case-fatality rate (CFR)} = \frac{\text{deaths among those affected}}{\text{number of individuals affected}} * 100.$$

The CFR represents the severity of a disease in terms of the associated mortality. Thus, this measures the most important aspect of

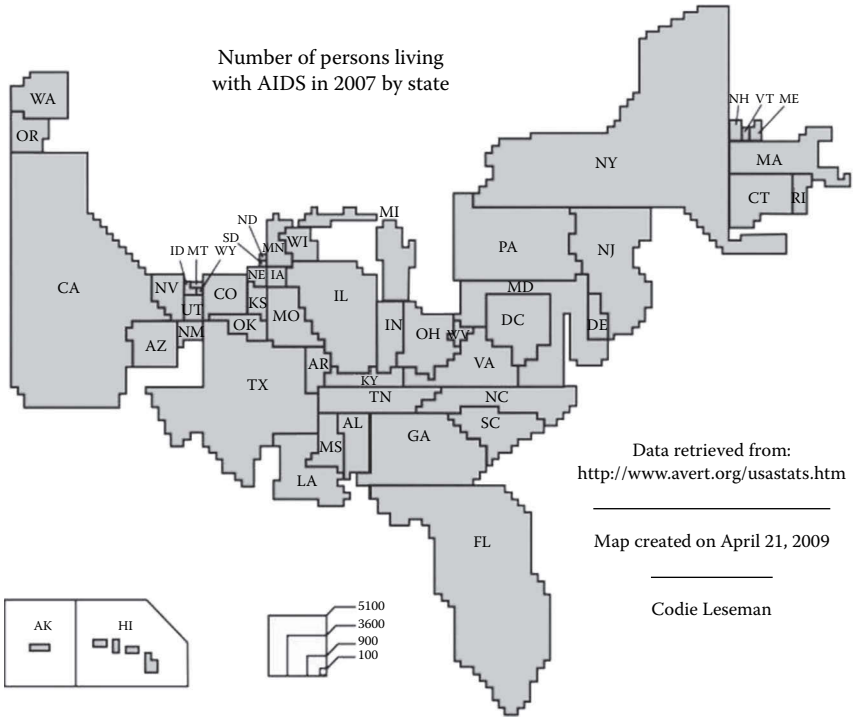

**FIGURE C.1** Cartogram: number of persons living with AIDS in 2007 by state in the United States. (From CodieMaps. *Using a Cartogram to Map AIDS in the USA, 2011*. https://codiemaps.wordpress.com/tag/cartogram/, last accessed April 15, 2015. With permission.)

C

prognosis that is important for both the patient and the doctor. The CFR is high for diseases such as rabies and tetanus, and low for diseases such as typhoid and influenza. Case fatality can be considered to measure the virulence of a disease and can help in planning control measures. The CFR is intimately related to duration, for example, 1-year case fatality of leukemia is very different from a 5-year case fatality. For this reason, the CFR is customarily used for diseases of short duration such as peritonitis.

Since everybody dies anyway, case fatality must have a qualifier for duration within which death would be counted. But this is hardly ever done. Case fatality rate is mostly used in hospital setups where some events are bound to be fatal during hospital stay despite best care. But some fatalities may be avoided. Case fatality per 1000 patients admitted can be an indicator of the quality of care in a hospital, particularly when calculated separately for each disease or condition. It may reflect the ability to manage critical patients with different diseases. There is a rider though. Because some hospitals are specialized to treat serious and terminal cases, interhospital comparison on the basis of gross fatality may not be valid. The same is true for different units of a hospital. However, trend within a hospital can certainly be monitored over time using this indicator. Mortality within 48 h in many cases is determined by the condition of the patient at the time of admission instead of the quality of medical care. When mortality within 48 h is excluded, this rate is called the *net fatality rate* or *net death rate*. This is relatively more valid for comparison between units or between hospitals.

The CFR in a hospital should be interpreted with caution because **Simpson paradox** may operate. This is illustrated by the data in Table C.2. In this example, case fatality in patients in two hospitals is the same on aggregate (19.8% and 20.0%), but glaring differences emerge when it is broken down by age and severity of illness of the patients. If one looks at the top row for the total alone in this table, it would seem that the two hospitals have nearly the same case-fatality rates. The breakdown by age in the next two rows shows that both the hospitals have nearly the same case-fatality rates in each age group also. But further breakdown by severity of illness in the subsequent rows shows that hospital A has less fatality in every group. Why then are the rates in the aggregate the same? The reason is that hospital A is catering much more to serious cases and to older cases. These have higher fatality although less than in hospital B for such patients. The breakdown clearly establishes better performance of hospital A. This was otherwise concealed by the aggregate rate in the top three rows of the table. Li et al. [1] give a similar example of CFR in the context of H5N1 avian influenza.

**TABLE C.2**
**Case-Fatality Rate (CFR) in Two Hospitals by Age of Patients and Severity of Disease**

| Severity and Age | Hospital A | | | Hospital B | | |
|---|---|---|---|---|---|---|
| | ***n*** | **Deaths** | **CFR (%)** | ***n*** | **Deaths** | **CFR (%)** |
| *Total* | *800* | *158* | *19.8* | *600* | *120* | *20.0* |
| –60 years | 280 | 38 | 13.6 | 340 | 48 | 14.1 |
| 60+ years | 520 | 120 | 23.1 | 260 | 72 | 27.7 |
| *Mild* | *200* | *28* | *14.0* | *350* | *62* | *17.7* |
| –60 years | 60 | 5 | 8.3 | 190 | 21 | 11.1 |
| 60+ years | 140 | 23 | 16.4 | 160 | 41 | 25.6 |
| *Moderate* | *300* | *51* | *17.0* | *200* | *41* | *20.5* |
| –60 years | 120 | 13 | 10.8 | 120 | 19 | 15.8 |
| 60+ years | 180 | 38 | 21.1 | 80 | 22 | 27.5 |
| *Serious* | *300* | *79* | *26.3* | *50* | *17* | *34.0* |
| –60 years | 100 | 20 | 21.0 | 30 | 8 | 26.7 |
| 60+ years | 200 | 59 | 29.5 | 20 | 9 | 45.0 |

The reverse of what is seen in this example can also happen. There might be a large difference in aggregate mortality rates in two hospitals falsely showing that the quality of care in one hospital is better than in the other. This might vanish when adjustment for severity of cases is made. Silber and Rosenbaum [2] have discussed this aspect in detail.

An improvement of 1.5/1000 in case fatality in the case of stage IV cancer has a different implication than a similar improvement in cases of peritonitis. Such gains may look statistically the same but have different social implications. You should be careful in interpreting such improvements. Put value to the outcome and interpret accordingly.

Biostatistically, case fatality, along with remission, is an important consideration in **epidemiologic consistency** of **prevalence** and **incidence** of a condition. CFR, expressed per case, is a proportion and can be treated as a **binomial** variable for the purpose of finding the confidence interval and for test of hypothesis. For most diseases, this rate is small, and the same precautions are required as for any small $p$ in a binomial setup. For example, this may be unreliable for small samples. For a sufficiently large sample, **Gaussian** approximation can be used for statistical inferences.

## case reports

The detailed documentation of an unusual case is called a case report. The details may include the demographic particulars of the patient, etiology of the condition, presenting signs and symptoms, treatment history, disease-related experiences of the patient, timeline, any complications, photographs, laboratory and radiological investigation reports, diagnosis, current treatment, outcome, and prognostic implications. The emphasis is generally on what is unusual about this case or what makes it so unique, and then what lessons can be drawn. Related references of the literature are provided in a case report. An informed written consent is taken from the patient or his/her relative, yet the reporting is done in a manner in which the identity of the patient remains undisclosed.

New information given in a case report can provide learning with regard to exceptions to the rules—thus making the medical fraternity aware of the unusual events that can possibly happen. Statistically, the role of case reports is only to provide instances of outliers. Such outliers can disturb the main theme of the findings. These can help to prepare exclusion criteria for subjects in a research study. Such criteria are specified at the time of writing a research **protocol**. If an unanticipated unusual case appears during the course of the study, this can be excluded from analysis and described separately as a case report.

## cases (selection of)

Although the term *case* is generic, a person with disease or a condition of interest is customarily called a case. The question of the selection of cases is relevant mostly for case–control studies because,

for these studies, random selection is not all that important, and the selection of cases can substantially affect the results. Case–control studies are discussed under the topic **retrospective studies**.

The source of cases with disease or any other outcome of interest can be hospital inpatients, patients seen as outpatients, cases identified in a survey, cases listed in records of a health facility, etc. Hospital-based studies may be biased for, say, subjects from upper socioeconomic class, whose nutritional status may be different, or for any other factor influencing hospital intake. Population-based studies can become very expensive. Each, however, has relevance in specific situations.

A case could be either newly diagnosed (incident) or an already existing (prevalent) subject with disease. Inclusion of prevalent cases, particularly for chronic disease, can easily increase the sample size, but care is required at the time of interpretation of results because the factors determining the duration of disease can be important. Note that duration decides that a case is prevalent or not at a particular point in time. Mild cases or those physically strong may survive longer and add to the prevalence. At the same time, cases surviving for long are more likely to have recall lapse. Newly diagnosed cases do not have any such problem and are thus preferable for research.

Selection bias is said to have occurred when the study group has a different composition with regard to etiologic factors such as heredity, age, gender, nutrition status, and addictions, compared with the composition in the target population. Studies on volunteers or on clinic subjects almost invariably suffer from such a bias. A method of selection that has a random component is considered insulation against such bias. But such selection fails to take cognizance of special bias that can result from sources such as improper definition of the population. In a study on causes of psychiatric illness in old age, if the subjects are those who are single and of age 70 years or above at the time of enrollment, the bias occurs because some with severe illness may have already expired before attaining the age of 70 years. Also, in the case of analytical studies such as in the case–control setup, random selection does not help much since the emphasis is on comparing apples with apples to come to a fair conclusion on association or causation [1]. It is important to properly sort relevant factors from irrelevant factors. Nonrandom selection of cases (and controls) can restrict the applicability of results to a wider population but can enable valid conclusion on antecedent–outcome relationship. Sometimes this is more important than generalization. External validity may have to be sacrificed to achieve internal validity. In experiments and clinical trials, the focus is on causal inference, and that is achieved more by baseline equivalence of cases and controls rather than by random selection from the population. Random allocation takes care of statistical need of probabilistic base for inference.

An important consideration in the selection of subjects for any study is the feasibility of obtaining data on them. This means that the subjects must be approachable and cooperative. For a case–control study, accurate and complete information must be available on the subjects so that they can be correctly classified into exposed and nonexposed groups, and the effect of other characteristics on the outcome can be properly assessed.

## case series/studies

A case series is obviously a series of cases of specific type and is an extension of **case reports**. The cases share some common feature(s) to be part of a series. For example, they may be suffering from the same disease, or they may be undergoing the same regimen of treatment. In medical research, a case series signifies a **descriptive study**, although here no specific design for selection of cases is formulated. Neither a provision of control nor any protocol for allocation of treatment regimens is made. No cause–effect, not even associations, can be concluded by a case series, but they are capable of generating a hypothesis for planning an **analytical study**.

There is a question regarding the minimum number of cases required for it to be called a series. An analysis of case series articles appearing in the PubMed database published in 2009 found that the median number of cases reported per series was 7 and the range was 1–6432 [1]. The authors suggest that a case series should contain no less than four cases. If they are so few, the cases are individually described, but if they are many, the results can be summarized in terms of tables and figures with means, proportions, and rates. Inclusion and exclusion criteria should be specified in any case.

Popular among the case series is the first official documentation in 1981 of five young gay men with pneumocystis *Pneumonia carinii* in Los Angeles that were later identified to have HIV [2].

### *Case Studies*

A case study is the detailed study of an event and its origin, process, and consequences, with the purpose of deriving learning for wider application. Case studies have been found to be effective tools for teaching and learning various aspects of subjects such as their management with informatics technology. The primary advantage with this methodology is its flexibility, as case studies do not have to follow a fixed mold and can be done in a format suitable to study the event. For example, a case study can include results from several studies on that kind of event.

Medical case studies are sometimes confused with case reports. Indeed, the terminology has mixed use in the literature. A case report is for a single patient, whereas a case study is for a particular event. A case study of sudden rise in deaths from motor vehicle accidents within the precincts of a particular city would draw information from many sources and would try to reach to a reliable conclusion regarding the factors responsible for such a rise. This would not be so in a case report.

Biostatistics case studies can be on topics such as survival analysis and diagnostic evaluation of medical tools. A case study on survival analysis may discuss survival analysis methods used by various workers in different setups. The focus can be on the logical basis of the inferential methods used in different studies including validation or violation of the requirements of those methods. Alternative scenarios with modification in the data and alternative methods can be discussed, and the effect on conclusions can be indicated. As already stated, no specific format of case studies can be suggested to fit all.

## casewise, pairwise, and listwise deletion

The question of deletion of cases arises in a research setup when part of the values is missing or wrongly recorded for some subjects in a dataset. Missing values cannot be used in any analysis unless we impute them. Thus, they are excluded. We illustrate various types

of deletion with the help of data in Table C.3. Out of, say, 200 cases of liver disease, only those with missing data are shown. Two cases with nothing missing are also shown for illustration. All others with complete data are not shown.

While calculating something like mean and standard deviation (SD), you can exclude case numbers 79 and 164 for total bilirubin level, case numbers 14, 127, 164, and 183 for AST level, and case numbers 127, 164, and 191 for ALT level. These are the cases for which that particular information is missing. This is called **listwise deletion**. The description in the literature varies. Realize though that under this deletion, different means and SDs would be based on different cases—thus, they would not be strictly comparable.

For calculating the correlation between the AST level and the ALT level, you will have to exclude case numbers 14, 127, 164, 183, and 191 for which any of the two or both are missing. This is called **pairwise deletion**. For correlation between total bilirubin level and AST level, excluded cases will be numbers 14, 79, 127, 164, and 183. Again the two correlations are not based on the same subjects—thus, some comparability is lost. For running polytomous **logistic regression** with disease as dependent and total bilirubin and ALT levels as regressors, not only case numbers 127 and 164 will be excluded since they do not have vital information on their disease but also case numbers 79, 127, 164, and 191 because at least one of the data on regressors is missing. This also is an extension of pairwise deletion. Under this deletion, if regressors are AST and ALT levels, case numbers 14, 127, 164, 183, and 191 will be excluded, but case number 79 will be included. Thus, the two logistic regressions will have different cases. If all three are regressors, all cases listed in Table C.3 except numbers 92 and 132 will be excluded.

In order to base all the calculations on the same subjects, cases with any one piece or more information missing are excluded. This will exclude six out of the eight cases listed in Table C.3 for calculation of mean/SD, correlations, as well as logistic regression. This is called **casewise deletion** since the entire case is deleted as though that case is not in the sample. Statistically, this is the most desirable kind of deletion but has the potential to exclude a large number of cases since one or the other piece of information may be missing for many cases. This reduces the sample size and affects the statistical **power** to detect the kind of result you are hoping for. Also, the cases with incomplete information may be of specific type, and their exclusion can disturb the representativeness of the subjects, rendering the findings biased.

Missing data always present difficulties whatever you do. No deletion is better than the other unless the missing values are randomly distributed and the sample size is large enough to remain robust despite casewise deletions. The other option is **imputation**, although that also has its own problems. Thus, everything possible should be done to get correct and complete data on as many subjects as possible. Deletions and imputations are the last resort.

**TABLE C.3**
**Missing Data**

| Case No. | Total Bilirubin Level (mg/dL) | AST Level (U/L) | ALT Level (U/L) | Disease |
|---|---|---|---|---|
| 14 | 0.7 | Missing | 30 | Hepatitis |
| 79 | Missing | 32 | 51 | Cirrhosis |
| 92 | 2.1 | 25 | 58 | Malignancy |
| 127 | 1.7 | Missing | Missing | Missing |
| 132 | 1.9 | 43 | 47 | Malignancy |
| 164 | Missing | Missing | Missing | Missing |
| 183 | 2.2 | Missing | 35 | Hepatitis |
| 191 | 2.9 | 61 | Missing | Hepatitis |

## categorical data (analysis of)—overall

Conventionally, data on qualitative variables are called categorical, but data on those quantitative variables that have few categories are also considered categorical. Thus, data on age of adults divided into 20–29 years, 30–39 years, etc., are categorical. This is discussed in detail under the topic **variables**. Theoretically, age divided into 1-year intervals is also categorical but is considered as good as continuous, and categories are ignored for analysis. From the statistics viewpoint, it is not much important whether the data are categorical or not. What is more important is that the focus of conclusions is on proportions, percentages, or frequency of subjects falling into different categories, or on mean and SD of the values. The analysis of categorical data implies that the conclusions will be based on what proportion of cases fall into different categories. In health and medicine, this kind of inference is extensively drawn. Even the quantitative values such as hemoglobin levels are many times categorized into anemia being present or absent because of the convenience in understanding such categories.

If there is just one variable with two categories such as yes/no or present/absent (binary or dichotomous variable), this is analyzed by using binomial distribution that includes its Gaussian approximation for a large sample. This is presented under the topic **binomial distribution/probability**. If this variable has more than two categories (**polytomous**), the interest would be usually to know whether or not they fall into a specified pattern. This almost invariably happens with **nominal** categories and is discussed under the topic **goodness-of-fit**. For large samples, this uses **chi-square** as the criterion for testing the hypothesis on specific pattern of frequencies. Small samples require considering **multinomial distribution**.

The basic statistical method of analysis of categorical data is indeed chi-square for testing of hypotheses regarding not only goodness-of-fit but also many other types of problems. This is used to test the hypothesis regarding the association between two categorical variables when the data are cross-classified into an $R \times C$ **contingency table**. These methods are presented under **chi-square for larger two-way tables** in this volume. A similar method is applicable to three-way tables. **Log-linear models** can be used to understand the pattern of frequencies in different cells in two- or three-way tables. All these methods require large samples.

A special case of an $R \times C$ table is the **two-by-two table**. For small samples, a $2 \times 2$ table is analyzed by the Fisher exact test. Such tables are extensively used to calculate odds ratio and relative risk. These are also used in crossover trials and equivalence tests with binary response, and in assessing sensitivity and specificity and predictivities of medical tests. A $2 \times 2$ table also arises in case of matched pairs for which the **McNemar test** is used for large samples and the **exact test** for small samples. All these methods are discussed separately under the respective topics. For assessing the degree of association, various methods are discussed in this volume for **association between dichotomous categories** and for **association between polytomous characteristics**. For dichotomy in repeated measures, see the **Cochran *Q* test**.

The methods indicated so far are valid when the categories have no order or, if they have order, it can be ignored. For ordinal categories, there is a separate **chi-square for trend in proportions**. The degree of **association between polytomous characteristics** can also be assessed. **Nonparametric methods** based on ranks are also commonly used for analyzing data with ordinal categories.

When the dependent in a regression setup is categorical, logistic regression is the method of choice. This is among the most popular methods of data analysis in biostatistics. Full length books are available on this topic, but the essentials are presented under the topic **logistic regression**. Logistic regression can be used for ordinal categories also.

We have discussed a large number of methods of analysis of categorical data in this book, but the discussion is still not comprehensive. For more details, consult Stokes et al. [1].

## categorical variables, *see* variables

## categories of data values

Categories naturally arise for many medical measurements, while for some others, they are created. Natural categories occur for **nominal** variables such as blood group, occupation, site of injury, site of cancer, type of disease, and complaints. They are called nominal categories. They do not have any natural order—none is more or higher than the other. This can be dichotomous with two categories (sex: male and female) or can be polytomous as in the examples just cited.

Categories for **ordinal variables** are also mostly perceived as natural. Examples are severity of disease categories such as none, mild, moderate, serious, and critical; opinion from most unfavorable to most favorable; obesity as thin, normal, overweight, obese, and morbidly obese; and test result as negative, equivocal, probably positive, and definitely positive. These are called ordinal categories and arise mostly because we do not have a suitable measurement of the underlying continuum. The main reason for nonavailability of a metric scale is that many of these characteristics are multifactorial. For example, disease severity depends on signs and symptoms, and measurements such as blood pressure and plasma glucose levels, radiological assessment, part affected, etc. To pool them together on a metric scale is a challenge. Sometimes ordinal categories are used for convenience and easy communicability. Obesity is an example that can be exactly measured by body mass index, but some workers may like to consider other features also such as waist measurement and skinfold thickness for categorizing obesity. If so, the categories just mentioned may be more convenient. It is easy to categorize burns as severe on visual inspection alone, whereas a large number of assessments may be needed to say that the extent of burns is 83%.

Sometimes a device to measure a characteristic is easily available but is not adopted because such a level of accuracy is not needed. Smoking can be measured as the number of cigarettes smoked, but categories such as none, light, moderate, and heavy seem to serve the purpose sufficiently well in many clinical situations. Age can be measured in terms of years, but categorization into child, adult, and old may be adequate in some situations. Note that ordinal categories also have names and thus can be called *ordinal nominal* in that sense. However, this is different from ordinal metric categories as discussed later in this section.

The basic advantage of using ordinal categories rather than metric measurements is convenience in eliciting, recording, and reporting. The use of any sophisticated device is avoided. Ordinal categories are often easier to comprehend than metric categories. In the process, however, valuable accurate information is lost, and the analysis of data is rendered less efficient. Metric measurements are amenable to a host of mathematical manipulations that are not possible with ordinal measurements. Thus, hard measurements such as blood pressure level are preferred instead of grade of hypertension, and prostate volume instead of grade of enlargement. If the efforts required for hard measurements are enormous such as in measuring the size of the brain, or when no metric scale is available, use ordinal categories. However, beware of anomalies in some ordinal categories. What is mild for one person may be moderate for you. Very rarely these terms are strictly defined.

Quite often, numerals are associated with ordinal categories such as 0 for none, 1 for mild, 2 for moderate, and 3 for serious. These numbers are then subjected to all sorts of algebraic calculations. Such calculations are valid only when the moderate degree is considered two times the mild degree and the serious degree is considered three times the mild. These numerals also assume that the difference between mild and no disease is the same as that between serious and moderate disease. In practice, this may not be so. Thus, caution is required in assigning numerals to ordinal categories and in drawing conclusions when based on calculations involving such numbers. Note that these are not codes or scores.

### *Categories for Metric Measurements*

Exact measurements on the metric scale are indeed statistically preferable to ordinal categories. The irony is that sometimes circumstances force grouping of metric data into categories even after exact data are obtained. The weight of a woman may be recorded to the nearest kilogram but may have to be categorized into 5 kg intervals such as (40–44), (45–49), etc. Data reported in this manner are called **grouped data**; the process is commonly referred to as categorizing continuous variables, and the groups are called **class intervals**. The reasons for doing this may be one or more of the following:

- Consider a dataset containing systolic BP levels of 1200 persons. The only effective way to present these in a report is by using groups in mmHg such as (100–109), (110–119), (120–129), etc., and stating the number of subjects in each such group. This saves space and at the same time makes the data more intelligible. Storage of grouped data may take only about half a page or 1 kB of space, whereas storage of 1200 individual values may take four pages or 8 kB of space. Such grouping also makes the data more sensible, while 1200 ungrouped values may be difficult to comprehend.

  Groups such as (0–4) and (5–9) for age assume that age is noted in terms of *completed* years or age last birthday. The interval (5–9) actually means 5 to less than 10 years and can also be written as (5–10) years. It is customary in such statistical grouping that the upper end of the interval is considered to belong to the next interval. Mathematically, these are written as [0–5), [5–10), etc., but this kind of exact notation is seldom used in practice. Wherever the intervals are continuous in this book, the convention of (0–4), (5–9), etc., is followed.
- It is well known that the end digit is predominantly 0 or 5 in many data values. This happens either because of approximation done by subjects themselves at the time of inquiry, such as stating one's age as 45 years instead of the more exact 44, or because of the observer's bias such as in recording a systolic 130 mmHg instead of the exact 132. Intervals (105–114), (115–124), (125–134), etc., or (108–112), (113–117), (118–122), etc., would dilute the effect of such digit preference. In another setting, suppose waist and hip sizes are measured without sufficient care

and could be in error of up to 5 mm. Grouping of waist–hip ratio in intervals (0.7–0.8), (0.8–0.9), (0.9–1.0), etc., would minimize the effect of such errors, and the purpose of assessing central obesity could still be adequately achieved despite errors, provided they are minor.

The preceding two reasons are valid for grouping at the stage of reporting or analysis, but sometimes even the recording is done in a grouped form. This is done for the following reasons:

- Eliciting a woman's age and anybody's income is sometimes considered a lack of courtesy. Some people prefer to keep such information confidential. Stating them in a grouped form may be more acceptable. The exact value remains confidential, yet data available are in a usable form.
- Many clinicians are accustomed to think in terms of anemia being present or absent and its degree as mild, moderate, or severe in place of exact hemoglobin or hematocrit values. Thus, they sometimes prefer grouped values. Two or more measurements can also be simultaneously considered in this kind of grouping. Categorization of growth of a child into excessive, normal, retarded, and dismal depends not only on height and weight but also on the age of reaching different milestones of development. Such multifactorial grouping is sometimes more relevant for the practice of medicine.
- In an experiment on lethal dose of a drug in mice, it is much easier to observe each morning and record the number of dead mice than to keep a continuous watch and note the exact time of death. In this case, the survival time would be available in 24 h categories. Serum glucose level is measured in units of 5 mg/dL because the analyzer in some cases is so calibrated. Thus, 5 mg/dL categories are inadvertently formed. Greater accuracy may be redundant in this case. If better accuracy is needed, cost and efforts may substantially increase.

Whenever data are available in an exact form, statistical analysis should be done using the exact data. Grouping in this case renders analysis less efficient in the sense that some important features of the data may fail to emerge. Calculations for metric categories are generally done using the midpoint of the categories. This unrealistically considers that all subjects with values in a category have the same value as the midpoint. Statistical inference becomes less efficient as the methods assume that the values in grouped data are flat within each interval. This is against the factual position since discontinuity is imposed by categorization across interval boundaries. The interval 160–169 of systolic BP forgets that 168 mmHg is more than 162 mmHg, and the difference is more than between 168 and 170, which now belongs to separate categories. Cutpoints of intervals are mostly arbitrary, and different cutpoints can give different results. In some cases, though, this loss can be compensated by increasing the sample size. A larger sample size helps to capture a better spectrum of values even when data are grouped. In fact, in cases in which grouped data can be rapidly obtained at a substantial saving, more reliable results can be obtained by investigating a larger sample within the same cost. In such a situation, grouped data on metric measurements can be rightly advocated. However, it is important that the number of groups and the width of intervals are carefully chosen so that the essential features of data are not compromised and the relevance is not lost. As a side note, metric categories also have order and thus are ordinal—ordinal metric to be more specific.

At the extreme is dichotomizing a continuous variable. An example is dividing medical measurements as normal and not normal. Whereas this could be a clinical necessity to decide whether or not to start the treatment, analysis of dichotomized continuous data entails severe loss of data information. For example, in a regression analysis, to develop a prognostic model for patients with primary biliary cirrhosis, bilirubin as a continuous explanatory variable explained 31% more of the variability in the data than when bilirubin was dichotomized at the median [1].

### *Statistical Features of Categories*

Statistical methods of analysis depend on statistical features of the categories. Most basic categorization is in two categories: yes/no, male/female, disease/no disease, survived/died, treated/not treated, etc. These are called **dichotomous categories**. The opposite of this are **polytomous categories** in which a variable has more than two categories. Blood group, site of lesion, complaints, and occupation are examples of variables with polytomous categories. Ordinal categories also are always polytomous since the concept of grading mostly exists only for three or more nominal categories (see the next paragraph). For analysis of categorical data of different types, see **categorical data (analysis of)**.

Metric categories can be dichotomous or polytomous. Diastolic blood pressure (BP) <90 mmHg and ≥90 mmHg are dichotomous. In this setup, we can have order (one is higher than the other)—pointing to the limitation of our statement that ordinal categories exist only for three or more categories. For diastolic BP, polytomous metric categories in mmHg can be 60–69, 70–79, etc.

Except for complaints, all categories mentioned in this section are **mutually exclusive and exhaustive**. Data on such categories are generally expressed in the form of **contingency tables**. On the contrary, complaints of a patient coming to a clinic are neither mutually exclusive nor exhaustive. If the complaints categories are pain, vomiting, constipation, and feeling of tiredness, a patient can have two or more complaints at the same time. This is called multiple response. Neither of these are exhaustive since a patient can have a complaint other than the four listed. Statistical analysis of such data requires special care as mentioned for **multiple responses**.

## causal chain/pathway

Causal chain and causal pathway are synonyms for the series of events that lead sequentially one to another, finally giving rise to the outcome of our interest. The causal chain starting from DNA to RNA to proteins leading finally to biological functions is well known. In the context of a disease, a causal chain is the etiological pathway—how the disease started, what course it took and why, and why this is in the present condition. A **causal diagram**, as described for myocardial infarction under the next topic, is a visual description of the chain of events.

Pecoraro et al. [1] have found that minor trauma, cutaneous ulceration, and wound-healing failure could be the causal sequence for 72% of the cases in their series of diabetic patients with limb amputation. Thus, practical interventions that cause limb loss in such cases can be devised. As illustrated by Li and Lu [2], biostatistical study of the causal chain of how diseases respond to drugs can lead to new

uses of the existing drugs. An understanding of the ways in which xenobiotic substances perturb biological systems and lead to adverse outcomes can help to devise tools to avoid such outcomes [3].

Experiments are generally more effective in establishing a causal chain than **observational studies**, but these may be very expensive and time consuming. Biostatistical **models** can help to study causal chains in a quantitative manner and provide them much needed exactitude.

## causal diagrams

Causal diagrams depict the causal pathway between an antecedent and an outcome using nodes and arrows that are drawn with due consideration of the intermediaries and confounders. Thus, they represent a web of causation. Such diagrams are commonly used in epidemiologic research. Causal diagrams are explained by Greenland et al. [1] and recently discussed for matched designs by Mansournia et al. [2]. These diagrams are also called **etiology diagrams**.

One such diagram is in Figure C.2. This tries to describe the causation of myocardial infarction (MI). The process leading to MI is intricate, and the exact web of causation is still not fully known. This is just our hypothesis and is untested. The arrows show the direction of the effect from the cause. Nodes are the factors. If this figure is to be believed, ageing, personality profile, lifestyle, and genetic predisposition are independent of one another, and they together or alone give rise to the factors that ultimately cause MI. They are the *ancestors* in this web of causation; stress and anxiety is the *child* of the personality profile, while smoking is the child of emotional disturbance, stress and anxiety, and lifestyle. You can see that this causal diagram ignores other factors such as peer pressure and home environment as the cause of smoking. These possibly are represented by lifestyle in this diagram. This diagram proposes that hypertension is the child of genetic predisposition, changes in the arterial walls, and emotional disturbances, and has ageing and personality profile as ancestors. Smoking is in the causal pathway of MI but is not a direct contributor—its contribution is through hyperlipidemia and atherosclerosis. If this diagram is to be believed, lifestyle does not cause hypertension but is mediated through lack of physical exercise and obesity. Many would not agree with this proposition. Despite such complexity in the diagram, this still is possibly not a complete representation of the web of causation of MI. Perhaps any causal diagram is a simple version of the complex process—and thus fits into the definition of a **model**. In this diagram, there is no two-headed (bidirectional) arrow, but this can be used in a causal diagram when X affects Y and Y affects X. In Figure C.2, hypertension can sometimes lead to change in arterial walls in place of age-dependent changes to the walls of arteries leading to hypertension.

The difficulty with causal diagrams is that they trace causal path without specifying the quantitative effect. For example, Figure C.2 does not say how much is the effect of stress and anxiety on smoking and how much is of lifestyle. Also, the shape of the relationship is not depicted. Yet a properly drawn diagram is useful in visualizing the web of causation and to identify where to attack to prevent the disease, or to reduce the risk, or even what etiological factors to assess while examining a case with the disease.

## causal inference, *see* cause–effect relationship

## cause–effect relationship

Cause–effect relationship is said to exist between an antecedent and an outcome when a change in the value of the antecedent necessarily causes a change in the outcome. By far, the most compelling

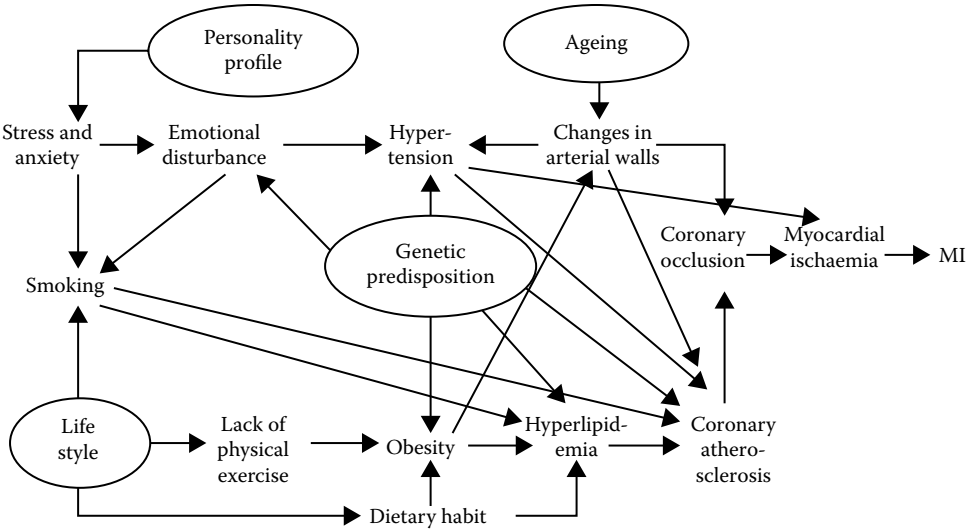

**FIGURE C.2** Hypothetical causal diagram for myocardial infarction (MI).

C

evidence of cause–effect is provided by **experiments** where an intervention is intentionally introduced to see how the outcome changes. "All" other factors are controlled by design or eliminated by analysis. This includes **clinical trials**. However, some unknown factors can provide a distorted picture. The effect could be random, at least in part, while we see it as causality. Under certain strict conditions, **observational studies** too can provide evidence of cause–effect. We examine both in the following paragraphs.

### *Causal Inference in Clinical Trials*

It is generally believed that properly conducted experiments—whether in the laboratory or in the clinic—provide compelling evidence for or against any cause–effect relationship between the antecedent and the outcome. The antecedent could be the regimen under trial, and the outcome may be any that indicates efficacy. However, there are limitations: compelling evidence—yes; indisputable evidence—no.

An antecedent is not considered a cause unless it has a plausible biological explanation for the effect. However, a trial can be conducted without full knowledge of the biological relationship, and this relationship can be explored later after the trial is over. In that case, however, the relationship is interpreted as a mere association and not cause–effect until such time that biological plausibility is established.

A perfectly valid trial in terms of randomization, control, and blindness may still provide results that are difficult to apply elsewhere. First, the selected subjects may not be representative of the target population; second, the conditions under which a trial is done may be too restrictive; and third, different trials may give different results. These differences propel synthesis techniques such as meta-analysis that allow a more reliable conclusion regarding causality [1].

**Randomized controlled trials** are one of the many ways, perhaps the most dependable, to establish the properties of a regimen. But there might also be alternate methods of arriving at credible answers. They all should match. In addition, all such trials are plagued with epistemic uncertainties—unrecognized factors may affect the outcome. A positive aspect of varying results of different trials on the same regimen is that they raise awareness about the uncertain domain and bring humility to our endeavors.

### *Correlation versus Cause–Effect Relationship in Observational Studies*

Some professionals feel that a randomized controlled trial is the only mode to provide scientific evidence of a cause–effect relationship. A moment's reflection will convince you that this is not so. Most accept that cigarette smoking *causes* lung cancer, but no trial has ever been conducted. The controlled experiments do provide direct evidence, but evidence from observational studies can be equally compelling when **confounders** are really under control and the results replicate in a variety of settings.

Keep in mind though that an association or a correlation does not indicate cause–effect. In health measurements, association can arise because of a large number of intervening factors. It is rarely a cause–effect type of relationship unless established by a carefully designed study that rules out the possibility of a significant role of any confounding factor. McLaughlin et al. [2] report from epidemiological studies that women in the United States with cosmetic breast implants have two- to threefold risk of suicides compared to the general population. This is statistically significant. However, this by itself does not support a cause–effect relationship. They speculate that psychopathological condition of women may be a confounding factor since this condition can contribute to the need for a breast implant as well as suicide. They also remark that any study aiming to investigate this relationship for cause–effect should also rule out year of birth, family history of psychiatric admission, etc., as factors. More important threats to cause–effect inference are not the known confounders but the unknown ones.

A strong correlation between heights of siblings in a family exists not because one is the cause of the other but because both are affected by parental height. Similarly, correlation between visual acuity and vital capacity in subjects of age 50 years and above is not of the cause–effect type but arises because both are products of the same degeneration process. No one expects vision to improve if vital capacity is improved by some therapy. The maternal mortality rate declined in Mexico between 1960 and 2010, and the proportional mortality from coronary diseases increased. These too have a strong negative correlation, but they do not exhibit a cause and effect type of relationship. Counterfactuals provide useful armory to refute causality.

An unusual confounding factor may provide useful information in some cases. Persons with depressed mood may have an elevated risk of lung cancer because of a third intervening factor—smoking [3]. Depressiveness seems to modify the effect of smoking on lung cancer either by a biologic mechanism or by affecting smoking behavior. This example illustrates how a seemingly nonsense correlation can sometimes lead to a plausible hypothesis. Another example is the parental age gap influencing the sex ratio of the firstborn children [4]. At the same time, our existing knowledge tells us that no drug can change the blood group. There is no need of empirical evidence to confirm this.

### *Criteria for a Correlation to Indicate Cause–Effect*

For an association or a correlation to indicate a cause and effect, the following points should be carefully examined:

- Association should be present not only in the prevalence but also in the incidence. This should continue to be statistically significant when the effect of other confounding factors is eliminated by means of a method such as multiple regression. If feasible, confirm this by an experiment. This is possible only for potentially beneficial regimens and not for potentially harmful regimens.
- Association or correlation must be consistent across various groups, periods, and geographical areas. Wherever or whenever the postulated cause is present, the effect must also be present. If an association is found between lipoprotein(a) and incidence of coronary artery disease (CAD) in Canada, Singapore, England, and South Africa, which has persisted since this protein was first discovered, then this is likely to be a cause of CAD, although this could be one of the many causes.
- There must be a dose–response kind of relationship in the sense that if the cause is present in higher amounts or in greater intensity, then the chance of effect should also be high. The more one smokes, the higher the risk of lung cancer becomes.
- The relationship should also be specific, i.e., if the postulated cause is absent, then the effect should also be absent. However, make a distinction between a necessary cause and a sufficient cause. A necessary cause is an exposure that is *required* for a particular outcome to occur—without this, the outcome would not occur, but the outcome may

not occur even when the necessary cause is present. A sufficient cause is an exposure that will produce the outcome. The outcome may occur due to other causes without the sufficient cause. For example, infection is necessary for typhoid to occur but not sufficient.

- The relationship must be biologically plausible, which means an explanation linking the two in a causal way is available. For example, cigarette smoke has cotinine that easily affects lung cells and causes aberrant cell behavior. Thus, a biological explanation is available.
- It is generally stated for a cause–effect relationship that the degree of association or the correlation should be high. This may be so when the factor under investigation is a dominant cause. The correlation between parental levels and children's level of cholesterol is not high, but this does not exclude genetic influence as a cause of raised cholesterol level in children whose parents have high level. When a correlation, albeit low, is consistently present, a causal relationship can still be inferred, but that would be one of the many causes. It should, however, be statistically significant so that **sampling fluctuation** is adequately ruled out as a likely explanation. In addition, also note that the correlation coefficient can be small just because a small range of values has been observed.

The causal role of elevated serum cholesterol in atherosclerotic CAD, for example, fulfills all these criteria. A consistent association has been found in prevalence as well as in incidence in a large number of studies carried out in populations with different backgrounds. A gradient in risk of the disease has been seen with rising cholesterol level. In controlled clinical trials, cholesterol-lowering drugs and diet therapy have been shown to result in a reduction of coronary events. Angiographic regression of coronary lesions has also been demonstrated. Biological plausibility has been established from animal and human studies that have demonstrated cholesterol deposition in atheromatous plaques.

### *Other Considerations in Cause–Effect Relationships*

Distinction may be made between a necessary cause and a sufficient cause as mentioned earlier in this section. Sexual intercourse is necessary for initiating pregnancy in natural course, but it is not sufficient. In fact, the correlation between the number of intercourses and the number of pregnancies, even without barriers, is negligible.

In this era of diseases with multifactorial etiology, one particular factor may not be sufficient to cause the disease. The presence or absence of one or more of the others may also be needed. Thus, a factor could be a contributing cause in the sense that it is a predisposing, enabling, precipitating, or reinforcing factor. For a detailed discussion of causal relationships in medicine, see Elwood [5]. Also, do not be carried away by the following popular perception: guns kill people! Guns are instrumental, but it is people who kill people. On the other hand, earthquakes do not kill people—it is the collapse of the brittle buildings that kills people.

The above discussion assumes that the role of chance and bias has been minimized, if not eliminated. Chance due to sampling fluctuation is adequately ruled out by demonstrating statistical significance. **Bias** can occur due to a host of factors such as the selection process, observational methods, differential recall of past events, and suppression of information. Measures such as standardization of methods, training, randomization, and matching can be used to minimize the bias. The cause–effect hypothesis is strengthened when all alternative explanations are also studied and shown to be not tenable. A larger sample size does help in increasing confidence, but its role in causal analysis beyond statistical significance is marginal.

## cause of death

According to the World Health Organization (WHO) [1], cause of death is the disease or injury that initiated the train of morbid events leading directly to death, or the circumstances of accident or violence that produced the fatal injury. Thus, this is the underlying cause of death and not the immediate cause of death. For example, for injuries, the cause could be road accident, fall, self-harm (e.g., suicide), interpersonal violence (e.g., homicide), collective violence (e.g., war), etc. It is long realized that the assessment of cause of death has a substantial subjective element. To minimize this, an **International Classification of Diseases (ICD)** is available that is periodically revised (generally every 10 years) to incorporate new knowledge.

In countries where facilities are available, cause of death is recorded in **death certificates**. This certification is nearly complete in countries where each death is attended by a qualified medical professional. In other countries, mostly developing nations, the method of verbal autopsy is adopted that requires interviewing the immediate family about the conditions leading to death. Besides the demographic details about the informant and the deceased, the certificate contains minimal information on the immediate and underlying cause as illustrated in Figure C.3.

According to the WHO estimates [3], nearly 56 million deaths occurred globally in the year 2012, of which 23.0% were due to infectious and parasitic diseases, 67.8% due to noncommunicable diseases, and 9.2% due to injuries. With aging of the population almost everywhere, the noncommunicable diseases are increasingly occupying the pie, and the role of infectious and parasitic diseases is shrinking.

Cause of death statistics raise sensitive issues about allocation of resources for control of diseases and about socioeconomic conditions that promote one cause at the expense of another. In terms of percentage, since total deaths are 100%, one may argue that myocardial infarction is better as a cause of death or cancer is better [4]. All causes cannot be controlled since death is inevitable.

## cause-specific death rate, *see* death rates

## cell frequency

A cell in a **contingency table** arises when the subjects are cross-classified into some categories. If the subjects are being divided by their blood group and sex, there would be eight cells in this contingency table—four for males and another four for females. The term *cell* is generally used for such cross-classifications by two or more attributes, but it can be used for **one-way tables** also. Cell frequency is the number of subjects falling into a particular cell.

If two variables under study are serum creatinine level and whether kidney disease is present or not, the number of subjects in your sample with level 1.2–1.4 mg/dL and with no disease is the cell frequency for this cell. The term can be loosely used for one-way classifications also, such as for the number of subjects with serum creatinine level 1.2–1.4 mg/dL, but is more appropriate when dealing with cross-classification. An example is in Table C.4 on survival of cases in different age groups undergoing gastrointestinal surgeries in a hospital over a 5-year period. In this table, the cell frequencies are the number of cases as mentioned in different cells. The entire grid is shown so that you can see the cells.

In Table C.4 are what are called *observed cell frequencies*. These are the numbers actually found in the study. The other term is *expected cell frequency*. This is used for the frequency you expect when the two or more characteristics under study are not associated. See **association and its degree** if you want to know about association. In Table C.4, a total of 126 out of 2321 patients died. This is 5.4%. If deaths have nothing to do with age, they will be uniformly distributed across all age groups at this rate. Observed deaths, for example, in age group 80–89 years is 4/31 = 12.9%. If age and deaths are not related, this also should be the same 5.4% as in the total. Thus, if deaths and age are not associated, the expected cell frequency for age group 80–89 years is 5.4% of 31, i.e., 5.4 × 31/100 = 1.67. Little arithmetic may tell you that this can also be written as 31 × 126/2321. In the

**TABLE C.4**
**Survival of Cases of Different Age Groups Undergoing Gastrointestinal Surgery in a Hospital over a 5-Year Period**

| Age Group (Years) | Survival | | Total |
|---|---|---|---|
| | Yes | No | |
| 0–9 | 30 | 1 | **31** |
| 10–19 | 82 | 4 | **86** |
| 20–29 | 259 | 17 | **276** |
| 30–39 | 343 | 12 | **355** |
| 40–49 | 415 | 12 | **427** |
| 50–59 | 460 | 31 | **491** |
| 60–69 | 407 | 26 | **433** |
| 70–79 | 170 | 19 | **189** |
| 80–89 | 27 | 4 | **31** |
| 90–99 | 2 | 0 | **2** |
| **Total** | **2195** | **126** | **2321** |

numerator is the product of the two marginal totals corresponding to the cell, and in the denominator is the grand total. The general formula for the $(i, j)$th cell in a two-way table is as follows. Rows and columns are counted only for the cells where frequencies appear. In Table C.4, the column containing the age groups and totals, and the last row containing the totals are not counted for demarcating the $(i, j)$th cell.

$$\text{expected cell frequency: } E_{ij} = \frac{R_i \times C_j}{G},$$

where $R_i$ is the corresponding row total, $C_j$ is the corresponding column total, and $G$ is the grand total. Thus, the observed cell frequency in the third row and first column is $O_{31} = 259$, and the expected cell frequency for no association is $E_{31} = \frac{276 \times 2195}{2321} = 261.0$. Such observed and expected cell frequencies are required for the calculation of **chi-square** for testing the hypothesis regarding association between two variables. This test uses the premise that the expected and observed frequencies in any cell should not be very different when there is no association.

It is not uncommon in medical data that some cells in a contingency table have no frequency or zero frequency. It is important for the purpose of analysis to distinguish between observed zeroes and structural zeroes. An observed zero is one where some frequency could have occurred but happens to be zero in the sample. This is not much of a problem and is treated just like any other small frequency. A structural zero occurs when it is just not possible to have any subject in the cell.

You will need these basic concepts to understand medical literature, when trying to analyze data from your own clinic, and when trying to do research. Cell frequencies play a vital role in the validity of a chi-square test as just mentioned. This is a large sample test and requires that at least 80% of the cells must have an expected frequency of at least 5, and none should have an extremely small frequency such as 0 or 1. If this happens, this can make chi-square invalid for these data. Merging of cells is the answer in such cases.

## censoring (of observations)

Censoring is used for incomplete values, particularly for durations. Duration is the time elapsed from a defined entry point to the defined exit point. This is also referred to as time-to-event where event is the exit. Duration is a difficult variable because it requires that each subject is observed for as long as it does not exit. If you are interested in the duration of survival of children born with thalassemia, some may survive for 80 years. It can be very expensive to continue the study for such a long period. We censor it somewhere and say that we will observe it for 10 years and no longer. Duration of survival for people alive at the cutoff time would never be known except that they survived for at least 10 years in this example. The method of **survival analysis** is geared to meet this contingency, which can rarely be handled in any other manner.

Censoring can also occur for other reasons, e.g., the person moves out, dies due to an unrelated cause, refuses to cooperate after some follow-up, etc. The primary cause of such incomplete observation, however, is, as just stated, that the end-point event does not occur during the follow-up period; the study is terminated after a fixed time.

The kind of censoring mentioned in the preceding example on thalassemia is called *right censoring*. In this case, the survival in censored cases is known to be greater than the specified duration, but the exact duration is not known because the event had not occurred when the study stopped. Right censoring is the most common type of censoring for duration so much so that the word right is dropped and such values are referred to as just censored. This kind of censoring is illustrated in Figure C.4a. A hollow square in this figure represents right censoring. In cases D, F, and H, this occurred because the study has ended, whereas in case E, it is due to loss of the subject for follow-up. Rearranging the durations from minimum to maximum leads to the situation as shown in Figure C.4b.

In *left censoring*, the beginning time is not known, though the end time is known. This also is an incomplete segment, but this kind of censoring is rare in survival studies. This is shown for subject A in Figure C.4a.

The third is *interval censoring*, which occurs when the time-to-event is known to have occurred within a specified time interval, but the exact time is not known. This happens when a continuous vigil on all subjects cannot be kept because it is impractical or too expensive. If you are undertaking periodic visits to inspect a process, the exact time of occurrence will not be known but only that it has occurred sometime since the previous visit. If a group of diabetic persons are being assessed quarterly for the development of retinopathy beginning with the diagnosis of diabetes, the elapsed duration will be known only in quarterly intervals. The exact day or week will not be known.

For the methods of survival analysis, the censoring scheme should have nothing to do with the future survival or time-to-event. This means censoring should not provide any tilted information regarding duration in that group. This condition is generally fulfilled in right-censored values arising from the termination of the

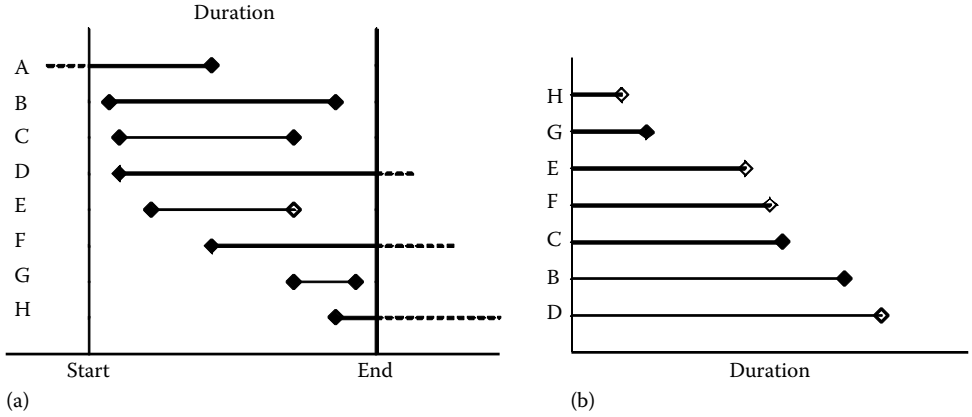

**FIGURE C.4** Censored and complete values (a) before ordering and (b) after ordering.

follow-up. But caution is required in those lost to follow-up for other reasons. In the case of prostate cancer, if a man is not traceable after a certain period, this should not be because he has moved to his family in the last moments of life or has dropped out of the study because he felt he has recovered. The implicit assumption in survival analysis is that the prospects of survival of censored cases are the same as those of uncensored cases. You should be convinced that this condition is met before using the methods of survival analysis.

## census

In contrast to sampling, census is the complete enumeration. The term is usually used for population counts that take place once in 10 years in many countries around the world, but it can be used for other statistical **populations** as well.

Population census looks like the first common statistical activity undertaken even in the ancient world. It may have been first carried out by Babylonians around 3800 BC [1]. The objective is to assess the needs of the population such as food, education, and health, which can be interpreted by the number of people in different age–sex groups in different areas. It can tell us several other interesting facts about the population. For example, the 2011 census in the United Kingdom revealed that 9% of people living as a couple were in an inter-ethnic relationship in England and Wales, which is up 2 percentage points from 2001 [2].

A census can be taken by several methods. In England, Wales, Scotland, and Northern Ireland, the householder receives a questionnaire in the post, completes it, and either submits it online or sends it back in the post. In some other countries, such as Ireland, a large field force visits every household in the land to deliver, and then collect, census questionnaires. The countries of Eastern Europe generally carry out interview censuses, where the enumerators collect and record the information on the householder's behalf [3]. Some countries, such as Finland, update their population register online by records of births, deaths, migration, etc. They can get the complete count and demographic details of the population anytime.

For a manual census of general population, an enumerator goes from house to house and visits other institutions such as hostels where people generally reside, and records elementary demographic details of each person such as age, sex, and occupation. In India, for example, the count is adjusted to be accurate for sunrise on March 1 of the first year of the decade. The last one was done in the year 2011. This included homeless people who sleep on pavements, railway stations, etc. Rural and urban areas are divided into census blocks for enumeration purposes for administrative convenience and to ensure that nobody is missed. The 2011 census in India also elicited information on type of drinking water and type of toilets in the households, besides age, sex, occupation, and housing of the people.

Generally, a short form is completed for each household. For example, for the U.S. census in 2010, the form contained only 10 questions. A sample of households may complete a more detailed questionnaire. Census data provide useful information for planning health services for different segments of population, as well as for assessing the impact of the health services. The data provide an accurate denominator for many rates such as birth rate and death rate.

We can think of a census of out- and in-patients for a hospital, although the term census is not used for this population. Because of computerization in most parts of the world, this is now easily done. The cases can be analyzed not just for their demographics (and compared with the demographics of the catchment area to identify the kind of people who more commonly come for different departments of the hospital) but also for the diseases from which they are suffering. Many hospitals may have a database of millions of patients accumulated over time, particularly if they form a consortium. Analysis of such a huge database for meaningful messages has become an important requirement as evidenced by rising science of data analytics and data mining.

## central limit theorem (CLT)

Considered as the most beautiful result in statistics, the central limit theorem (CLT), in its easily understandable form, states that irrespective of the statistical **distribution** of the variable $x$ (called the *underlying distribution*), the mean $\bar{x}$ of values in independently and randomly drawn sample subjects tends to follow a **Gaussian distribution** in repeated samples as the sample size increases. We have stated this in a blanket form, which seems practically true, but there are minor caveats such as that $x$ must have finite variance (theoretically there are distributions with infinite variance). There are also generalizations of the CLT, but those are not important for most medical applications. The CLT was first formulated by Laplace in 1812, but its utility was realized at the end of the nineteenth century when Aleksandr Lyapunov gave the first rigorous proof [1]. Polya first used the name central limit theorem in 1920.

Aleksandr Lyapunov

Figure C.5a shows a likely statistical distribution of years of survival of cancer patients. This is highly skewed. If we take several samples of size 10 and calculate average survival duration of the patients in each sample, the **sampling distribution** of mean would be nearly as shown in Figure C.5b. This is much more symmetric than the distribution of the original values. If we take several samples of size 40 and calculate the mean of each, the distribution of average survival time would be almost Gaussian as shown in Figure C.5c.

The theorem basically is for all those summaries that use the linear combination of sample values. It is applicable to sample mean since the numerator of $\bar{x} = \sum x/n$ is a sum. The CLT says that the distribution of the linear combination of a large number of values tends to become Gaussian. Thus, the theorem also applies to variance where the numerator $\sum(x-\bar{x})^2$ is also a sum, only that it

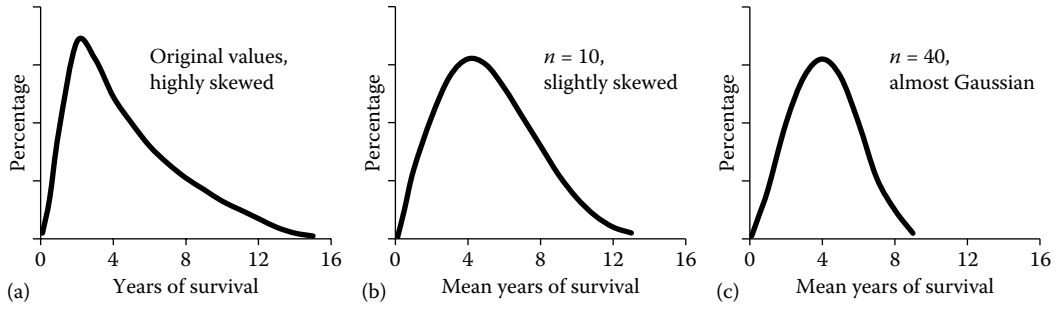

**FIGURE C.5** (a) Highly skewed distribution of survival time of cancer patients and the distribution of its mean with increasing sample size; (b) $n = 10$; (c) $n = 40$.

requires a larger $n$ for such complicated sums. This also applies to sample proportion since this proportion $p = \Sigma x/n$, where $x = 1$ for characteristic present and $x = 0$ otherwise. The numerator of the **regression coefficient** as well as of the **correlation coefficient** is also a sum of cross-products—thus, CLT is applicable to them also. Relative risk and odds ratio are ratios, and their logarithm is eligible to be under CLT; however, for these, a relatively larger sample size is required. All these tend to have a Gaussian distribution for large $n$. On the other hand, summaries such as median, mode, and percentiles are not based on sums or linear combinations—thus, CLT is not applicable to them. In general, they cannot be assumed to follow a Gaussian distribution for large $n$.

This theorem implies that the distribution of a variable such as survival duration may be highly **skewed**, but the distribution of *mean* survival duration becomes Gaussian when it is based on a large number of randomly selected subjects. This result places the Gaussian distribution at the center of the statistical methods. Skewed and other types of distributions such as **bathtub** and **Weibull** are difficult to handle, and this difficulty can be circumvented by increasing the sample size and considering the sample mean as the summary of choice for inference. At the same time, this theorem also underscores the need to have a large sample particularly when the underlying distribution is far from Gaussian and also that the samples must be drawn randomly.

How large is large for the CLT to be applicable? This depends on how different is the underlying distribution from Gaussian. For a slightly skewed distribution, perhaps a sample of size 10 is enough for the CLT to provide valid results, particularly for mean. This size could work for other non-Gaussian but *symmetric* distributions, e.g., the mean of values from the **uniform distribution** quickly follows the CLT. For a moderately skewed distribution, a sample of size 30 may be enough. For a highly skewed distribution such as that of tumor markers, you may need a sample of at least 100. Such a large sample size may be required also for a variable that follows a bathtub type of distribution. For most quantitative medical variables, however, a sample of size at least 30 does the job reasonably well for mean.

Aside from the fact that the CLT is focused on the Gaussian distribution of sample mean, it also obviates the need to depend on something like sample median for inference on skewed distributions if a sufficiently large sample is available. The sample median has problems with regard to its distribution and consequently in working out a confidence interval and in testing of hypothesis. These are easily worked out when the inference is based on sample mean. For example, it is well known that the **standard error (SE)** of the sample mean is $\sigma/\sqrt{n}$. The SE of other sample summaries such as median, mode, and percentiles is not commonly known. Thus, the CLT serves a twin purpose—(i) for enabling a Gaussian distribution and (ii) for removing dependence on median-like statistically difficult measures. However, for one sample, median or mode can be preferred in specific situations, particularly for small samples from non-Gaussian distributions.

## central values (understanding and which one to use), *see also* mean, median, and mode (calculation of)

Central value is the generic term for all those measures that can be considered to be representative of a dataset or of a **distribution**. As an exercise, consider the following simple data on duration of survival (years) of 14 patients after detection of esophagus cancer:

3, 7, 10, 5, 4, 4, 29, 5, 6, 3, 8, 4, 6, 7

If you are asked to choose a central value that could represent these durations, what would you choose? The natural answer is either mean or median or mode. Depending on the nature of values, one of these is considered as the most representative central value. Mean, median, and mode are also called **measures of central tendency** as they *tend* to lie somewhere in the center of the data.

The important question is, "Which is the best measure of central value for a given set of data?" For this, it is essential to first understand mean, median, and mode with correct perspective. While the details of their calculations in grouped and ungrouped data are given under the topic **mean**, **median**, **and mode**, the following is a brief description that can help to understand these measures. We subsequently give guidelines about which measure to choose and when.

### *Understanding Mean, Median, and Mode*

As just stated, a value nearly in the center, or commonly observed, can be considered as a representative of the central value. The arithmetic mean, commonly called an average, is a very popular measure of central value. If $x_1, x_2, \ldots, x_n$ are $n$ observations in our sample, the sample mean is $\bar{x} = \sum x_i/n$. The median is the middle value, which is obtained as the $\left(\frac{n+1}{2}\right)$th value if $n$ is odd after arranging in ascending order, and the average of $\left(\frac{n}{2}\right)$th and $\left(\frac{n}{2}+1\right)$th if $n$ is even. The mode is the most common value.

The following are the data on cases of acute polymyositis of the back in 38 women.

C

Duration of immobility (days):

| | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 7 | 5 | 9 | 7 | 36 | 4 | 6 | 7 | 5 | 8 | 3 | 6 | 5 |
| 7 | 8 | 10 | 7 | 14 | 10 | 9 | 4 | 6 | 11 | 9 | 6 | 5 |
| 8 | 8 | 6 | 7 | 5 | 5 | 12 | 3 | 5 | 9 | 10 | 7 | |

Mean = 7.9 days
Median = Average of the 19th and 20th values after rearranging in ascending order = (7 + 7)/2 = 7 days
Mode = 5 days and 7 days, occurring in 7 patients each

A distribution containing two modes such as in this example is called a **bimodal distribution**. Mean is denoted by $\bar{x}$ for sample and by μ for population. No such universally accepted notations are available for median and mode.

A visual display can help to understand the real meaning of mean, median, and mode. Figure C.6 is a simple plot of points explaining the meaning of these measures. This displays the duration of hospital stay (days) after a surgery for 30 patients (numeric data not shown). The mean is the center that balances the beam on which the points are plotted. This balancing is a very useful feature of this central value. The median is such that half of the dots are less than or equal to the median. Although it is not so clear in Figure C.6 because of the **discrete** data, half of the values will be more than the median and the other half less. This may or may not happen with the mean. The mode clearly refers to the peak.

Figure C.7 depicts the location of the mean, median, and mode in symmetric, right-skewed, and left-skewed distributions (see **skewness**). Whereas the three coincide in the symmetric unimodal distribution, they change the order as the shape changes from right-skewed to left-skewed. In the left-skewed distribution, the value of mean is least, followed by median and then mode. These happen to be in the same order as they appear in the dictionary. The reverse happens in the case of the right-skewed distribution. The median is closer to the mean, but the gap between the median and mode is relatively large just as in a dictionary. Thus, values of mean, median, and mode give a fairly good idea of the skewness of the data values.

### *Which Central Value to Use and When?*

If you want to tell a patient one duration of immobility generally seen in cases of acute polymyositis of the back, would you use the mean, median, or mode? The mean is the popular choice because it is simple to calculate and easy to understand. It certainly should be preferred except in cases in which it can mislead. Add to the data in our example two more cases with durations 32 and 47 days. There is already a case of immobility of 36 days. The mean now becomes 9.5 days. Because 31 out of 40 patients are immobile for 9 days or less, 9.5 days cannot be a representative central value. The mean is vitiated due to **outliers**. Outliers are unusually high or unusually low values that do not go along with the other values. Whenever such values are present, the mean is not a good choice. In such instances, use the median because it is not affected by unusually high or unusually low values. For these 40 durations, the median is the average of the 20th and 21st values in ascending order. This again is (7 + 7)/2 = 7 days.

Use the mode when the interest is specifically in the most common value or the "typical" value. Consider the incubation period of cholera from exposure to the appearance of symptoms. This generally ranges from 1 to 4 days, but the most common (mode) is 2 days. This mode has special significance in this case because it can help to estimate a peak occurrence if the exposure is from a common source. Thus, hospitals can be geared up to handle the cases. In our example on duration of immobility, there are two modes—5 and 7 days—each seen in nearly one-fifth of the patients. *The mode can be multiple, but the mean and median are always unique*. The practical utility of the mode is sometimes lost when it is more than one except when it is genuinely bimodal. In the case of **nominal data**, the mode is an appropriate central value.

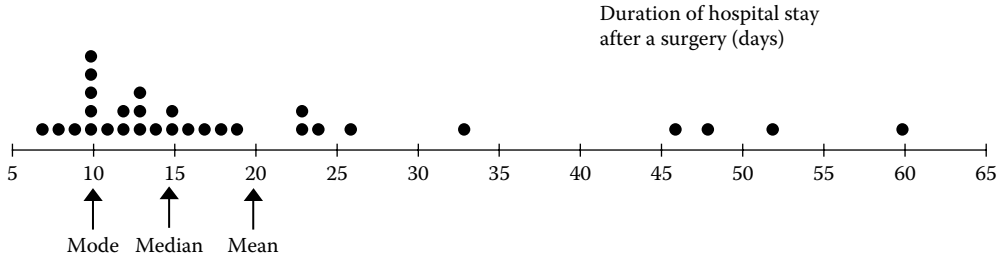

**FIGURE C.6** Schematic of mean, median, and mode.

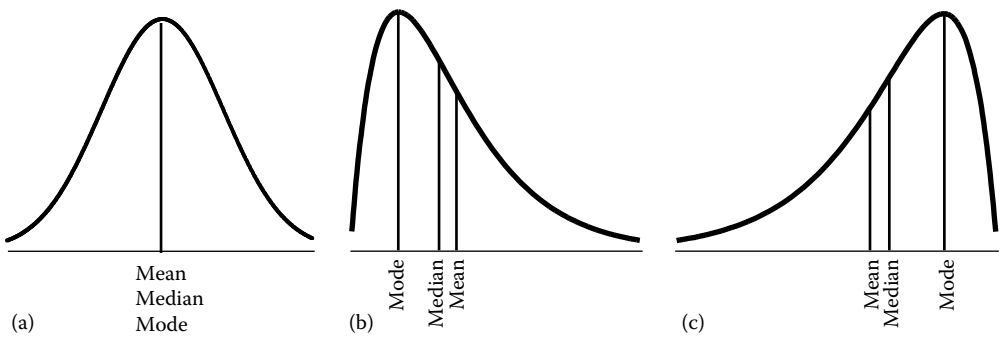

**FIGURE C.7** Location of mean, median, and mode in (a) symmetric, (b) right-skewed, and (c) left-skewed distributions.

Our guideline for choosing an appropriate central value is as follows: Always prefer mean to represent the central value except when (i) outliers are present (use the median then) or (ii) the interest is specifically in the most common value (use the mode then). If multiple modes are present, use the mean. In a large number of situations in medicine and health, the opportunity to choose may not arise because the three central values tend to be the same. Nonetheless, use the following precautions:

- These guidelines are for representing values in one sample, and not applicable to statistical inference such as confidence intervals and tests of hypothesis where mean outscores due to **central limit theorem**.
- The mean and other measures of centrality are sometimes misused. One misuse occurs when they are cited without the accompanying variability of the underlying values. The mean of the fasting plasma glucose level could be 105 mg/dL when the range is 90–110 mg/dL and also when the range is 60–200 mg/dL. The same means in these two cases have entirely different implications. Mean must always be accompanied by a measure of **variation**.
- Mean can be ridiculous when outliers are present. If 8 out of 10 persons in a sample do not take alcohol and 2 persons take 120 mL each per day, it is unwise to say that the average intake per person is 24 mL. Similarly, the average number of legs per person in this world is less than 2 as some do not have one or both legs. Mean, median, and mode are much more meaningful when they are based on relatively homogenous groups. For example, the mean survival period of assorted patients admitted to a hospital could be an inappropriate measure of efficiency since there would be cases of hernia with minimal risk of death and cases of peritonitis with grave prognosis. The survival period could be widely different in these cases.
- The number of values on which a mean is based must always be stated. The mean of values in two or three subjects has little meaning. The mean of 5 subjects may be the same as that of 200 subjects, but the two means have very different reliability.
- The other common misuse occurs when a mean or median is applied to one particular case in place of a group. If the median survival time after detection of a malignancy is 3 years, it does not imply that a person with this malignancy is likely to survive for 3 years. Even when the term "likely" is added, the statement does not become valid. The only correct statement is that nearly half survive for 3 years or less and the other half for more than 3 years.
- Arriving at a conclusion in medicine based on mean alone without considering other correlates could be misleading. If an antihypertensive drug is able to reduce diastolic blood pressure by 10 mmHg on average after 1 week of use by patients with hypertension, other considerations such as side effects, cost, and convenience of intake cannot be ignored altogether while evaluating the usefulness of the drug.
- Most scientific applications would be careful about the misuses just mentioned, but popular media such as television channels and newspapers sometimes pick up average values and report them without sufficient care about the variability attached to them. Thus, the public is not properly informed. This can cause all sorts of problems regarding the perception of a disease or in understanding the gravity of a health problem.
- In the case of binary data coded as 0 for absence and 1 for presence, the mean is the proportion of the subjects with presence of the characteristic.

For calculation of mean, median, and mode in different setups, such as in grouped data, see **mean**, **median**, **mode** (**calculation of**).

C

## centroid method of clustering, *see also* cluster analysis

Centroid is one of the several methods of **hierarchical** agglomerative clustering where the distance between two clusters is measured by the distance between their means (centroids in case of multivariate data). Clustering is the process of putting similar units in one group and dissimilar units in distinct groups. In the hierarchical agglomerative process, the two most similar units are put into one group at the first stage. This group is now considered as one entity. Now the distance of this entity from other units is compared with the other distances between various pairs of units. Again, the closest are joined together. This hierarchical agglomerative process goes on in stages, reducing the number of entities by one each time. This is a bottom-up approach. The process is continued until all units are clustered together as one big entity, although it can be stopped midway when the desired kind of clusters is obtained. Note that in the hierarchical method, subsequent clusters completely contain previously formed clusters.

It may not be immediately clear how to compute the distance between two entities containing, say, $I$ and $J$ units, respectively. Several methods are available such as **single linkage**, **complete linkage**, and **average linkage**. Different methods can give different results. Consider entity A comprising $I$ units ($a_1$, $a_2$,…, $a_I$) and entity B comprising $J$ units ($b_1$, $b_2$,…, $b_J$). Then, in the centroid method, the distance between entity A and entity B is equal to the distance between the mean of units in entity A and the mean of units in entity B. In other words, find the mean $\bar{a}$ of all units of entity A and the mean $\bar{b}$ of all units in entity B, and then compute the distance between $\bar{a}$ and $\bar{b}$. The distance can be obtained by different methods, but the most popular is the square of the **Euclidean distance**. In this case, this is defined as $d_{AB} = (\bar{a} - \bar{b})^2$ when $\bar{a}$ and $\bar{b}$ are univariate, and as $d_{AB} = \Sigma(\bar{a} - \bar{b})^2$ when $\bar{a}$ and $\bar{b}$ are multivariate quantities (the sum is over the elements of the multivariate quantity). These are obtained after **standardization** (by subtracting mean and dividing by the standard deviation) so that large values of any particular variable do not disproportionately affect the distance. Since it is based on means, the distance calculated by the centroid method is not much affected by outliers compared with other methods (such as complete linkage and single linkage), but this may not be sufficiently good to obtain internally homogeneous and externally isolated groups.

The centroid distance between them is the distance between $\bar{a}$ and $\bar{b}$. This method was originally proposed by Sokal and Michener in 1958 [1]. For further details of the centroid method, see Everitt et al. [2]. This method is also called the **group average method**. Since in calculating this distance we have disregarded that entity A has more units and entity B has less units, this is called the **unweighted group average method** (**UPGMA**). In Figure C.8, entity A has 17 units and entity B has 6 units. When this is weighted by the number of units, this becomes the weighted method.

The group average method is seen as a compromise between single linkage and complete linkage methods. In single linkage, the distance between entities is considered to be the same as between the closest units of the two clusters (nearest neighbor), and in complete

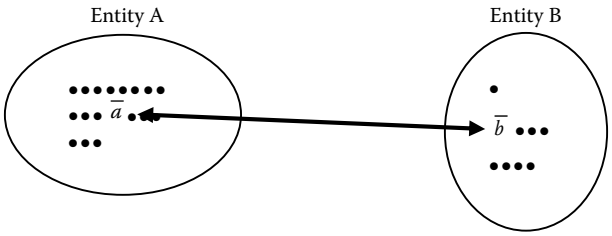

**FIGURE C.8** Centroid distance between entity A and entity B.

linkage the distance between the farthest units (farthest neighbor). Group average uses the distance between the entity averages.

We could not locate relevant examples in health and medicine where the group average method alone has been used. It has been mostly used in conjunction with other clustering methods. Feher and Schmidt [3] found group average the best out of many methods they tried for clustering molecular conformations.

## champaign glass effect, *see* health inequality

## chance, *see also* uncertainties

Anything unknown or too complex that makes it beyond human comprehension is termed chance. When we flip a coin, what determines that it will show head or tail? It probably depends on the size and weight of the coin, its position at the time of flipping, and the force with which flipping is done. Yet, can you flip it repeatedly to turn head each time? Such is the power of chance. When travelling in a vehicle, it is nearly impossible under normal circumstances to predict whether an accident will occur, and whether or not this will be fatal. Do we fully know why some women get breast cancer and others do not? **Risk factors** are called as such as they have a chance element, and all risk factors put together remain incapable of prediction with certainty. Because of the prominent chance element in all this, the prediction also is in terms of chance, statistically called **probability**.

Probability is by far the most common measure of chance. It quantifies and gives us a tool to differentiate one chance with the other. If the chance of death of a critically injured patient is 20% and of a typhoid patient is 0.4%, we know that the chance of death of a critically injured patient is not just steeply higher than that of a typhoid patient but is 50 times. This comparative evaluation of chance is hardly possible in any other way.

Chance is central to statistical thinking. If there is no chance, statistics does not apply. This is the basic difference between classical mathematics and statistics. The omnipresence of chance in health and medicine also explains why statistics pervades so much in medical sciences. This is what has given rise to a full-fledged science of **biostatistics**. No medical variable can be exactly predicted with certainty. There is always a need to attach probability to any medical prediction. On the contrary, for example, physical forces and their reactions can be exactly predicted. The role of chance is either absent or practically negligible in those sciences.

Several other examples can be cited. Ageing is a natural process, but some feel its effects more than others, to a varying degree. Some smokers develop lung cancer; others do not. Part of all such variation can be traced to factors such as personality traits, lifestyle, nutritional status, and genetic predisposition. However, these known factors fail to explain the entire variation. Two patients apparently similar, not just with regard to the disease condition but also for all other known factors, can respond differently to the same treatment regimen. Even susceptibility levels sometimes fail to account for all the variation. Thus, chance remains a factor. In some situations, these chance factors could be very prominent contributors to uncertainties, and in some situations, they can be minor.

## chance node, *see* decision analysis/tree

## chaotic measurements

Colloquially, chaos is a disorderly state, and chaotic measurements are the assessment of variables with haphazard values. Note that haphazardness is not random. Mathematically though, chaos has an enormous effect on outcome due to minor variation in initial or input values. Thus, this is intimately related to **butterfly effect** and is a consequence of extreme sensitivity of the outcome to the initial conditions. Chaotic systems limit our ability to predict even the deterministic phenomenon, least the stochastic phenomenon we encounter in health and medicine.

Sometimes chaotic values are confused with random variations. There is a clear distinction between the two. Chaotic values show a steep change over time or over stages with only a slight disturbance in initial values or input values, but they can still be largely predicted and modeled. This implies that we can say with considerable assurance what outcome is going to result when initial values are slightly different. This is mostly deterministic such as doubling at each passing stage. This cannot be done with random variations, although these variations too in statistics are modeled to follow a Gaussian pattern in the long run. This implies that random variations remain close to zero or near the amount of bias most of the time for fixed inputs. The chaotic values, on the other hand, can be very high, which in statistics are termed outliers.

For an application of chaotic measurements in modeling epileptic brain, see Fiasché et al. [1].

## charts (statistical)

Charts are organization of knowledge into some kind of figure for visual depiction. Statistical charts can be graphical or textual. For **graphs**, see this topic. In addition to those described there, we have also described **agreement charts**, **control charts**, **growth charts**, and **pedigree charts** under these topics. All these are factually diagrams. A more appropriate use of the term chart is for a figure that organizes *textual* information into boxes for depicting linkages of concepts, events, or activities. One such chart is in Figure C.9 on conventional diabetes screening. Specifically, this is called a *schematic chart*. Notice how it summarizes the steps to be taken at each phase of screening.

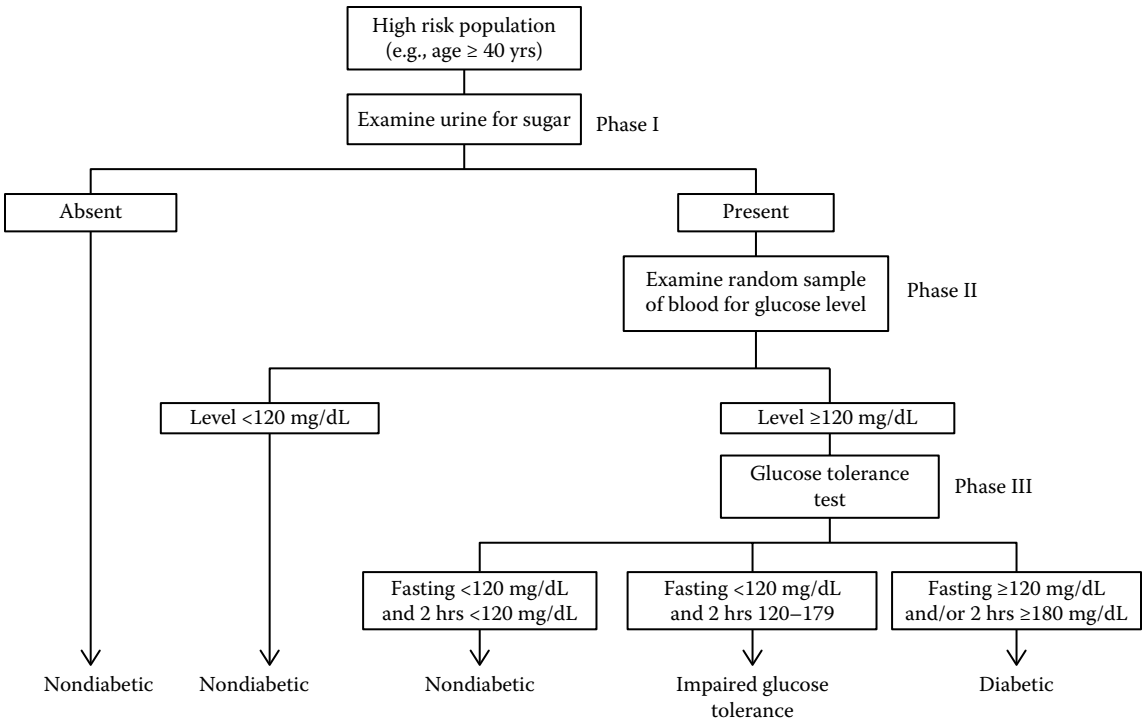

**FIGURE C.9** Scheme of multiphasic screening for diabetes mellitus.

There are other types of charts in health and medicine. Some of these are the Snellen chart, the retrospective chart, the medication chart, and the color chart. These are not statistical charts and are not in our purview.

## child mortality rate, *see* mortality rates

## chi-square—overall

A technical brief of chi-square distribution appears toward the end of this section. In health and medicine, we are mostly concerned about its application and we start with the applied aspects.

Chi-square is a versatile statistical method for the testing of several types of **hypothesis** relating to count of units (frequencies) in different groups. The most elementary of these is for finding whether or not frequencies in different groups follow a specified pattern. This is called a test for **goodness-of-fit**. Incidentally, this is also an easy portal to explain the essentials of the method of chi-square as follows.

Consider the data in the top row of Table C.5. This is a one-way table that gives blood group pattern of a sample of 150 cases of HIV. The problem we address is to find whether HIV positivity has any **association** with blood group pattern. This is the same as finding whether any blood group is more commonly seen in HIV cases. This can be tested only with comparison of the blood group pattern in the population from which these cases have come. Suppose the pattern in the population for blood groups O, A, B, and AB is 6:5:8:1. Since 6 + 5 + 8 + 1 = 20, this hypothesis in terms of probabilities is

$$H_0: \pi_1 = 6/20 = 0.30, \pi_2 = 5/20 = 0.25, \pi_3 = 8/20 = 0.40, \text{ and } \pi_4 = 1/20 = 0.05.$$

Note that the sum of these probabilities is 1.00.

**TABLE C.5**
**Calculation of Chi-Square for Testing the Null Hypothesis Regarding the Specified Pattern in HIV Cases**

| | Blood Group | | | | |
|---|---|---|---|---|---|
| | **O** | **A** | **B** | **AB** | **Total** |
| Observed frequency ($O_k$) | 57 | 36 | 51 | 6 | **150** |
| Expected frequency under $H_0$ ($E_k$) | 45.0 | 37.5 | 60.0 | 7.5 | **150.0** |
| $O_k - E_k$ | 12.0 | –1.5 | –9.0 | –1.5 | **0** |
| $(O_k - E_k)^2/E_k$ | 3.20 | 0.06 | 1.35 | 0.30 | **4.91 = $\chi^2$** |

Denote the observed frequencies in the four blood groups in the sample by $O_1$, $O_2$, $O_3$, and $O_4$, respectively. That is, $O_1 = 57$, $O_2 = 36$, $O_3 = 51$, and $O_4 = 6$. If $H_0$ is really true, then *expected frequencies* (see **cell frequency**), denoted by $E$'s, would be in the ratio specified in the hypothesis, i.e., $E_k = n\pi_k$ ($k$ = 1, 2, 3, 4). For $n$ = 150, $E_1$ = 150 × 0.3 = 45. Similarly, $E_2 = 37.5$, $E_3 = 60$, and $E_4 = 7.5$. A large difference between $O$'s and $E$'s would suggest that the observed pattern is different from that stipulated in the null hypothesis. This would be evidence against $H_0$ and in favor of $H_1$. It seems that the examination of the differences $(O_k - E_k)$ for different $k$ would be helpful. Since the total of the expected frequencies has to be the same 150 as that of the observed frequencies, it is imperative that some of these differences are negative and some positive, and the sum $\Sigma(O_k - E_k)$ would be always 0. As in the case of deviations $(x_i - \bar{x})$ for calculating SD, the square of these differences gets rid of the negative sign. This gives $(O_k - E_k)^2$. The magnitude of these squares is the key to the plausibility of $H_0$. But a difference of 1.5 over the expected 7.5 in blood group AB has a different meaning than the same difference over the expected 37.5 in blood group A. The former difference is one-fifth

of the corresponding expected frequency, whereas the latter is not even one-twentieth. Thus, the squared differences should be viewed in relation to the expected frequencies. The quantity $[(O_k - E_k)^2/E_k]$ becomes relatively free of the differentials in the magnitude of the expected frequencies in different groups and helps to give nearly equal weight to the groups. In place of taking the average of these quantities, this time, obtain the sum $\Sigma[(O_k - E_k)^2/E_k]$. This quantity is based entirely on frequencies and thus is unit free. This obviates the need to take the square root as is done at the time of calculating SD. To indicate that the quantity is a square, the sum is called chi-square ($\chi^2$). This is the **test criterion** in this case. Thus,

$$\text{chi-square (one-way table): } \chi^2 = \sum \frac{(O_k - E_k)^2}{E_k};\ k = 1,2,\ldots,K,$$

where $K$ is the total number of cells in the **contingency table**. In our example, $K = 4$.

Note that $E$'s are obtained assuming that $H_0$ is true. Thus, the value of $\chi^2$ in the formula given in this equation is under $H_0$. When $H_0$ is true, the difference between $O_k$ and $E_k$, i.e., $(O_k - E_k)$, should be small, and consequently the value of $\chi^2$ should also be small. In other words, a large value of $\chi^2$ is unlikely if $H_0$ is true. If the sample gives a large $\chi^2$, it provides evidence against $H_0$.

The ***P*-value** in this case is the probability of occurrence of the value of the criterion as extreme as or more extreme than obtained for the sample data. This requires distribution of the criterion under $H_0$. Such a distribution of $\chi^2$ is known. The exact shape of the distribution varies according to what is called the degrees of freedom (df). The df, in turn, depends mostly on the number of cells $K$. The concept of **degrees of freedom** is explained separately. The software automatically finds the df also and provides the ***P*-value**. If this $P$-value is less than the predetermined level of significance $\alpha$, reject the null; otherwise, do not reject the null.

In the case of the data in Table C.5, the df = $K - 1 = 4 - 1 = 3$. The calculations are presented in subsequent rows of this table. These show $\chi^2 = 4.91$. If a computer software package is used, it will automatically compare the calculated value of $\chi^2$ with its known distribution for 3 df and give $P = 0.178$. Otherwise, because 4.91 is less than the critical value 7.815 of chi-square for 3 df at 5% level of significance, the $P$-value is more than 0.05. Thus, the value 4.91 of $\chi^2$ obtained for these data is not all that unlikely when $H_0$ is true. That is, the frequencies observed in different blood groups in the example are not very inconsistent with the $H_0$. The sample values do not provide sufficient evidence against $H_0$, and it cannot be rejected. A preponderance of any blood group in cases of HIV cannot be concluded on the basis of this sample.

This inference is drawn despite an apparently clear excess of blood group O (57 subjects versus an expected 45) in this sample of HIV cases. This is because such a frequency *pattern* is not very unlikely to occur when the sample comes from the general population where the blood group ratios are as given in the null hypothesis. For further analysis, see **partitioning of chi-square**.

### Cautions in Using Chi-Square Test

The chi-square test does not require the frequency pattern to be Gaussian nor does it require any other specific pattern. Thus, the *chi-square test is a distribution-free procedure*. The following cautions are still needed:

- The use of chi-square for categorical data is well established, but $\chi^2$ itself is a **continuous variable**. Theoretically, it is based on an approximation. This approximation works fine when the expected frequency in any cell is not less than 5. When the number of categories $K$ is large, there can be a small relaxation. A rule of thumb is as follows: not more than one-fifth of categories (i.e., $K$/5 cells) should have $E_k < 5$, and almost none should be less than 1. When small frequencies are expected in many cells under $H_0$, either because of a small sample or because of very small $\pi$ in some cells, an exact **multinomial test** should be used.
- It is necessary to realize that chi-square is calculated from the actual frequencies in the cells. Percentages cannot be used.
- The chi-square test is basically a two-tailed test. Statistical significance in this case implies only presence of some difference from $H_0$, and it can seldom be labeled positive or negative. If the observed frequency is less than the expected frequency in one cell, it has to be more in one or more of the other cells because the total for both the observed and the expected frequencies is the same. In our example, the observed frequency is more for blood group O but less for the other three blood groups. Thus, the alternative hypothesis $H_1$ is two-sided. Some other tests, particularly when there are only two cells (**binary variable**), can have a one-sided alternative.
- The $\chi^2$ criterion is the sum $\Sigma[(O_k - E_k)^2/E_k]$. This would be large even if one particular difference $(O_k - E_k)$ is large. Thus, rejecting $H_0$ tells us only that there is at least one cell where the observed frequency is substantially different from the expected under the null hypothesis. It does not say where. On the other hand, if a large difference is present in only one cell, this can be masked by small differences in the other cells. This is what might be happening for blood group O in our example. For a more focused inference, further analysis by partitioning of chi-square may be helpful.

### Chi-Square Distribution

Mathematically, chi-square with $\nu$ df is defined as the sum of squares of $v$ independent standard Gaussian variates. As explained under that topic, if a variable $x_i$ has a **Gaussian distribution** with mean $\mu_i$ and variance $\sigma_i^2$, the standard Gaussian variate is $(x_i - \mu_i)/\sigma_i$. Thus, when $x_i$'s are independent,

$$\text{chi-square: } \chi^2 = \sum_{i=1}^{v} \frac{(x_i - \mu_i)^2}{\sigma_i^2}.$$

The degrees of freedom depend on the number of *independent* variates. When there is a restriction, such as that the total of observed frequencies is the same as the total of expected frequencies, the number of independent variates decreases by the number of restrictions. A different distribution of $\chi^2$ for different df is analogous to a different distribution of diastolic blood pressure in different age groups. Shapes of the distribution for some specific df's (denoted by $n$ in this figure) are given in Figure C.10. This gives you an idea how different df's can provide very different shapes and consequently different $P$-values. Also note that the shape of the chi-square distribution quickly looks like that of a Gaussian distribution even for 10 df.

Our description of chi-square is by way of an introduction to this extremely versatile procedure. As mentioned earlier, the chi-square test is used in a large number of setups. We have divided them into

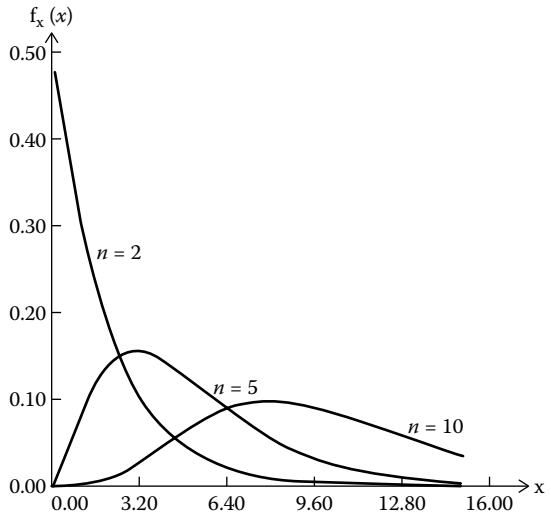

**FIGURE C.10** Shape of the distribution of chi-square for specified df's (denoted by *n* in this figure). (From Dudewicz EJ. *Introduction to Statistics and Probability.* Holt, Rinehart and Winston, 1976: p. 457.)

small segments to retain focus and to keep the text manageable. For details, see the next few topics.

## chi-square test for 2 × 2 tables, *see also* chi-square test for odds ratio and relative risk

If you are not familiar with the basics, see **chi-square—overall**. Among a large number of applications of chi-square, this section is restricted to two dichotomous variables, i.e., both characteristics observed as present or absent. One dichotomous variable could identify the presence or absence of the characteristic of interest, and the second variable could identify groups such as with and without disease, with disease A and with disease B, male and female, young and old, or any other such groups. These groups are independent, and the setup is essentially **bivariate**. Since both variables have two categories, this gives rise to a 2 × 2 table. This can also arise in a variety of other situations. One common situation is in calculating the **odds ratio** and the **relative risk**. The kind of contingency table arising in such cases is shown in Table C.6. $O_{rc}$ is the observed frequency in the $(r, c)$th cell ($r = 1, 2$; $c = 1, 2$), and inside the parentheses in each cell in the table are the corresponding probabilities. The dot in the subscript is for the corresponding total. The table is shown as though the relationship between antecedent and outcome is under study, but in fact, these can be any two dichotomous categories. This is also known as a *fourfold table*. There is a numerical example later in this section that provides a concrete view of this kind of table.

**TABLE C.6**
**General Structure of a 2 × 2 Contingency Table**

| Variable 2 (Outcome) | Variable 1 (Antecedent) Present | Absent | Total |
|---|---|---|---|
| Present | $O_{11}$ ($\pi_{11}$) | $O_{12}$ ($\pi_{12}$) | $\boldsymbol{O_{1\bullet}(\pi_{1\bullet})}$ |
| Absent | $O_{21}$ ($\pi_{21}$) | $O_{22}$ ($\pi_{22}$) | $\boldsymbol{O_{2\bullet}(\pi_{2\bullet})}$ |
| **Total** | $\boldsymbol{O_{\bullet 1}(\pi_{\bullet 1})}$ | $\boldsymbol{O_{\bullet 2}(\pi_{\bullet 2})}$ | $\boldsymbol{n}$ |

Even though the null hypotheses of no **association in prospective**, **retrospective**, and **cross-sectional studies** are different as explained under that topic, and consequently the interpretation is different, it can be shown that the test criterion is the same for all of them. Under any of those three $H_0$'s, the expected frequency in the $(r, c)$th cell, when the samples are independent, is given by

$$E_{rc} = O_{r\bullet} * O_{\bullet c};\ r, c = 1, 2.$$

Consider, for example, a study where $H_0$: $\pi_{11} = \pi_{21}$. This hypothesis implies in the context of Table C.6 that the proportion of subjects with antecedent in the two outcome categories should be the same. Each of these proportions would be the same as in the two categories combined. A similar statement should also be true for subjects without antecedent. This gives

$$(E_{11}/O_{1\bullet}) = (E_{21}/O_{2\bullet}) = (O_{\bullet 1}/n)$$

and

$$(E_{12}/O_{1\bullet}) = (E_{22}/O_{2\bullet}) = (O_{\bullet 2}/n)$$

or

$$E_{11} = \frac{O_{1\bullet}O_{\bullet 1}}{n},\quad E_{21} = \frac{O_{2\bullet}O_{\bullet 1}}{n},\quad E_{12} = \frac{O_{1\bullet}O_{\bullet 2}}{n},\quad E_{22} = \frac{O_{2\bullet}O_{\bullet 2}}{n}.$$

These are exactly the same as stated in the formula given in the topic **cell frequency**. The hypothesis of homogeneity in prospective and retrospective studies can also be shown to lead to the same formula.

Now the test criterion is

$$\text{chi-square for } 2 \times 2 \text{ table: } \chi^2 = \sum_{rc} \frac{(O_{rc} - E_{rc})^2}{E_{rc}};\quad r, c = 1, 2.$$

The justification is the same as explained for **chi-square**, and the applicability also requires each expected cell frequency to be at least five. In a 2 × 2 table, df = 1. There is freedom to choose the frequency arbitrarily in only one cell. The others are automatically decided because the row and column totals are considered fixed as illustrated in the following example. The test procedure is to calculate $\chi^2$ and find the probability $P$ of obtaining this or a higher value. A small value of $P$, as usual, is the evidence against $H_0$. If the $P$-value is sufficiently small, less than the predetermined level of significance, reject $H_0$; otherwise do not reject it. The whole procedure is illustrated in the following example.

Let the interest be in finding whether or not the prevalence of anemia in women is related to their parity status. Parity status is divided into two categories: two or less and three or more. Suppose the observed prevalence in a cross-sectional survey of 100 randomly selected women from a specified population is as given in Table C.7. In these data, 14 × 100/60 = 23% of women of parity ≤2 have anemia versus 16 × 100/40 = 40% women of parity ≥3. Is this association really present in the population?

The null hypothesis in this cross-sectional study would be that parity status has nothing to do with anemia status. This is the hypothesis of independence. That is, $H_0$: $\pi_{rc} = \pi_{r\bullet} * \pi_{\bullet c}$. If parity status has nothing to do with anemia status, then the ratio of anemics in both parity groups would be the same. That is, 30% of 60 women with parity ≤2 and 30% of 40 women with parity ≥3 should be anemic.

**TABLE C.7**
**Anemia and Parity in a Cross-Sectional Study of 100 Women**

| | Observed in the Survey | | | Expected under $H_0$ | |
|---|---|---|---|---|---|
| **Anemia** | **Parity ≤2** | **Parity ≥3** | **Total** | **Parity ≤2** | **Parity ≥3** |
| Present | 14 | 16 | **30** | 18 | 12 |
| Absent | 46 | 24 | **70** | 42 | 28 |
| **Total** | **60** | **40** | **100** | **60** | **40** |

Such expected frequencies under $H_0$ are also given in Table C.7. These can be verified to follow the formula given earlier. Thus,

$$\chi^2 = \frac{(14-18)^2}{18} + \frac{(16-12)^2}{12} + \frac{(46-42)^2}{42} + \frac{(24-28)^2}{28} = 3.17.$$

Only one cell frequency in a 2×2 table can be freely determined since the totals are considered fixed. If the number of nonanemics in the group with parity ≥ 3 is 18, then the number of anemics in this group has to be 22 (so that the total with parity ≥ 3 remains 40), that of anemics of parity ≤ 2 has to be 8, and that of nonanemics in this group has to be 52. Only that will keep the row and column totals unaltered.

A computer-based statistical package gives $P(\chi^2 \geq 3.17) = 0.075$. If the level of significance is $\alpha = 0.05$, this $P$-value is not sufficiently small. Thus, the $H_0$ cannot be rejected. The evidence in this sample of 100 women is not sufficient to conclude that the prevalence of anemia in women is related to parity status. The initial assumption ($H_0$) of no relation can be conceded in the absence of sufficient evidence against it.

There are several topics in this volume that are intimately related to this section. The same hypothesis can also be tested with the ***z*-test** for proportions. The $z$-test can also be used to find whether or not a predetermined medically significant difference is present between the two groups.

Sometimes the **Yates correction for continuity** is advised for this chi-square test for 2×2 tables. As already mentioned, the test described in this section is for large samples and requires that no expected cell frequency is less than five. For small samples, see the **Fisher exact test**. For paired data, see the **McNemar test**.

## chi-square test for larger two-way contingency tables

The preceding section is on **chi-square test for 2×2 tables**. This means that both the characteristics (or variables) are **dichotomous**. But a large number of variables are not dichotomous. Blood group has four categories. Subjects may be categorized for smoking as those who have never smoked, ex-smokers, mild smokers, and heavy smokers. All **polytomous** categories can be dichotomized, such as blood group into B and non-B groups and smoking into yes and no; but quite often, such dichotomy fails to serve the purpose. In some situations, such as in assessing the trend in proportion of sexually mature girls (with regard to, say, breast stage) of age 14 years with different grades of anemia, it is better to have as many grades of anemia as is feasible. Thus, $R \times C$ contingency tables are not uncommon, where the number of rows in the table is $R$ and the number of columns is $C$—either or both of them being more than 2.

The inference generally needed from such tables is whether the two variables are associated. If an association is found, further analysis can be done to measure the degree of **association**, to ascertain the presence of trend, if any, or to find which particular cell or cells in the contingency table are contributing to the relationship. The method for finding the presence or absence of association is basically the same for $R \times C$ tables as for 2×2 tables, although some generalization is needed. This section first discusses $2 \times C$ (or $R \times 2$) tables and then goes on to discuss $R \times C$ tables. The concern in this section is with a setup where both the variables are qualitative. If one of them is quantitative, examine whether methods such as **logistic regression** can be used. As in the case of 2×2 tables, the presumption throughout this section is that $n$ is large and additionally that the frequency in at least 80% of the cells is 5 or more. For small frequencies, the **Fisher exact test** can be extended to $R \times C$ tables. For more on this, see Mehta and Patel [1].

### *One Dichotomous and the Other Polytomous Variable (2×C Table)*

Consider an investigation on the relationship between dioxin dosage and enlarged prostate. Dioxins are by-products of combustion and other processes. They persist at lower levels virtually everywhere—in air, water, and soil. They are known to be disrupters that can offbalance the endocrine system. Children are particularly vulnerable. This can affect behavior, immune function, neurological development, and gender development. In an experiment, a group of 100 mouse fetuses are randomly divided into four equal groups and are exposed to none, low, medium, and heavy doses of a dioxin-like chemical. These dosages are in relative terms, but even a heavy dose would be a microdose. This experiment is along the lines reported by vom Saal et al. [2]. The numbers of fetuses that developed enlarged prostate are given in Table C.8. Some fetuses were lost and could not be observed.

The **null hypothesis** for rejection is that there is no effect of differential dose of dioxin on the incidence of enlarged prostate. If this $H_0$ is true, the enlarged prostate would be divided among the dose groups according to the total number of fetuses in each group. This means that 21 enlarged prostate cases should be in the ratio 23:25:25:20. This total is 93. The expected frequencies under $H_0$ therefore are 21 × 23/93, 21 × 25/93, 21 × 25/93, and 21 × 20/93, or 5.19, 5.65, 5.65, and 4.52, respectively. If the expected frequency in the $r$th row and the $c$th column is denoted by $E_{rc}$, it should be clear that

$$E_{rc} = O_{r\bullet} * O_{\bullet c}/n; \; r = 1, 2, \ldots, R; \; c = 1, 2, \ldots, C,$$

where $O_{r\bullet}$ is the total of the $r$th row, $O_{\bullet c}$ is the total of the $c$th column, and $n$ is the grand total. In this example, $R = 2$, $C = 4$, $O_{1\bullet} = 21$, $O_{2\bullet} = 72$, $O_{\bullet 1} = 23$, $O_{\bullet 2} = 25$, $O_{\bullet 3} = 25$, $O_{\bullet 4} = 20$, and $n = 93$. From the formula just given, $E_{11} = 5.19$, $E_{12} = 5.65$, $E_{13} = 5.65$, and $E_{14} = 4.52$. These are the same as obtained before. Also, $E_{21} = 17.81$, $E_{22} = 19.35$, $E_{23} = 19.35$, and $E_{24} = 15.48$. Now a test criterion is required.

**TABLE C.8**
**Dioxin Dosage and Enlarged Prostate in Mice**

| Enlarged Prostate | Dosage | | | | |
|---|---|---|---|---|---|
| | **None** | **Low** | **Medium** | **Heavy** | **Total** |
| Yes | 2 | 5 | 6 | 8 | **21** |
| No | 21 | 20 | 19 | 12 | **72** |
| **Total** | **23** | **25** | **25** | **20** | **93** |

### *Chi-Square for* R×C *Table*

Following the argument similar to that explained for **chi-square—overall**, the test criterion for an $R \times C$ table is

$$\text{chi-square for } R \times C \text{ table: } \chi^2 = \sum_{rc} \frac{(O_{rc} - E_{rc})^2}{E_{rc}};\ r = 1, 2, \ldots, R;\ c = 1, 2, \ldots, C,$$

where $E_{rc}$ is as already mentioned. The present section is restricted to the case in which $R = 2$ but $C > 2$; however, there is no such restriction for the above criterion. A large value of $\chi^2$ would indicate that the observed frequencies are very different from those expected under the null hypothesis and thus would provide evidence against the null. For it to be statistically significant, the $\chi^2$ value should be as large as is very unlikely to occur under $H_0$. As usual, it is considered very unlikely when the chances are less than the level of significance, say, 0.05. Statistical packages would readily give this *P*-value, so that a conclusion can be immediately drawn. This would again depend on the df. On the lines discussed under **degrees of freedom**, it can be seen for an $R \times C$ table that df = $(R - 1)(C - 1)$. In Table C.8, only $(2 - 1)(4 - 1) = 3$ cells out of 8 can be freely chosen because the row totals and column totals cannot be disturbed. This is the df in this example.

For the data in Table C.8, by the formula just given,

$$\chi^2 = \frac{(2-5.19)^2}{5.19} + \frac{(5-5.65)^2}{5.65} + \cdots + \frac{(12-15.48)^2}{15.48} = 6.13.$$

A statistical package gives $P = 0.105$ for 3 df. This shows that the chance of data coming from a population for which $H_0$ is true is not sufficiently small. The plausibility of $H_0$ is not adequately ruled out. Thus, $H_0$ cannot be rejected. The conclusion is that the dose level of the chemical does not significantly affect the proportion with enlarged prostate in these data.

The chi-square criterion in the above equation considers each dose level in this example on a nominal scale and is oblivious of its ordinal character. If the gradient or the trend is the concern, proceed as discussed under **chi-square test for trend in proportions and deviation from trend**. If there are repeated measures of the same subjects, use the **Cochran *Q* test**. For details, see Agresti [3].

### *Two Polytomous Variables*

Now we extend the method to $R \times C$ tables where both $R$ and $C$ are more than two. The objective is to find whether one qualitative variable is related to or affected by the other. For example, the interest may be in the relationship of extent of smoking (none, mild, moderate, heavy) to **social classification** of people. Or it may be on the influence of nutritional status (good, fair, poor) of pregnant women on maternal complications. Both variables are polytomous in these examples.

The basic method for finding whether or not the two qualitative variables with multiple categories are associated continues to be the same chi-square as given above provided the condition of large $n$ is met. The following example illustrates the method.

Douglas et al. [4] investigated the seasonality of sudden infant death syndrome (SIDS) by age at death in the United Kingdom. A total of 13,990 such deaths were observed. They provided data for each calendar month of death and each year of age. A summary is given in Table C.9. This table has $R = 4$ rows and $C = 3$ columns excluding totals. The total $n$ is very large, and no expected cell frequency under $H_0$ would be less than 5. Thus, this is a very appropriate case for applying the chi-square test. Statistically, this is a cross-sectional study in which 13,990 sudden deaths are divided by age at death and calendar month of death. The null hypothesis is that age at death of infants was not associated with the calendar month of death. The expected frequency under this $H_0$ can be obtained for each cell by the formula given earlier and the chi-square value by the above-mentioned formula or by statistical software. A software package obtained $\chi^2 = 40.46$ for these data. This has $(4 - 1)(3 - 1) = 6$ df. The package gives $P = 0.000$ (it should be stated as $P < 0.001$). This is far less than the conventional 0.05. Thus, $H_0$ was rejected, and it was concluded that age at death was indeed associated with the calendar month of death. Perusal of the data indicates that the deaths were proportionately more in January to April for those who died after 5 months of age. The biological implication of this result is not clear.

**TABLE C.9**
**Age and Calendar Month of Sudden Infant Deaths**

| Age at Death (Months) | Calendar Month of Death | | | |
|---|---|---|---|---|
| | Jan–Apr | May–Aug | Sep–Dec | Total |
| <2 | 831 | 490 | 745 | **2066** |
| 2–4 | 3163 | 1833 | 3022 | **8018** |
| 5–8 | 1457 | 750 | 1104 | **3311** |
| 9–12 | 283 | 140 | 172 | **595** |
| **Total** | **5734** | **3213** | **5043** | **13,990** |

Chi-square for $R \times C$ tables is valid for retrospective and prospective studies as much as for cross-sectional studies. Thus, the method remains the same for the three types of design. However, the nature of the null hypothesis, and hence of the conclusion, changes. As explained under **association in prospective, retrospective, and cross-sectional studies**, the null hypothesis in the case of a cross-sectional study is of independence of the two variables. If this is rejected, an association is concluded. In the case of retrospective and prospective studies, the null hypothesis is of a similar pattern of proportions in different groups. This is the hypothesis of homogeneity.

For completeness, it should be reiterated for $R \times C$ tables that the method of chi-square is again suitable only for large $n$. Strictly speaking, no expected cell frequency $E_{rc}$ should be less than five. As stated earlier, if there is a large number of cells, then possibly some relaxation can be made, but not more than 20% of expected cell frequencies should be less than five and none should be very small, say less than one. When the numbers are really small, you may have to collapse rows or columns or both. In an extreme case, the table may have to be collapsed to 2×2 and use the **Fisher exact test** if cell frequencies continue to be small. Collapsing should be done in a manner that biological relevance is not lost.

The chi-square test mentioned above evaluates only whether an association is present or not. The association may be present in specific cells, but the number of subjects in the other cells can mask it. This can be unmasked by a suitable **partitioning** of the table. Another point of interest may be the degree of association between two qualitative variables. For this, see **association between polytomous characteristics (degree of)**. For association in matched pairs with many categories ($C \times C$ tables), see the **McNemar–Bowker test**. The association in larger tables can also be studied by **log-linear models**.

C

## chi-square test for goodness-of-fit, *see* goodness-of-fit

## chi-square test for odds ratio and relative risk, *see also* chi-square test for 2 × 2 tables

Those not familiar with the **odds ratio (OR)** and **relative risk (RR)** may like to view these topics first. Also see **test of hypothesis** for apprising yourself about statistical tests. The chi-square test is used to test the null hypothesis ($H_0$) that OR = 1 or RR = 1 depending on whether the study is retrospective (from the outcome to the antecedent) or prospective (from the antecedent to the outcome). These two null hypotheses say that there is no relationship between the antecedent and the outcome. We explain these tests for OR and RR separately in the following paragraphs. These are basically same as the **chi-square test for 2 × 2 tables** for two independent samples.

### *Chi-Square Test for OR*

The $H_0$ in this case almost invariably is that OR = 1. This says that the presence of the antecedent is as common in cases as in controls. Since OR = RR if the outcome is rare, $H_0$: OR = 1 also says that the presence or absence of the antecedent does not influence the outcome in situations where the outcome is rare. A simple statement that takes care of both the directions of the relationship is that there is no association under $H_0$ between the antecedent and the outcome. The alternative could be one-sided ($H_1$: OR < 1 or $H_1$: OR > 1) or two-sided ($H_1$: OR ≠ 1). The latter is applicable when there is no a priori assurance that the relationship could be one-sided. The two-sided hypothesis is tested by classical **chi-square**. For the one-sided alternative, use ***z*-test**.

Suppose that 80 promiscuous males who were recently found to be HIV positive and 160 promiscuous controls (two controls per case) of the same age and socioeconomic–cultural–ethnic background are asked about their sexual behavior in terms of average frequency of extramarital contacts per month during the last 2 years. The data obtained are in Table C.10.

**TABLE C.10**
**Extramarital Contacts in HIV+ Subjects and Controls**

| | Average Extramarital Contacts/Month | | |
|---|---|---|---|
| **Group** | **One or More** | **Less Than One** | **Total** |
| HIV+ | 38 | 42 | **80** |
| Controls | 51 | 109 | **160** |
| **Total** | **89** | **151** | **240** |

The column totals in this case are 89 and 151, respectively, and $n = 240$. Thus, for chi-square, the expected **cell frequency** $E_{ij}$ in the $(i, j)$th cell is given by

$$E_{11} = \frac{80 \times 89}{240} = 29.67, \quad E_{12} = \frac{80 \times 151}{240} = 50.33,$$

$$E_{21} = \frac{160 \times 89}{240} = 59.33, \quad E_{22} = \frac{160 \times 151}{240} = 100.67.$$

Therefore, $\chi^2 = \Sigma[(O - E)^2/E]$ gives

$$\chi^2 = \frac{(8.33)^2}{29.67} + \frac{(8.33)^2}{50.33} + \frac{(8.33)^2}{59.33} + \frac{(8.33)^2}{100.67} = 5.58.$$

A computer package gives for 1 df $P(\chi^2 \geq 5.58) = 0.018$. The *P*-value is exceedingly small. There is an exceedingly small chance that this sample has come from a population where $H_0$: OR = 1 is true. Reject $H_0$ and conclude that OR ≠ 1. HIV positivity is associated with one or more average extramarital contacts per month in promiscuous males. In this case, OR = (38 × 109)/(51 × 42) = 1.93. This shows that the odds of one or more extramarital contacts per month are nearly twice as much in HIV-positive males as in the controls.

### *Chi-Square Test for RR*

This is similar to the test for OR just described. The null hypothesis is RR = 1 (no relationship). Consider the data in Table C.11 on lower tract illness in boys born to women of age <26 and ≥26 years.

For the data in Table C.11, the expected frequencies under $H_0$ can be calculated as usual, and chi-square can be calculated by the formula given for OR. This gives

$$\chi^2 = \frac{(48 - 37.29)^2}{37.29} + \frac{(117 - 127.71)^2}{127.71} + \frac{(65 - 75.71)^2}{75.71} + \frac{(270 - 259.29)^2}{259.29} = 5.93.$$

A statistical software package gives $P = 0.015$. The null hypothesis is rejected. Conclude that RR ≠ 1.

Note that chi-square is a two-tailed test and so the conclusion too is two-sided. If there is an a priori reason to ensure that RR would be more than 1, then $H_1$: RR > 1. It may be prudent then to use ***z*-test**.

## chi-square test for three-way contingency tables

If you are not already familiar with chi-square for two-way tables, familiarize yourself with the details described under the **chi-square**

**TABLE C.11**
**Maternal Age and Lower Respiratory Tract Illness (LRI) in Infant Boys**

| | LRI | | |
|---|---|---|---|
| **Maternal Age (Years)** | **Yes** | **No** | **Total** |
| <26 | 48 | 117 | **165** |
| ≥26 | 65 | 270 | **335** |

**test for larger two-way contingency tables**. These methods are extended in this section for three-way tables.

A three-way contingency table arises when the classification of the subjects is done with respect to three variables. Thus, this is a genuine multivariate categorical data setup—a step more than the bivariate setup in two-way contingency tables. The variables could be either on a nominal or on an ordinal scale. If any of them is on a metric scale, then it should be either discrete with a small number of values or continuous divided into a small number of broad categories for the methods of this section. This means that a variable such as aspartate aminotransferase (AST), formerly called serum glutamic-oxaloacetic transaminase (SGOT), should have categories such as (in U/L) 0–49, 50–99, and 100+ at least for constructing a contingency table and not small categories like 0–9, 10–19, 20–29, etc. In any case, the categories should be **mutually exclusive and exhaustive**. The interest must be in proportions of subjects in different categories and not the mean level.

Table C.12 is an example of a three-way table where the variables are visual acuity (VA), age group, and gender. Besides row and column, the third dimension is called *layer*. The numbers of rows, columns, and layers can be denoted by $R$, $C$, and $L$, respectively. In Table C.12, $R = 5$, $C = 3$, and $L = 2$. We have chosen to consider VA categories as main columns and gender as a subclassification (layer). You may wish to switch the labels, and that would be equally valid. The order of this table is $5 \times 3 \times 2$. The body of the table has 30 cells. The columns and rows with totals are not included in this count.

Denote the probability that a random person from the target population falls in the $(r, c, l)$th cell by $\pi_{rcl}$ ($r = 1, 2, \ldots, R$; $c = 1, 2, \ldots, C$; $l = 1, 2, \ldots, L$), and the observed frequency in the cell by $O_{rcl}$. The methods described in the present section are valid for large $n$ and need $E_{rcl} \geq 5$ in at least 80% of the cells, where $E$ is the expected cell frequency under the null hypothesis ($H_0$). One method for obtaining $E$'s for three-way tables will be described shortly. The case for small $n$ is too complex. In any case, it is seldom prudent to classify a small number of subjects simultaneously by three characteristics. Each of these characteristics will have a minimum of two categories, and thus, there are at least $(2 \times 2 \times 2 =) 8$ cells in a three-way contingency table.

The analysis of three-way contingency tables described in this section is not necessarily a comparison of three groups. One group of subjects can be cross-classified by levels of two variables. For example, Table C.12 can be considered to cross-classify subjects in three VA groups by age and gender.

As in the case of two-way tables, the null hypothesis in a three-way table could be that of homogeneity of different types, or of independence, depending upon individual variables being factors or responses. In Table C.12, if a sample of 520 males and 480 females was chosen and their age and VA elicited, then gender is a factor and the other two (VA and age) are responses. In this case, $H_0$ could be that age and VA have the same pattern of relationship in males as in females. If a sample of 1000 subjects is chosen and they are cross-classified by age, gender, and VA, then all three are responses, and $H_0$ is that of independence of the variables. Luckily, no matter what the type of $H_0$ is, the calculation proceeds along the same lines. Only the interpretation differs. The calculation is in terms of the usual $\chi^2 = \Sigma(O - E)^2/E$, although the calculations of $E$'s are not so straightforward in this case. These are illustrated in the following example.

Consider a survey carried out in Brazil among female family planning clients to study the profile of women who approve of sterilization [1]. The profile was studied in terms of the age of the women, the number of living children (LC), and the age of the youngest child. The data obtained on 1250 approvers are given in Table C.13.

**TABLE C.13**
**Women Approving Sterilization in a Survey in Brazil**

| | Observed Frequencies | | | |
|---|---|---|---|---|
| **Age of Woman and LC[a]** | **Age of the Youngest Child (Years)** | | | |

C

This is a cross-sectional study and all the three variables are responses. Thus, the appropriate $H_0$ is of independence, which in this case says that sterilization approvers are not concentrated in any specific combination of the categories of age, LC, and age of the youngest child.

Consider LC to be in rows so that $R = 3$, age of the youngest child in columns so that $C = 3$, and the age of woman in layers so that $L = 2$. The corresponding indexing subscripts are $r$, $c$, and $l$, respectively. The bottom part of the table is a two-way table with age collapsed. Total 1 and Total 2 give another two-way table with LC collapsed. The last row is a one-way table with age of women and LC collapsed.

Following a procedure similar to the one used for two-way tables, the expected frequencies for some cells under $H_0$ are calculated next. These are obtained by multiplication of the corresponding row, column, and layer totals divided by the grand total as illustrated in the following:

$$E_{111} = 1250 \times \frac{461}{1250} \times \frac{410}{1250} \times \frac{414}{1250} = 50.08 \text{ (observed} = 37),$$

$$E_{211} = 1250 \times \frac{334}{1250} \times \frac{410}{1250} \times \frac{414}{1250} = 36.28 \text{ (observed} = 63),$$

$$E_{311} = 1250 \times \frac{455}{1250} \times \frac{410}{1250} \times \frac{414}{1250} = 49.43 \text{ (observed} = 77), \text{ and}$$

$$E_{112} = 1250 \times \frac{461}{1250} \times \frac{410}{1250} \times \frac{836}{1250} = 101.13 \text{ (observed} = 40).$$

These frequencies are for the first four cells (excluding Total 1) of the first column in the table. The numerators are the corresponding marginal totals. All other expected frequencies can be calculated in a similar manner. These and their totals are arranged in Table C.14.

**TABLE C.14**
**Expected Frequencies of Women in the Example When They Are Not Affected by Age of Woman, Number of Living Children (LC), and Age of the Youngest Child**

| | Expected Frequencies | | | |
|---|---|---|---|---|
| | Age of the Youngest Child (Years) | | | |
| **Age of Woman and LC** | **–1** | **1–4** | **5+** | **Total** |
| | **Age ≤ 30 Years** | | | |
| LC < 3 | 50.08 | 56.31 | 46.29 | **152.68** |
| LC = 3 | 36.28 | 40.80 | 33.54 | **110.62** |
| LC > 3 | 49.43 | 55.58 | 45.69 | **150.70** |
| **Total 1** | **135.79** | **152.69** | **125.52** | ***414*** |
| | **Age > 30 Years** | | | |
| LC < 3 | 101.13 | 113.71 | 93.48 | **308.32** |
| LC = 3 | 73.27 | 82.38 | 67.73 | **223.38** |
| LC > 3 | 99.81 | 112.23 | 92.26 | **304.30** |
| **Total 2** | **274.21** | **308.32** | **253.47** | ***836*** |
| | **All Ages** | | | |
| LC < 3 | 151.21 | 170.02 | 139.77 | **461** |
| LC = 3 | 109.55 | 123.18 | 101.27 | **334** |
| LC > 3 | 149.24 | 167.81 | 137.95 | **455** |
| **Total** | ***410*** | ***461*** | ***379*** | ***1250*** |

Note that the totals given in bold italics match the corresponding observed totals in Table C.13. The calculation of $\chi^2$ is done as usual with the following formula:

$$\text{three-way table: } \chi^2 = \sum_{rcl} \frac{(O_{rcl} - E_{rcl})^2}{E_{rcl}};$$

$$r = 1, 2, \ldots R;\ c = 1, 2, \ldots C;\ l = 1, 2, \ldots, L.$$

Under $H_0$, this follows a chi-square distribution with df = $(R - 1)(C - 1)(L - 1)$. In this example, df = $(3 - 1)(3 - 1)(2 - 1) = 4$ and $\chi^2 = 277.47$. A software package gives $P << 0.05$. Thus, the hypothesis of independence is rejected. Conclude that at least two of the three variables are associated among the family planning approvers.

The detailed calculations are not shown. The purpose is to illustrate the *type* of calculations required in a three-way setup. Analysis of such tables of higher dimensions is indeed complex, but this should not be a worrying factor as long as valid conclusions can be drawn. Statistical software packages do such calculations easily.

Chi-square in the above formula gives an overall test. If significant, it indicates only that an association is present *somewhere*. To find exactly where this association is, one approach is partitioning as discussed under **partitioning of chi-square** for a one-way table. The second and more versatile approach is using **log-linear models**. When one of the variables can be considered dependent as in the case of prospective and retrospective studies, use **logistic regression**. This can handle a large number of variables simultaneously.

## chi-square test for trend in proportions and deviation from trend

A version of **chi-square** is available that can be used for testing the presence or absence of an increasing or decreasing trend in proportions in **ordinal** categories. Before we give the details of the procedure followed for this test, consider the following example.

The data in Table C.15 are from an experiment on mice exposed to different dosages of dioxin to find the effect on developing enlarged prostate. It is easy to see from the first three rows of Table C.15 that the proportion with enlarged prostate increases with dose of dioxin. But that is the observation in this sample. Is there a substantial likelihood that the trend will persist in repeated samples?

**TABLE C.15**
**Dioxin-Treated Fetal Mice with Enlarged Prostate and Some Calculations for Chi-Square for Trend**

| | Dosage Score ($x_k$) | | | | |
|---|---|---|---|---|---|
| | **0** | **1** | **2** | **3** | **Total** |
| Number of mice ($n_k$) | 23 | 25 | 25 | 20 | **93** |
| With enlarged prostate ($O_{1k}$) | 2 | 5 | 6 | 8 | **21** |
| Proportion with enlarged prostate ($p_k = O_{1k}/n_k$) | 0.09 | 0.20 | 0.24 | 0.40 | **0.2258** |
| $O_{1k}x_k$ | 0 | 5 | 12 | 24 | **41** |
| $n_k x_k$ | 0 | 25 | 50 | 60 | **135** |
| $n_k x_k^2$ | 0 | 25 | 100 | 180 | **305** |

A study of trend in proportions is relatively simple when the ordinal categories can be assigned a valid **score**. For the data in Table C.15, these scores for dosages could be 0, 1, 2, and 3 for none, low, medium, and heavy doses, respectively. Note that such linear scores have an inbuilt assumption that the difference between the effect of the no-dose and low-dose categories is the same as that between the heavy- and medium-dose categories, the effect of a heavy dose is three times that of a mild dose, etc. These scores are considered as usual metric quantities amenable to algebraic manipulations. This may not be exactly true in many situations. Yet, such scores seem to work reasonably well as an approximation in most practical situations.

One can also think of nonlinear scores for assessing trends. Condom use among patients with sexually transmitted diseases can be categorized as never, sometimes, often, and almost always. Spouse infection percentage may follow a trend in this case depending on the frequency of condom use. The scores to the regularity of condom use can be given as 0 for never, 1 for sometimes, 3 for often, and 6 for always. A scoring that adequately expresses the intensity of categories is not easy to devise, but some methods of determining scores are discussed under **scoring systems** in this volume. Results for trend would differ depending upon what scores are used.

Some additional calculations shown in Table C.15 are needed to compute the chi-square for the trend in proportions. The proportion with an enlarged prostate in this example steadily rises from 0.09 for no dosage of a dioxin-like chemical to 0.40 for a heavy dosage. Among various methods available to find the statistical significance of this trend, one method is to calculate

$$\text{chi-square for trend: } \chi^2_{\text{trend}} = \frac{(\sum O_{1k}x_k - O_{1\cdot}\bar{x})^2}{p(1-p)(\sum n_k x_k^2 - n\bar{x}^2)};\ k = 1, 2, \ldots, K,$$

where $O_{1\cdot} = \Sigma O_{1k}$, $n = \Sigma n_k$, $p = O_{1\cdot}/n$, and $\bar{x} = \Sigma n_k x_k/n$. The notation $x_k$ is for the dosage score. The criterion in this expression follows a chi-square distribution with only 1 df. A test can be performed as usual by finding the *P*-value. Sometimes this is called the **Cochran test for linear trend**.

In the case of Table C.15, $n = 93$, $O_{1\cdot} = 21$, $\bar{x} = 135/93 = 1.4516$, $p = 21/93 = 0.2258$, $\Sigma O_{1k}x_k = 41$, and $\Sigma n_k x_k^2 = 305$. Thus,

$$\chi^2_{\text{trend}} = \frac{(41 - 21\times 1.4516)^2}{0.2258\times 0.7742\ (305 - 93\times 1.4516^2)}$$
$$= \frac{110.5947}{19.0610}$$
$$= 5.80.$$

A computer package gives $P = 0.016$ for this value of chi-square at 1 df. Since this is less than 0.05, reject the null hypothesis of no trend at 5% **level of significance** and conclude that a trend in proportions is present. Note the following:

- When the scores are equally spaced as in Table C.15 ($x_k$ = 0, 1, 2, and 3), the chi-square in the criterion in the above equation tests linearity. Thus, the test performed above is for assessing *linear trend*. With only four categories in Table C.15, it may not be a good idea to investigate a curve. But the presence of a curve can also be tested by suitably modifying the scores. In this example, these could be changed to 0, 1, 4, and 9 (square of $x_k$) or any other plausible values for investigating a trend other than linear.
- The overall chi-square (as calculated by the usual method) value for the data in Table C.15 is 6.13. The difference between this and the value of $\chi^2_{\text{trend}}$ is the chi-square for deviation from the trend, i.e.,

$$\chi^2_{\text{deviation},(K-2)\text{df}} = \chi^2_{\text{overall}(K-1)\text{df}} - \chi^2_{\text{trend, 1 df}},$$

  where the left-hand side is the chi-square for deviation from the trend. A large value of this chi-square would indicate that a trend other than that studied is significant. In that case, other kinds of trend can be tried. For the data in Table C.15,

$$\chi^2_{\text{deviation,2df}} = 6.13 - 5.80 = 0.33.$$

  This is not significant ($P > 0.05$). The trend, in this case linear, seems adequate, and there is no statistical need to study any other kind of trend.
- As for any chi-square, this procedure is valid for only large $n$. In fact, all $n_k$'s should be reasonably large. Also, many $p_k$'s should not be close to 0 or close to 1.
- In this example, the chi-square for trend is significant, although the overall chi-square is not. This can happen because the test for trend has greater power to detect trend than the overall chi-square test. It is important to realize that the chi-square for trend and the general chi-square test the same null hypothesis, namely, equal proportions in different categories, but they are designed to detect different types of alternatives. The $\chi^2_{\text{trend}}$ is specially designed for the alternative that a trend exists in proportions, whereas the usual chi-square is an overall test for any type of association.
- Ordinal data are sometimes perceived to arise from categorical metric data. For investigating the association between maternal drinking and congenital malformations, Grauband and Knor [1] categorized the average number of alcohol drinks per day as 0, <1.0, 1.0–2.9, 3.0–5.9, ≥6.0. Since the categories are metric, midpoints seem to be the most appropriate scores for this kind of analysis. You should try to resist the temptation to use equally spaced scores such as 0, 1, 2, 3, and 4 in such cases since the drink categories are not following such linear pattern.

## choroplethic map, *see also* thematic map, spot map

Choroplethic map is a geographical map where areas are shaded according to the grading of the indicator under study. Areas with similar values get the same shade, and the shading becomes darker as the rate increases. This kind of map is good for an indicator that can be considered evenly distributed over all units of the area with the same shade. One such map is shown in Figure C.11 that depicts under-five mortality rates (U5MR) in the countries of the Asia-Pacific region for the year 2000. In this map, for example, all states of India are assumed to have the same under-five mortality. Australia has very low mortality and thus is lighter in color, and Laos and Cambodia have very high mortality and thus get the darkest color.

The selection of class intervals is critical for choroplethic mapping as different class intervals and different number of categories

C

**FIGURE C.11** Choroplethic map of under-five mortality rate in countries of the Asia-Pacific region.

can provide a different picture. In Figure C.11, the categories of U5MR are four (very low, low, high, and very high), but the cutoffs are not mentioned. Quite often, the categories of indicator values in choroplethic maps are arbitrarily chosen of equal width, and the number of categories also remains arbitrary. This introduces considerable subjectivity in the cognition and perception obtained from the maps. A discussion on this aspect is given by Indrayan and Kumar [1], who advocate that the categories should be natural, as dictated by the data, in place of arbitrary choices. These natural categories can be identified by consensus in the groups obtained by various methods of **cluster analysis**, and the picture thus obtained can be substantially different from the one based on equal-width categories. The four categories (excluding "data missing") shown in Figure C.11 are based on consideration of the statistical proximity in rates based on one method of cluster analysis but not on consensus across methods.

For further details of choroplethic maps, see Slocum et al. [2].

## civil registration system, *see* birth and death registration

## circular sampling, *see* systematic sampling

## classification, *see also* discriminant analysis/functions, cluster analysis

Classification is a generic term used for putting units into categories so that similar ones go into the same category and those that differ go into another category. When the categories are not known and are to be established, this is done through **cluster analysis**. In statistics, the term *classification* applies when the categories are already known. Statistical classification is assigning a unit to its most likely category out of a few possible known options. This presupposes that the broad category is known but the specific category is not known and is surmised on the basis of whatever ancillary information is available on that unit. For example, we may know that the patient has a liver disease but do not know which liver disease—it could be malignancy, cirrhosis, or hepatitis. On the basis of clinical and laboratory parameters, the patient is classified into one of the three possible categories and treated accordingly.

You can see that the statistical classification is based on probabilities. The unit is assigned to that category that is most likely, and this likelihood is obtained on the basis of the ancillary information.

Classification requires that a rule be established that can evaluate the probability of the unit belonging to each of the possible categories. This is called a *classification rule* or a *classification model* or *classification criteria*. The general procedure for this is to study the ancillary information of a sample of $n$ units whose classification is already known. Use this to develop a relationship between the probability of each category and the ancillary information. Check that this rule is working well not just on the sample used to develop it but also on another sample. This is done by preparing, what is called, a *classification table* (an example is in Table C.16). Its **robustness** for minor variations in the ancillary information is also ensured.

**TABLE C.16**
**Classification Table for Dichotomous Categories**

| Classified by the Model | Observed in the Sample | | |
|---|---|---|---|
| | Disease Present | Disease Absent | Total |
| Disease present | 65 | 5 | **70** |
| Disease absent | 35 | 95 | **130** |
| **Total** | **100** | **100** | **200** |

Only after such **validation** can this rule be used to classify the subjects whose categories are not known. Despite full care, many classification models fail to perform well in practice because possibly some crucial information was not considered at the time of developing the model, or there were other unsuspecting mishaps such as **confounding** or **multicollinearity** among the data used as ancillary information, or because the information on the category or the ancillary factors for some units was not correct.

Out of many possible **algorithms**, the easiest is when there are only two possible categories. These could be such as the person has a particular disease or not, the person is likely to survive for at least 5 years or not, a bone found in an excavation belongs to a male or a female, a medical test is sufficiently good for detecting a condition or not, or any other yes/no or positive/negative type of categories. The most common method for analyzing the relationship of dichotomous categories with other factors is logistic regression. Details are given under the topic **logistic regression**, but briefly, in a logistic regression, the probability of one of the dichotomous categories is considered as the dependent variable and the ancillary information is considered as independent variables. This is run for $n$ units whose category is already known and a logistic model is obtained. As a first step, this model is tried out on the base units that were used to develop the model. A unit is classified as positive if its model-predicted probability exceeds 0.5; otherwise, it is classified as negative. If this model performs well (say, it is able to correctly classify at least 90% units—called *classification accuracy*), the model is considered good.

The classification rule is tried on another sample where also the classification is already known. Note that the classification accuracy can be evaluated in this case since their category is already known. It is only after such external validation that a model such as logistic is adopted for classification of future units.

The results in Table C.16 are for a case–control study of 100 cases and 100 controls. Logistic regression was run for some variables containing the ancillary information. The classification accuracy of this model is (65 + 95)/200 = 80%, as these many were correctly classified. This is not bad. However, also consider that the model has been able to correctly classify 95 of 100 negative subjects but only 65 of 100 positive subjects. Thus, the model is mostly good in identifying subjects with no disease but performs poorly in correctly classifying subjects with the disease. The overall classification accuracy may mask specific performance of the classification model. Just be careful about such anomalies.

For multiple categories, the method of discriminant function is commonly used for classification. The details again are under the topic **discriminant analysis**, but briefly, mostly a set of linear combinations of the variables in the ancillary information is obtained in this method that has the maximum classification accuracy. If there are $K$ categories, a total of $(K - 1)$ combinations would be required under this method. These would divide $n$ subjects into $K$ **mutually exclusive and exhaustive categories**. The same combinations can be used to classify future units provided that the model is validated and robust.

The term classification is also used for nonstatistical categorization in health and medicine, for example, social classification of people based on income, education, and occupation, and classification of subjects in a clinical trial into those with no disease (controls), mild disease, moderate disease, serious disease, and critical disease. Such classifications have no probability element and are thus called nonstatistical.

## classification and regression trees

Classification and regression trees are a method that can help in predicting one of the many possible categories of a subject. The **dependent variable** must be **categorical** for this method. The emphasis in this method is on simplification of a complex process without compromising the accuracy of prediction. It determines a set of logical *if–then* conditions instead of linear equation for predicting the category of a subject. Such statements are straightforward, easily understood, and intuitively appealing. The method is nonparametric and does not need Gaussian distribution of the underlying variables; it does not need linearity either. The tree method is particularly suitable for data exploration where a priori information is scanty, and where biological reasons are not immediately available for classification. The method can sometimes reveal simple relationships between just a few variables that can go unnoticed by other methods.

Consider predicting whether a subject with multiple injuries (in motor vehicle accident, earthquake, etc.) is going to be a survivor with no disability, is going to be a survivor with some disability, or is not going to survive at all. The dimension of injuries can be observed as organs affected, severity of injury, number of fractures, etc. The individual's own characteristics such as age, sex, muscular strength, and bone density may be the other determining factors for the outcome. Emergency help (time elapsed since injury), available medical facilities, and expertise of the medical care providers are also important. In place of saying that one factor will contribute 5%, another 10%, etc., would it not be nice to say that if the head is injured, the age is less than 60 years, and medical help is excellent but available 2 h after the injury, then the person is most likely to survive but will have residual disability? Classification and regression tree has precisely this function.

The tree algorithm, as the name suggests, devises split nodes that generate branches by using if–then rules. The adequacy of prediction is tested at each step. A fresh split node is not needed when the preceding node does not improve the accuracy of prediction. It is possible that a tree so created still fails to correctly classify an adequate percentage of subjects. As in all other prediction methods, this failure would indicate that the predictors chosen for this purpose are not of the right kind. Also, if the tree becomes very large with many branches, it loses much of its operational utility.

The tree method is complex and we are describing only the essential features. For details, see Breiman et al. [1]. Briefly, the algorithm begins by identifying a **predictor** that splits the total subjects into two groups such that the subjects are similar within groups and dissimilar across groups, and the classification is correct for the largest percentage of subjects. The groups can be such that they have the strongest association with the response categories. If a predictor is quantitative, various cutoff points are tried, and the one providing the least within-groups **sum of squares** is chosen. For a qualitative predictor with $K$ categories, all $(2^K - 1)$ possible splits are tried. Then the process is repeated at second and subsequent steps with new predictors. The process stops when it does not significantly add to the accuracy of classification.

It is customary in classification and regression trees to define a "loss function" for misclassification. Some misclassifications have more severe implications than others, and for them, a larger loss is defined. The loss may be in terms of financial cost, in terms of inconvenience to the health agencies and the person concerned, or simply statistical with regard to the increase in **least squares** or increase in **proportional reduction in error**.

There is some similarity between classification trees and **discriminant analysis**. In the latter case, all predictors are considered together to classify a subject, whereas in the trees, one or a few predictors are considered in the first step, another one or more in the second step, yet another set in the third step, etc. More than three steps make the process too complex and generally not considered appropriate for classification trees.

Téllez-Gabriel et al. [2] used classification and regression tree analysis to establish two groups of patients of head and neck

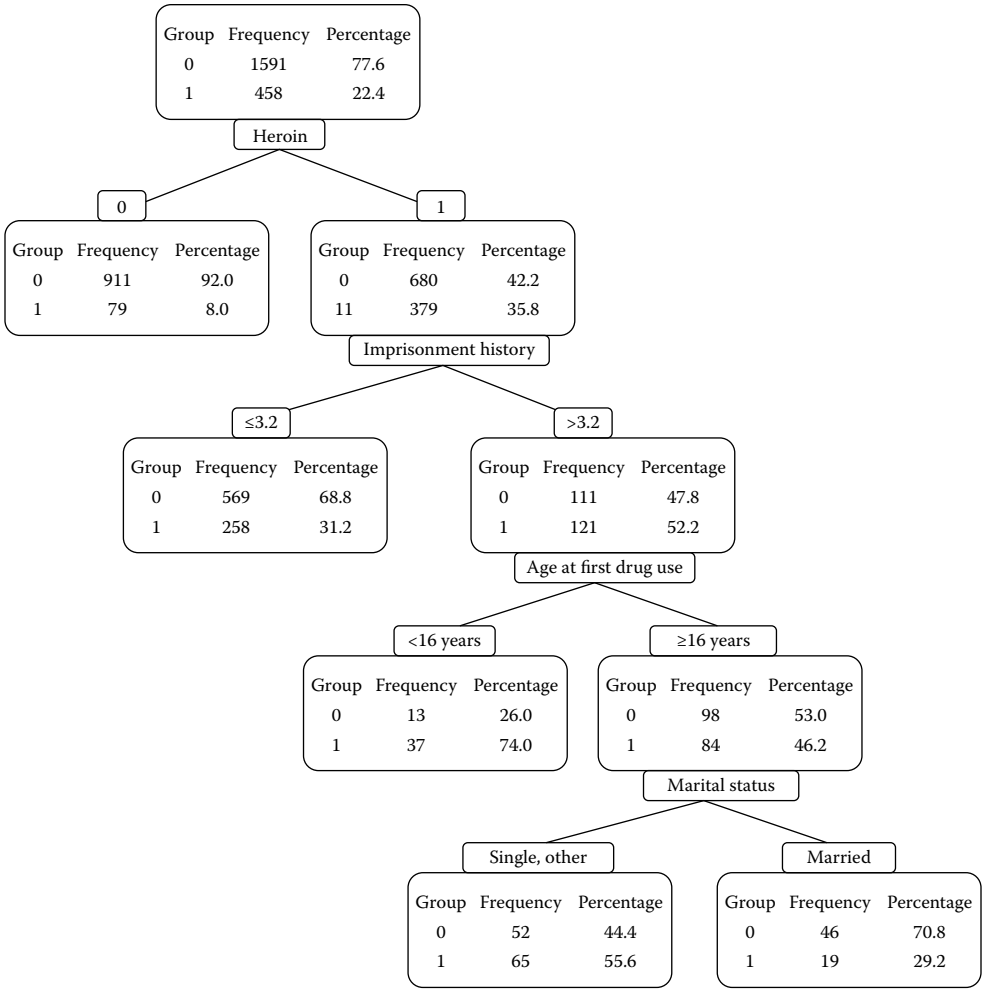

**FIGURE C.12** Classification and regression tree on training data (Code 1: prisoners with the history of drug injection). Note: At each node, the group with the highest percentage was considered as the predicting group. (From Rastegari A et al., *Addict Health* 2013 Winter–Spring;5(1–2):7–15. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3905563/. With permission.)

squamous carcinoma according to their RAB25 mRNA level and their risk of death. Rastegari et al. [3] have provided a simple example of use of classification and regression trees for factors influencing drug injection history among prisoners in Iran (Figure C.12). This is not an ideal example but illustrates the application.

## class intervals

Class intervals divide the range of possible values of a variable on a **metric scale** into a small number of **categories** in order to facilitate the understanding and communication of the essentials, particularly the distribution, of a dataset. For example, for diastolic level (mmHg) of blood pressure (BP), you can have the number of people (frequency) with BP in class intervals 70–74, 75–79, 80–84, etc. This is also called grouping of data. Each interval has a lower limit and an upper limit, and the difference is called the width of the interval. In our example, each interval has width 5 mmHg, although the difference between the upper and lower limit is 4. This is because BP is measured in terms of integers, and the interval 70–74, for example, has values 70, 71, 72, 73, and 74, which are five values.

An inbuilt problem with the data reported in class intervals, such as cited for BP, is that the values 70 and 74 fall in the same interval, whereas values 74 and 75 fall in different intervals despite a relatively small difference. When you decide to use intervals, you automatically decide to live with this anomaly. However, a method such as **cluster analysis** can be used to discover natural cut points so that values within each interval have some kind of **affinity** compared with values in different intervals. For details, see Indrayan and Kumar [1], who have discussed it in the context of **choroplethic map**.

Formation of class intervals looks innocuous but requires extreme care. Many questions need answering before this can be done: how many intervals are appropriate, what should be the width of each

interval, should the width of all intervals be equal, whether any gap such as between 74 and 75 mmHg in our BP example should be allowed, etc. Common sense does play an important role in answering these questions, but the following guidelines may be helpful.

The question of class intervals arises only when you have a reasonably large sample. In case you have only six values, for example, there is no need to use class intervals since all these six values can be exactly stated. A rule of thumb is that you should have at least 10 values, preferably 20 or more values, before thinking of class intervals. It is customary to divide the range of values from minimum to maximum into at least four intervals for small $n$ and up to 12 intervals for large $n$. Equal intervals are preferred, but they are not a prerequisite. Thus, for diastolic BP of 15 persons that range from 68 to 90 mmHg, the intervals could be 68–73, 74–79, 80–85, and 86–91 mmHg. But for a sample of 80 persons, shorter intervals can be considered. If BP of 2000 persons is available, the intervals cannot be too short since the number of intervals should not exceed 12. Having a large number of intervals defeats the purpose of parsimony that class intervals are supposed to provide.

Same width of the intervals helps in interpretation. One can easily find which values are more common and which values are rather extreme. But exceptions can be made. Age intervals such as 0–1 year, 1–2 years, etc., for growth parameters in children are unacceptable since height and weight change so much from 0 to 1 month, 1 to 2 months, etc. For growth, monthly intervals may be needed up to, say, 6 months of age and then possibly quarterly intervals up to the age of 1 year. For health outcomes in general population, age intervals 0–1, 1–4, and 5–14 years are generally considered good. These do not have equal width.

The age intervals we just mentioned apparently have a gap, such as between 4 and 5 years. If the age is 4 years and 8 months on the date of interview, where will that child be placed? The convention in medical sciences is to record age in terms of completed years after the age of 1 year. Thus, a child of age 4 years and 8 months has completed 4 years but not 5 years. He or she will belong to the interval 0–4 years. Actually there is no gap between the intervals. Similarly, BP is measured in integers, although theoretically it is possible to have diastolic BP = 84.7 mmHg. We did not consider this possibility earlier in this section since such accuracy is not needed for BP measurement. Thus, there is no gap between, say, 80–84 and 85–89 mmHg intervals.

Another problem with the class intervals is our preference for categories beginning with 0 or 5. Hardly ever would one like to have intervals of width 7 or 8. Depending on the scale, the intervals would have width 0.1, 0.5. 1.0. 5, 10, etc. This arises from what is called **digit preference**. This causes no problem as long as the reporting and recording of values is accurate. However, often age 72 years is reported as 70 years and BP 137 mmHg is reported as 135. If that happens, you may like to consider different intervals such as 68–72, 73–77, etc. These would ameliorate the adverse effect of digit preference.

A further word of caution is in order. Class intervals should be used only for reporting of data and not for computations. Computations, such as for mean and standard deviation, have to needlessly assume that all the values in the interval are equal to its midpoint. For example, if you have 17 persons with BPs in the interval 80–84 mmHg, the calculations will be done as though all 17 values are 82 mmHg. This may be far too much of an approximation in some cases. Moreover, if exact values are available, there is no need to resort to any approximation. In some situations, though, the values are available in class intervals only. The age of women may be easy to elicit in the range, say, 20–29 years because some feel reluctant to give exact age. Similarly, for experiment on mice where they rapidly die, you may be able to visit the laboratory once every morning and note how many died during the last day. In this case, the exact time of death will not be available.

## clinical equipoise, *see* equipoises

## clinical equivalence, *see* equivalence (types of) in clinical trials

## clinically important difference, *see* medically important effect (the concept of)

## clinical tolerance range, *see also* medically important difference (test for detecting)

This is the deviation from the norm or from the expected that can be possibly allowed without compromising the welfare of the subject. For example, whether the systolic blood pressure is 184 or 186 mmHg, both require same treatment. If yes, this deviation of 2 mmHg is within the clinical tolerance. However, possibly 184 and 198 mmHg are too different to have the same clinical implication. Similarly, forgetting to take a drug once a week when the regimen is three times a day can be considered within clinical tolerance; forgetting to take four to five times a week can have some implication on the rate of recovery and cannot be ignored.

The term *tolerance* is quite often used to also assess the practical utility of the statistical models that calculate certain difficult-to-measure medical parameters. If brain volume by actual measurement is 1272 cc and by using a model based on simple measurements is 1258 cc, one may say that this difference is within clinical tolerance. But if the model tells us that the volume is 1225 cc, the difference does not look like within clinical tolerance. Whereas a too wide or too small difference can be easily interpreted without error, the difficulty arises when the difference is neither too big nor too small. As of now, no objective criteria are available, and they do vary from parameter to parameter, physician to physician, patient to patient. However, there are measurements for which there is a consensus. For example, Vanhatalo et al. [1] consider 3–10 min as the tolerance range for completing four constant-work-rate knee-extension exercise bouts inside the bore of 1.5 T superconducting magnet. This might be what is generally acceptable. In addition, for laboratory measurements, principles of **quality control** as described under this topic can be used to define tolerance range.

The third use of the clinical tolerance range is in assessing the acceptable doses such as of a drug or of radiation in radiotherapy. This relates to the side effects. Minor side effects in small percentage of subjects are tolerated, but drugs with major side effects or with side effects in a large percentage of cases are not approved.

Sometimes the normal range of medical parameters is termed as *tolerance range* as done by Shin et al. [2] for HbA1c values. Normal glucose tolerance range also illustrates similar usage.

## clinical trials (overview)

More for convention than semantics, medical experiments on human beings are called *trials*. The objective is to study the cause–effect relationship between a medical intervention and a health outcome in human subjects. Since the subjects are human, a large number of issues crop up ranging from stricter ethics to profound variations. Thus, trials do need extra care.

Clinical trials have a long history. Laplace wrote in 1825 that it is sufficient to "test each treatment on the same number of patients, while keeping all circumstances perfectly similar" [1]. In 1925, Fisher introduced randomization that helped eliminate biases due to uncontrolled factors and provided basis for using statistical inferential method. The first randomized clinical trial was done in 1946 on streptomycin by British Medical Research Council for the treatment of tuberculosis. The methodology of double blinding reached maturity in the 1970s [1].

Clinical trials are mostly done to investigate new modes of therapy. Research on new diagnostic procedures also falls in this category. Most clinical trials are carried out meticulously involving heavy investment. Since variation between and within subjects occurs due to a large number of factors, it is quite often a challenge to take full care of all of them. **Epistemic uncertainties** also play a significant role. It is imperative in this situation that the rules of **empiricism** are rigorously followed. This means that the trial should be conducted in controlled conditions so that the influence of extraneous factors is minimized, if not ruled out. Also, the trials should be conducted with a sufficient number of patients so that a trend, if any, can be successfully detected. Clinical trials are done in ideal conditions as much as possible to provide a realistic estimate of the **efficacy**. For estimating **effectiveness** in practical conditions, **pragmatic trials** are favored.

A human experimentation cannot be done unless sufficient reasons are present. The medical community must be sufficiently uncertain about the effect of the intervention under the trial. The regimen must have passed through rigors of preclinical phases before reaching humans (see **phases of the trials**). Preclinical phases involve studying biochemical properties and experiments on suitable animal models. It must be clearly established that the intervention is more likely to be beneficial than harmful. The motto "Do no harm" is scrupulously followed in all medical research including trials. If any unsuspecting harm is detected later on, the intervention is immediately discontinued. Patients, then clinicians, should be the overriding considerations instead of the researchers.

By their very nature, all trials are **prospective studies** where the **antecedent** is the intervention and the **efficacy** and safety are the outcomes. A follow-up is built into all the trials. Thus, many ideas discussed under observational **prospective studies** apply to the trial setup as well. All trials involve careful consideration of issues such as selection of subjects and controls, **randomization** and **matching**, and **blinding**, **masking**, and **concealment of allocation**. All these are presented separately under the concerned topic.

From the etiological point of view, clinical trials can be divided into six broad categories: therapeutic trials, diagnostic trials, screening trails, prophylactic trials, field trials, and vaccine trials. A brief description about them is given next. Clinical trials are a huge concern with several books devoted to this topic. Our description here is brief and introductory. For details, see, for example, Chow and Liu [2].

### *Therapeutic Trials—Efficacy and Side Effects*

The primary objective of a therapeutic clinical trial usually is to evaluate the safety and efficacy of a treatment regimen in individuals with different levels of severity of disease and of various backgrounds such as different age, sex, and nutritional status. Extreme care is required because therapeutic trials generally involve exogenous material that may have side effects, and may not be beneficial at all relative to the existing modes of therapy. For this reason, before a therapeutic trial is undertaken, it is necessary to be sufficiently convinced regarding intoxicity and potentiality as a beneficial regimen. Thus, the previous phases in the laboratory must have provided unequivocal results. Since the clinical trials are precarious, they are pursued in phases, particularly for a new formulation or substance as for drug development.

Efficacy is always related to a particular outcome. Terms such as recovery and discharge are vague for the outcomes. They must be specified either in terms of measurements such as glomerular filtration rate for kidney diseases, in terms of images such as x-ray for dislocated joint, or in terms of any such objective criterion. Also, the duration after which the outcome is to be assessed should be specified—within a day, within a week, etc. This applies to death also. Everybody dies, but if a death occurs 3 months after a surgery, should this be ascribed to the surgery? The follow-up period for different outcomes of interest must also be fully specified.

There are other issues as well relating to the outcomes. The actual interest may be in cardiovascular outcomes, but for expediency, change in blood pressure level can be considered as a surrogate endpoint. Large cohorts and long follow-up are expensive—surrogates tend to make them expedient. For example, microalbuminuria is a promising surrogate of renal protection in many cases. However, do not use surrogates indiscriminately. Examine first whether they are indeed valid markers for the hard endpoint you are looking for. The surrogate should accurately assess not only the benefit or the lack of it but also the harm. A correlate may not be a suitable surrogate.

Outcomes can also be assessed at prespecified interim stages. This can help in discontinuing a trial if confirmed results are available one way or the other. Desired efficacy may be proved, or unacceptable severe side effects may appear. Sample size can also be reassessed. However, interim appraisals can unblind the study. For details, see **adaptive designs** and **stopping rules**.

A regimen should not be assessed only in terms of its benefits or efficacy. Except possibly those that alter lifestyle, no intervention is without risk of **side effects** and toxicity. Thus, the benefit must be seen in relation to the possible risk. This has special relevance to potentially hazardous drugs. In some situations, **safety** is more important than efficacy. For an account of benefit–risk assessment of various regimens, see Korting and Schafer-Korting [3].

Some of the side effects, now generally termed adverse events, may be preexisting or may occur in any case in a person or even a group of persons, but some could be attributed to the regimen. How can this attribution be achieved? Methods are available that help to categorize side effects into those that are definitely due to the regimen, possibly due to the regimen, and unlikely to be due to the regimen. For this, one procedure is to withdraw the treatment and administer it again, and see if the side effect disappears and recurs.

What side effects should be considered common and what should be considered rare in a therapeutic trial? Of course, this will depend on the nature of the side effect. We have provided a guideline in the topic **adverse effects** and **adverse patient outcomes** that applies to the side effects as well. For this, it is necessary to define all side effects and record them, including time of onset, time of resolution, severity, relation to study regimen, action taken, and outcome. In addition, significant aberrations in laboratory values may also have to be defined.

Among other issues related to therapeutic trials are (i) **efficacy and effectiveness**; (ii) **equivalence and noninferiority trials**; (iii) various **designs of the trials** such as **randomized controlled trials (RCTs)**, **crossover**, ***N*-of-1**, **up-and-down**, and **sequential**; and (iv) biostatistical ethics that comprise issues such as **equipoises**. These are discussed under the respective topics.

### *Clinical Trials for Diagnostic and Prophylactic Modalities*

Diagnostic trials are for modalities that help in diagnosis rather than in therapeutics. They are almost invariably conducted in clinics. Prophylactic trials are for prophylactic measures that prevent either the disease or its complication. Prophylactic trials can be conducted in clinic as well as in the field in a community.

The intervention in a diagnostic trial is not a therapeutic agent but a procedure that can change the diagnosis and thus the course of the treatment. Thus, it has the potential to improve decision-making and patient management.

From the ethics point of view, noninvasive procedures such as measuring blood pressure (BP) and weight do not cause much anxiety except for time, cost, and inconvenience to the patient, but an invasive procedure such as endoscopy has the potential to cause harm to the health of the patient. More care is required for a trial on an invasive procedure.

As discussed under **randomized controlled trials (RCTs)**, most RCTs have a **parallel control** group, but many diagnostic trials are self-controlled. For comparison of prostatic specific antigen levels and ultrasound images for prostate cancer, both procedures would be done on the same set of patients. Agreement between the two can be evaluated, but to find which is better, a **gold standard** is needed. For example, magnetic resonance imaging can be considered gold and can be compared with arthroscopy as the reference for detection of meniscal ruptures. When a reference is available, the diagnostic efficacy in terms of **sensitivity** and **specificity**, and **predictivities** can be obtained.

When a group of suspected cases is available that meets specific inclusion and exclusion criteria, the diagnosis would be established by a gold standard in some of them. The diagnostic procedure under trial would also be used on all the suspected cases, and some would be found positive. This would yield a 2×2 table of the type shown in Table C.17. In this table, $(a + c)$ cases were found to have the disease by gold standard and $(a + b)$ by the procedure under trial. Thus, various validity parameters can be estimated such as sensitivity and specificity.

**TABLE C.17**
**Results of a Diagnostic Trial**

| Results of the Diagnostic Procedure under Trial | Actual Disease | | |
|---|---|---|---|
| | Present | Absent | Total |
| Positive | $a$ | $b$ | $a + b$ |
| Negative | $c$ | $d$ | $c + d$ |
| **Total** | $a + c$ | $b + d$ | $n$ |

Haig et al. [4] report a prospective, masked, controlled diagnostic trial to determine the sensitivity and specificity of electrodiagnostic consultation for the clinical syndrome of lumbar spinal stenosis. A total of 150 suspected cases were included. Out of these, clinical consensus on diagnosis was reached for 55 cases. This was considered the gold standard for this study. Electrodiagnostic measurements such as paraspinal EMG score and composite limb and paraspinal filtration score were evaluated for their sensitivity and specificity against this gold standard.

Prophylaxis is a procedure that promotes health or controls primordial factors that adversely affect health. A prophylactic trial is generally conducted in the field where a community is involved. This is discussed later in this section. But it can be conducted in a clinical setup also. An example is prophylactic nasal continuous positive airway pressure after major vascular surgery. Amnioinfusion for meconium stained amniotic fluid in labor at the time of childbirth is a prophylactic procedure that can be tried for specific types of births. As with all other trials, prophylactic trials are also restricted to a particular segment of the subjects. For example, for a prophylactic drug such as aspirin to reduce cardiovascular events, the participants may be vulnerable people of age 50 years or more.

The principles of clinic-based prophylactic trials are the same as for therapeutic trials. Perhaps a prophylactic procedure is somewhat insulated against harmful effects, and thus slight relaxation in ethics may allow stricter control over confounding factors. Community-based trials in the field have a different setup, whether for therapeutic modality, for prophylactic agent, or for a screening procedure. These are discussed next.

### *Field Trials for Screening, Prophylaxis, and Vaccines*

Field conditions, where a segment of the population is involved, are different from clinical conditions. Many confounders such as the severity condition of the patient can be controlled in the clinic but would be difficult to control in the field. In any case, **field trials** are done for modalities that can be used on mass scale on the general population or its segment. Thus, they can have wider health policy implications that clinical trials seldom have.

In public health, field trials are sometimes done with the health facility as the unit of experiment. The intervention could be training to the peripheral workers (such as for Pap smear) to find out whether that improves the case detection rate against a control area where no such training was given. Issues in such trials may be slightly different from those that were discussed in this section for individual-based trials.

Screening is quite in vogue for cancers. The prostate, lung, colorectal, and ovarian cancer screening trial initiated in 1992 in the United States has enrolled more than 150,000 participants [5]. Nearly half are randomly assigned to the intervention (screening), and the other half remained as control. Whether screening helps in reducing cancer mortality is yet to be seen. Many collateral benefits emerged though. For example, it was found that chest radiograph abnormalities not suspicious for lung cancer are common, and prostate volume and age are independently associated with increased prostatic specific antigen in men undergoing screening. A second example is a randomized mass screening trial for abdominal aortic aneurysm. Ten-year results show 73% reduction in mortality by this aneurysm in those screened as compared to those not screened [6].

Note how **screening trials** look like they are based on mass screening but the procedures used are hospital based. Sankaranarayanan et al. [7] report a community-based trial wherein all persons of age 35 years or older were screened for oral cancer in intervention villages

and not screened in the control villages. The screening was done three times at 3-year intervals for signs of oral cancer. There were nearly 60,000 eligible subjects in the intervention group and nearly 55,000 in the control group. The villages were **cluster-randomized** rather than individual-randomized to receive or not receive the intervention. The difficulty was, as in most field trials, low **compliance** when referred for confirmatory examination that has to be done in a hospital. In this trial, compliance was lower than 70%.

A **prophylactic trial** in the field could be for a strategy such as lifestyle changes for coronary disease or could be for vitamin intake—even drugs that are stipulated to prevent occurrence or recurrence of adverse events. Giving vitamin A supplements to infants and young children to improve their retinol level is an example of such an intervention. Although there is a fine distinction between preventive and prophylactic measures, we are including both into the prophylactic category. Such trials have tremendous value in policy formulation, in saving lives, and in improving health, but they do not receive that kind of attention.

A prophylactic trial is not necessarily conducted in the general population. The vitamin A trial cited in the preceding paragraph is for children. A trial on an educational campaign for responsible sexual behavior may target adolescents. Another trial on hematinic supplementation may target antenatal women of low socioeconomic stratum.

Consider the following example. A total of 198 refugees were selected in Kenya by multistage **cluster sampling** and were divided almost equally to receive the intervention and placebo by cluster randomization [8]. The intervention was insecticide-treated personal clothes and linen, and the placebo in this case was plain water treatment. Double blinding was done for malaria parasite smear. The odds of malaria infection in the intervention group were reduced by about 70%.

**Vaccine trials** are conducted in phases as therapeutic trials but need even more precaution. The need for extra care arises from the applicability of vaccines to a large segment of populations who are not sick but are at risk, as opposed to therapeutics that is applied only to patients and administered under close supervision. A feature of vaccines is immunogenicity, which might be an important consideration in some diseases, in addition to protective efficacy. In others, duration of protection may be important. Quality and quantity of immune responses required for protection against infection and against development of disease are scientific challenges. In the case of HIV, for example, there could be a vaccine that inhibits HIV infection, and there could be a vaccine that inhibits or retards development of disease—AIDS—in those already infected.

In view of the complexities involved in vaccine trials, an additional phase called phase IIB (see **phases of clinical trials**) is sometimes advocated. This is also called the "test of concept" phase. The aim of phase IIA could be to establish the schedule of administration for different age groups, as it would be most likely a factorial experiment with dose level as one factor and age group as the second factor. Thus, four phases are required for vaccine trials instead of the usual three. The objective of phase IIB is to evaluate whether the vaccine has any (>0%) efficacy at all. In a phase III trial for vaccines, this objective shifts generally to at least 30% efficacy. The participants in phase IIB are not necessarily representative of the target population. For phase III, a representative sample is indicated. Phase IIB also assesses the operational efficiency, whereas the objective of phase III is to produce compelling evidence of efficacy for licensure from regulatory agencies.

A phase III trial for a vaccine has to be a large-scale trial so that adequate numbers developing the disease, particularly in the control group, are available. The total number of subjects may run into thousands, and the follow-up too may go up to several years. Since phase III is an expensive trial for vaccines, phase IIB becomes a highly desirable proposition to indicate whether or not to proceed to phase III. Phase IIB, however, increases the time frame because this too can take at least a couple of years.

In addition to what have already been mentioned, other related issues separately discussed in this volume for clinical trials are **compliance**, **CONSORT statement**, **multicentric trials**, and **registration of trials**. Further details of clinical trials are discussed by Shih and Aisner [9].

## clinimetrics, *see also* scoring systems for diagnosis and for gradation of severity

Metrics is generally identified by quantitation and calculations in any science. Clinimetrics goes beyond these calculations and seeks to place the quantities and calculations in a clinical context so that decisions in the interest of the patient can be taken on the basis of measurements after assessing their implications. The focus in clinimetrics is on quality of measurements and their performance. In a way, this takes away subjectivity from decisions, which might otherwise be difficult to justify logically. You would agree that logic is the cornerstone for medical decisions. The term *clinimetrics* was introduced by Feinstein [1] in 1983.

Many mathematical formulas have unknowingly entered into medical practice back door through computer-based systems. They directly produce results without the user being aware of the back-end calculations. Examples such as the bispectral index, high-performance

liquid chromatography, and evoked potential can be cited that directly produce results, without revealing the complex calculation. These are examples of clinimetrics tools. Gill [2] has given details of clinimetrics of laser Doppler imaging in assessing depth of burns.

**Indicators** and **indexes** can be considered components of clinimetrics. But the major focus of this gradually developing science is on the methodology for developing **scoring systems** that have the requisite applicability. These components of clinimetrics are concerned with the quality of the measuring instruments and look at the process of tool development rather than the tools themselves.

**Reliability**, **validity**, and responsiveness of such measuring tools are an integral part of their quality. A measuring tool should also be sufficiently sensitive to detect clinically relevant improvements attributable to therapeutic interventions. Close collaboration among clinicians, biostatisticians, and epidemiologists is required for the development of clinimetrics as a science of consequence.

## Clopper–Pearson bound/interval, *see also* exact confidence intervals (CIs), Wilson interval

The Clopper–Pearson interval is the most widely used "exact" confidence interval for binomial π. Whereas the CI for a large sample can be obtained by using **Gaussian** approximation, Clopper–Pearson provides almost an exact interval that is supposed to be valid for small *n* also. Agresti [1] has quoted articles that say that this interval is extremely conservative and not so exact as made out. Conservative means that the interval will actually contain higher than 95% probability when computed for 95% confidence.

Suppose the interest is in estimating the chance of uterine prolapse in women who come with complaints of micturition disturbance and vaginal discharge. If only $n = 12$ women with such complaints could be examined and three had uterine prolapse, the proportion ($p$) is 3/12 = 0.25. Another sample may give another proportion. How does one find limits within which this proportion is not unlikely to lie in all such patients? In this case, since $np = 3$ is small, the Gaussian approximation cannot be used. The confidence interval for π in case of a random sample of small *n* is obtained by using the sum of binomials and the values from the **beta distribution**, which, in turn, can be obtained from the ***F*-distribution** (see Johnson and Kotz [2] for details). This involves some approximation because an exact 95% probability cannot be obtained for **discrete variables** such as the binomial. The quantity π in this case is the actual proportion of women with uterine prolapse among the population of women with those complaints. The confidence interval (Clopper–Pearson interval) is given by

$$\left(1+\frac{n-x+1}{x[F_{\alpha/2}\text{ at }2x,\ 2(n-x+1)df]}\right)^{-1},$$

$$\left(1+\frac{n-x}{(x+1)[F_{1-\alpha/2}\text{ at }2(x+1),2(n-x)df]}\right)^{-1},$$

where $n$ is the total sample size, $x$ is the number of successes or positives, and $F$ is the value of $F$ at the subscripted probability (percentile) and at the stated degrees of freedom. In our example of uterine prolapse, $n = 12$ and $x = 3$. For 95%, CI, $F$-values are at probabilities 0.025 and 0.975 at df = (6, 20) for the lower limit and df = (8, 18) for the upper limit. These $F$-values are 0.19 and 3.02 from the $F$-table found in statistics books. Thus, the 95% CI for π is

$$\left(1+\frac{12-3+1}{3\times 0.19}\right)^{-1}\text{ to }\left(1+\frac{12-3}{4\times 3.02}\right)^{-1},\text{ or 0.054 to 0.57.}$$

For those who are comfortable with beta distribution, the interval can also be written more simply as

$$\text{Idf.Beta}(\alpha/2,\ x,\ n-x+1),\ \text{Idf.Beta}(1-\alpha/2,\ x+1,\ n-x).$$

These are the inverse distribution functions of beta distributions for cumulative probability α/2 and (1 – α/2), respectively, with 1 added to $n - x$ the first time (lower limit) and to $x$ the second time (upper limit). Statistical software packages generally follow this method in place of going through $F$-distribution. Both are equivalent, though. As you can see, the Clopper–Pearson interval could be larger than needed because of 1 added to the parameters for both sides of the limit. This interval is conservative anyway as stated earlier and becomes too conservative if the anticipated value of π is close to 0 or 1. Because of this, many people prefer **Jeffreys interval**.

Instead of going through the rigmarole of complex mathematics, presented next is a graphical method for obtaining Clopper–Pearson CI when the sampling is random. This involves some approximation but is still useful for practical applications.

The 95% CI for π corresponding to different values of the observed sample proportion $p$ can be read from Figure C.13. This is drawn for some specific values of $n$. The upper and lower limits are read off the vertical axis using the pair of curves corresponding to the sample size $n$. The sample proportion $p$ is on the horizontal axis. If your $n$ is not exactly as shown, visual interpolation can be done to get an approximate CI. The figure is large relative to the other figures in this book so that this can be actually used.

For our example of 3 women with uterine prolapse out of 12 examined with complaints of micturition disturbance and vaginal

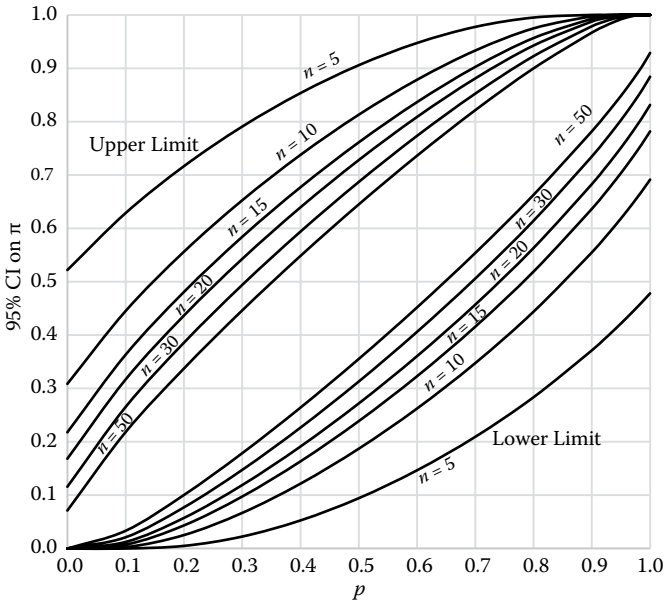

**FIGURE C.13** The 95% Clopper–Pearson confidence interval (CI) for π for different sample sizes.

discharge, $n = 12$ and Figure C.13 does not give a CI curve for this $n$. However, visual interpolation for $n = 12$ corresponding to $p = 0.25$ gives (0.06, 0.58) as the CI. Thus, the chance of uterine prolapse in women with those complaints can be anywhere between 6% and 58%. Such a wide interval may not be helpful, but that is what could be obtained on the basis of this small sample.

If $n = 50$, the 95% CI for observed $p = 0.25$ from Figure C.13 is (0.14, 0.39) approximately. This is much narrower. You may wish to calculate CI for $n = 120$, now using Gaussian approximation because of the large $n$. For this $n$, the 95% CI is (0.17, 0.33). Note how the CI narrows as $n$ increases. Two useful observations can be made on the CIs obtained for different values of $n$ in our example:

- As $n$ increases, the CI narrows, but this gain decreases with increasing $n$. The width of the interval for $n = 12$ is $0.58 - 0.06 = 0.52$, for $n = 50$ is $0.39 - 0.14 = 0.25$, and for $n = 120$ is $0.33 - 0.17 = 0.16$. Increasing $n$ from 12 to 50 reduced the width to less than half, but increasing $n$ from 50 to 120 reduced it to only two-thirds. Thus, the law of diminishing returns is applicable here also.
- Relative to $p = 0.25$, the first interval for $n = 12$ is highly asymmetric. The lower limit 0.06 is closer to $p = 0.25$ than the upper limit 0.58. This asymmetry declines as $n$ increases, and the CI for large $n$ becomes symmetric around the value of $p$. Also, symmetry increases as $p$ becomes closer to 0.5.

### *Clopper–Pearson Bound for π When the Success or the Failure Rate in the Sample Is Zero Percent*

Consider again a situation in which a surgeon performs the same operation on 10 different patients for kidney stone with complete success without a single complication. Thus, the complication rate is $p = 0$ in this sample. Can it be concluded that the complication rate would continue to be zero for all such operations in the future? Or is this just good luck for the 10 patients who happened to be operated on during that period? In statistical language, can $p = 0$ be used as an estimate of π in the calculation of SE($p$)? The answer obviously is no. In such situations, where the observed $p$ is the extreme value, the true complication rate can be estimated only by obtaining a one-sided **confidence bound** for π.

The 95% confidence bounds for extreme results for various sample sizes are displayed in Table C.18. These are again based on the exact binomial distribution and are called the Clopper–Pearson bounds.

Consider the previous example of a surgeon with no complication in 10 surgeries for kidney stone. For this surgeon, $p = 0$ and $n = 10$. The upper bound for the true complication rate, corresponding to 95% confidence, from Table C.18 is 27%. Thus, you could be 95% confident that the complication rate in the long run would not exceed 27%; that it could be as high as 27% may have set an alarm. The claim of 0% complication rate based on the experience for 10 subjects is not tenable. If no complication is observed in a series of 50 such surgeries, then the confidence bound corresponding to $n = 50$ from Table C.18 is only 6%. Note again how important the size of the sample is in determining the bound and in arriving at a focused conclusion.

An exactly similar situation arises when the observed $p$ is 1.0. In this case, for example, for $n = 15$, the lower bound for π corresponding to 95% confidence is 0.82. The limits in Table C.18 are given for specific values of $n$. For other values of $n$, such as $n = 18$, an approximate CI can be obtained by suitably interpolating between the relevant curves.

Although the discussion is for $p = 0$ and $p = 1$, it suggests extra caution in obtaining CI for π when $p$ is extremely small or extremely high. The conventional two-sided CI in this case can go beyond 1 or can start from a negative value. Obviously, such values are impossible for any proportion. In such cases, examine if one-sided bound serves the purpose instead of two-sided CIs. In many situations, bounds serve the purpose well.

There is another method to obtain CI for binomial π. For this, see **Jeffreys interval**. Jeffreys adds ½ to the value of $x$ and $n - x$ in place of adding 1. This may be more exact than Clopper–Pearson interval. Also see **Wilson interval**.

**TABLE C.18**
**95% Confidence Bounds for Extreme Results**

| If the Sample Size $n$ Is | If the Sample Percentage Is 0%, the True Percentage Could Be as High as | If the Sample Percentage Is 100%, the True Percentage Could Be as Low as |

## cluster analysis

The problem addressed in cluster analysis is the division of subjects or units into an unspecified number of **affinity** groups. The grouping is done in such a manner that units similar to one another with

respect to a set of variables are classified to one group and the dissimilar ones to another group. Thus, natural groupings in the data are detected. For instance, this is unwittingly done in assigning grades to students in a course where the instructor looks for rational cutoff points. Sometimes only two grades A and B are considered enough; sometimes they go up to E. In another setup, the method can also create taxonomic groups for future use. An example is of cases falling into various diagnostic groups on the basis of their clinical features. A name is subsequently assigned to these groups depending on their etiology or features. Although overlapping clusters can be conceived so that one or more units belong simultaneously to two or more clusters, this section is restricted to exclusive clusters. Cluster analysis is a nonparametric procedure and does not require values to follow a Gaussian or any other pattern. Also, this procedure is primarily used for **multivariate** observations and not so much for univariate observations.

### *Measures of Similarity*

Division of subjects into a few but unknown number of affinity or natural groups requires that proximity between subjects is objectively assessed. Those with high proximity go into one group, and those with low proximity are assigned to some other group. Thus, the subjects resembling one another are put together in one group. As many groups are formed as needed for internal homogeneity and external isolation of the groups (Figure C.14). The points plotted in Figure C.14b are the same as in Figure C.14a, but now the affinity groups are shown.

Similarity between two subjects can be measured in a large number of ways. The methods are different for **qualitative** than for **quantitative** variables. In the case of **binary** qualitative variables in a $K$-variable multivariate setup, the affinity can be shown in the form of a $2\times2$ table as in Table C.19. There is a total of $K$ variables out of which matches between the $i$th and the $j$th units occur in $k_{11} + k_{22}$ variables. A popular measure of similarity in this case is

$$\text{simple matching coefficient: } s_{ij} = \frac{k_{11} + k_{22}}{K};\ i, j = 1, 2,\ldots, n.$$

Note that $s_{ij}$ is the ratio of the number of variables on which the $i$th and the $j$th units match to the total number of variables. This can be calculated for each pair of units. Similar measures are available for polytomous variables [1]. This reference also discusses strategies for mixed sets (quantitative and qualitative) of variables.

In the case of quantitative variables, the usual Pearsonian **correlation coefficient** can be used as a measure of similarity. If $y_{i1}, y_{i2},\ldots, y_{iK}$ are $K$ quantitative (multivariate) measurements on the $i$th subject and $y_{j1}, y_{j2}, \ldots, y_{jK}$ on the $j$th subject, the correlation between the two can be directly calculated. Note that this is being used here for assessing similarity between subjects, whereas the general use is to measure strength of correlation between variables. A more acceptable method in this case is to compute a **measure of dissimilarity** instead of similarity. This, between the $i$th and the $j$th subjects, can be measured by

$$\text{Euclidean distance: } d_{ij} = \sqrt{\Sigma_k (y_{ik} - y_{jk})^2};\ i, j = 1, 2,\ldots, n.$$

This is calculated after standardization (**$z$-score**) of the variables so that the scales do not affect the value. Otherwise, the variables with larger numerical values will mostly determine clustering. This distance can also be calculated for a setup with one variable ($K = 1$). In this case, this reduces to a simple difference between the values.

On the basis of such measurement of similarity or dissimilarity, the subjects are classified into various groups using one of the several possible algorithms. A very popular one is **hierarchical clustering**. With hierarchical algorithm, two units (or subjects) that are most similar (or least distant) are grouped together in the first step to form one group of two units. This group is now considered as one entity. Now the distance of this entity from other units is compared with the other distances between various pairs of units. Again, the closest are joined together. This hierarchical agglomerative process goes on in stages, reducing the number of entities by one each time. The process is continued until all units are clustered together as one big entity. Described later in this section is a method to decide when to stop the agglomerative process so that natural clusters are obtained. This process is graphically depicted by a **dendrogram** of the type shown in Figure C.15. Note that in this method, subsequent clusters completely contain previously formed clusters.

It may not be immediately clear how to compute the distance between two entities containing, say, $n_1$ and $n_2$ units, respectively.

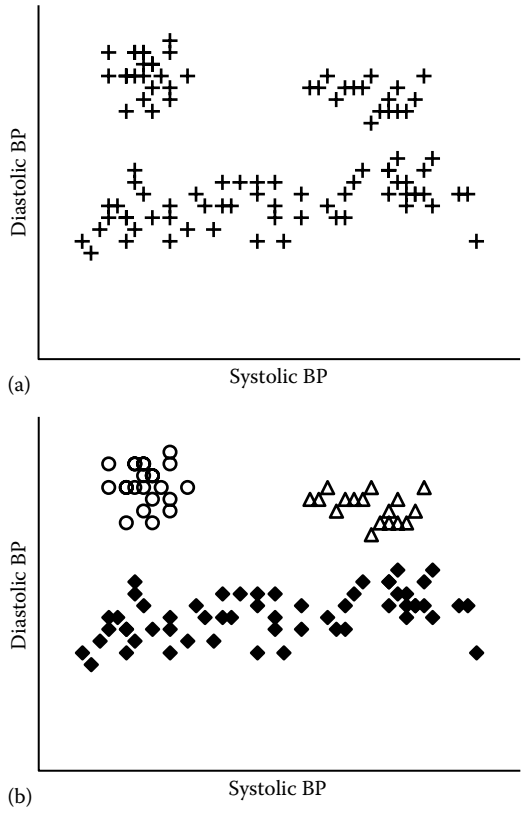

**FIGURE C.14** Scatter plot of diastolic and systolic levels of blood pressure: (a) affinity not shown and (b) one form of affinity groups.

**TABLE C.19**
**Matches and Mismatches in Variables in Two Units Measured on *K* Binary Variables**

| | ***i*th Unit** | | |
|---|---|---|---|
| ***j*th Unit** | **Yes** | **No** | **Total** |
| Yes | $k_{11}$ | $k_{12}$ | $\boldsymbol{k_{11} + k_{12}}$ |
| No | $k_{21}$ | $k_{22}$ | $\boldsymbol{k_{21} + k_{22}}$ |
| **Total** | $\boldsymbol{k_{11} + k_{21}}$ | $\boldsymbol{k_{12} + k_{22}}$ | $\boldsymbol{K}$ |

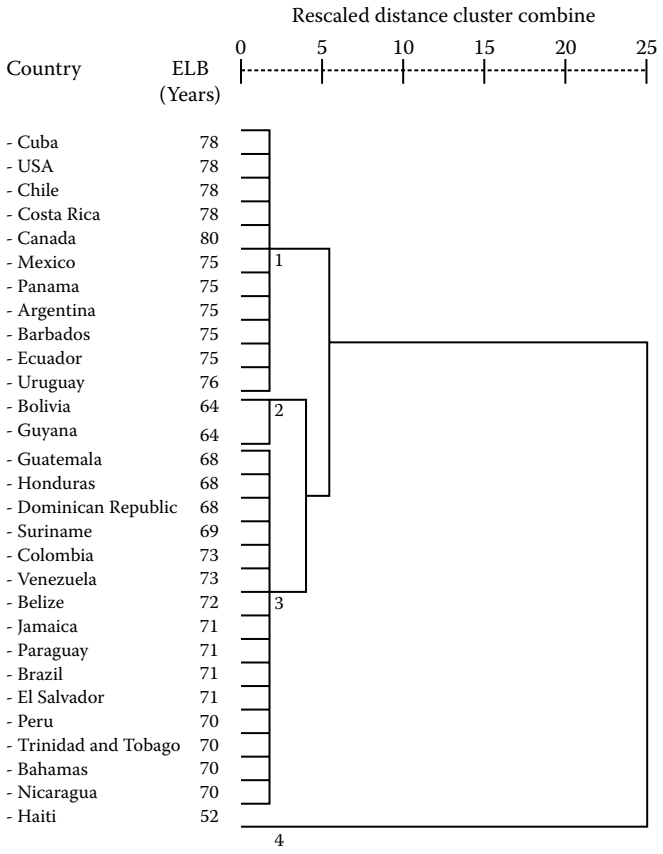

**FIGURE C.15** Dendrogram of Pan-American countries for expectation of life at birth (2004): average linkage method.

Several methods are available. One is to consider all units in an entity centered on their average. Another method is to compute the distance of each unit of one entity with each of the other entity and take the average. A third method is to base it on the nearest units. There are several others. Depending on how this distance is computed, names such as **centroid**, **average linkage**, **single linkage**, etc., are given to these methods. Different methods can give different results. Jain et al. [2] have studied relative merits and demerits of some of these methods on random data. No specific guideline can be given, but a method called **complete linkage** has been found to perform better in not discovering false cluster. This method uses the farthest distance between units belonging to different entities as the measure of distance between two entities.

Cluster analysis can also be done on just one variable. Figure C.15 shows the dendrogram obtained for Pan American countries when clustered on the basis of 2004 values of expectation of life at birth (ELB). The method followed for this clustering is the average linkage. The distance on the horizontal axis is rescaled in proportion to the actual distances between entities. The algorithm detected four clusters as shown from 1 to 4 in the figure. These are given in Table C.20. The fourth cluster has only one country, namely, Haiti, which has very low ELB. Note the gap in ELB between clusters that makes them distinct, and qualify them to be called natural clusters.

### *Deciding on the Number of Natural Clusters*

The most difficult decision in the hierarchical clustering process is regarding the number of clusters naturally present in the data. The decision is made with the help of a criterion such as pseudo-*r* or the **cubic clustering criterion** [3]. These values should be high compared with the adjacent stages of the clustering process. Another criterion could be the distance between the two units or entities that are being merged in different stages. If this shows a sudden jump, it is indicative of a very dissimilar unit joining the new entity. Thus, the stage where the entities are optimal in terms of internal homogeneity and external isolation can be identified. The entities at this stage are the required natural clusters.

**TABLE C.20**
**Clusters Discovered by Average Linkage Method for Pan-American Countries with Respect to the Expectation of Life at Birth**

| Cluster | Expectation Life at Birth (Years) |
|---|---|
| 1 | 80–75 |
| 2 | 73–68 |
| 3 | 64 |
| 4 | 52 |

The following comments regarding cluster analysis may be helpful:

- The algorithm just described is a hierarchical agglomerative algorithm. You can use a *hierarchical divisive algorithm* in which the beginning is from one big entity containing all the units, and divisions are made in subsequent stages. However, this is rarely favored because agglomeration is considered a natural clustering process.
- The other algorithm is nonhierarchical. This can be used when the number of clusters is predetermined. We do not recommend this algorithm because it does not adequately meet the objective of discovering an unspecified number of natural clusters.
- Cluster analysis methods have the annoying feature of "discovering" clusters when, in fact, none exists. A careful examination of the computer output for cluster analysis, particularly with regard to the criteria for deciding the number of clusters, should tell you whether or not natural clusters really exist.
- Since there is no target variable, the clusters so discovered may or may not have any medical relevance.
- Different clustering methods can give different clusters. One strategy to overcome this problem is to obtain clusters by several different methods and then look for consensus among them. Such consensus clusters are likely to be stable. The consensus may be difficult to identify in a multivariate setup. Indrayan and Kumar [4] have given a procedure to identify consensus clusters in the case of multivariate data.
- Cluster analysis has developed into a full subject by itself. Details of the procedures just described and of several other cluster procedures are available in a book by Everitt et al. [5].
- The clustering mentioned above is different from the clustering of subjects with disease in population units such as households. For this, papers by Mantel [6] and Fraser [7] may be helpful.

## clustering effect, *see* design effect and the rate of homogeneity

## cluster randomization, *see* block, cluster, and stratified randomization, and minimization

## clusters, *see also* cluster analysis

A cluster is a collection of units. The term is used generally for a collection of those units who have something in common. Thus, we can have a cluster of patients of a certain disease who are treated in a clinic, a cluster of households in a colony, a cluster of people living together as a family, a cluster of blood samples collected on a day for specific investigation, etc. Proximity may be physical, for a particular category of a characteristic, or for any such criteria. A distinctive statistical feature of clusters is their internal homogeneity and external isolation—each contains units similar to one another, but other clusters contain different types of units.

We can also have a cluster of variables such as height, weight, head circumference, and chest circumference, all of which are used for assessing growth of children, or a cluster of measurements for assessing kidney function, or a cluster of measurements for lung or liver function, etc. Thus, "cluster" is quite a general term, but, in this volume, we restrict to a cluster of units rather than to a cluster of variables.

Whereas clusters are many times predefined, sometimes statistical procedures are used to find internally homogeneous and externally isolated clusters. These can be understood as **natural clusters**. Generally, in this case, the number of clusters is not fixed. This depends on how many clusters will achieve the desired objective. For details, see **cluster analysis**. The other method could be to divide the subjects by a specified number of **quantiles**. This is used when the number of clusters is predetermined and internal homogeneity is a marginal issue instead of a core issue. One of the popular quantiles used for this purpose is **tertile**. This divides the subjects into three groups of equal size. For example, you can divide 1-year children into those with low, medium, and high weight using 8 and 10 kg as tertiles—which means thereby that one-third children have weight less than 10 kg, one-third between 10 and 12 kg, and one-third 12 kg or more.

The other important issue is the cluster size. This is the number of units in a cluster. If something like tertiles are used as cutoffs, the size is predetermined to be one-third of the total $n$. When natural clusters are used, however, one cluster may have very different number of units than the others, e.g., only 3 subjects in one cluster and 18 in the other depending on their **affinity**. In the case of **cluster sampling** for field surveys, the clusters are mostly villages, and these could greatly vary in size. Such clusters are chosen for managerial convenience.

## cluster sampling

The term *cluster sampling* is used when clusters of units are selected instead of individual units. **Clusters** are collections of similar units. They may be physically contiguous such as dwelling units, students in a class, or patients in a hospital ward, or any such groups.

When the size of the clusters is not large, i.e., when they generally contain a small number of subjects, then it is sometimes advisable that these units are not sampled further. All the elements in the selected clusters are then surveyed. This tends to increase the total number of subjects in the sample without a corresponding increase in the cost. When subjects in close proximity are included in the sample, the travel time and cost are saved. If a population comprises a total of $N$ clusters, then $n$ clusters out of $N$ are randomly selected. If the $i$th cluster has $M_i$ subjects, then a total of $\Sigma M_i$ elements of these $n$ clusters are investigated. This is called cluster random sampling (CRS). This sampling gives extremely good results when the units within the clusters are heterogeneous with respect to the outcome of interest. The method is used also in settings with a large number of units, but then they are divided into small clusters. A schematic presentation of cluster sampling is shown in Figure C.16, where clusters are delimited by bold lines and 3 have been selected out of 10 clusters. The units in sample are those with dots.

Besides the fact that CRS helps to increase the size of the sample and thus the **precision** (without a corresponding increase in the cost), the other advantage relative to **simple random sampling** (SRS) is that the **sampling frame** of the units is not required and the only frame required is the list of clusters. For example, it is easy to draw a list of hospitals than a list of patients of a particular disease. In this case, hospitals are the clusters of patients of that disease. In another setup, a family could be a cluster of interest. Cluster sampling is also very easy to administer. Since the survey of subjects within the cluster is quick due to close proximity, CRS is sometimes considered a **rapid assessment method**. At one time, the World Health Organization (WHO) recommended this kind of sampling

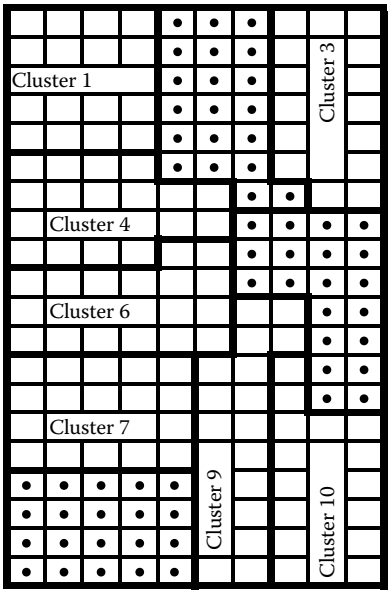

**FIGURE C.16** Schematic presentation of cluster sampling.

C

to estimate the percentage of children immunized in a community, particularly in developing countries. Their recommended strategy was 30 clusters of size 7 each—called **30 × 7 sampling**. Bennett et al. [1] have given some very useful details of this methodology. The methodology has become popular and is used in many other setups, more for convenience than for statistical propriety. The 30 × 7 methodology is appropriate when the anticipated prevalence is around 50% and the precision required is ±10% points. For other setups, a different size of cluster and a different number of clusters may be needed. Since the immunization level in most countries has reached 70% or 80%, this methodology has become outdated for immunization surveys. However, such CRS is used as a rapid assessment method for assessing the status of other aspects of health as in estimating prevalence of poor vision in old age as per the example given later in this section.

As you will see shortly, a disadvantage of CRS is that the elements within a cluster tend to be similar to one another and produce a clustering effect. This is also called the **design effect**. This effect reduces the chances of getting the full spectrum of subjects in the sample. To compensate for this, a larger sample may be required relative to SRS. However, it sometimes happens that even a large sample chosen by CRS is less expensive to investigate than a small sample chosen by SRS. Intercluster comparison is not valid in the case of CRS.

It is customary in the case of CRS that the population is divided into clusters of equal or approximately equal size, although this is not a prerequisite. The size of cluster—that it should have 20, 30, or 50 subjects—is generally determined by administrative convenience, such as the ability of a team to finish the survey in 1 day. However, the number of clusters would depend on the statistical requirement of reliability of the estimate.

The following example illustrates one application of cluster sampling. For a survey on prevalence of poor vision (visual acuity <6/36 in the better eye with corrective glasses if any) in persons of age 50 years and above (50+) in a district with half a million population, suppose 20 clusters of size 30 each are selected as per the following scheme:

a. A list of census blocks is prepared along with the population of each, and this is cumulatively added.
b. Since the sampling fraction is one cluster per (500,000/20 =) 25,000 population, one number less than or equal to 25,000 is randomly selected. Then, 25,000 is sequentially added every time in a systematic fashion, and thus a sample of 20 numbers is obtained. Twenty blocks containing the chosen 20 numbers are selected from the list made in (a). These blocks are now in the sample.
c. Home visits are made from a geographically random point in each of the selected blocks, and the first 30 persons of age 50+ residing in contiguous houses are listed and examined for visual acuity. This gives one cluster of 30 subjects from each selected block.

The scheme in this example is similar to the one recommended by WHO for surveys to assess immunization coverage in developing countries, but it is not exactly the same. Note the following features of the CRS in this example:

- The frame required is only the list of census blocks, which in any case is generally available. No listing of households or of persons of age 50+ is required.
- The selection of blocks is on the basis of the size of the population. This is inherent in step (b). Blocks with a larger population have a higher chance of being included in the sample. This is called sampling with **probability proportional to size** (PPS). Details of this method are given under that topic. The size in this case is the population in the blocks, and the subjects are the persons of age 50+. It is reasonable to expect that this age group would have nearly the same proportion in each census block. The PPS sampling makes the estimate self-weighting, and the usual sample proportion becomes a statistically valid estimate of the population proportion. Weighted calculations, as done for **stratified random sampling** (StRS), are not required.
- Starting from a geographically random point ensures random sampling but may require a map of each of the selected blocks.
- The houses to be visited are contiguous. This should make the survey substantially faster. Because of this property, it is valid to consider it as a rapid assessment method. It is up to the investigators to define contiguity. These could be houses lined up on both sides of a street or houses whose entrance is closest to the previously selected houses. This must be defined before the survey begins.
- The total number of clusters of size 30 would be large in a district that has a population of half a million. A sample of 20 clusters is relatively small. This would be generally the case in CRS.

Not all of the first 30 persons of age 50+ in a cluster selected for the survey may be available, and some may not cooperate in the examination of their vision. In practice, the **nonresponse** could be large in this kind of CRS and may have to be tackled separately.

## Cochrane collaboration/reviews

Cochrane reviews [1] are internationally recognized systematic reviews of medical literature on specific topics relating to prevention, diagnosis, and treatment of various diseases. They follow a strict protocol using tools such as full literature search, study flow diagram [2], and **meta-analysis**, and are believed to come up with the best available evidence on specific aspects of health care. Many consider this as "research into research."

Cochrane reviews are a collaborative effort, known as Cochrane collaboration. The reviews were founded by Iain Chalmers in 1991, but he preferred to call them Cochrane collaboration [3].

These reviews are published online in The Cochrane Library and regularly updated to provide the latest information. More than 5000 reviews are available in this library as of 2015. The reviews intend to provide answers to everyday questions such as whether vitamin D supplements prevent cancer in adults, or whether zinc helps in common cold. However, the answer may be inconclusive depending upon what type of information is available in the literature. For example, Goda et al. [4] found that the percentage of inconclusive reviews in the field of pediatric gastroenterology has increased from mere

9% in the block years 1998–2002 to 24% in the years 2008–2012. They included Cochrane reviews as well as other reviews in their study. The reasons they cited for inconclusive reviews are heterogeneity of studies and small sample size. Another reason could be increased awareness among researchers about the importance of the methodology.

The Cochrane Library allows free access to the abstract of the reviews but requires a subscription for accessing the full texts. However, some governments such as in Scandinavian countries have obtained license for free viewing by their health professionals. A word of caution for those who tend to take Cochrane reviews as the gold standard: sometimes an overview of Cochrane reviews is needed to come to some definitive conclusion. For example, a large number of interventions address the problem of preterm births, and in an evaluation of 56 Cochrane reviews, Piso et al. [5] found not more than one-fourth of these interventions effective in lowering the incidence of preterm births. Remember that Cochrane reviews suffer from the same ailment that all systematic reviews do. They are based on published research, and we all know about **publication bias** that inhibits reporting and publication of the trials with negative results. Thus, the results based on published research tend to provide a biased picture in favor of the positive findings.

## Cochran *Q* test

The Cochran *Q* test is an extension of the **McNemar test** for 2×2 tables to *T* repeated measures with **dichotomous** outcome. This tests whether or not the effect at *T* repeated measures is the same. *T* can also be the number of treatments on the same group of subjects, or different group with one-to-one **matched** subjects. This test criterion is given by

$$\text{Cochran } Q = (T-1)\frac{T\Sigma_t P_t^2 - P^2}{TP - \Sigma_i S_i^2},$$

where $T$ = number of repetitions

$P_t$ = number of positives at the $t$th ($t$ = 1, 2,…, $T$) repetition

$P$ = $\Sigma_t P_t$ = total number of positives

$S_i$ = number of positives for the $i$th ($i$ = 1, 2, …, $n$) subject in $T$ repetitions.

For large $n$, $Q$ follows a **chi-square** distribution with df = $(T-1)$. Thus, the ***P*-value** can be obtained. You may never need to use this formula since the software will give the *P*-value. The exact distribution of $Q$ is also known, which is valid for small $n$ also. A good statistical package will give you exact *P*-value as well. The test was first proposed by William Cochran in 1950 [1]. The following example illustrates the calculation for those who want to see exactly how it works.

William Cochran
(Courtesy of Fabian Bachrach Studio.)

Thirty patients of benign prostatic hyperplasia (BPH) whose disease was under control were assessed for their perceived health at monthly intervals for 4 months. The data obtained are shown in Table C.21.

**TABLE C.21**
**Self-Perceived Satisfaction with Health of BPH Patients at Monthly Intervals**

| Subject (*i*) | Time 1 | Time 2 | Time 3 | Time 4 | $S_i$ |
|---|---|---|---|---|---|
| 1 | 0 | 1 | 1 | 1 | 3 |
| 2 | 0 | 1 | 0 | 0 | 1 |
| 3 | 1 | 0 | 1 | 1 | 3 |
| 4 | 1 | 1 | 1 | 1 | 4 |
| 5 | 0 | 0 | 0 | 1 | 1 |
| 6 | 0 | 1 | 1 | 1 | 3 |
| 7 | 1 | 0 | 0 | 0 | 1 |
| 8 | 0 | 0 | 1 | 0 | 1 |
| 9 | 0 | 1 | 0 | 0 | 1 |
| 10 | 1 | 1 | 1 | 1 | 4 |
| 11 | 0 | 1 | 1 | 1 | 3 |
| 12 | 0 | 1 | 1 | 0 | 2 |
| 13 | 0 | 0 | 1 | 1 | 2 |
| 14 | 1 | 1 | 0 | 0 | 2 |
| 15 | 0 | 1 | 0 | 1 | 2 |
| 16 | 0 | 0 | 1 | 1 | 2 |
| 17 | 0 | 0 | 0 | 1 | 1 |
| 18 | 0 | 0 | 1 | 1 | 2 |
| 19 | 1 | 1 | 0 | 1 | 3 |
| 20 | 1 | 1 | 1 | 0 | 3 |
| 21 | 0 | 0 | 0 | 1 | 1 |
| 22 | 0 | 1 | 1 | 1 | 3 |
| 23 | 0 | 0 | 1 | 1 | 2 |
| 24 | 1 | 1 | 1 | 1 | 4 |
| 25 | 0 | 1 | 1 | 1 | 3 |
| 26 | 0 | 0 | 0 | 1 | 1 |
| 27 | 0 | 1 | 1 | 0 | 2 |
| 28 | 0 | 0 | 0 | 0 | 0 |
| 29 | 1 | 1 | 0 | 1 | 3 |
| 30 | 0 | 0 | 1 | 1 | 2 |
| **Sum $P_t$** | **9** | **17** | **18** | **21** | **65** |

*Note:* 0 = not satisfied; 1 = satisfied.

A software package gives $Q = 10.862$ and exact $P$-value = 0.012. For those who want to see what is going on underneath, note for these data that $T = 4$, $P_1 = 9$, $P_2 = 17$, $P_3 = 18$, and $P_4 = 21$. Thus, $P = 9 + 17 + 18 + 21 = 65$. Also $S_1 = 3$, $S_2 = 1$, $S_3 = 3$, …, $S_{30} = 2$ as given in the last column of the table. Substituting these values gives

$$Q = (4-1)\frac{4\times(9^2+17^2+18^2+21^2)-65^2}{4\times 65-(3^2+1^2+\ldots+2^2)}$$

$$= 3\times\frac{4\times 1135-4225}{260-173} = 10.86.$$

This is the same as was just obtained by the software package. At $T - 1 = 4 - 1 = 3$ df, the critical value of chi-square is 7.815 at $\alpha = 0.05$. Since the calculated value is higher, $P < 0.05$ and the result is statistically significant. The same was obtained by the exact $P$-value. Conclude that self-perceived satisfaction in these people is different at different time points.

For $T = 2$, Cochran $Q$ reduces to McNemar $\chi^2$ as it should. If you find $Q$ statistically significant and want to find where this difference actually is, do McNemar for pairs of interest using the **Bonferroni** procedure. This procedure for multiple comparisons is separately explained. If there are a total of $K$ pairwise comparisons of interest, the Bonferroni procedure requires that you use **significance level** $\alpha/K$ for each comparison instead of $\alpha$. This keeps the total probability of **Type I error** less than $\alpha$.

## Cochran test for linearity of trend, *see* chi-square test for trend in proportions and deviation from trend

## coding

This is the process of assigning numbers to qualities. This helps in converting long textual characteristics to a single or few digits, thereby helping in data entry and in analysis. For example, we can have code 1 for cancer of lung, 2 for cancer of cervix, 3 for cancer of breast, etc. You can see that codes are used for **nominal categories**.

It is customary to code values of **binary** variables as 0 for absent and 1 for present. For example, you can assign code 1 to people with a particular disease and 0 to those without disease. When this is done, the proportion of persons with the disease is the average of these 0's and 1's. This explains why a proportion also is a form of mean, and thus eligible to get advantage of the **central limit theorem** for a **Gaussian distribution** for large $n$. Such coding also helps in obtaining unifying **regressions** and their proper interpretation. Consider the following hypothetical regression equation for healthy adults:

[A] sysBP(mmHg) = 110 + ⅓*Age(years) – 3*Sex,

where sysBP is the systolic level of blood pressure, and sex is coded as 0 for females and 1 for males. When these codes are substituted, the equation is

for males (sex = 1): sysBP(mmHg) = 107 + ⅓*Age(years),

for females (sex = 0): sysBP(mmHg) = 110 + ⅓*Age(years).

Thus, a single equation [A] yields two equations—one for males and one for females. This kind of binary coding is also called creating **indicator variables**. In this example, sex is an indicator variable when coded as 0 and 1. This kind of coding is almost invariably used for the outcome in **logistic regression** and commonly for binary **regressors**.

The situation with multiple categories is not so simple. Code 1 for cancer of lung, 2 for cancer of cervix, 3 for cancer of breast, etc. cannot be used in equations since, in this case, code 2 is not double of code 1, and the difference between code 3 and code 2 is not code 1. They need to be recoded as described for indicator variables. The moral is that codes per se cannot be used as quantities.

Next is the coding of **ordinal categories**. Coding none, mild, moderate, serious, and critical condition as 0, 1, 2, 3, and 4, respectively, also cannot be used as quantities since two moderate cases (code = 2) are not equal to one critical case (code = 4). However, in some specific situations, these can be used as quantities, now called **scores**. For example, if you want to investigate the relationship between duration of survival in cases with different degrees of severity of any disease, such codes can be used as scores for assessing their effect on duration of survival. The underlying requirement for such use is that the difference in survival between mild and moderate cases is the same as between serious and moderate cases. If this is likely, codes for ordinal categories can be used as scores. Remember though that these codes, when used as scores, are linear since they are increasing by the same quantity (1 in this case) as we move up in severity of disease. Scores can be nonlinear also such as 0, 1, 3, 6, and 10 depending on the assessment of severity; however, codes cannot be nonlinear.

Metric categories such as age 15–19, 20–24, 25–29, etc., can also be coded as 1, 2, 3, etc. This, in fact, is a simple linear transformation—in this case, $\text{code} = \frac{\text{midpoint of the inerval} - 12}{\text{width of the interval}}$. The width of the **class interval** is actually 5 although it looks like 4. Thus, these codes can indeed be used as scores with no issues related to coding, but there are issues with using categories for a variable on **metric scale** of the type of age. For details, see **categories of data values** in this volume. There are exceptions where this does not apply. The average number of alcohol drinks per day can be categorized as 0, <1.0, 1.0–2. 9, 3.0–5. 9, and ≥6.0. Since the categories are metric, midpoints seem to be the most adequate scores for this kind of analysis. Try to resist the temptation to use equally spaced codes 0, 1, 2, 3, and 4 as scores in such cases since these categories do not follow this linear pattern.

## coefficient of correlation, *see* correlation coefficient (Pearsonian/product–moment)

## coefficient of determination, *see also* multiple correlation

Coefficient of determination of a model is a measure of its goodness of fit to the observed values. This is mostly used for regression models and can be understood in two ways:

$$\text{coefficient of determination: } \eta^2 = \frac{\text{Reg SS}}{\text{SST}} = 1 - \frac{\text{SSE}}{\text{SST}},$$

where RegSS is the sum of squares due to regression, SST is the total sum of squares, and SSE is the sum of squares due to error (also called residual sum of squares). An explanation is as follows.

A regression model is considered a good fit if the **residuals** $e = (y - \hat{y})$ are small, where $\hat{y}$ is the predicted value of $y$. Since residuals fluctuate around zero in any case, small residuals would

necessarily yield a small sum of squares $\Sigma e^2$. This is the residual **sum of squares**, popularly called the sum of squares due to error (SSE). Its magnitude, when compared with the total sum of squares, $SST = \Sigma(y - \bar{y})^2$, provides a measure of "lack of fit" of the regression, and (SST – SSE) is called the regression sum of squares (RegSS). These have associated degrees of freedom (df's) as in the case of ANOVA. RegSS measures how much of the total sum of squares the regression has been able to account for. The larger the $\eta^2$, the better the fit. If the residual sum of squares is as small as, say, 10% of the total sum of squares, then $\eta^2 = 0.90$. The fit, then, is said to account for 90% variation in *y*. A fit with such high $\eta^2$ should be adequate in most cases, especially if *n* is large.

There are two important underlying features of the coefficient of determination. First, the dependent must be quantitative and not qualitative since the usual regression is obtained for quantitative dependent only. The independent variable could be quantitative, qualitative, or a mixture of both. Second, there must be a **model** for predicting or explaining the values.

The positive square root of the coefficient of determination, η, exists but has no particular name when the relationship is nonlinear. This square root is called the coefficient of **multiple correlation** when the relationship is *linear* and the number of independent variables is more than one. This is denoted by *R*. No meaning can be attached to the direction of correlation when the number of regressors is more than one. Thus, the sign of *R* is always considered positive. This is the correlation between *y* and its values predicted by the linear regression. Thus, the term *coefficient of determination* should be used only for nonlinear regressions. Many researchers erroneously use the term coefficient of determination for the coefficient of multiple correlation.

## coefficient of reproducibility, *see* Guttman scale

## coefficient of variation

**Variation** among values has a tendency to be higher for values that are numerically bigger. For example, variation, as measured by the **standard deviation (SD)**, would be higher for cholesterol level than for bilirubin level since the cholesterol levels are more than 100 mg/dL but bilirubin levels are between just 0.20 and 1.10 mg/dL. Thus, variation in one variable cannot be compared with variation in another variable if we use SD. To correct this "anomaly," particularly for comparison, coefficient of variation (CV) is calculated as follows:

$$\text{coefficient of variation: CV} = \frac{\text{SD}}{\text{mean}}.$$

Since the units of measurement (g/dL or mmHg or any other) cancel out in such a ratio, the CV is independent of units and makes it a valid index for comparison of variations in variables on very different scales and different units. Thus, the CV removes the contextualization of variation.

An SD of 5 mmHg for systolic BP readings is small, but an SD of even 3 g/dL for Hb level is large. If the mean systolic BP level of the subjects under study is 132 mmHg, then SD = 5 mmHg is only 3.8% of the mean. If the mean Hb level is 15 g/dL, SD = 3 is 20% of the mean. The latter SD is surely higher, relatively speaking. Thus, SD by itself cannot be used to *compare* variability in two different kinds of variables. Its ratio with the mean can be used. For example, it can be concluded on the basis of CV that the variation between healthy individuals in thermoregulation (oral, rectal, and skin temperatures) is small and that in renal functions (urinary flow, creatinine clearance, urea clearance, etc.) is high. In the former case, the SD does not generally exceed 1% of the mean value, but in the latter case, the SD could be as much as 50% of the respective averages. Cardiovascular functions (systolic/diastolic BPs, heart rate, etc.) are somewhere in between with SD around 5%–15% of the mean.

Figure C.17 shows plots of the value of serum uric acid and blood ammonia in a sample of subjects. They are plotted in a manner that the variability looks equal. It all depends on the scale chosen on the *x*-axis. In these subjects, the level of serum uric acid is between 2.5 and 9.1 mg/dL, the SD is 2.44 mg/dL, and the CV is 44%. Against this, the level of blood ammonia ranges from 80 to 110 μg/dL, and the SD is 9.78 μg/dL. The CV is only 10%. Thus, variability is much lower in blood ammonia than in serum uric acid. The graphs could be deceptive as in this example.

The following example illustrates a useful application of the CV. The R–R interval in the electrocardiograms (ECG) can be used to evaluate brainstem function. This interval is highly variable in healthy subjects. The R–R interval is measured several times in a subject in one ECG, and the mean and SD are obtained. Thus, CV can be obtained for each subject separately. Nezu et al. [1] studied 18 children with severe brain damage and 22 controls. They obtained the results shown in Table C.22.

**TABLE C.22**
**Mean Coefficient of Variation (CV) of R–R Intervals in Cases with Different Conditions**

| Condition | *n* | Mean CV of R–R Intervals (%) |
|---|---|---|
| Neurologically normal controls | 22 | 5.56 |
| Patients complicated with respiratory insufficiency (RI) | 10 | 2.19 |
| Patients with severe athetotic cerebral palsy (SA) | 8 | 11.30 |
| Patients with brain death (included in RI group also) | 4 | 1.00–1.29 |

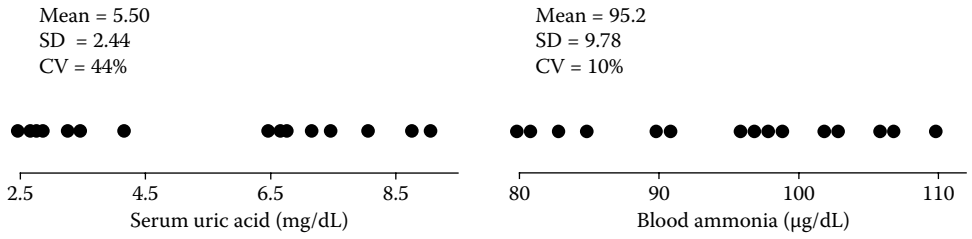

**FIGURE C.17** Less SD but higher CV of serum uric acid levels relative to blood ammonia levels.

C

The authors did not investigate the cause of the higher CV in the severe athetotic cerebral palsy (SA) group but concluded on the basis of the extremely low CV in patients with brain death that the CV of the R–R interval may be useful for quantitative evaluation of severe neurological deficit. In general, the CV of R–R intervals is also reduced in the aged and possibly also in subjects suffering from essential hypertension.

Chang et al. [2] have described another useful application of CV. They measured the nuclear diameter of cancer cells by ocular micrometry and calculated the CV. Recurrent cases and cases in which death occurred had higher CV than their respective complements. They concluded that the extent of variation as measured by the CV of the nuclear diameter of cancer cells offers a prognostic adjunct to standard clinical and histological analysis.

Although CV is unit free, it is affected by change of origin and scale since mean and SD are affected. Thus, it can give a misleading result for data on an interval scale where zero has no substantive meaning and a constant can be added or subtracted. Otherwise, also if some values of a variable are negative and others positive, the mean could be small or close to zero. In this case, the CV will undesirably inflate. This will happen if you are measuring the change from time 1 to time 2, pre to post, etc. Thus, use the CV for **ratio scale** data only where zero is defined and values are positive. Strictly speaking, from this point of view, the CV should not be used for a measurement such as BP and Hb levels since zero is not possible in living subjects. However, we see no such problem in the examples cited earlier in this section since no negative values are possible.

The CV can also be used as an index of reliability in repeated measurements. For details, see Shechtman [3].

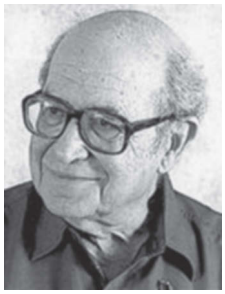
## Cohen kappa, *see also* Bangdiwala B

This measures the extent of **agreement** in qualitative assessments between two observers. Thus, this is applicable when $n$ subjects are categorized into same $K$ categories by two independent observers. This is a matched pairs setup that would lead to a $K \times K$ table. In place of two observers or two raters, you can have two methods, two sites, two laboratories, or any other such comparison.

In terms of notations,

$$\text{Cohen kappa: } \kappa = \frac{\Sigma O_{kk} - \Sigma(O_{k\bullet}O_{\bullet k}/n)}{n - \Sigma(O_{k\bullet}O_{\bullet k}/n)},$$

where $O_{kk}$ is the cell frequency in the $k$th row and the $k$th column (diagonal element) of the $K \times K$ table, $O_{k\bullet}$ is the marginal total in the $k$th row, $O_{\bullet k}$ is the marginal total in the $k$th column, and $n$ is the grand total. The first term in the numerator is the observed agreement, and the second term is the chance agreement as explained next. Thus, the numerator is the agreement in excess of chance. The denominator is its maximum possible value. Further explanation is given later in this section with the help of an example. Cohen kappa was first proposed by Jacob Cohen in 1960 [1].



Jacob Cohen

An example is comparing response evaluation criteria in solid tumors and volumetric evaluation for colorectal cancer with liver-limited metastasis using $n = 45$ computed tomography (CT) images [2]. In this case, the categories were partial response, stable disease, and progressive disease, a total of $K = 3$ categories of responses in the study. Assessing optical disc characteristics by two or more observers, results of Lyme disease serological testing by two or more laboratories and comparison of x-ray images with Doppler images are the other examples of the problem of qualitative agreement. The objective is to find the extent of agreement between two or more methods, observers, laboratories, etc. In some cases, for example, in comparison of two laboratories, agreement has the same interpretation as **reproducibility**. In the case of comparison of observers, it is termed *interrater reliability*. In all these cases, only one group of subjects is assessed twice. Cohen kappa is easy to understand when the meaning of qualitative agreement is clear.

### *The Meaning of Qualitative Agreement*

For simplicity, we will focus for the time being on the presence or absence of a characteristic assessed by two observers on the same group of subject. An example is presence or absence of a lesion in x-rays read by two observers. Suppose the observations are as given in Table C.23.

The two observers agree on a total of 29 + 11 = 40 cases in this example. This is the sum of the frequencies in the leading diagonal cells. In the other 20 cases, the observers do not agree. Apparently, the agreement = 40/60 = 66.7%. But part of this agreement is due to chance, which might happen if both are dumb observers and randomly allocate subjects to present and absent categories. This chance agreement is measured by the cell frequencies expected in the diagonal when the observer's ratings are independent of one another. These expected frequencies are obtained by multiplying the respective marginal totals and dividing by the grand total, as obtained for calculating the **chi-square**. This explains why we subtract $O_{k\bullet} \times O_{\bullet k}$ from the numerator and the denominator while calculating Cohen kappa.

**TABLE C.23**
**Presence or Absence of a Lesion Assessed by Two Radiologists in X-Rays of 60 Suspected Cases**

| | Observer 1 | | |
|---|---|---|---|
| **Observer 2** | **Present** | **Absent** | **Total** |
| Present | 29 | 7 | **36** |
| Absent | 13 | 11 | **24** |
| **Total** | **42** | **18** | **60** |

For the data in Table C.23, the chance-expected frequencies are 36 × 42/60 = 25.2 and 24 × 18/60 = 7.2 in the two diagonal cells. The total of these two is 32.4. Agreement on so many cases is expected by chance alone. Thus, agreement in excess of chance is in only 40.0 – 32.4 = 7.6 cases. The maximum possible excess is 60.0 – 32.4 = 27.6.

The measure of agreement is the ratio of the observed excess to the maximum possible excess, in this case 7.6/27.6 = 0.275 or 27.5%. Thus, the two observers in this case do not really agree much on rating of x-rays for the presence or absence of lesion. Most of their agreement is due to chance. Now consider the following example where the number of categories is three.

Detection of intrathecal immunoglobulin G (IgG) synthesis is important in patients with suspected multiple sclerosis. Isoelectric focusing is a method used for the detection of intrathecal IgG synthesis. Let this be assessed as positive, doubtful, and negative by two laboratories on 129 patients. The results are in Table C.24. In this case,

$$\kappa = \frac{(36+12+55)-(44\times 44/129+25\times 21/129+60\times 64/129)}{129-(44\times 44/129+25\times 21/129+60\times 64/129)}$$
$$= \frac{54.155}{80.155} = 0.68.$$

Generally speaking, a kappa value equal to 0.68 is adequate to conclude fair agreement, but the investigation in this example is on reproducibility between laboratories. If both the laboratories are using standardized tools and methods, the agreement should be close to 1. Thus, the reproducibility of the method of isoelectric focusing between the laboratories for assessing intrathecal synthesis cannot be considered good in this case despite a not so disappointing value of kappa.

Kappa is used mostly to assess how close the agreement is to 1 rather than how far is it from 0. The following scale is suggested.

| Kappa | Strength of Agreement |
|---|---|
| <0.3 | Poor |
| 0.3–0.5 | Fair |
| 0.5–0.7 | Moderate |
| 0.7–0.9 | Good |
| >0.9 | Excellent |

The following comments regarding Cohen kappa may be helpful:

- There are some other measures of agreement for qualitative variables. These are discussed by Agresti [3]. He also describes other agreement assessment models such as log-linear, Rasch, and latent class models. A competitor of Cohen kappa is **Bangdiwala B**. A comparison of these two is presented by Munoz and Bangdiwala [4].
- Cohen kappa is valid for nominal categories only. Ordinal or metric categories are considered nominal by this measure and the order is ignored. The other assumptions are that (i) the subjects are independent; (ii) the observers, laboratories, or methods under comparison operate independently of one another; and (iii) the rating categories are mutually exclusive and exhaustive. These conditions are easily fulfilled in most practical situations.
- Although rare, you may sometimes find reference to **weighted kappa**. Here, the cells are assigned a weight according to the degree of disagreement they exhibit. Thus, cells in the diagonal, since they are in full agreement, get zero weight. Off-diagonal cells get varying weight depending upon either the perceived importance of the involved cells or some objective criterion such as quadratic weight. All this makes kappa too complex and possibly not as useful.
- The kappa value is +1 for complete agreement and 0 if the agreement is the same as expected by chance. However, the value does not become –1 for complete disagreement. Thus, *it is a measure of the extent of agreement but not of disagreement*.
- For the formula of variance of kappa for large samples, see Fleiss et al. [5]. This variance can be used to construct a confidence interval and to test a hypothesis on the value of kappa. Standard statistical software packages generally have provision to do these calculations.
- Kappa values from different studies may not be comparable as the value also varies with prevalence, which is the number of subjects in categories relative to the total. If one study has 30% subjects in category A and another study has 50%, the value of kappa will differ even if the extent of agreement is the same. In situation of rare events, a low kappa may not necessarily reflect low level of agreement.
- Kappa does not distinguish between +/– **discordance** and the reverse –/+ discordance. Both get the same weight. Thus, kappa can be 0.9 in 100 subjects when all discordances are of the +/– type and none of the –/+ type.
- The discordance between two raters can be due to bias of one rater to classify differently or could be a genuine difference in assessment. Kappa does not distinguish these two different kinds of discordance, and both are combined.
- Cohen kappa can also be used for assessing **test–retest reliability** in qualitative data.

C

## cohort studies, *see also* prospective studies

A **cohort** is a group of subjects that share a common base and observed forward in time. In the case of a usual prospective study, the subjects can be enrolled continuously and can leave the study abruptly, whereas, in the case of cohort, enrollment, joining, or leaving in the middle is rarely admissible. In a study on use-effectiveness of oral contraceptive pills [1], the users joined the group when they started using the pills and left when they stopped using them. They could not join 2 or 3 months after starting the pill. All subjects of a cohort do not have to start from the same calendar time, but they all start from the time of occurrence of the same event.

The term *cohort* generally connotes a substantial time gap between exposure and outcome, and the observation spans all or most of this period. There could be a cohort of children born in a particular year followed up for growth pattern, or a cohort of adults residing in an area at a time followed up for diet–exercise and occurrence of coronary events. There could be a cohort of smokers and a matched cohort of nonsmokers residing in an area at a particular time followed up for 20 years for the development of chronic obstructive pulmonary disease. Many other examples can be cited. Such cohorts are called **concurrent cohorts** when exposed and unexposed groups are followed up in future. If the group identified for the study is the one that has been recently exposed to a risk factor, it is called an **inception cohort**. For example, an inception cohort of early rheumatoid arthritis can be studied for assessing predictive factors of orthopedic surgery.

It is not necessary that the follow-up chronology is in the future; it could be in the past also. Sokal et al. [2] carried out a cancer risk study in 1992 on the basis of the records of women sterilized with transcervical quinacrine hydrochloride pellets in Chile between 1977 and 1991. Traceable women were also interviewed. Despite being based on past records, it is not a retrospective study since the direction of investigation is from antecedent to outcome. A **historical cohort** or **retrospective cohort** is a group of subjects with exposure in the past, investigated for development of an outcome. Terms such as *retrospective follow-up* and *historical prospective* are also used for this kind of methods. This requires that past records are fully available. See the following examples.

Richards et al. [3] report findings of a 53-year follow-up of a 1946 birth cohort, initially consisting of 5362 children of nonmanual and agricultural workers, and a random sample of one-in-four manual workers selected from all single and legitimate births that occurred in England, Scotland, and Wales during 1 week in March 1946. (Note the rigorousness with which the specifications are stated.) The cohort was studied on 21 occasions between birth and age 53 years. Information about sociodemographic factors and medical, cognitive, and psychological function was obtained by interview and examination at each point of contact. They concluded that birthweight and postnatal growth are independently associated with level of cognition at different ages. In this case, the main outcome of interest was level of cognition, and the antecedents were birthweight and postnatal growth. The outcome was repeatedly measured over the period so that the cognition achieved at different ages could be studied. Postnatal growth may be a function of birthweight, but as far as cognition was concerned, this study found that the two act independently.

Neary et al. [4] carried out a retrospective cohort study of all nonelective general and orthopedic surgical procedures performed on a total of 1869 patients in a hospital in the United Kingdom during the calendar year 2000. Outcomes were identified from various related hospital databases, and case notes of those who died were reviewed. Note that the study was from antecedent to outcome, but the subjects belonged to a past period. The study found that increasing age, size of operation, and American Society of Anesthesiologists (ASA) grade were significantly associated with higher risk of death by 1 year. The authors concluded that a simple scoring system could be used to identify high-risk patients among those who required nonelective surgery. Such patients could be targeted for interventions for reducing the risk of death. The conclusion reached is the same as anticipated by common sense. Yet the study has value, first for documenting the evidence and second by linking it to the scoring system. The study would hold greater value had the relative risk been quantified and if its confidence interval provided.

## collinearity, *see* multicollinearity

## communality of a variable

In a **multivariate** setup, communality is the proportion of variance of a particular variable $x_k$ that is shared with other $x$'s. Note the social overtones of such sharing, hence the term communality. This is frequently used in the context of **factor analysis** to measure how much variables share with the extracted factors. The basic premise of factor analysis is that various variables have one or more common factors. Thus, sharing is built in into the concept of factor analysis. High communality of several $x$'s indicates that the factor analysis would be successful. The remainder variance, after subtraction of the communality, is considered unique to $x_k$ as it is the part not shared with the other variables.

In factor analysis, the calculation of communality is based on what is called **factor loadings** of the variables. This is the correlation between the variable and the factor. Loading can be negative since this is correlation. Its square is the percent variance in that variable explained by the concerned factor. If loading of the $k$th variable for the $j$th factor is $l_{jk}$, the communality of the $k$th variable is

$$\text{communality of } x_k\text{: } c_k = \Sigma_j l_{jk}^2.$$

This can be understood as the square of the **multiple correlation** coefficient ($R^2$) for the regression model predicting $x_k$ from the extracted factors. This is the proportion of variance of a variable explained by all the factors together. Factor loading is calculated for each factor and each variable, whereas communality is calculated for the variables when the factors are combined.

The results of a factor analysis of an 11-point questionnaire on family burden of a particular disease, for example, are given in Table C.25. Factor analysis extracted three factors. For variable $x_1$ (loss of earnings), communality $c_1 = (0.87)^2 + (0.07)^2 + (0.11)^2 = 0.7739$. This is high relative to, say, variable $x_9$ (dependence on

**TABLE C.25**
**Results of a Factor Analysis of an 11-Point Questionnaire on Family Burden of a Disease**

| | Loadings | | | |
|---|---|---|---|---|
| Variable | Factor 1—Economic | Factor 2—Social | Factor 3—Mental | Communality (Sum of Squares of Loadings) |
| $x_1$ Loss of earnings | 0.87 | 0.07 | 0.11 | 0.7739 |
| $x_2$ Hospital expenses | 0.75 | 0.15 | 0.23 | 0.6379 |
| $x_3$ Depression | 0.01 | 0.43 | 0.88 | 0.9594 |
| $x_4$ Disruption of life | 0.22 | 0.58 | 0.41 | 0.5529 |
| $x_5$ Desertion by friends | 0.05 | 0.92 | 0.12 | 0.8633 |
| $x_6$ No recreation | 0.02 | 0.69 | 0.38 | 0.6209 |
| $x_7$ Helplessness | 0.14 | 0.56 | 0.69 | 0.8093 |
| $x_8$ Mental agony | 0.08 | 0.24 | 0.97 | 1.0049 |
| $x_9$ Dependence on others | 0.20 | 0.24 | 0.32 | 0.2000 |
| $x_{10}$ Family secluded | 0.12 | 0.85 | 0.73 | 1.2698 |
| $x_{11}$ Loans | 0.97 | 0.23 | 0.18 | 1.0262 |

others) whose communality $c_9 = (0.20)^2 + (0.24)^2 + (0.32)^2 = 0.2000$. In this example, loss of earning is explained best by the factors, and depression is not explained well.

See **factor analysis** to further understand the application of this method. For other methods of calculating communalities, see Gorsuch [1].

## comparative mortality ratio

Comparative mortality ratio is the ratio of two **death rates** with some common base. Common base means that both the rates should be per 1000 population, per 1000 births, per 1000 cases, etc. This is defined as

$$\text{comparative mortality ratio} = \frac{\text{death rate-1}}{\text{death rate-2}} * 100,$$

where the two death rates have some common base.

The term *comparative mortality ratio* is yet to achieve a common global meaning. One popular use of the comparative mortality ratio is in the ratio of expected number of deaths arrived by standardization to the actual deaths. If the **standardized death rate** is 5.5 per thousand population for a country where the **crude death rate** is 8.5 per thousand population, the comparative mortality ratio for this country is $100 \times 5.5/8.5 = 65\%$. For another country, this might be 138%, which would imply that the standardization has reverse effect.

The utility of the comparative mortality ratio increases when both the rates are standardized to the same standard structure. If this ratio for the United States compared to Venezuela is 95%, since both rates refer to the same standard population, this can be interpreted as saying that the death rate in the United States is 95% of that in Venezuela. Although both rates under comparison are standardized for the same age structure (thus comparable), the effect of the chosen standard is not eliminated by this comparison. If another standard age structure is chosen, the ratio can become very different.

The utility of the comparative mortality ratio increases further when several populations are compared. For example, if the US age-standardized heart disease death rate in white males is considered 100, the comparative mortality ratio for age-standardized death rate is more than 120 for many health service areas (HSAs) in the mid-southeast and less than 80 for many HSAs in the west. Thus, the comparative mortality ratio is one more method to know which segment of population has relatively higher or lower mortality. Strategies for controlling mortality can be accordingly devised.

An example of this is a study of site-specific cancer mortality in Greece. Alexopoulos et al. [1] found 3.5-fold variations in cancer mortality ratios among men across broad occupational groups. Such variation across occupations for the same cancer might stimulate thinking, and preventive actions can be taken regarding the job-related factors.

1. Alexopoulos EC, Messolora F, Tanagra D. Comparative mortality ratios of cancer among men in Greece across broad occupational groups. *Int Arch Occup Environ Health* 2011 Dec;84(8):943–9. http://www.ncbi.nlm.nih.gov/pubmed/21331610

## comparison groups

Comparison groups help to attach meaning to the findings where stand-alone may not carry much of a meaning. If you are told that the 5-year survival rate in patients of cancer of the esophagus of age 60–65 years is 32%, what do you make of this? This suddenly acquires significance when compared with, say, 85% survival in healthy subjects of corresponding age. This comparison might be inadvertent, but values acquire interpretation when put into context. Relativity such as high or low, more or less, better or worse, or even same is inherent in much of our thought process. An explicit comparison group is helpful in proper interpretation. This must be explicitly stated, particularly in a research setup, since different comparison groups can give different results.

A comparison group has special significance in clinical trials, particularly in phase III (see **phases of clinical trials** for details). Phase I is primarily to establish tolerability, and this does not require any comparison group. In phase II also, the objective might be to test the concept in the sense that the regimen has at least minimum **efficacy** for pursuing it further. In this case also, comparison group is not necessary, although this helps in confirming that the observed efficacy is not due to a **placebo** effect. In a rare case a regimen is developed for a disease with no existing treatment, the interest might

C

be in its absolute efficacy even in phase III. There are conditions for which no cure exists, but there is hardly any ailment for which no treatment is available. That treatment may have low efficacy is a different matter. Thus, the objective in almost all phase III trials is to establish that the regimen is better than the existing treatment. In this case, the comparison group is given the existing treatment. In the context of the usual clinical trials, the comparison group is called a parallel **control group**. In before–after experiments and trials, the comparison is with the preintervention values.

Ideally, the comparison group must be identical to the active group. In our example, the comparison of 32% 5-year survival in cancer cases with 87% in healthy controls is valid only when both relate to the same parent population. In a clinical trial, the control group must be similar to the active group except that the active group receives the regimen under examination and the control group receives nothing or placebo or the existing regimen. This brings in the question of **baseline equivalence** of the groups. Two popular methods to achieve this equivalence are **randomization** and **matching**. Randomization is used when the group sizes are reasonably large and ethically justified, and matching is generally used for small groups or when randomization is not feasible.

## comparison of intercepts in two or more simple linear regressions

For simplicity, we restrict ourselves to only **simple linear regression** in this section where the **intercept** is the value of the dependent variable $y$ at $x = 0$. The intercept in this setup is conventionally denoted by $\alpha$ for the population and by $a$ for the sample. It is important in some health setups such as the bilirubin level at age = 0, i.e., at the time of birth. You might be running a simple linear regression of bilirubin ($y$) on age ($x$) for male and female singleton children in a well-to-do segment of a population, and may be interested in comparing the bilirubin level at birth in the two sexes based on subsequent trend. Statistically, this is the same as comparing the intercepts, which really means testing the **null hypothesis** $H_0$: $\alpha_1 = \alpha_2$, where the subscripts are for group 1 and group 2, respectively.

In our example, the group of male children is independent of the group of female children since they do not, in any way, affect the bilirubin level of the other group. Any comparison between the independent groups is easier relative to the comparison between the dependent groups. Dependence arises when, for example, the comparison is of the intercept of the regression of bilirubin on age in male children with this intercept in female children in the same family. In this case, you can see that bilirubin and albumin levels in the same family would be correlated—thus, the comparison requires this correlation to be factored. This is a rare problem and is not discussed further. It is mentioned here so that you become aware that this can happen.

### *Comparison of Two Intercepts in Independent Groups*

Consider the intercepts of the simple linear regression of bilirubin level on age in male and female children not belonging to the same family. These two are independent groups. For simplicity, we assume that the slopes of the two regressions are the same. In this situation, the null hypothesis $H_0$: $\alpha_1 = \alpha_2$ can be tested by setting up a joint model of the type $y = \alpha + \beta z + \beta x$, where $z$ is the indicator variable for sex, taking value 0 for males and 1 for females. Thus, the intercept for males is $\alpha$ and that for females is $(\alpha + \beta)$. Statistical software can be asked to test $H_0$: $\beta = 0$ in the regression equation just mentioned, which is the same as equal intercepts.

In case you want to do it yourself or want to learn what goes behind the computer calculations, here are the two solutions. An approximate solution that might work well for large samples is to find the **standard errors** (SEs) of the respective intercept estimates, and use the fact for independent samples that estimated SE $(a_1 - a_2) = \sqrt{\text{SE}_{a_1}^2 + \text{SE}_{a_2}^2}$, where estimated $\text{SE}_a^2 = \text{MSE}\left[\frac{1}{n} + \frac{\bar{x}^2}{\Sigma(x-\bar{x})^2}\right]$ for simple linear regression. This is calculated separately for the intercepts $a_1$ and $a_2$ in the two regression equations. When the distribution of the dependent $y$ (or the residuals) is Gaussian, the test statistic as usual is

$$\text{Student } t = \frac{a_1 - a_2}{\text{estimated SE}(a_1 - a_2)}$$

with df = $(n_1 + n_2 - 4)$ for the null that the two intercepts are equal ($H_0$: $\alpha_1 = \alpha_2$). The df actually is $(n_1 - 2) + (n_2 - 2)$. For large samples, the **central limit theorem** can be invoked for non-Gaussian distributions. Reject the null in favor of the two-sided alternative at 5% level of significance when $|t|$ > table value of $t$ at the specified df. If the null is $\alpha_1 - \alpha_2 = \delta$ (that is, the intercepts differ by at least some medically important quantity $\delta$), the test statistic modifies to $t = (a_1 - a_2 - \delta)/\text{SE}(a_1 - a_2)$.

The test described in the preceding paragraph can be improved if the residuals for the two groups under comparison have nearly the same variance. This is implicit in the case of the previous test also. When variances are equal, you can improve its estimate by calculating

$$\text{pooled estimate of the residual variance: } s_{y.x}^2 = \frac{\text{SSE}_1 + \text{SSE}_2}{n_1 + n_2 - 4},$$

where SSEs are the error sum of squares of the respective regressions. This is the new MSE for this setup. When this is used, the

$$\text{pooled estimate of SE } (a_1 - a_2) = s_{y.x}^2 \left[\frac{1}{n_1} + \frac{1}{n_2} + \frac{\bar{x}_1^2}{\text{SS}(x_1)} + \frac{\bar{x}_2^2}{\text{SS}(x_2)}\right],$$

where SSs are the sum of squares due to $x_1$ and $x_2$, respectively. All these sums of squares come from the regression analysis. Under Gaussian conditions, $t = (a_1 - a_2)/[\text{estimated SE}(a_1 - a_2)]$ has a Student $t$ distribution with df = $(n_1 + n_2 - 4)$ under the null that the two intercepts are equal ($H_0$: $\alpha_1 = \alpha_2$). Reject the null if the ***P*-value** corresponding to the calculated value of $t$ is less than the predetermined $\alpha$ **level of significance**; otherwise, do not reject the null. All this is essentially the same as described in the preceding paragraph except that we have an improved estimate of the residual variance. In place of separate MSEs of the two individual regressions, we now have one MSE, denoted by $s_{y.x}^2$, from the combined sample.

Another approach could be to find the $100(1 - \alpha)\%$ **confidence intervals** (**CIs**) for the two intercepts and see if these CIs overlap. If the CIs overlap, the difference between the intercepts is not statistically significant at $\alpha$ level of significance; otherwise, the difference is significant. For these CIs, the pooled estimate of the SE, as just stated, is used.

## comparison of one sample mean and proportion with a prespecified value

The question of comparison of one sample with a prespecified value arises when we want to assess if the sample values agree or disagree

with some known value or a hypothesized value of a **parameter**. The parameters considered in this section are either mean or proportion, which incidentally are also the most commonly used parameters. Mean is used when the data are quantitative and the proportion when they are qualitative.

### *Comparison with a Prespecified Mean*

Let the interest be in finding whether patients with chronic diarrhea have the same average hemoglobin (Hb) level as normally seen in healthy subjects in the area. Suppose the mean normal level of Hb is 14.6 g/dL. This is assumed to be known and fixed for the present example. Since chronic diarrhea can only decrease the Hb level, and not increase it, it is a one-tailed situation. In an unlikely event of sample mean being >14.6 g/dL, the evidence is immediate that Hb level does not decrease in chronic diarrhea patients, and there is no need to proceed further. Although a higher mean can occur by chance in the sample when the population mean is less than 14.6 g/dL, let us keep that aside for the moment.

Suppose further that a random sample of 10 patients with chronic diarrhea is investigated, and the average Hb level is found to be 13.8 g/dL. Thus, the sample mean is lower than normal. This would occur if the sample happens to comprise subjects with a lower level. Such subjects are not uncommon in the healthy population as well. If another sample of 10 patients is studied, the average could well be 14.8 g/dL. Can it be concluded with reasonable confidence on the basis of the previous sample that patients with chronic diarrhea indeed have a lower Hb level on average?

There is only one sample in this example, and the comparison is with the known average in the healthy subjects. It is a one-sample problem, although the comparison is of two means—one observed in the sample and the other known for the healthy population.

The **null hypothesis** in the preceding example is $H_0$: $\mu = 14.6$ g/dL. Since the possibility of a higher average Hb level in patients with chronic diarrhea is ruled out, the alternative hypothesis is one-sided. That is, $H_1$: $\mu < 14.6$ g/dL. If $H_0$ is rejected, then $H_1$ is considered true.

The first step is to choose an appropriate criterion to test the hypothesis. The value of this criterion is then calculated assuming that $H_0$ is true. Then the probability of the observed or a more extreme value is obtained. This is the ***P*-value**. If this probability is very small, $H_0$ is considered not plausible and rejected. The conclusion then reached is that $H_1$ is true. If the *P*-value is not sufficiently small, say not less than 0.05, the null hypothesis is conceded. As mentioned in **tests of hypothesis (philosophy of)**, this does not imply that $H_0$ is accepted. It is just that it cannot be rejected on the basis of that sample because **sampling fluctuation** is not adequately ruled out as a likely explanation.

Heuristically, the answer depends on the magnitude of the difference between the sample mean and the known mean of the healthy subjects. In the preceding example, this difference is 13.8 – 14.6 = –0.8 g/dL. This magnitude is assessed relative to the expected variation in means from sample to sample. This variation is measured by the **standard error (SE)** of the mean, $\sigma/\sqrt{n}$. In a rare case when $\sigma$ is known, the criterion for testing this hypothesis is

$$\text{Gaussian test: } z = \frac{\bar{x} - \mu_0}{\sigma/\sqrt{n}}.$$

This follows a **Gaussian distribution** provided that the underlying distribution of *x*'s is also Gaussian. The value of this criterion is used to find if *P*-value is sufficiently small.

In practice, the standard deviation (SD) $\sigma$ would be rarely known and is replaced by its sample estimate *s*. This converts it to **Student *t***. Thus, the criterion for this setup is

$$\text{Student } t\text{-test (one sample): } t_{n-1} = \frac{\bar{x} - \mu_0}{s/\sqrt{n}},$$

where $\mu_0$ is the value of the mean under $H_0$. This criterion is valid under mild conditions. One of the conditions is that the observations are independent. In the context of this example, this means that the Hb level in one subject should not have any influence on the level in other subjects. This is clearly satisfied in this example, but there are situations where independence is violated. The other condition is that the distribution of *x*'s themselves is Gaussian, which also implies that the distribution of sample mean $\bar{x}$ is Gaussian. Because of the **central limit theorem**, this condition can be relaxed if sample size is large. The higher the value of *t*, the greater the chance that the sample has not come from a population with mean $\mu_0$. In that case, the decision to reject $H_0$ would have less chance of error. When this probability of **Type I error** is low, say less than 0.05, $H_0$ can be safely rejected. The exact *P*-value for a particular value of *t* is provided by most of the standard statistical packages. As mentioned under **Student *t***, the distribution of *t* depends on the degrees of freedom, df. For *t* in the formula just given, df = $(n - 1)$. This is specified as a subscript of *t*.

Consider our example of the Hb level in chronic diarrhea patients. Suppose that in a random sample of size $n = 10$, the levels in grams per deciliter are as follows:

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| 11.5 | 12.2 | 14.9 | 14.0 | 15.4 | 13.8 | 15.0 | 11.2 | 16.1 | 13.9 |

These give mean $\bar{x} = 13.8$ g/dL and SD $s = 1.67$ g/dL.

The hypothesis under test is that the average Hb level in the patients with chronic diarrhea is the same 14.6 g/dL that is normal in healthy subjects. Thus, $H_0$: $\mu = 14.6$ g/dL. The alternative as already explained is $H_1$: $\mu < 14.6$ g/dL. In this case, under $H_0$,

$$t_9 = \frac{13.8 - 14.6}{1.67/\sqrt{10}} = -1.51.$$

A statistical package gives $P(t < -1.51) = 0.0827$. This is the probability of getting the sample mean this much or more extreme in favor of $H_1$. Since this $H_1$ is one-sided, the probability required is also one-tailed. In this case, *P* is more than 0.05. Thus, the chance is more than 5% that the sample has come from a population with mean 14.6 g/dL. Therefore, this $H_0$ cannot be rejected. The difference between the sample mean 13.8 g/dL and the population normal 14.6 g/dL is not statistically significant. This sample does not provide sufficient evidence to conclude that the mean Hb level in chronic diarrhea patients is less than normal.

The conclusion in this example is partly the result of the high variability in the Hb level in the sample patients. Whereas it was only 11.2 g/dL in one patient, it was 16.1 g/dL in another. Widely scattered values gave a high value of sample SD *s* and led to the expectation of high intersample variability. Consequently, it became difficult to say anything definite about the lower mean Hb in these patients.

### *Comparison with a Prespecified Proportion*

Now consider qualitative data where the interest is in proportion. Suppose that a pharmaceutical company claims that its particular

drug has at least 72% efficacy in the long run. Thus, the null is $H_0$: $\pi = 0.72$. To test this claim, you try the drug on a random sample of $n = 40$ patients and 28 respond positively. Thus, the efficacy is 70%. Now the question is, can population proportion still be at least 72%? If not, the inference would be that it is less than 72%. The null would be rejected in favor of this alternative. Thus, the alternative hypothesis is $H_1$: $\pi < 0.72$. Inference on any **binary variable** such as this is always based on **binomial distribution**, but a Gaussian approximation can be used when the sample size is large. For small $n$, see **exact tests** based on binomial distribution described for the **McNemar test**.

How much $n$ is large? For small $\pi$, we need really large $n$, and for $\pi$ around 0.5 not as large. The rule generally followed for being able to use the Gaussian approximation is $n\pi \geq 8$. This implies that $n$ should be at least 400 for $\pi = 0.02$ (2%) and should be just about 20 for $\pi = 0.4$. When $n$ is this large, the criterion to test the null $H_0$: $\pi = \pi_0$ is

$$\text{large sample test for one sample proportion: } z = \frac{p - \pi_0}{\sqrt{\pi_0(1-\pi_0)/n}}.$$

This is referred to the Gaussian distribution to find the $P$-value. In our example,

$$z = \frac{0.70 - 0.72}{\sqrt{0.72 \times 0.28/40}} = -0.28\,.$$

Since the alternative is of the "less than" type, the $P$ is the probability in the left tail (i.e., $P(z < -0.28)$). This gives $P = 0.39$ for a Gaussian distribution. Since this is much more than the conventional level 0.05, the null cannot be rejected. Conclude that the efficacy could be (not that it is) 72%.

## comparison of one sample proportion with a prespecified value, *see* comparison of one sample mean and proportion with a prespecified value

## comparison of two or more correlation coefficients

We restrict this section to comparing **Pearsonian correlation** coefficients. This is also what is most commonly required in practice. Other kinds of correlations such as Spearman and point biserial are excluded from the present discussion. You may be aware that Pearsonian correlation coefficient is a measure of only the **linear** relation. When the relationship is nonlinear, only the linear component is considered by this correlation coefficient.

The problem of comparing two or more correlations can arise in two different setups:

1. Comparing the correlations between the same variables in two independent groups such as the correlation between kidney size and height in males compared with the same correlation in females. In this setup, males and females are independent groups since the values in one group do not alter the values in the other group.
2. Comparing different correlations in the same group such as comparing the correlation between kidney size and height with the correlation between creatinine level and weight when both the correlations are obtained for the same group of male subjects. In this setup, since the values belong to the same group of subjects, the two correlations are not strictly independent. In this example, an overlap can also occur when the two correlations share a common variable, such as kidney size appearing in both the correlations. This kind of dependence gives rise to further statistical problems.

Both these setups are discussed below.

### *Comparing Correlations in Two or More Independent Groups*

The distribution of the Pearsonian correlation coefficient ($r$) in general is not Gaussian. However, for large samples, the **central limit theorem** (CLT) may help. You may have noticed that the formula for calculating $r$ has *sum* of cross-products in the numerator. Because of this sum, the central limit theorem is applicable, and we can say that the distribution of the sample correlation coefficient follows a **Gaussian distribution** for large $n$ even when the distributions of the variables $x$ and $y$ are not Gaussian. Under these conditions, one can think of using the **Student *t*-test** for comparing the two independent correlations. For this test, an estimate of the **standard error (SE)** of $r$ is needed for calculating the SE of the difference $r_1 - r_2$. SE of $r$ is a complex expression except when the population correlation coefficient $\rho = 0$ (in this special case, estimated $\text{SE}(r) \approx \sqrt{1-r^2}/\sqrt{n-2}$ ). Also, this $t$ requires comparatively very large $n$ for CLT to be effective. Thus, for comparing two independent Pearsonian correlations, it is customary to use **Fisher *z*-transformation**. This is given as

$$\text{Fisher } z\text{-transformation: } z = \frac{1}{2}\ln\left(\frac{1+r}{1-r}\right),$$

$$\text{and estimated SE}(z) = \sqrt{\frac{1}{n-3}}\,.$$

This transformation was proposed by Fisher in 1921 and was shown to follow an approximate Gaussian distribution even when $n$ is not very large [1]. This also works well for relatively small samples but requires that at least one of the variables follows a Gaussian distribution.

For comparing two independent correlations, under the null hypothesis that the two correlations in the populations are equal ($H_0$: $\rho_1 = \rho_2$), calculate

$$z = \frac{z_1 - z_2}{\sqrt{\frac{1}{n_1 - 3} + \frac{1}{n_2 - 3}}}\,.$$

Reject the null at 5% **level of significance** when the calculated value of $|z| > 1.96$. Since the estimated SE is being used, this, in fact, should be Student $t$ with $\text{df} = (n_1 + n_2 - 6)$ but is still considered Gaussian $z$ because both are equivalent for large samples.

There are cautions, though. (i) Correlations in two groups are comparable (just as almost any other sample summary) when the two groups follow the same method of measuring the variables, same range restriction, etc. (ii) Make a distinction between a correlation coefficient and a **regression coefficient** (slope). In one setup, the variable $y$ may increase on average by 5 units for each unit increase in $x$ and in the other setup by only 2 units, yet both can have equal correlations (Figure C.18b). Because of higher scatter, solid dots have lower correlation in Figure C.18a compared with hollow squares, but both have nearly the same regression coefficient.

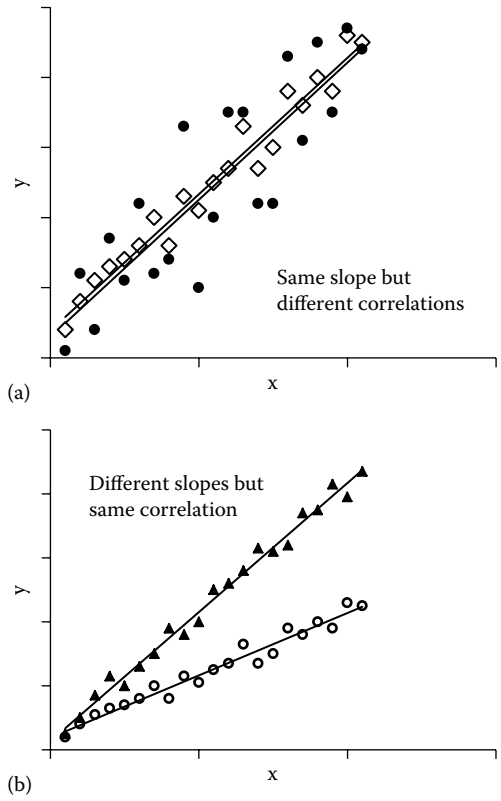

**FIGURE C.18** (a) Nearly same slope but different correlations. (b) Different slopes but nearly same correlations.

In both these figures, the intercept is the same but that also can be different.

The procedure for comparing more than two correlations is not straightforward. The details are provided by Fleiss [2] in the context of **meta-analysis** where the researcher would like to know that the correlations reported in different studies are homogeneous. A relatively simple procedure for large $n$ in each sample is as follows. Suppose you have $K$ independent samples and the correlation coefficient in the $k$th ($k = 1, 2, \ldots, K$) sample is $r_k$. The test criterion is

$$Q = \sum_{k=1}^{K} W_k (z_k - \bar{z})^2,$$

where $z_k = \frac{1}{2}\log[(1 + r_k)/(1 - r_k)]$, $W_k$ is the reciprocal of the variance of $z_k$, i.e., $W_k = (n_k - 3)$ since $1/(n_k - 3)$ is the variance of $z_k$, and $\bar{z} = (\Sigma_k W_k z_k)/(\Sigma_k W_k)$. This is the **weighted average** of the Fisher $z$-transformations of the values of the correlation coefficients. Under the null hypothesis of equality of correlations, $Q$ follows a chi-square distribution with df = $(K - 1)$. This is a fairly general procedure that can be applied for comparing any parameter in $K$ independent samples whose estimate follows a Gaussian distribution for large $n$. That is, you can have another summary in place of the correlation coefficient. Use the chi-square distribution to find the ***P*-value** corresponding to the calculated value of $Q$, and reject the null if the $P$-value is less than the prespecified level of significance.

If a statistical package is used to do these calculations, examine if the facility for such comparison is available in the software. Most packages as of now do not have direct facility to do these tests. You may have to write the commands or programming codes with the assistance of a biostatistician, or search the Internet for such commands prepared by someone else. See Weaver and Wuensch [3] for more details.

### *Comparing Two or More Related Correlations*

The problem of comparing two correlated correlations is not simple. Correlated correlations can arise in a variety of setup. First are the correlations $r_{xy}$ and $r_{xz}$ where $x$ is the common variable, and both are obtained from the same set of data. This comparison will tell whether $x$ is related more with $y$ than with $z$. Second are the correlations among nonoverlapping variables such as comparing $r_{xy}$ with $r_{uv}$. When calculated from the same data, these correlations between ostensibly unrelated variables may also be related. Comparison of correlated correlations in both these setups leads to complex test criteria. Weaver and Wuensch [3] have provided the formulas and also examples. Further details are available in Raghunathan et al. [4] and Meng et al. [5].

### *Test of Significance of One Sample Correlation Coefficient*

The $z$-transformation can also be used to test the null $\rho = \rho_0$, rejection of which would indicate that the correlation coefficient is statistically significantly different from $\rho_0$. For this, calculate $z_0 = z_0 = \frac{1}{2}\ln\left(\frac{1+\rho_0}{1-\rho_0}\right)$ and

$$z\text{-test for one-sample correlation coefficient } (H_0\colon \rho = \rho_0)\colon\ z = \frac{z - z_0}{\sqrt{\frac{1}{n-3}}},$$

provided $n$ is large and at least one of $x$ and $y$ has a Gaussian distribution. In case the objective is to find whether a particular correlation coefficient observed in the sample is significant or not (this is the same as testing the null $\rho = 0$), this changes to

$$\text{The Student } t\text{-test for one sample correlation coefficient } (H_0\colon \rho = 0)\colon\ t = r\sqrt{1 - r^2}/\sqrt{n-2},$$

with df = $(n - 2)$. This does not require a large sample but requires Gaussian distribution of the values. If the $P$-value from this is less than the level of significance, conclude that the correlation coefficient is statistically significant.

C

## comparison of two or more odds ratios

Two kinds of comparison can arise in case of **odds ratios**. First is when the **logistic regression** is run separately for two groups such as for males and females with the same dependent and regressors, and you want to compare the odds ratio (OR) in one group with the other for any particular regressor. For example, the dependent can be logit of probability of death within 5 years with stage of cancer as one of the regressors, and this regression is run separately for males and females. In this situation, the two groups are independent and

$$\text{SE}[\ln \text{OR}_1 - \ln \text{OR}_2] = \sqrt{[\text{SE}(\ln\text{OR}_1)]^2 + \text{SE}[(\ln\text{OR}_2)]^2}.$$

The SEs on the right-hand side of the equation are **standard errors** of $\ln(\text{OR}_1)$ in the first group and of $\ln(\text{OR}_2)$ in the second group. For large samples, these SEs can be obtained by the formula given for **confidence interval for odds ratio**. Since OR is a ratio, it does not directly follow a Gaussian distribution—logarithm makes it linear and allows you to exploit the premise of the **central limit theorem**. Thus, lnOR becomes Gaussian for large samples, so does the difference in lnORs. Thus, the test criterion for testing the null $\text{H}_0$: $[\ln\text{OR}_1 - \ln\text{OR}_2] = \delta$ is

$$z = \frac{[\ln\text{OR}_1 - \ln\text{OR}_2] - \delta}{\text{SE}[\ln\text{OR}_1 - \ln\text{OR}_2]}.$$

For equality of ORs, $\text{H}_0$: $\delta = 0$ that would be rejected if the calculated value of $z$ for the available samples is less than the threshold at the specified level of significance. For 5% level of significance, this threshold for a **two-tailed test** is 1.96. Note that this test is for lnOR and not for OR itself. Also, this is valid only for large samples. In any case, the concept of OR is hardly ever applicable to small samples. This test presumes that the two groups have been studied with similar methodology and similar care, and there is no factor other than the group (sex in our example) that can affect the ORs. The procedure is extendable to more than two groups provided they are independent and each has a large sample.

The second setup is when you want to compare the OR of one regressor with the OR of another regressor in the same regression equation. If the logistic regression is

$$\text{logit}(\pi) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_K x_K + \varepsilon,$$

the null hypothesis now is $\text{H}_0$: $\beta_1 = \beta_2$. These are the effects of $x_1$ and $x_2$, respectively, on logit($\pi$). Thus, this null tests whether the effect of the regressor $x_1$ is the same as of $x_2$ in the presence of the other/s when both $x_1$ and $x_2$ are binary. In our example, we can divide stages of cancer into two categories such as stage I/II and stage III/IV, and age as <70 and ≥70 years, and the question to be answered is whether age has more influence on 5-year survival or the stage has more influence. Since both $x_1$ and $x_2$ are in the model, the question actually is about the effect of cancer stage when age is fixed, and the effect of age when stage is fixed. This setup is too complex and is explained by Hosmer et al. [1].

Another question is regarding the additional effect of $x_2$ when $x_1$ is present. The measurement of effect is in terms of OR in the present context and is called sequential OR. This question is not really a comparison of two ORs but is related. In our example, this is the effect of age on mortality when we know the cancer stage. Statistical significance of this can be tested by calculating the difference in $-2\ln L$ under the model with $x_1$, $x_2$ and with only $x_1$, and checking the additional contribution with chi-square at 1 df for large $n$. This procedure can be extended to find the statistical significance of combined effect for any number of regressors in the presence of (or adjusted for) other regressors.

## comparison of two or more proportions

Under **Gaussian conditions**, the difference between proportions $p_1$ and $p_2$ in two independent groups is statistically assessed by

$$\text{Gaussian test: } z = \frac{|p_1 - p_2|}{\sqrt{p(1-p)(1/n_1 + 1/n_2)}},$$

where $n_1$ and $n_2$ are the respective sample sizes and $p = (n_1p_1 + n_2p_2)/(n_1 + n_2)$. This is the combined proportion in the two samples. This combination is applicable in this case since under the **null hypothesis**, the two proportions are the same ($\text{H}_0$: $\pi_1 = \pi_2$) and the test criterion is obtained under this null. The denominator is the estimated **standard error (SE)** of the numerator in the case of independent samples. Because of *estimated* SE in the denominator, this actually is **Student *t***, but for large sample sizes where this is applicable, Student $t$ is almost the same as Gaussian $z$ and it is customary to use Gaussian $z$. The value of $z$ is referred to a Gaussian distribution, and a two-sided ***P*-value** is obtained.

For the data in Table C.26, for comparing prevalence of anemia in parity ≤ 2 with the prevalence in parity ≥ 3,

$$\cdots z = \frac{|14/60 - 16/40|}{\sqrt{30/100(1-30/100)(1/60+1/40)}} = 1.78.$$

Corresponding to this value of $z$, two-sided $P = 2 \times 0.0375 = 0.075$ when both negative and positive sides are considered, i.e., parity ≤ 2 may have more anemia or may have less anemia than parity ≥ 3. Since the $P$-value is not less than 0.05, the null cannot be rejected.

For large $n$, this procedure should give the same $P$-value as obtained by the **chi-square** criterion. In fact, there is a theoretical relationship saying that $z^2 = \chi^2$ with 1 df. This is called the equivalence of the 1 df $\chi^2$ to $z$. An advantage of the $z$-criterion is that $\text{H}_0$ can be directly tested against the **one-tailed alternative**. Then the $P$-value is obtained for one tail only. This would be twice the two-tailed probability if the one-tailed probability is not directly available. In case of chi-square, the $P$-value obtained would be two-tailed.

**TABLE C.26**
**Anemia and Parity in a Cross-Sectional Study of 100 Women**

| | Observed in the Survey | | |
|---|---|---|---|
| **Anemia** | **Parity ≤ 2** | **Parity ≥ 3** | **Total** |
| Present | 14 | 16 | **30** |
| Absent | 46 | 24 | **70** |
| **Total** | **60** | **40** | **100** |

Most software packages require only the entry of data in a specific format and a command to compute chi-square. *P*-values with and without **Yates correction** will be automatically obtained. Many packages issue a warning in case *n* or **expected cell frequencies** are small or automatically compute the **Fisher exact test** in this case. The purpose of providing formulas here is to explain the underlying principles. Many users these days would not actually use these formulas and would not manually calculate the value of $\chi^2$ or $z$ or, for that matter, any other given in this book.

### *Comparing Proportions in More Than Two Populations*

Suppose in Table C.26, parity is measured in five groups as 0, 1, 2, 3, and 4+. If the null hypothesis is that the proportion of anemic women is the same in each parity, this can be tested by the usual chi-square. The hypothesis of equality of proportions is the same as of independence. When we say that the proportions are the same in each parity, it implies that the proportion anemic is not affected by parity. However, keep in mind that the alternative hypothesis for the usual chi-square is that the proportions are not the same—there is some difference somewhere. If the alternative is some kind of trend that says that the proportion anemic increases as the parity increases, another test called **chi-square for trend** should be used. This question will arise only for ordinal categories such as parity in our example and not for nominal categories.

## comparison of two or more regression coefficients

You may be aware that the **regression coefficient** in simple linear regression measures the slope or gradient of the linear relationship. This defines the steepness. For example, the relationship between age and blood pressure is generally steeper in females than in males. That is, rise in BP with age is faster in female adults compared with males. This is one example where the comparison of the regression coefficients can provide useful information. We cite some other examples later in this section.

Statistically, the null hypothesis under consideration is $H_0$: $\beta_1 = \beta_2$, where β's are the two regression coefficients in two regression lines—one for each group. Their sample estimates are denoted by $b_1$ and $b_2$. Note that the subscripts here are for the groups and not for the regressors. Thus, these $\beta_1$, $\beta_2$ and $b_1$, $b_2$ have different meanings from what you see in multiple regressions.

The problem of such a comparison can arise also when the regression coefficients are for different variables within the same group. An example of the latter is comparing the regression coefficient of carbohydrate intake on total cholesterol level in a group of obese females and the regression coefficient of fat intake on total cholesterol level in the same group of subjects. You can see that this comparison would be valid only when the regression coefficients are **standardized**. This comparison would tell that cholesterol level is affected more by carbohydrate intake or by fat intake in obese subjects when nothing else is considered.

Another setup could be comparing the regression coefficient of carbohydrate intake on total cholesterol level with the regression coefficient of carbohydrate level on HDL cholesterol. When standardized, this comparison will tell whether the total cholesterol is affected more by carbohydrate intake or the HDL cholesterol is affected more. One can think of other setups as well. In these latter setups, the values of the regression coefficients could be related. These setups are complex and we do not discuss them any further. One method for this kind of setups is given by Clogg et al. [1].

For simplicity, we present the method of comparison for two groups. The method is extendable to more than two groups—only that the notations become messy.

### *Comparing Two or More Regression Coefficients in Independent Groups*

A simple but approximate method for independent groups is as follows. Obtain the estimated **standard errors (SEs)** of the sample regression coefficients by using the formula $\text{SE}_b^2 = \dfrac{\text{MSE}}{\Sigma(x-\bar{x})^2}$, where MSE is the mean square error (see **mean square in ANOVA**). This is obtained separately for the two groups. Then calculate the estimated SE of the difference in sample regression coefficients as $\text{SE}(b_1 - b_2) = \sqrt{\text{SE}_{b1}^2 + \text{SE}_{b2}^2}$. Now the test criterion is

$$t = \frac{b1 - b2}{\text{estimated SE}(b1 - b2)}.$$

This follows the **Student *t*** distribution with df = $(n_1 - 2) + (n_2 - 2) = n_1 + n_2 - 4$ under the **Gaussian conditions** and the null that the two regression coefficients are equal.

The method just mentioned is approximate since it does not use combination of the samples from both the groups for estimation of the SE. These two samples can be combined if the two groups have nearly the same variance of the **residuals**. In this case, an improved estimate of the MSE is given by

$$\text{pooled estimate of the residual variance: } s_{y.x}^2 = \frac{\text{SSE}_1 + \text{SSE}_2}{n_1 + n_2 - 4},$$

where SSEs are the **error sum of squares** of the respective regressions. When this is used,

$$\text{estimated SE}^2\,(b_1 - b_2) = s_{y.x}^2 \left[\frac{1}{\text{SS}(x_1)} + \frac{1}{\text{SS}(x_2)}\right],$$

where SSs are the sum of squares of $x$'s in the two regression equations. The test criterion is $t = (b_1 - b_2)/[\text{estimated SE}(b_1 - b_2)]$ with df = $(n_1 + n_2 - 4)$ as before under the Gaussian conditions and under the null hypothesis of equality of the regression coefficients.

Another approach for this setup could be to find the confidence intervals (CIs) for each of the two regression coefficients at $100(1 - \alpha)\%$ confidence level, where α is the level of significance, and see if these CIs overlap. If they do, the difference is not statistically significant; if not, the regression coefficients are significantly different. The method can be extended to regression coefficients in more than two groups.

## comparison of two or more regression lines

Quite often the objective is to compare the trends in two groups such as treatment and control groups or males and females. Most statistical software packages have still not been given intelligence to do this comparison directly. You may be required to specify the right model or use a modified procedure. Among various ways that this comparison can be done, the following illustrates one for comparing **simple linear regressions**. This procedure compares both the **intercepts** and the **slopes** at the same time.

C

Define an **indicator variable** $z$ and assign it a value 0 for group I and a value 1 for group II. The variable has no meaning except to indicate the group. For this reason, this is also called a **dummy variable**. Remind yourself that in the case of regression, $x$'s are considered fixed and they can have any appropriate value. Thus, a regressor variable of the type of $z$ is admissible. Now fit the following regression model to the data. The data should have values of $x$ and $y$ as before, as well as the values of $z$ as assigned above.

$$y = b_0 + b_1x + b_2z + b_3xz.$$

You can easily see that for group I, since $z = 0$, the model is

$$y = b_0 + b_1x,$$

and for group II, since $z = 1$, the model is

$$\begin{aligned} y &= b_0 + b_1x + b_2 + b_3x \\ &= a + bx, \end{aligned}$$

where $a = (b_0 + b_2)$, and $b = (b_1 + b_3)$.

Compare the latter two equations and note that $\beta_3 = 0$ implies same slope but different intercepts, i.e., the lines in the two groups are parallel, and $\beta_2 = 0$ implies same intercept in the two groups but different slopes; $\beta_2 = 0$ and $\beta_3 = 0$ together imply that the regression lines in the two groups are identical.

The test of these hypotheses can be done as usual for **regression coefficients**. The only additional requirement is that the variance in the two groups is the same. If the two lines are found not significantly different when $n_1$ and $n_2$ are sufficiently large to provide enough statistical **power**, the data from two groups can be pooled and a unified regression can be fitted that would have better reliability because of increased $n$. For this, pool the data and run the regression on $x$ and $z$ again.

The procedure can be easily extended to compare more than two lines. We are not going to discuss here this extension as it becomes mathematically complex. If interested, see Milliken and Johnson [1].

## comparison of two or more relative risks

For this section, we presume that you are familiar with the basics of relative risk (RR) and understand why we use its logarithm (lnRR) for most statistical inferences on RR. You may like to review the topic **relative risk**.

Two kinds of comparison can arise in case of RR. One is when this is calculated separately for two independent groups. For example, this may be RR of death within a period of 10 years for stage I of oral cancer versus no cancer for males and females. In this case, one RR is for males and one for females, and these RRs are compared to find whether they are different or not in the corresponding populations. Another comparison is RR of low birth weight in anemic women of age 20–24 years versus nonanemic, and similarly RR in women of age 25–29 years, to check if they are significantly different or not. In both these setups, the groups are independent since the outcome in one group does not affect the outcome in the other—the cases are different in the two groups. In this situation,

$$\mathrm{SE}[\ln \mathrm{RR}_1 - \ln \mathrm{RR}_2] = \sqrt{[\mathrm{SE}(\ln \mathrm{RR}_1)]^2 + [\mathrm{SE}(\ln \mathrm{RR}_2)]^2}.$$

The SEs of $\ln(\mathrm{RR}_1)$ in the first group and $\ln(\mathrm{RR}_2)$ in the second group on the right-hand side of the equation can be obtained by the formula given for **confidence interval for relative risk** for large samples.

RR is a ratio and cannot be expected to follow a Gaussian pattern. Logarithm linearizes this and helps in exploiting the premise of the **central limit theorem** to say that the statistical distribution of lnRR will be approximately Gaussian for large $n$. Thus, the test criterion for testing the null $\mathrm{H}_0$: $[\ln \mathrm{RR}_1 - \ln \mathrm{RR}_2] = \delta$ is

$$z = \frac{[\ln \mathrm{RR}_1 - \ln \mathrm{RR}_2] - \delta}{\mathrm{SE}[\ln \mathrm{RR}_1 - \ln \mathrm{RR}_2]}.$$

For equality of RRs, $\delta = 0$ and reject equality of RR in the two groups if the calculated value of $z$ for your samples is less than the threshold at the specified level of significance. For 5% level of significance, this threshold for a **two-sided alternative** is 1.96. Note that this test is for lnRR and not for RR itself. Also, this is valid only for large samples. The concept of RR is hardly ever applicable to small samples. This test presumes that the two groups have been studied with similar methodology and similar care, and there is no factor other than the group that can affect the RRs. The procedure is extendable to more than two groups provided they are independent and each has a large sample.

The second setup is when you want to compare the RR of one risk factor with the RR of another risk factor in the same group of subjects. In our example, besides the stage of cancer, we may be interested in the effect of age also. Age may be divided as <70 and ≥70 years. The question is whether age has more influence on 10-year risk of death or the stage has more influence. For this, you may like to refer to Hosmer et al. [1].

## competing risks

Competing risks are the **mutually exclusive and exhaustive** factors that compete with one another to cause the same outcome. For example, cardiovascular diseases and malignancies are the competing risks for death in old age. In this case, death is the outcome of interest. Both diseases can occur together in the same person, but the **cause of death**, when medically established, has to be only one of these. A large number of risks simultaneously operate, but when only one of them can succeed in reaching to the outcome, they will be called competing. In this case, occurrence of one will prevent any other to cause the outcome.

In another setup, surgery (say, radical prostatectomy) and radiotherapy are competing strategies for treating prostate cancer. But only one of them can be applied. When death is considered the outcome of interest, 15-year follow-up and competing risks analysis shows that the nonmetastatic (less severe) patients with surgery have nearly 1.76 times chance of survival compared to those on radiotherapy, but the performance is nearly the same in metastatic patients [1].

The objective of competing risks methodology is to delineate the risk from each competing factor such that the sum of these risks is 1. The methodology is based on cause-specific hazards and provides a kind of "real-world" probabilities occurrences of an event due to competing causes compared to single cause probabilities that could be contaminated by other causes. Take the example of deaths due to lung cancer in people of age 60 years and above who smoked for at least 200 pack-years of cigarette. These deaths will not be just because of smoking but also because of ageing and other ailments afflicting these people. The conventional analysis will attribute

deaths at different ages as though they are from lung cancer alone since the subjects are suffering from this disease. The fact is that the deaths are contaminated by ageing process and comorbidities. The competing risk methodology will filter out causes and provide risk "purely" due to lung cancer.

The methodology is mathematically complex; those interested may see Andersen et al. [2]. However, the concept and applicability of competing risks may be clear from the preceding discussion. The following example may help in appreciating the application of competing risk methodology.

Kandala et al. [3] analyzed 239,000 patients in the National Joint Registry for England and Wales for 10-year revision rate of total hip replacement. This was the outcome of interest. This was studied for each of the five prosthesis types such as cemented and cementless with ceramic-on-ceramic bearing surfaces or ceramic-on-polyethylene bearing surfaces. These were considered as competing risk for revision of hip replacement. Cemented prostheses with ceramics-on-polyethylene bearing surfaces had the lowest revision rates.

## complete linkage method of clustering,
*see also* **cluster analysis**

See **cluster analysis** for basic details of this kind of analysis. Complete linkage is one of the several methods of hierarchical clustering. In hierarchical clustering, a measurement of dissimilarity such as **Euclidean distance** is used to classify the units into various groups using one of the several possible algorithms. Two units (or subjects) that are most similar (or least distant) are grouped together in the first step to form one group of two units. This group is now considered as one entity. Now the distance of this entity from other units is compared with the other distances between various pairs of units. Again, the closest are joined together. This hierarchical agglomerative process goes on in stages, reducing the number of entities by one each time. The process is continued until all units are clustered together as one big entity. See **hierarchical clustering** for a method to decide when to stop the agglomerative process so that natural clusters are obtained.

The primary problem in clustering is computing the distance between two entities containing, say, $I$ and $J$ units, respectively. Several methods are available. One is to consider all units in an entity centered on their average. Another is to compute the distance of the units that are farthest in the two entities. A third method is to base it on the nearest units. There are several others. Complete linkage is one such method. Different methods can give different results, but complete linkage is considered the most appropriate for many applications. This method was first proposed by Sorensen [1] in the context of similarity in plant species.

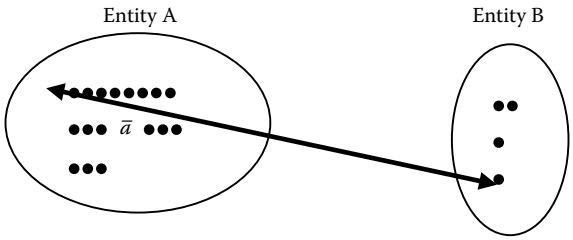

**FIGURE C.19** Complete linkage distance between entity A and entity B.

In complete linkage method of clustering, the distance between two clustered entities is measured by the distance between the farthest located units of the entities. If one entity has 7 units with values denoted by $(x_1, x_2, \ldots, x_7)$ and the other has 4 units with values denoted by $(y_1, y_2, y_3, y_4)$, the first step would be to calculate the distance between $x_1$ and $y_1$, $x_1$ and $y_2$, …, $x_2$ and $y_1$, …, $x_7$ and $y_4$. The maximum of these 28 distances will be considered as the distance between these two entities (Figure C.19). If entity A contains $I$ units $(a_1, a_2, \ldots, a_I)$ and entity B contains $J$ units $(b_1, b_2, \ldots, b_J)$, then, under the complete linkage method, the distance between these two entities is measured as $d_{AB} = \max_{ij}(d_{ij})$, where $d_{ij}$ is the distance between the $i$th unit of the first entity and the $j$th unit of the second entity. This method can be easily extended to a multivariate setup.

A large distance indicates that the entities are really very different from each other and thus should not be clustered together. If this distance is small, the entities can be considered similar, and you can merge these two entities together to form a bigger entity.

In a Monte Carlo comparison of six methods of hierarchical clustering on random data, complete linkage has been found the most adequate method not to discover false clusters [2]. Wentzensen et al. [3] used the complete linkage method for hierarchical clustering of disease groups and human papilloma virus genotypes for 2780 women who underwent colposcopy at baseline.

## completely randomized designs

In the context of biostatistics, design is the prefixed structure for collecting the observations for an empirical research. Such a study is likely to have at least two series of measurements that could be for different groups of subjects or the same group repeatedly measured. The design of an experiment is called completely randomized when the allocation of subjects to the groups is entirely at random with no consideration of any other factor. For example, if you have 60 eligible subjects for a trial and you divide them randomly into three groups to receive placebo (no drug), low dose, and high dose of

drug A, this is a completely randomized design. But if you consider something like age, sex, and severity of disease for allocation, the design is no longer completely randomized. Completely randomized is also called single-factor design—the factor being the dose of the drug in this example.

C

Suppose the interest is in conducting the same trial in males and females. This classifies the subjects. You will obviously have three groups of males with none, low, and high doses of drug A, and similar three groups of females. These cannot be considered six independent groups for **randomization**, since the randomization is now restricted to males and females separately. This is not a completely randomized design with one factor at six levels. This is a two-factor $3 \times 2$ design since one factor (dose) has three levels and the other factor (sex) has two levels. This is analyzed by a two-way analysis of variance.

There is a twist, though. If the dose of drug A is considered as factor 1 at three levels and another regimen B as factor 2 at two levels (yes/no), this can still be conducted as a completely randomized design. Since there is no classification factor for subjects, the eligible subjects can be randomly allocated to these six groups. These groups will have a group, for example, with high dose of drug A and no regimen B and another group with low dose of drug A and with regimen B. Thus, the **one-way ANOVA** of the data from this design will reveal whether the outcome in these six groups is significantly different or not. But this analysis will not find the significance of the **main effects and interactions** of the factors. For this, the analysis needs to be done by **two-way ANOVA**.

An experiment with repeated measures can also follow a completely randomized design when subjects are unrestrictedly randomly allocated to the groups receiving different regimens. However, because of repeated measures, this cannot be analyzed by one-way ANOVA. For analysis of this design, see **repeated measures ANOVA**.

In contrast to the completely randomized design is the **randomized block design** where the subjects are first sorted into homogeneous groups, called blocks, and the levels of the intervention are then randomly assigned within the blocks. The blocks can also be considered as strata or a factor. We have given the example of an experiment in males and females where sex is the blocking factor that divides subjects into homogeneous groups assuming that male subjects are homogeneous within themselves and so are the females. But the two groups are expected to provide very different responses. If you already know that the response does not differ by sex, you may as well plan completely randomized design without classification of the subjects by sex.

## compliance (in clinical trials)

Compliance in clinical trials is adherence to the **protocol**. This term is particularly used for the subjects when they comply with the regimen they are allocated. Noncompliance, differential compliance, and poor compliance adversely affect the validity of the results of a clinical trial. This is one of the issues that distinguishes **efficacy** with **effectiveness**. Effectiveness of a regimen is the response in actual practical conditions, including lack of compliance.

An intervention study such as a clinical trial requires active participation and cooperation of the study subjects. After agreeing to participate, some subjects may deviate from the protocol for a variety of reasons. These include developing side effects, forgetting to take their medication, or simply withdrawing their consent after randomization. Analogously, in a trial of surgical therapy, those who were randomized to one group may choose to obtain alternative treatment on their own initiative. In addition, there may be instances in which participants cannot comply, such as when the condition of a randomized patient rapidly worsens to a point where continuation in the trial becomes contraindicated. Following the regimen partially is called partial compliance.

The problem of compliance could be particularly acute in a field trial. Sankaranarayanan et al. [1] report a community-based trial wherein all persons of age 35 years or older were screened for oral cancer in intervention villages and not screened in the control villages in India. The difficulty was, as in most field trials, low compliance when referred for confirmatory examination that has to be done in a hospital. In this trial, compliance was lower than 70%.

In a clinical trial setup, subjects in the active treatment group may drop out more because of discomfort or poor taste of the drug, even when the placebo looks like the drug and the trial is randomized. On the other hand, the subjects in the treatment group may stay if they see improvement in their condition, whereas the placebo group can become noncompliant. The compliance rate in this case is related to the efficacy of the regimen, and the comparison can be jeopardized. The difference may also be related to prognostic factors such as occurrence of nausea in the treatment group but not in the control group. If so, the comparability may be lost despite full randomization and despite random selection of subjects from the target population. Such differential compliance is statistically more challenging when it comes to the analysis of the data.

The other problem is lack of compliance with the protocol by the observers or the investigators. This problem can be severe if many observers are involved. Multiple observers are natural in a **multicentric trial**, and therefore such trials are especially vulnerable to such bias. More intensive efforts in terms of training and periodic assessment of the methods and the procedures followed by different observers may be helpful in minimizing this bias.

Poor compliance can force a trial to stop midway if the results are not going to meet the validity requirements. Take preemptive steps to minimize such losses. The problem of achieving and maintaining high compliance is an issue that needs consideration in the design and conduct of all clinical trials. **Blinding and masking** are among the strategies that can help to minimize loss in compliance. Whenever noncompliance or partial compliance occurs, this should be disclosed at the time of the reporting. Statements such as **CONSORT** require that this be fully described so that the reader can make his/her own judgment.

Some participants in a trial may become noncompliant despite all reasonable efforts. Try to obtain complete information on these subjects. Adjust the results in accordance with the outcome observed in those who are similar to the ones who dropped out.

## components of variance, *see* variance components analysis

## composite curve

Composite curve is the one that results from a mixture of two or more distinct curves. We illustrate this for a **distribution** curve that results from mixing of two different distributions.

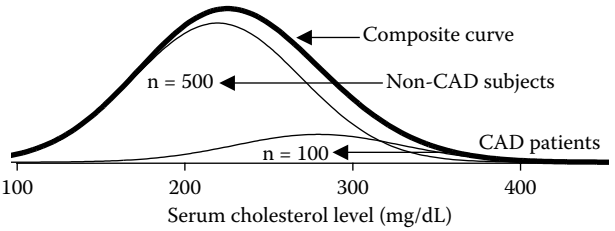

**FIGURE C.20** Mixing of two distinct groups resulting in a nice composite curve.

The pattern of distribution of the serum cholesterol level in two distinct groups as well as jointly in their mixture is shown in Figure C.20. The group of patients with coronary artery disease (CAD) has mean 280 mg/dL and standard deviation (SD) 50 mg/dL. There are 100 such subjects. The non-CAD group contains 500 subjects, and its mean is 220 mg/dL (SD = 50 mg/dL). The pattern is **Gaussian** in both groups. When these two groups are combined, the resultant again is a Gaussian curve with mean 230 mg/dL and SD 50 mg/dL as before. This is shown by the thick curve in Figure C.20. The composite curve is nice and masks the fact that this actually is made up of two distinct groups. When only the composite curve is available, it is extremely difficult to make out that two very different groups constitute the population. It is only through extraneous information that any clue to the presence of such distinct groups would be available.

## composite index

A composite index is a combination of two or more indexes. An **index** by definition itself is composite in the sense that it puts together information on several aspects into a single metric. Composite index is a further combination. The need of a composite index arises because many aspects are sometimes combined to measure health in its comprehensive form, and it is difficult to express this by one index.

An index can be defined as a combination of two or more **indicators** stated relative to a base or a standard. Indicators measure a single and specific aspect of health. No index is yet available that measures health in its entirety. Since health in its comprehensive form is also understood as state of well-being, it can encompass diverse aspects such as physical health, income, satisfaction, social relations, and cultural activities. The Office of National Statistics of UK is trying to develop a measure of national well-being. A debate is going on regarding what should this contain. For example, this may have indexes that measure how people feel in control of themselves, make choices, and have a sense of purpose and belonging. The following are two categories of some of the currently more popular composite indexes of community health.

The first one is the set of indexes of comprehensive health. These try to incorporate several aspects of health, although they still fail to capture the complete well-being. One popular such composite index at public health level is the **human development index**. This has components on education, income, and life expectancy at birth. Each of these components is measured by an index. The other popular index at community level is **physical quality of life index** that consolidates infant mortality rate, life expectancy at 1 year, and literacy. For individual level, see **quality of life index** that considers domains such as physical well-being, psychological well-being of the person, and psychological well-being divided into negative and positive feelings, self-esteem, memory, etc.

The second set of composite indexes comprises indexes of health gap at community level. The most prominent among these is the **disability adjusted life years (DALYs)** based on years of life lost due to premature mortality and the equivalent life lost due to various forms of disability. Also see multidimensional poverty index [1] and index of need for health resources [2], which also are composite indexes of different aspects of health needs.

## computer-aided diagnosis, *see* expert systems

## concealment of allocation, *see* blinding, masking, and concealment of allocation

## concomitant variable, *see* dependent and independent variables (in regression)

## concordance and disconcordance

Concordance is similarity. In health and medicine, we may be interested in concordance between methods, between observers, between laboratories, between measurements, etc. The underlying connotation in this term is qualitative assessment than quantitative assessment. The corresponding term for quantitative "concordance" is agreement where each value is assessed against its paired value. For this, see **agreement assessment (overall)** in this volume. Whereas assessment of the difference between values of body mass index (BMI) before and after an exercise–diet regimen requires agreement assessment, comparing the degree of obesity by BMI and the category of waist/hip ratio in the same group of subjects would require concordance. If both the methods agree for the degree of obesity in most people, the methods can be said to have good concordance for assessment of obesity. The degree of this kind of concordance is statistically measured by **Cohen kappa** and **Bangdiwala B**.

The term *concordance* is also used for consistent observations, particularly in the context of *ordinal* categories. Consider two characteristics on ordinal scale such as severity of disease and obesity. One may have $R = 4$ categories and the other $C = 3$ categories. The interest is in measuring the strength of association between these two ordinal characteristics. The data can be arranged in an $R \times C$ table. The association is high if the higher category of one is more frequently seen with the higher category of the other. The association between severity of disease and obesity is high if more severe cases are obese. This is also called concordance. If less severe cases are mostly obese, this is discordance. For various measures of ordinal association using concordant and disconcordant pairs, see **association between ordinal characteristics (degree of)**.

Disconcordance is the lack of concordance—the values do not match. The most pronounced application of this is in the analysis of pair-matched data by the **McNemar test** that is based on disconcordant pairs rather than concordant pairs.

## confidence band for regression line/curve

As happens with all sample estimates, **regression** lines and curves also fluctuate according to the sample values. Statisticians have worked out limits outside which the regressions are unlikely to lie with a certain degree of confidence. Since we have a line or a curve, these limits produce a band instead of limits, which is called confidence band. For simplicity, we explain this band for a regression line (**simple linear regression**) and illustrate also for a simple **curvilinear regression**. The concept and the methods are the same for a complex-shaped curve. Confidence band requires **standard error** (SE) of the regression coefficients. These SEs measure the variation expected from sample to sample.

### *SEs and Confidence Intervals (CIs) for the Regression*

When there is only one independent variable $x$, the regression equation is $\hat{y} = a + bx$. The estimated SEs for this simple linear regression are as follows:

$$\text{SE}(a) = \sqrt{\text{MSE}\left(\frac{1}{n} + \frac{\bar{x}^2}{\Sigma(x-\bar{x})^2}\right)}, \quad \text{and} \quad \text{SE}(b) = \sqrt{\frac{\text{MSE}}{\Sigma(x-\bar{x})^2}},$$

where MSE = SSE/($n$ – 2), and SSE is the **error sum of squares**. If α is the intercept and β is the slope parameter in the population, under Gaussian conditions,

CI for α: $a \pm t_\nu$*SE($a$)

CI for β: $b \pm t_\nu$*SE($b$),

where $t_\nu$ is the value of **Student *t*** at $\nu = (n - 2)$ df. An example in the next paragraph illustrates these CIs. Statistical software packages work out these CIs easily. Similar procedure is used for various regression coefficients in multiple linear regression. Statistical software packages do this also easily.

### *Confidence Band for Simple Linear Regression*

When we consider the CI for the regression line, which is based on both $a$ and $b$, we get a confidence band. As always, this band depends on the SE of $\hat{y}$. This is different when it is for the mean of $y$, also called the *estimated value* of $y$, and when it is for an individual value of $\hat{y}$, called the *predicted value* of $y$. You may be aware that any regression pertains to the *mean* of $y$ for given $x$'s, although this is often used for predicting individual values. Predicting individual values has a much larger SE. These SEs have complex forms for multiple regression, but they can be easily stated for a simple linear regression. Sometimes the software does not provide these SEs, and you may have to calculate these yourself. Under certain general conditions, for simple linear regression of $y$ on $x$,

$$\text{SE (estimated mean of } y_x) = \sqrt{\text{MSE}\left[\frac{1}{n} + \frac{(x-\bar{x})^2}{\Sigma(x-\bar{x})^2}\right]} \quad \text{(C.1)}$$

$$\text{SE (predicted individual value of } y_x) = \sqrt{\text{MSE}\left[1 + \frac{1}{n} + \frac{(x-\bar{x})^2}{\Sigma(x-\bar{x})^2}\right]}, \quad \text{(C.2)}$$

where $y_x$ is the value of $y$ at given $x$. MSE is always generated by the software.

If the dependent of interest is duration of analgesia ($y$) induced by different doses of a drug ($x$), and $n$ = 15, MSE = 6.50, $\bar{x}$ = 11.2 μg, and $\Sigma(x-\bar{x})^2$ = 18.07, then for $x$ = 8, SE(estimated mean of $y$ at $x$ = 8) = $\sqrt{[6.50\{1/15 + (8-11.2)^2/18.07\}]}$ = 2.03 from Equation C.1. The SE(predicted individual value of $y$ at $x$ = 8) = $\sqrt{[6.50\{1 + 1/15 + (8-11.2)^2/18.07\}]}$ = 3.26 from Equation C.2. The SE of the predicted value is much higher. Prediction of an individual value of $y$ is always less precise than the prediction of mean of $y$. These SEs are used to generate the confidence band for the regression line. Confidence band would be different for mean than for individual values depending upon which SE is used. Since $x$'s are considered known, everything is fixed in this SE. As $x$ moves away from its mean, the SE increases because of the term $(x-\bar{x})^2$. This provides a band of the type shown in Figure C.21a.

Under Gaussian conditions, the confidence band is obtained by calculating the limits $\hat{y} \pm t_{n-2}\text{SE}(\hat{y})$ for different values of $x$ in the given range, where the value of $t$ corresponds to the required

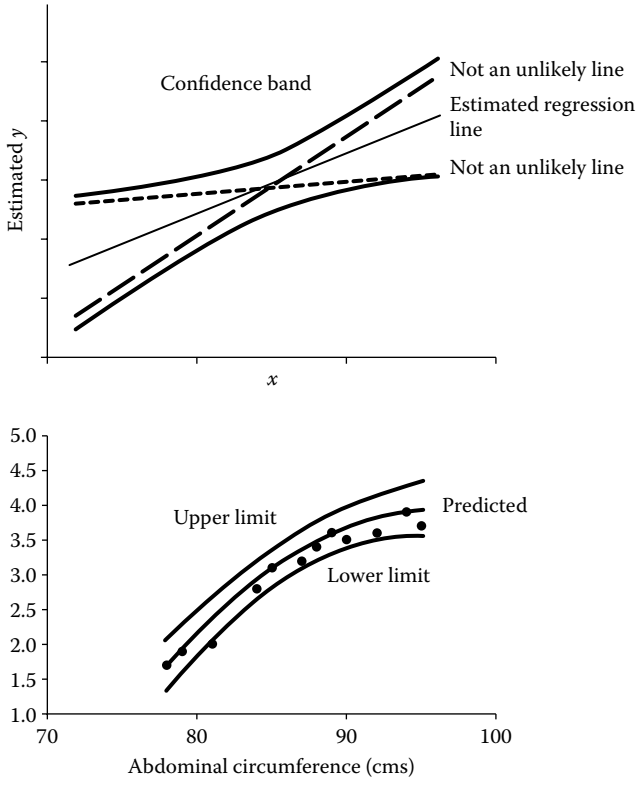

**FIGURE C.21** Confidence band (a) for a regression line and (b) for a quadratic curve.

confidence as usual. The confidence band specifies the *area* within which the regression line can lie—better phrased as outside of which the regression is extremely unlikely to lie. For example, it could be as steep as shown by the dashed line in Figure C.21a, or as flat as shown by the dotted line. Only statisticians seem to know the wide variation that can occur in the estimation of $y$ from a regression line. Many medical professionals use the line obtained from their data as the true line without realizing the variation around it. Figure C.21b has such a band for a quadratic regression. This is just to illustrate the shape of the confidence band for a curvilinear regression.

In the case of multiple linear regression, the width of the CI for estimated $y$ decreases in most situations as the number of regressors increases because of reduced SSE and MSE. However, in some situations, width increases because of loss of df. Loss of df can cause the MSE to increase, which consequently increases the width of the CI. For this reason, an adequate sample size becomes doubly important in case of multiple regression.

## confidence bounds, *see also* confidence intervals

Confidence bound is a one-sided lower or upper limit established by the sample that is likely to cover the value of the **parameter** under estimation with a prespecified degree of confidence. It contrasts with **confidence interval**, which is two-sided and provides both lower and upper limits. Confidence bound is used when it is known that the parameter value is almost surely in one direction as illustrated in the following example.

Suppose a new iron supplement is formulated that is quickly absorbed by the body and has low cost compared to the existing supplements. Previous experimentations and early phases of clinical trials have established that this formulation cannot harm, but a bigger trial is planned to find how much difference it makes in the mean hemoglobin (Hb) level of those who are anemic. Clearly, in this case, the interest is in the minimum gain in the mean Hb level below which it is unlikely. Under **Gaussian conditions** (either the underlying distribution is nearly Gaussian if the sample size is small or the sample size is large), at $100(1-\alpha)\%$ confidence,

$$\text{lower confidence bound for mean } \mu\text{: } \bar{x} - t_{\upsilon(1-\alpha)}\frac{s}{\sqrt{n}},$$

where $\bar{x}$ is the sample mean, $s$ is the sample standard deviation (SD), $n$ is the sample size, and $t_{\nu(1-\alpha)}$ is the value of **Student *t*** at $\nu$ degrees of freedom (df) for probability $(1-\alpha)$. In this case, $\nu = n-1$. Note that $s/\sqrt{n}$ is the **standard error (SE)** of $\bar{x}$. In an unlikely case of known SD $\sigma$, $s$ is replaced by $\sigma$ in this equation, and $t$ is replaced by the $z$-value from Gaussian distribution. For 95% confidence bound, $z = 1.645$.

In our example, if the average gain in Hb level in a sample of $n = 60$ subjects is 1.7 mg/dL with SD = 0.4 mg/dL, the lower bound for mean at 95% confidence level is

$$1.7 - 1.671 \times 0.4/\sqrt{60} = 1.61,$$

where 1.671 is the value of Student $t$ at 59 df corresponding to 0.95 probability. Thus, there is only 5% chance that the mean gain in the population will be less than 1.61 mg/dL. Note that this inference is for mean in the population and not for individual values. Individual gain in Hb level would vary much more.

$$\text{Upper confidence bound for mean } \mu\text{: } \bar{x} + t_{\upsilon(1-\alpha)}\frac{s}{\sqrt{n}}.$$

Similar to Gaussian conditions for being able to use Student $t$ in calculating the bounds, the requirement for calculating confidence bounds for population proportion $\pi$ is that the sample size must be large such that $np$ and $n(1-p)$ are both more than 8, where $p$ is the sample proportion. When this requirement is met,

$$\text{lower confidence bound for proportion } \pi\text{: } p - z_{(1-\alpha)}\sqrt{\frac{p(1-p)}{n}},$$

and

$$\text{upper confidence bound for proportion } \pi\text{: } p + z_{(1-\alpha)}\sqrt{\frac{p(1-p)}{n}},$$

where $z_{(1-\alpha)}$ is the value of Gaussian $z$ at $(1-\alpha)$ probability. For 95% confidence, $z_{0.95} = 1.645$, and for 90% confidence, $z_{0.90} = 1.28$. Such bounds for proportion are useful when you want to say, for example, that a minimum of 4% children in an area are affected by a particular ailment rather than saying that somewhere between 2% and 9% are affected.

Similar confidence bounds can be obtained for other parameters such as difference in means, difference in proportions, odds ratio, and relative risk. Under Gaussian conditions, these take the form of sample estimate plus (for upper bound) or minus (for lower bound) the $z$-value times the SE of that sample estimate. The method is similar to the one mentioned for **confidence interval** for that parameter. However, the case of $p = 0$ or $p = 1$ deserves special consideration. It is possible in the sample that you get all positives or all negatives. For confidence bounds in this case, see **Clopper–Pearson bounds/interval**.

## confidence intervals (the concept of)

Confidence interval (CI) for a population **parameter** is the range within which it is likely to lie with high probability. A more correct interpretation is that CI is the range outside of which the parameter value is unlikely to lie in repeated samples. This likelihood is called the **confidence level**. A confidence level of 95% is almost universally accepted in health and medicine.

Jerzy Neyman

Jerzy Neyman introduced the CI in statistical testing in 1937 [1]. (For the relation between the CI and the test of hypothesis, see **confidence interval versus test of significance**.) The CI envisages that the parameter value is fixed, but repeated samples give different CIs depending on the sample values such that it is highly likely to contain the value of the parameter. Figure C.22 aptly explains the CI and shows that different samples can give varying CIs, but the chances are small that it does not contain the value of the parameter. In this illustration, sample no. 7 does not contain the value of the parameter—all others do. CIs can be explained further as follows.

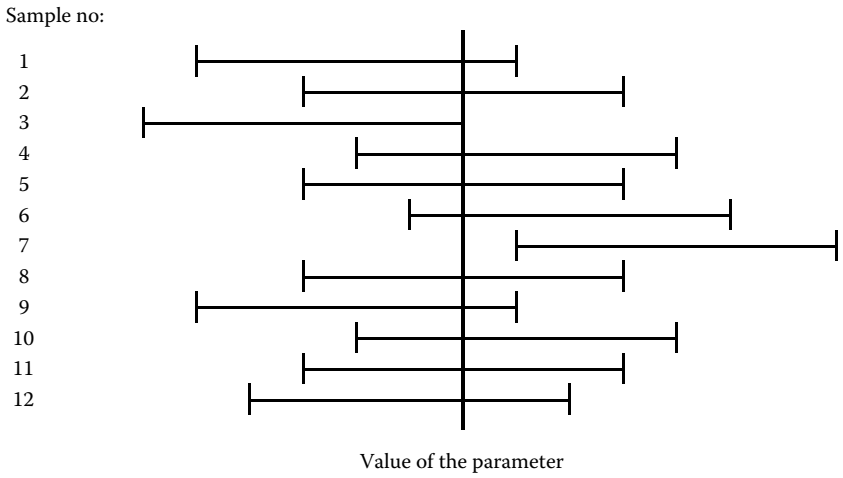

**FIGURE C.22** Varying CIs in different sample, mostly containing the value of the parameter.

Medical empiricism is all about groups rather than individuals. Suppose a research finds that the positive predictivity of a new diagnostic procedure is 70%. How confident could you be that a similar study on another group of subjects would not give predictivity less than 70%? Since sample values differ from sample to sample, it is useful to find how different the results are likely to be in different samples. However, repeated samples actually are not studied. Methods are available that would provide an interval within which the actual result is likely to lie in repeated samples. This interval can be obtained by using the data of only one sample when randomly drawn, and is called the CI. This is also called an **interval estimate**. The basic function of a CI is to provide a range that cannot be denied for the value of the parameter.

Because of profound medical uncertainties, particularly the sampling fluctuations, it is never possible to work out an interval with 100% confidence. Generally, a confidence level of 95% is used. Statistically, a confidence interval gives a range with a substantial hope that it will include the parameter of interest. The confidence level associated with the interval (say 90%, 95%, or 99%) gives the percentage of all such possible intervals in repeated samples that will actually include the true value of the parameter. Note that a CI tells us what to expect in the long run. It does not say anything about a particular sample.

The CI gives rise to the **bikini syndrome**. *What it reveals is interesting but what it conceals is vital.* Some researchers may argue that they already know about 95% and want to know about the other "behind-the-scene" 5%. Luckily for biostatistics, rarely in medical research, if ever, 95% will be known a priori. Even when 5% is masked, the revelation of the other 95% as plausible turns out to be a good piece of information.

The general strategy for calculating a 95% CI that works fairly well in most cases when $n$ is large is as follows:

1. Find the sample analog of the population parameter for which the CI is needed.
2. Estimate its **standard error (SE)**.
3. 100*(1 – α)% CI is the (sample analog ± $t_{\nu(1-\alpha/2)}$SE), where $t_{\nu(1-\alpha/2)}$ is value of Student $t$ at $\nu$ df and probability (1 – α/2).

This is what is followed in our description of CI for various parameters under separate topics in this volume. This assumes that the actual value of the population SD σ is not known as would happen in almost all practical situations. Discussion in this volume is mostly restricted to confidence level 95% because that is the most commonly used level. However, the CI can be obtained with any other confidence level. In the case of sufficiently large $n$, or when the population SD σ is known, the multiplier $t_{(1-\alpha/2)}$ reduces to the corresponding Gaussian $z$. The Gaussian multiplier for large $n$ is approximately 1.96 for 95% confidence and 2.58 for 99% confidence. That is, the 95% CI is obtained by ±1.96*SE limits and 99% by ±2.58*SE limits. The 90% CI is obtained by ±1.645*SE, and the 80% CI by ±1.28*SE. The exact value of the multiplier can be obtained from the Gaussian distribution.

Some intricacies of CI can be explained with the help of an example. The following comments largely apply to all CIs, although they are explained in the context of one example. Suppose a random sample of 100 hypertensives with mean diastolic BP 102 mmHg is given a new antihypertensive drug for 1 week as a trial. The mean level after the therapy came down to 96 mmHg. The mean decrease in these 100 subjects is $\bar{d} = (\bar{x}_1 - \bar{x}_2) = 6$ mmHg, and suppose the SD of the decrease is $s_d = 5$ mmHg. This $s_d$ is obtained as usual for the differences between the matched pairs. What is the 95% CI for the actual mean decrease in the population? After taking the difference, the problem reduces to one-sample mean. For this, the procedure described under **confidence interval (CI) for mean** is followed.

Since $n = 100$, $v = 100 - 1 = 99$. Thus, the 95% CI for the mean decrease in this example is

$$(6 - t_{99} \times 5/\sqrt{100},\ 6 + t_{99} \times 5/\sqrt{100}).$$

From a software package, $t_{99} = 1.99$ for 0.975 probability. Because of the symmetry of **Student *t***, this means that the range (–1.99, +1.99) contains 95% of values of $t$. Therefore, the 95% CI is

$$(6 - 1.99 \times 5/\sqrt{100},\ 6 + 1.99 \times 5/\sqrt{100}) = (5,7) \text{ mmHg}.$$

- Note that the CI (5, 7) mmHg in this example is for the *mean* decrease. The decrease in 95% of *individual* patients is likely to vary in the interval $(\bar{x} - 1.96s,\ \bar{x} + 1.96s)$ or in the interval (6 – 10, 6 + 10), that is, (–4, 16) mmHg, provided the underlying distribution is Gaussian. Individual variation is much higher than the variation in means. The minus sign indicates that some patients may show a rise in diastolic BP to the extent of 4 mmHg despite the drug instead of a decline. Care is required to maintain the distinction between SD and SE.

- It is important to realize that a 95% CI gives limits that are likely to contain the value of the parameter. Thus, the CI is to be interpreted as a useful quantity in the long run. If 100 such trials are done, nearly 95 of them may give a mean decrease between 5 and 7 mmHg. The other 5 trials can give either a higher or a lower decrease. As emphasized earlier, the value of the CI is more in what it does not contain. In this example, the CI suggests that the chance of a mean decrease being either less than 5 mmHg or more than 7 mmHg is very remote.
- Sometimes, an approximate multiplier 2 is used instead of exact 1.96. Such an approximation is often preferred not only for convenience but also because this slight increase tends to cover the mild departure from the Gaussian pattern as the distribution is seldom exactly Gaussian in practice. This approximation, however, can create an anomaly in some situations. In our example, $t_{99} = 1.99$, and this is less than 2. Thus, the CI based on $t$ would be smaller than the CI based on the Gaussian pattern if 2 is used. The fact is that $t$ has a larger variance, and it should always give a larger CI relative to the Gaussian CI. The exact value of $t$ does not allow any departure from the Gaussian condition that the approximate multiplier 2 based on $z$ does.
- For small $n$, when the underlying distribution is Gaussian and σ is not known, the value of $t_v$ could be very different from the Gaussian values. For example, if $n = 6$, then $v$ is 5 and $t_v$ for 95% CI is 2.571 and for 99% CI is 4.032. These are very different from Gaussian values 1.96 and 2.58, respectively. For large $n$, the $t$-value can be approximated by the Gaussian $z$-value, but there is no need to use such an approximation because exact values of $t$ are available for any specific df.
- *Role of sample size in obtaining a narrow CI.* In our example with $n = 100$, the 95% CI for a decrease in diastolic BP level is between 5 and 7 mmHg. This is fairly narrow. If $n = 10$, with no other change, the 95% CI is

$$(6 - t_9 \times 5/\sqrt{10},\ 6 + t_9 \times 5/\sqrt{10}),$$

or

$$(6 - 2.262 \times 5/\sqrt{10},\ 6 + 2.262 \times 5/\sqrt{10}),$$

or (2.4, 9.6) mmHg.

Small $n$ increases the CI in two ways: (i) by increasing the SE and (ii) through an increase in $t$-value. Thus, the CI for $n = 10$ is relatively very wide compared with $n = 100$. A focused conclusion is illusive when $n$ is small. This again underscores the statistical importance of a large sample size. Also note that the width of CI depends mostly on $n$ and SE and not on the **effect size**.

Proportion and mean (or their function such as difference) are just about the two most common parameters on which confidence intervals are drawn. There might be isolated examples in which the interest is in the CI for the median or for a decile, even σ. The basic methodology to obtain 95% CI is to get the 2.5th and 97.5th percentiles of the distribution of the corresponding "statistic" in the sample. The difficulty is that the distribution of statistics other than the mean, and hence the 2.5th and 97.5th percentiles, is not easy to obtain. Regular statistical packages are not of much help in obtaining such CIs. Some feel comfortable with bootstrap method, which can be used for any parameter and any distribution, but it looks like this method lacks the rationale that the methods just described provide. **Confidence interval (CI) for the median** is separately described, which might be a good alternative in some situations. For details of how to obtain the CI for other **quantiles**, see Conover [2]. The CI for ratios such as **odds ratio** and **relative risk** are also discussed separately in this volume.

## confidence interval (CI) for attributable risk (AR)

As explained for **attributable risk**, this actually is the difference between two proportions—one measuring risk in the group with exposure and the other measuring risk in the group without exposure, provided that the groups are independent. If the 5-year risk of death in 70-year-old patients with a disease is 22% and in patients without the disease is 15%, the attributable risk of death due to the disease is the difference 7%. Note that the groups are independent in this case. Thus, the confidence interval for attributable risk in this case is obtained as for difference in proportions in independent samples. For this, see **confidence interval (CI) for difference between means/proportions**. We do not wish to repeat that here.

Attributable risk can also be obtained in case of **matched pairs**. Table C.27 illustrates one such application where the groups with therapy and without therapy are one-to-one matched. The *risk* of interest in this case is Relieved within 1 Week.

The attributable risk in this case is also the difference between proportions. This is measured in a peculiar way. For an explanation and the CI, see **confidence interval (CI) for difference between means/proportions**.

## confidence interval (CI) for correlation coefficient

See the topic **correlation coefficient** to apprise yourself with this statistical measure. The confidence interval (CI) on this depends on its **sampling distribution** as does any other CI. The central limit theorem can be invoked to stipulate a Gaussian distribution of $r$ for large $n$, where $r$ is the correlation coefficient in the sample and $n$ is the sample size. This is attained for moderate $n$ when the correlation coefficient (ρ) in the population is close to zero, since then the distribution of $r$ is symmetric if the underlying distribution of $x$ and $y$ is bivariate Gaussian. As the value of |ρ| becomes large, the sampling distribution of $r$ becomes increasingly skewed. Thus, a larger $n$ is

**TABLE C.27**
**Trial for Therapy for Common Cold: Matched Pairs**

| | Without Therapy (Control Group) | | |
|---|---|---|---|
| **With Therapy (Experimental Group)** | **Relieved within 1 Week** | **Not Relieved within 1 Week** | **Total** |
| Relieved within 1 week | 22 | 15 | **37** |
| Not relieved within 1 week | 5 | 8 | **13** |
| **Total** | **27** | **23** | **50** |

required for it to become nearly Gaussian. However, the standard error (SE) of $r$ is complicated. In view of these issues, the following method for finding CI on ρ is used.

This method is based on Fisher $z$-transformation given by $z_r = \frac{1}{2}\ln\frac{1+r}{1-r}$. This tends to become Gaussian as $n$ increases. The beauty of this transformation is $\text{var}(z) = \frac{1}{n-3}$. The corresponding population parameter is $\zeta_\rho = \frac{1}{2}\ln\frac{1+\rho}{1-\rho}$. Thus, for large $n$,

$$95\%\text{ confidence CI on } \zeta_\rho: \left(\text{L} = z_r - 1.96\sqrt{\frac{1}{n-3}},\ \text{U} = z_r + 1.96\sqrt{\frac{1}{n-3}}\right).$$

This CI is converted back to ρ as follows:

$$95\%\text{ CI on } \rho: \left(\frac{e^{2L}-1}{e^{2L}+1},\ \frac{e^{2U}-1}{e^{2U}+1}\right).$$

We illustrate this with the help of an example. Suppose you find $r = -0.62$ between shock index and quality of life index in a random sample of $n = 84$ subjects suffering from acute coronary syndrome. Since $n$ is large, we can use our method to find the CI. This gives $z_r = \frac{1}{2}\ln\frac{1-0.62}{1+0.62} = -0.725$ and standard error $= \sqrt{\frac{1}{84-3}} = 0.111$. Thus, the 95% CI on $\zeta_\rho$ is $-0.725 \pm 1.96 \times 0.111$, or (–0.943, –0.507). When converted back to ρ, this gives

$$95\%\text{ CI on } \rho: \left(\frac{e^{-2\times0.943}-1}{e^{-2\times0.943}+1},\ \frac{e^{-2\times0.507}-1}{e^{-2\times0.507}+1}\right), \text{ or } (-0.737, -0.468).$$

There are extremely few chances (<5%) that this interval will not contain the population correlation coefficient.

## confidence interval (CI) for difference between means/proportions

The interest in many situations is in the magnitude of the difference in proportions or in means of two groups under study. The types of differences that are of special importance in medicine are between a placebo and a drug, between drug 1 and drug 2, between males and females, etc. The procedure to obtain the **confidence interval (CI)** for the difference between means is different from the procedure for the CI for difference in proportions, and these procedures are different for independent samples and for matched pairs. The following is restricted to a setup that follows **Gaussian conditions**. These conditions generally require that the underlying distribution is not far away from **Gaussian** if the sample size is small. For small samples from non-Gaussian distribution, **nonparametric methods** are used.

### *Two Independent Samples*

In the case of sample means in two independent groups, the **standard error (SE)** of the difference in means is given by

$$\text{SE}(\bar{x}_1 - \bar{x}_2) = \sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}},$$

where $s_1^2$ and $s_2^2$ are the sample variances in group 1 and group 2, and $n_1$ and $n_2$ are the respective sample sizes. If population variances are nearly equal (**Levene test** is used to check this), you can pool the variances of the two samples and get a better estimate. Then

$$\text{SE}(\bar{x}_1 - \bar{x}_2) = s_p\sqrt{\frac{1}{n_1} + \frac{1}{n_2}},$$

where $s_p = \frac{(n_1-1)s_1^2 + (n_2-1)s_2^2}{n_1+n_2-2}$ is the **pooled variance**. Then

$$\text{CI for difference in two means: } (\bar{x}_1 - \bar{x}_2) \pm t_v{*}\text{SE}(\bar{x}_1 - \bar{x}_2).$$

The value of the **degrees of freedom** for this $t$ is given by $\upsilon = n_1 + n_2 - 2$ and is obtained from the Student $t$ distribution at probability $(1 - \alpha/2)$.

For unequal variances, Welch $t$ is used. The CI remains the same, but the df of $t$ reduce to some extent by using a complex formula stated under **Welch *t***.

For difference in proportions, several forms of *estimated* SE are available [1]. But the following is widely used when both samples are large and independent of one another:

$$\text{SE}\,(p_1 - p_2) = \sqrt{\frac{p_1(1-p_1)}{n_1} + \frac{p_2(1-p_2)}{n_2}},$$

where $p_1$ and $p_2$ are the proportions observed in the samples from groups 1 and 2, respectively, and the sample sizes are $n_1$ and $n_2$. Now, under Gaussian conditions,

$$95\%\text{ CI for difference in two proportions: } (p_1 - p_2) \pm 1.96{*}\text{SE}(p_1 - p_2).$$

For illustration, consider the following example. In a randomized controlled trial, patients with peptic ulcers were put on two treatment regimens: one based entirely on drugs, and the other based on minimal drugs but supplemented by a change in lifestyle. In the first group, 12 out of 30 responded after a month, and in the second group, 28 out of 50 responded. How does one find the 95% CI for the difference in proportions in the two groups, and how does one explain its meaning?

In this example, $p_1 = 12/30 = 0.40$ and $p_2 = 28/50 = 0.56$. Since $n_1$ and $n_2$ are both sufficiently large, the general procedure as stated above can be used. The sample analog of population difference in proportions $(\pi_1 - \pi_2)$ is $(p_1 - p_2)$. We need to use its SE to get the CI.

$$\text{SE}\,(p_1 - p_2) = \sqrt{\frac{0.40\times0.60}{30} + \frac{0.56\times0.44}{50}} = 0.1137.$$

The 95% CI for $(\pi_1 - \pi_2)$ is

$$(0.40 - 0.56) - 1.96 \times 0.1137,\ (0.40 - 0.56) + 1.96 \times 0.1137$$

or (– 0.38, +0.06).

The 95% CI for the difference in the response rate is –0.38 to +0.06, but it also says there is a 5% chance that the difference will be outside these limits. The negative difference indicates that it is not unlikely in the long run that the response rate in the "change in the lifestyle" group will be even lower than that in the exclusive drug group.

Note also that $(\pi_1 - \pi_2)$ in some cases can be interpreted as **attributable risk (AR)**, and the same method is used for finding the CI for AR.

### *Matched Pairs*

Paired samples in medicine arise primarily in two situations: (i) in a **before–after study** with no parallel **controls** where the same subjects are measured twice—before and after the stimulus; and (ii) in a strict one-to-one **matching** where a parallel control group of different subjects is present, but each control subject is matched to the corresponding case for nearly all the characteristics that can affect the outcome, except of course the stimulus itself. The control group is not necessarily a **placebo**. It can be an active control that has received another stimulus under comparison. For matched controls, mild matching by one or two characteristics such as age and sex generally is not considered adequate for paired analysis—instead such control group is considered independent and analyzed by the methods previously described in this section.

The procedure for calculating the CI for mean difference in the case of matched pairs is the same as that for the mean of one sample after obtaining the differences. The mean and SD of these differences can be obtained, and for the CI, see **confidence interval (CI) for mean**.

Proportions in the case of paired samples are not so straightforward. The responses in this case would be as given in Table C.28. The counts are of subjects who remain at the same level after the stimulus and those who change.

Consider a sample of $n = 70$ patients with kidney disease. They were dialyzed by the regular machine for 1 week and 49 (70%) showed significant improvement. The following week, they were dialyzed by a new machine and 56 (80%) showed significant improvement. Since the patients are the same, these are not independent samples, and the method for difference in proportions in independent samples is not applicable. These results are stated in Table C.29.

In this example, 40 patients responded well to both the machines. This is *a* in Table C.28. Suppose that 5 did not respond well to either machine. This is *d* in Table C.28. In a paired setup such as this, the difference in proportions is measured in terms of the ratio

$$d = \frac{|b-c|}{n},$$

**TABLE C.28**
**Counts for Paired Sample Response**

| Characteristics before the Stimulus | Characteristics after the Stimulus: Present | Characteristics after the Stimulus: Absent | Total |
|---|---|---|---|
| Present | *a* | *b* | ***a + b*** |
| Absent | *c* | *d* | ***c + d*** |
| **Total** | ***a + c*** | ***b + d*** | ***n*** |

**TABLE C.29**
**Example of Counts in Paired Setup**

| Significant Improvement with Machine 1 | Significant Improvement with Machine 2: Yes | Significant Improvement with Machine 2: No | Total |
|---|---|---|---|
| Yes | 40 | 9 | **49** |
| No | 16 | 5 | **21** |
| **Total** | **56** | **14** | **70** |

with

$$\text{SE}(d) = \sqrt{\frac{(b+c)n-(b-c)^2}{n^3}},$$

where the notations are the same as in Table C.28. Thus, for large samples,

95% CI for difference in proportions in paired setup:
$d \pm 1.96*\text{SE}(d)$

For the dialysis data in Table C.29, this CI is

$$\frac{|9-16|}{70} \pm 1.96\sqrt{\frac{(9+16)70-(9-16)^2}{70^3}},$$

or

$$0.10 \pm 1.96 \times 0.0704,$$

or $\quad (-0.04, 0.24).$

The improvement by machine 2 could be up to 24%, but machine 2 can give 4% less performance than machine 1. This result is not unequivocal for these machines.

1. Brown L, Li X. Confidence intervals for two sample binomial distributions. *J Stat Planning Inf* 2005;130:359–75. http://www.sciencedirect.com/science/article/pii/S037837580400271X

## confidence interval (CI) for mean

**Confidence interval** for mean is the range outside which the population mean is unlikely to lie. Consider a new herbal drug, which is tried on a group of 50 coronary disease patients and which reduced lipoprotein(a) level by an average of 9 mg/dL in 3 months. Because of **sampling fluctuation**, another group may show a very different reduction or no reduction at all. The CI delineates the limits of the likely values on average; in fact, it specifies values beyond which the average reduction is very unlikely.

The **central limit theorem (CLT)** tells us that the distribution of the sample mean is always nearly **Gaussian** for large *n*. The underlying distribution of measurements on individual subjects is then immaterial. The distribution of the duration of survival of patients after detection of leukemia is skewed and far from Gaussian. Yet, when mean survival times are obtained in many samples, each of large size, these means still follow a nearly Gaussian pattern. The property of the Gaussian distribution can be invoked to obtain 95% CI for μ as $[\bar{x} - 1.96\text{SE}(\bar{x}), \bar{x} + 1.96\text{SE}(\bar{x})]$. This gives

95% CI for μ (σ known): $(\bar{x} - 1.96 * \sigma/\sqrt{n},\ \bar{x} + 1.96 * \sigma/\sqrt{n})$. (C.3)

However, σ is rarely known. It is then replaced by the sample SD *s*. Because of this replacement, the Gaussian distribution can no longer be used, and we need to use **Student *t*-distribution** instead. Thus

95% CI for μ (σ not known): $(\bar{x} - t_v * s/\sqrt{n},\ \bar{x} + t_v * s/\sqrt{n})$, (C.4)

where $t_v$ is the value of *t* at $v = (n - 1)$ df. For 95% confidence, this corresponds to the probability of 0.975 so that the total probability in the two tails outside $\pm t_v$ is 0.05. The CI in the preceding equation is valid only when the underlying distribution is Gaussian, especially

for small $n$. For large $n$, this can be used even when the underlying distribution is not Gaussian because the distribution of $\bar{x}$ is still approximately Gaussian for such $n$. In other words, when the underlying distribution is Gaussian, use Equation C.3 for known σ and Equation C.4 for unknown σ, irrespective of $n$ being small or large. For non-Gaussian distribution, they are valid for large $n$ only. For small $n$, generally, **confidence interval (CI) for median** is obtained.

## confidence interval (CI) for median, *see also* exact confidence intervals (CIs)

The **confidence interval** (CI) for a population median is the range outside which it is unlikely to lie. The CI for median is generally obtained where mean is not a good measure of central value. The methods for obtaining the CI for underlying **Gaussian** and for non-Gaussian distributions are different.

### *CI for Median of a Gaussian Distribution*

When the underlying distribution is Gaussian, the standard error SE(median) = 1.253*σ/√$n$ and the sampling distribution of median is Gaussian. You can see that this SE is about 25% larger than the SE for mean. This indicates that sample median is not a precise estimate and should not be used in situations where mean can be used. If your interest remains firm with median because of specific interest in the middle value, when the underlying distribution is Gaussian and $n$ is large, use

95% CI for population median: sample median ±1.96*1.253*σ/√$n$.

If you do not know σ, replace it with sample SD $s$ and replace 1.96 by the $t$-value corresponding to the appropriate df as in the case of computing **confidence interval (CI) for mean**. Realize though that you may never use median and may never need CI for median when mean is appropriate. This CI is given here only for the sake of completeness.

### *CI for Median under Non-Gaussian Conditions*

Median becomes relevant when the measurements follow a highly skewed pattern, as often seen in sick subjects. Median is not a summation-type statistic like mean is, and thus the **central limit theorem** does not generally apply, and large $n$ does not help median to attain Gaussianity. Thus, a different method is needed if the underlying distribution is far from Gaussian, particularly if $n$ is small. For example, it is known that the distribution of serum glucose level in diabetics is **right-skewed** and that of Hb level in anemics is **left-skewed**. (In both these cases, it may be truncated depending on the threshold used for defining diabetes and anemia, respectively.) When no such a priori information about the form of the distribution is available, it is difficult to judge the shape of the distribution from small samples. When the distribution is known or suspected to be far from Gaussian, the methods to be used for small $n$ are given for **exact confidence intervals (CIs)**. These methods do not depend on the shape of the underlying distribution.

## confidence interval (CI) for odds ratio (OR)

You may like to review the topic **odds ratio** (OR) if the basics of OR are not clear. We use the same notations. This section is divided into two parts—for independent samples and for matched pairs. The OR is generally calculated for case–control studies, and the two groups are independent samples when the cases comprise a different group of subjects than the control group, and there is not much matching. If the cases and controls are one-to-one matched for many antecedent factors or those who are naturally matched such as twins, the method of CI is different and is described separately in this section.

### *Confidence Interval for OR (Independent Samples)*

OR is a ratio and its natural logarithm (ln) is a linear function. The distribution of OR can be shown to be highly skewed, but lnOR has a nearly Gaussian pattern for large $n$. It has been established for large $n$ that the estimated

$$\text{SE (ln OR)} = \sqrt{\frac{1}{a}+\frac{1}{b}+\frac{1}{c}+\frac{1}{d}},$$

where $a$, $b$, $c$, and $d$ are as follows:

- $a$ = number of subjects with presence of the antecedent factor among those with positive outcome (cases)
- $b$ = number of subjects with absence of the antecedent factor among those with positive outcome (cases)
- $c$ = number of subjects with presence of the antecedent factor among those with negative outcome (controls)
- $d$ = number of subjects with absence of the antecedent factor among those with negative outcome (controls)

For a sufficiently large sample, none of these numbers would be zero or small. If any of these is zero or small despite large $n$, add ½ to each of these in the denominators in the formula of SE given above. For large $n$,

95% CI for OR: exp[lnOR ± 1.96*SE(lnOR)],

where exp is the exponent on Naperian base $e$. Similarly, one-sided **confidence bound** can also be obtained.

For the data in Table C.30 on average extramarital contacts among HIV+ and controls, SE (ln OR) = $\sqrt{1/38+1/42+1/51+1/109} = 0.2809$. The sample size $n$ is sufficiently large in this case, and a Gaussian distribution of lnOR is expected. Thus, the 95% CI for OR is

exp[ln(1.93) ± 1.96 × 0.2809],

or ($e^{0.107}$, $e^{1.208}$), or (1.11, 3.35).

The odds ratio in this sample is ($ad$)/($bc$) = 38 × 109/(51 × 42) = 1.93, but it can well range from 1.11 to 3.35 in the target population. If only the one-sided (lower) bound with 95% confidence is required, this is exp[ln(1.93) – 1.645 × 0.2809] = 1.22. It can be stated with 95% confidence that the OR in the population is not less than 1.22.

### *Confidence Interval for OR (Matched Pairs)*

In the case of matched pairs, the odds ratio is calculated as odds ratio (matched pairs): $OR_M = B/C$, where $B$ and $C$ are the disconcordant

**TABLE C.30**
**Extramarital Contacts in HIV+ Subjects and Controls**

| | Average Extramarital Contacts/Month | | |
|---|---|---|---|
| **Group** | **One or More** | **Less Than One** | **Total** |
| HIV+ | 38 | 42 | **80** |
| Controls | 51 | 109 | **160** |

pairs. The distribution of $\ln OR_M$ is also nearly Gaussian for large $n$. This also implies that no $B$ or $C$ is small, say less than 5, where $B$ and $C$ are the disconcordant pairs of the two types. Statisticians have established for large $B$ and $C$ that

$$\text{SE}(\ln \text{OR}_M) = \sqrt{\frac{1}{B}+\frac{1}{C}}.$$

The 95% CI for log of odds ratio, as usual, is $\ln OR_M \pm 1.96$ SE($\ln OR_M$). In this case, this becomes

$$95\%\ \text{CI for } \ln \text{OR}_M:\ \ln\frac{B}{C} \pm 1.96 * \sqrt{\frac{1}{B}+\frac{1}{C}}\ .$$

Take the exponential of the limits and get

$$95\%\ \text{CI for OR in matched pairs: } \frac{B}{C}e^{\pm 1.96\sqrt{\frac{1}{B}+\frac{1}{C}}}.$$

While the CI for $\ln OR_M$ is symmetric, it is not symmetric for the OR itself. The following example illustrates the procedure to get the CI for $OR_M$ in case of matched pairs.

Consider a case–control study of births with multiple malformations. The malformations considered are cleft lip, cleft palate, anal atresia, heart defects, hypospadias, etc. They are considered multiple when at least two are present. The controls were one-to-one matched for birth order, maternal age, socioeconomic status, and the place of delivery. The objective is to find any excess of one gender over the other in such births. Suppose the data obtained are as shown in Table C.31.

In these data, the disconcordant pairs are $B = 60$ and $C = 50$. Thus,

$$\text{OR}_M = \frac{60}{50} = 1.20.$$

The odds are 1.2 times in these subjects that the malformed child is male and not female. Now,

$$\text{SE}(\ln \text{OR}_M) = \sqrt{\frac{1}{60}+\frac{1}{50}} = 0.1915.$$

Thus, the 95% CI for the odds ratio is

$$(1.2 \times e^{-1.96 \times 0.1915},\ 1.2 \times e^{1.96 \times 0.1915}),\ \text{or } (0.82,\ 1.75).$$

**TABLE C.31**
**Sex of Children with and without Multiple Malformations**

| | Matched Control | | |
|---|---|---|---|
| **Cases** | **Male** | **Female** | **Total** |
| Male | 70 | 60 | **130** |
| Female | 50 | 40 | **90** |
| **Total** | **120** | **100** | **220** |

## confidence interval (CI) for predicted *y* in simple linear regression

Predicted $y$ ($\hat{y}$) refers to an individual opposed to estimated $y$ that pertains to the mean of the group of subjects with specified $x$'s. The standard error (SE) of $\hat{y}$ is different than it is for the mean of $y$. Prediction of individual values has a much larger SE. These SEs have complex forms for multiple regression, but they can be easily stated for a simple linear regression. Sometimes software packages do not provide these SEs, and you may have to calculate these yourself. Under certain general conditions, for simple linear regression of $y$ on $x$,

$$\text{SE (estimated mean of } y_x) = \sqrt{\text{MSE}\left[\frac{1}{n}+\frac{(x-\bar{x})^2}{\Sigma(x-\bar{x})^2}\right]},$$

and

$$\text{SE (predicted individual value of } y_x) = \sqrt{\text{MSE}\left[1+\frac{1}{n}+\frac{(x-\bar{x})^2}{\Sigma(x-\bar{x})^2}\right]},$$

where $y_x$ is the value of $y$ at given $x$. MSE is always generated by the software. If the dependent of interest is duration of analgesia ($y$) induced by different doses of a drug ($x$), and $n = 15$, MSE = 6.50, $\bar{x} = 11.2$ μg, and $\Sigma(x-\bar{x})^2 = 18.07$, then for $x = 8$, SE(estimated mean of $y$ at $x = 8$) = $\sqrt{[6.50\{1/15+(8-11.2)^2/18.07\}]} = 2.03$. The SE(predicted individual value of $y$ at $x = 8$) = $\sqrt{[6.50\{1+1/15+(8-11.2)^2/18.07\}]} = 3.26$. The SE of the predicted value is much higher. Prediction of the individual value of $y$ is always less precise than the prediction of the mean of $y$.

These SEs can be used to generate the CI for an estimated value of $y$ and for a predicted value of $y$. Under Gaussian conditions, these are

95% CI for estimated mean of $y$: $\hat{y}_x \pm 1.96$*SE(estimated mean of $y_x$)

95% CI for predicted $y$: $\hat{y}_x \pm 1.96$*SE(predicted value of $y_x$)

In our example, suppose $\hat{y}$ from the simple linear regression at $x = 8$ is 10 h. Then

95% CI for estimated mean duration of analgesia at dose = 8 μg: $10 \pm 1.96 \times 2.03$

or

(6.02, 13.98) h

and

95% CI for predicted duration of analgesia for one patient at dose = 8 μg: $10 \pm 1.96 \times 3.26$

or (3.61, 16.39) h.

For duration of analgesia, the mean would be useful for comparing the efficacy of one drug with the other. In this example, the prediction interval for one patient may provide more useful information. For one patient, the interval from 3.61 to 16.39 h is too wide for any worthwhile conclusion. This highlights the limitation of prediction by regression—a limitation that is many times ignored.

C

## confidence interval (CI) for proportion, *see also* exact confidence intervals (CIs)

Confidence interval for population proportion $\pi$ is the range of values outside of which it is unlikely to lie. The procedure of obtaining the CI for proportion is easy for large $n$ but is relatively difficult for small $n$. We describe both in this section.

### *CI for Proportion $\pi$: Large* n

When $n$ is sufficiently large and $p$ not too small such that $np > 8$ and $n(1-p) > 8$, the sample proportion $p$ has an approximately Gaussian distribution. For this situation, a property of the Gaussian distribution is invoked to calculate the CI for $\pi$:

$$95\%\ \text{CI for } \pi \text{ (large } n\text{)}: p \pm 1.96*\text{SE}(p)$$

or

$$\left(p - 1.96\sqrt{\frac{p(1-p)}{n}},\ p + 1.96\sqrt{\frac{p(1-p)}{n}}\right),$$

where SE($p$) stands for standard error of $p$. In the long run, if repeated samples were taken, this CI would include the proportion $\pi$ in the target population. A property of the Gaussian distribution says that a distance of 1.96*SE on either side of $\pi$ would contain $p$ in 95% of samples. This is transformed to the statement that 1.96*SE on either side of $p$ is not an unlikely range for the value of the parameter $\pi$. Note the reverse direction of this statement.

The limits in 95% CI are sometimes called ±2SE limits as approximation. The lower limit is 2SE less than $p$, and the upper limit is 2SE more than $p$. It is customary to use the estimate of SE in place of SE itself because the actual SE would not be known. This can be safely done when $n$ is large, but not for small $n$. The multiplier 2 is an approximate value of exact 1.96. For the confidence levels other than 95%, this multiplier will change as per the Gaussian values.

Consider the following example. The management of cases of bronchiolitis in infants may become easier if somehow the course of the disease can be predicted on the basis of the condition at the time of hospital admission. One simple criterion for this could be the respiration rate (RR). Consider an investigation in which cases with RR ≥ 68 per minute are observed during their stay in the hospital. Suppose in a random block of 80 consecutive cases of bronchiolitis coming to a hospital with RR ≥ 68, a total of 51 (64%) are ultimately observed to have had a severe form of the disease, i.e., they either had a prolonged stay in the hospital, developed some complication, required endotracheal intubation or mechanical ventilation, or died. This 64 is the percentage observed in the present sample. Another sample from the same hospital may give a different percentage. What could be the percentage of cases with a severe form of the disease in the entire population of patients admitted to the hospital with a diagnosis of bronchiolitis and RR ≥ 68 per minute?

The best **point estimate** according to this sample is 64%. However, this estimate is likely to differ from the actual percentage in the whole population or when another sample is taken. Since $n$ = 80 and $p$ = 0.64, $np$ and $n(1-p)$ are large enough for an approximately Gaussian pattern. The ±1.96*SE limits in this example are

$$p - 1.96\ \text{SE}(p) = 0.64 - 1.96\sqrt{0.64 \times 0.36/80} = 0.53$$

and

$$p + 1.96\ \text{SE}(p) = 0.64 + 1.96\sqrt{0.64 \times 0.36/80} = 0.75.$$

Thus, the percentage with a poor prognosis can be anywhere between 53 and 75 in cases of bronchiolitis with RR ≥ 68. In other words, there is a chance between 53% and 75% that a case of bronchiolitis with RR ≥ 68 per minute at the time of hospitalization will require special handling.

Suppose that 6% of those with RR ≥ 68 per minute in the preceding example fail to survive. The 95% CI for the proportion dying is

$$(0.06 - 1.96\sqrt{0.06 \times 0.94/80}, 0.06 + 1.96\sqrt{0.06 \times 0.94/80}),$$

$$\text{or} \quad (0.01, 0.11).$$

Thus, the actual fatality rate could be anywhere between 1% and 11%. This is a wide interval relative to the case fatality of 6% observed in the sample in the sense that the case fatality could, in fact, be nearly double of what was actually observed. Compare it with the (53%, 75%) interval obtained earlier for cases with poor prognosis. This interval is narrow relative to the 64% rate observed in the sample. In general, the CI is narrow relative to $p$ when $p$ is around 0.5, say between 0.3 and 0.7, and it is wide relative to $p$ when $p$ is either very low or very high.

Other points to remember are as follows:

- Where the study group size is small and the proportion of interest is also small, use exact methods based on **binomial distribution** as mentioned next in this section.
- CI as just stated is valid only when the observed sample proportion $p$ is neither zero nor one. Confidence bounds for such extreme values are given by the **Clopper–Pearson bounds**. Also, if $p$ is too small or too large, the CI as just stated can yield a lower limit less than 0 or an upper limit greater than 1. This clearly is not possible for $\pi$. In such cases, it is customary to keep 1 as the upper limit and 0 as the lower limit, although this amounts to an approximation. Examine whether lower or upper **confidence bounds** as discussed separately are more appropriate in such cases.
- Strictly speaking, a 95% CI implies the probability is 0.95 that such a *random* interval contains the value of the parameter. The value of the parameter is fixed. However, in practical applications, 95% CI is interpreted as though this interval contains the parameter with probability 0.95. This is a loose statement but helps to grasp the essential feature of a CI. This book adopts an easy but not so accurate course and interprets 95% CI on a more practical basis as the interval that contains the parameter with probability 0.95.

**Sensitivity**, **specificity**, positive **predictivity**, and negative predictivity are all proportions, and their CIs are obtained as is usually done for proportions. On the contrary, parameters such as **relative risk (RR)** and **odds ratio (OR)** are ratios and they require a **logarithmic** transformation as described separately.

### *CI for Proportion $\pi$: Small* n

Suppose the interest is in estimating the chance of uterine prolapse in women who come with complaints of micturition disturbance and vaginal discharge. If only $n$ = 12 women with such complaints could be examined and 3 had uterine prolapse, the proportion is 3/12 = 0.25. Another sample may give another proportion. The quantity $\pi$ in this case is the actual proportion of women with uterine prolapse among the population of women with those complaints. How does

one find limits within which this proportion is not unlikely to lie in all such patients? In this case, since $np = 3$ is small, the Gaussian approximation cannot be used. The **exact** confidence interval for $\pi$ in case of small $n$ is obtained by using a **binomial distribution**. Instead of going through the rigmarole of complex mathematics, it can be obtained graphically by using the figure given for **Clopper–Pearson bounds/interval**. This involves some approximation but is still useful for practical applications.

## confidence interval (CI) for regression coefficient and intercept in simple linear regression

The confidence interval for **regression coefficient** is the range outside of which the actual value of this coefficient is unlikely to lie. As all sample estimates, the estimates of regression coefficients are also subject to **sampling fluctuation**. They also have a **standard error (SE)**, which provides a measure of their precision. This is used to obtain the CI under **Gaussian conditions**.

Most of the standard statistical software packages readily provide various SEs corresponding to the data entered for regression. Each regression coefficient $b_0$, $b_1$, $b_2$, …, $b_K$ will have its own SE, and the regression-estimated $\hat{y}$ also has an SE. Under the usual conditions, particularly when $n$ is large, these estimates follow a Gaussian pattern. Thus, a CI can be constructed. A standard statistical software package will readily provide these CIs. The expression for SEs in case of multiple regression is too clumsy. For those interested, the estimated SEs for simple linear regression $y = a + bx$ are as follows:

$$\text{SE}(a) = \sqrt{\text{MSE}\left(\frac{1}{n} + \frac{\bar{x}^2}{\Sigma(x-\bar{x})^2}\right)} \quad \text{and} \quad \text{SE}(b) = \sqrt{\frac{\text{MSE}}{\Sigma(x-\bar{x})^2}},$$

where MSE = SSE/($n$ – 2) and SSE is the **error sum of squares**. If $\alpha$ is the intercept and $\beta$ is the slope parameter in the population, under Gaussian conditions,

$$\text{CI for } \alpha\text{: } a \pm t_\nu * \text{SE}(a)$$

$$\text{CI for } \beta\text{: } b \pm t_\nu * \text{SE}(b),$$

where $t_\nu$ is the value from Student $t$ distribution at $\nu$ df corresponding to the desired level of confidence. In this case, $\nu = n - 2$.

For further details, see Chatterjee and Hadi [1].

1. Chatterjee S, Hadi AS. *Regression Analysis by Examples*, Fifth Edition. Wiley, 2012.

## confidence interval (CI) for relative risk (RR)

It would not be wrong to surmise that all users of statistical methods utilize software to perform the calculations. Nearly all standard statistical software packages do have the provision to calculate the RR and the CI for the RR corresponding to the prefixed confidence level. Nevertheless, the following details may be helpful in understanding the underlying procedure.

Suppose there are two populations in which the probabilities that an individual shows an outcome of interest are $\pi_1$ and $\pi_2$, respectively. Suppose also that a random sample of size $n_1$ from the first population has $a$ subjects showing the outcome (and a proportion $p_1 = a/n_1$), while the corresponding values for an independent sample from the second population are $n_2$, $b$, and $p_2 = b/n_2$, respectively. Then the estimated RR is the simple ratio of these proportions. Thus, lnRR (natural logarithm of RR) is a linear combination of the frequencies. The **central limit theorem** works not just for mean but for any linear combination. Because of this, lnRR has a Gaussian distribution for large $n$. It is thus easy to use lnRR for inference when $n$ is large. It is known for large samples that

$$\text{SE (lnRR)} = \sqrt{\frac{1}{a} - \frac{1}{n_1} + \frac{1}{b} - \frac{1}{n_2}}.$$

Therefore,

$$95\%\ \text{CI for RR: exp[lnRR} \pm 1.96 * \text{SE(lnRR)]},$$

where exp is the exponent to the Naperian base $e$ and is the inverse of the logarithm. As you can see, the CI is first obtained for lnRR, and then the exponent is taken to convert it to RR. The CI for lnRR will be symmetric, but this interval will not be symmetric to RR when exp is taken. Note, however, that the CI 0.125–0.5 when estimated RR is 0.25 has the same implication as CI 2–8 when estimated RR is 4. The width looks larger in the latter case, but both are one-half to two times of the estimated RR. The width of CIs for ratios is tricky. Ratios make better sense when examined on a log scale.

Martinez et al. [1] reported a prospective study on wheezing lower respiratory tract illness (LRI) during the first year of life of 500 boys and an almost equal number of girls. They were enrolled in Tucson, Arizona. One of the objectives was to explore maternal age as a risk factor for wheezing LRI. The data for the boys are given in Table C.32.

The outcome is the LRI. The estimated relative risk of wheezing LRI in boys with their mothers' age < 26 years compared to those with their mothers' age ≥ 26 years is

$$\text{RR} = \frac{48/165}{65/335} = 1.50.$$

Thus, boys born to younger women were 1.5 times likely to get LRI during their first year of life as compared to boys born to older women. Also, lnRR = ln(1.50) = 0.4055, and

$$\text{SE(lnRR)} = \sqrt{\frac{1}{48} - \frac{1}{165} + \frac{1}{65} - \frac{1}{335}}$$

$$= 0.1648.$$

from the formula given earlier.

Therefore, 95% CI for RR is

$$\exp(0.4055 \pm 1.9\,6 \times 0.1648)$$

$$\text{or} \quad (e^{0.082}, e^{0.729}) \quad \text{or} \quad (1.09, 2.07).$$

**TABLE C.32**
**Maternal Age and Lower Respiratory Tract Illness (LRI) in Infant Boys**

| Maternal Age (Years) | LRI | | Total |
|---|---|---|---|
| | Yes | No | |
| <26 | 48 | 117 | **165** |
| ≥26 | 65 | 270 | **335** |

It can be stated with 95% confidence that this interval contains the true RR in the population provided that the sample subjects can be considered random representatives.

1. Martinez FD, Wright AL, Holberg CJ, Morgan WJ, Taussig LM. Maternal age as a risk factor for wheezing lower respiratory illnesses in the first year of life. *Am J Epidemiol* 1992 Nov 15;136(10):1258–68. http://www.ncbi.nlm.nih.gov/pubmed/1476148

C

## confidence interval (CI) for variance

Though rarely used, CI for the population variance can be easily obtained, particularly when the sample is from a Gaussian distribution. It is well known for Gaussian distribution that the criterion $\frac{(n-1)s^2}{\sigma^2}$ follows a chi-square distribution with df = ($n$ – 1), where $n$ is the sample size, and $s^2$ and $\sigma^2$ are the usual notations for the sample and population variance, respectively. Thus, $P\left(\chi_i^2 \le \frac{(n-1)s^2}{\sigma^2} \le \chi_u^2\right) = 1-\alpha$, where $\chi_i^2$ is obtained from the chi-square distribution with df = ($n$ – 1) with probability α/2 in the left tail and $\chi_u^2$ has α/2 probability in the right tail. Statistical software packages would easily get these values; otherwise, one should take help of a chi-square table in statistics books. For 95% CI, these will have 2.5% probability in either tail. This statement can be converted to provide the required CI for $\sigma^2$. That is,

$$\text{95\% CI for variance: } \left(\frac{(n-1)s^2}{\chi_u^2}, \frac{(n-1)s^2}{\chi_i^2}\right).$$

If a sample of $n$ = 18 subjects gives $s^2$ = 30.00 for fasting blood glucose level, the 95% CI for variance is $\left(\frac{17\times 30}{30.19}, \frac{17\times 30}{7.56}\right)$ or (16.89, 67.46). The value 30.19 is the chi-square values at 17 df corresponding to 2.5% probability in the right tail, and 7.56 is the chi-square value with 2.5% probability in the left tail. You can see that this CI is not symmetric to the sample variance of 30.19 mg/dL$^2$.

Although theoretically not sound, the square root of these limits is considered 95% CI for the population standard deviation (SD) σ. In our example, these limits are (4.1, 8.2) mg/dL. The sample SD is $\sqrt{30.19} = 5.49$.

## confidence interval (CI) versus test of significance

There is a considerable debate about the actual utility of the concept of **statistical significance**. Two aspects in particular are discussed in this connection. The first pertains to the relationship between the **confidence interval (CI)** and **tests of significance**, and which of these is better for inference. This is the subject matter of this section. The second concerns **medical significance versus statistical significance**. Sometimes these two significances may be in conflict. A way to resolve this is suggested under that topic.

It may not be immediately evident that CI and the statistical tests are intimately related. In fact, they have a one-to-one correspondence. Consider the example where 8 births in a random sample of 60 are observed to be premature. The 95% CI for the proportion of premature births, as per the procedure given under **confidence interval for mean/proportion**, is

$$\frac{8}{60} - 1.96\sqrt{\frac{(8/60)(52/60)}{60}}, \frac{8}{60} + 1.96\sqrt{\frac{(8/60)(52/60)}{60}}$$

$$= (0.047,\ 0.219).$$

That is, there is a 5% chance that the actual percentage of premature births is less than 4.7 or more than 21.9. Any percentage between 4.7 and 21.9 is not unlikely. In other words, any percentage between 4.7 and 21.9 is plausible, whereas any percentage outside these limits is not. Thus, this sample does not provide sufficient evidence to reject the **null hypothesis** at **significance level** α = 0.05 if the hypothesized value of π is between 0.047 and 0.219, and it will reject the hypothesis if the hypothesized value is either less than 0.047 or more than 0.219. This is how the two procedures are equivalent.

A test of hypothesis, which is also called a test of significance, can be alternatively performed as follows. Calculate the CI corresponding to the level of confidence (1 – α = 0.95 or any other) you desire. Check whether the value of the parameter under null hypothesis ($H_0$) falls within the CI. If yes, do not reject $H_0$; otherwise, reject it. The level of significance for this test is α—the complement of the confidence level. If the test is to be carried out at α = 0.02, then obtain a 98% CI and check whether this contains or does not contain the hypothesized value of the parameter. Conversely, set the value of the test criterion equal to its critical values (upper and lower) at the desired level, and solve for the values of the parameter. That will give the required 100(1 – α)% CI. For a two-sample situation, if CIs for individual group means do not overlap, the sample means are significantly different. However, the converse is not true. It can be demonstrated that the CIs overlap, yet the two means are significantly different. An example quoted frequently is means = 17 and 9 based on independent large samples with **standard error (SE)** for each = 2.5. The 95% CIs are (12.1–21.9) and (4.1–13.9), respectively. These overlap, but the two-sample **Student** $t = (17 - 9)/\sqrt{[(2.5)^2 + (2.5)^2]} = 2.26$, providing evidence of statistical significance ($P$ < 0.05) of the difference.

The first point of the debate arises from the equivalence of CI with the corresponding test of significance. If both are equivalent, which one is preferable? Many consider CI a better procedure than the test because CI gives the spectrum of unacceptable values that are outside the interval. Marginal values, both inside and outside CI, can be identified. It is thus possible to exercise more caution when the hypothesized value is on the margin. A CI provides a range of probable values of a population parameter rather than a dichotomy as significant or not significant the way a statistical test does. A test of significance considers only the null value, whereas medical implications of the range of plausible values may be an important element to reach a valid conclusion.

There is another view that supports CIs. They use inductive logic. From the observed data, you come up with a range that is not unlikely. Thus, CIs can generate new hypotheses and provide new learning. They do not depend on the null hypothesis, which is assumed true for calculating $P$-values. In that sense, statistical tests use deductive logic of inference. Deductive logic is easy, direct, objective, and definitive, but it does not expand our knowledge. Inductive knowledge provided by CIs expands the horizon and is not limited to preconceived values, although it tends to be tentative.

On the other hand, the statistical tests have particularly valid applications in situations in which the present knowledge or a claim is to be refuted. If a decision is to be taken one way or another on the basis of a statistical result alone, perhaps the test of hypothesis provides clear evidence. The statistical tests also have a special place in the comparison

of two or more groups where the only objective is to find out whether they are different and the exact effect is not of immediate concern. Some feel lost without a ***P*-value**, which comes only for the statistical test. In a **regression** setup, the test of $H_0$ helps to decide whether to keep a variable or not as a suitable predictor. For further details of the debate about CI versus test of hypothesis, see Gardner and Altman [1].

The scientific community tends to accept new (data-based) findings when their statistical significance is adequately demonstrated. A $P < 0.05$ is generally accepted. Thus, $P = 0.06$ receives the same fate as $P = 0.30$. These two are clearly different and should have different implications. Note that the *P*-value is the probability of **Type I error**, i.e., rejecting $H_0$ when it is true. A 6% chance of error is higher than the threshold 5%, yet it is fairly low. A 30% chance of error is very high. Similarly, a *P*-value 0.03 is different from a *P*-value of 0.001. Using a cut point of 0.05 as is sometimes done for testing of hypothesis masks this difference. Thus, another point of debate is whether *P*-values, as they are, should be stated or only a cutoff such as 0.05 should be stated. The former is a more exact way of describing the situation, but the latter is simple to understand. Opinion is getting around to stating the exact *P*-values. However, as mentioned earlier, a cutoff is required in any case to make a decision one way or another without forgetting that *P*-values can provide graded evidence instead of simply the binary yes or no.

## confidence level, *see* confidence intervals (the concept of)

## confounders

A confounder or a confounding factor is an **antecedent** characteristic that can be described as a possible explanation of the outcome in addition to the antecedent under investigation. Thus, it is an extraneous factor that plays spoilsport. It can also be understood as the one that is related to the antecedent as well as to the outcome but is not in the causal chain under consideration. It mixes the association of disinterest with the ones of interest and blurs the causal pathway. Necessary but not sufficient criteria for a factor being a confounder are (i) it causes the outcome, (ii) it is associated with exposure, and (iii) it is not a descendent of exposure or outcome. One simple way to identify a confounder is to imagine that if there is no exposure under study, the association between the suspected factor and the outcome will remain or will vanish. If the association still remains, the factor is a confounder.

In a study on smoking and hypertension, one confounder is obesity (Figure C.23). Smokers tend to be obese, and hypertension is also related to obesity. In other words, obesity can also be at least a partial explanation for hypertension in addition to smoking, and it is not in the causal chain under study since smoking does not cause obesity. The effect of smoking and obesity on hypertension cannot be disaggregated unless obese and nonobese subjects are separately studied. The second confounding factor in this example is age. As age increases, the lifelong burden of smoking increases for smokers, and the chance of developing hypertension also increases because of age-related arterial changes. Thus, again, age as a possible explanation should be ruled out to find net effect of smoking on hypertension.

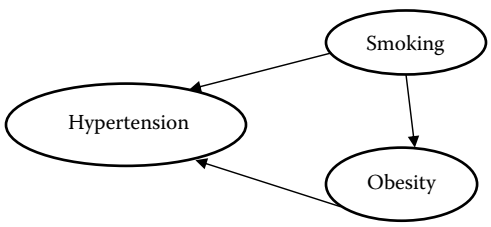

**FIGURE C.23** Obesity as a confounding factor for smoking and hypertension.

Confounders should be identified before data are collected for any research. Previous research, clinical insight, and clarity about the disease process can help in this identification. Age and sex are potential confounders in almost all medical setups. One easy method of identifying confounders is to draw a list of all possible factors that might influence the outcome of interest. The list may be based on your own knowledge, wisdom of seniors, or review of literature. Out of this list, choose the ones that would be studied as risk factors or antecedents for their role in the outcome. Among whatever remains in the list, confounders for that outcome are those that are related to any of the antecedents. This is different from a covariate. For relationship between smoking and hypertension, cholesterol level is a **covariate** but not a confounder assuming that cholesterol level has no relationship with smoking. On the other hand, sex is a confounder as it affects smoking as well as hypertension.

Note, however, that the confounders so identified would be restricted to those that are known. The knowledge could be incomplete, and the list may not be comprehensive. If so, epistemic uncertainties would remain in the results. Nothing can be done to remove this lacuna except to expand the horizon and look for factors that are not in the conventional domain.

The effect of confounders on the results can be eliminated either by developing a proper design or by performing a suitable statistical analysis. Any one of the following specific steps will help in controlling the effect of confounders:

1. Stratify the subjects by the level of the confounder. In our example on smoking and hypertension, stratify the subjects by levels of obesity. This will tell you the relationship between smoking and hypertension in obese subjects and in nonobese subjects separately.
2. Limit the study to one particular group of confounder such as only obese subjects in our example. At least for this group, you will have clear results.
3. Conduct multivariable analysis such as ordinary and logistic regression. In our example, when obesity is also entered as a regressor along with smoking, the effect of smoking will be automatically adjusted for any effect of obesity. In a regression setup, you can see that confounding is closely related to **multicollinearity**. If some of the regressors are highly correlated with one another, the results of regression are less reliable. Thus, confounding among regressors should not too pronounced.
4. Note also that these strategies can be adopted only when information on the confounding factor is available. In fact, the first two strategies require that this information should be available even before the data are collected at the planning stage. The third strategy can be adopted when the data on the confounding factor are collected along with the other data. When stratification is done, it should be sufficiently fine so that the strata are homogeneous. For

C

example, age into ≤45 and 45+ may not be fully effective. Also, in case of stratification, the result would be available separately for each stratum while the objective could be to get a combined result. Methods such as **Mantel–Haenszel** can be used to get a pooled estimate of the effect that gives larger weight to the bigger stratum. This does not work if **interactions** are present. In that case, do not pool the strata but present results separately for each stratum. In case the regression strategy is adopted, substantial difference between crude and adjusted effect implies that the factor is indeed a confounder. In this analysis, the adjusted effect will be the valid estimate as it removes the effect of the confounders.

## conjoint analysis

Conjoint analysis is done to find how preferences of the users are affected by the combination (when considered jointly) of the characteristics of the product. For hospital treatment, some prefer a big hospital because they are likely to have highly specialized doctors and latest gadgets, whereas others are happy with small hospitals where the care is more personalized; some would like to be treated by super-specialists, whereas for others, cost is a big constraint and do not mind being treated by general physicians; some would like shared rooms for social reasons and others like single room; some would like domiciliary care and others institutional care; and so on. In most cases, it is the combination of these various characteristics that determines whether a patient would use a particular facility or not. How does one find which factor is more important for a group of patients than the other factors? The answer is through conjoint analysis. The method is rooted in conjoint measurements proposed by Luce and Tukey [1] in 1964.

For conjoint analysis, the data collected from the users are in the form of their ranking for various combinations of the characteristics of the type shown in Table C.33. In this table, we have considered three **binary** characteristics of the treatment facility so that there are a total of $2 \times 2 \times 2 = 8$ combinations. Three patients were asked to rank these combinations from 1 to 8, from least preferred to most preferred. Patient 1 has the lowest preference for big hospital, treatment by a generalist, and a single room in the hospital. Patient 2 has the lowest preference for big hospital, treatment by a generalist, and a shared room. Similarly for other patients. On the basis of these data, can we find whether hospital size, the type of doctor, or type of room is more important for these patients?

The initial analysis is done separately for each patient. The first step obviously is to find the average rank of big hospital and the average rank of small hospital by patient 1, then by patient 2, and then by patient 3. For example, the average rank of small hospital by patient 2 is $(8 + 3 + 4 + 6)/4 = 5.25$, and the average rank of big hospital by this patient is $15/4 = 3.75$. For this patient, small hospital is more important than big hospital. If you repeat the exercise for patient 3, you will find that this patient also has preference for small hospital. We can find the average of these averages over the patients and find how different the ranking of the big hospital is from the ranking of the small hospital. The same can also be done for the type of doctor and the type of room. However, this simple procedure is not favored because this does not consider the effect of the combination. Our objective is to find which of these characteristics is a more important determinant when considered together with others, or to list them in order of their importance. The procedure described below is a simplistic version of an intricate method and is illustrated in Table C.34 for the data in Table C.33.

For each subject separately proceed as follows:

(i) Find the average rank for each level of each characteristic. Find its deviation from the mean. Call this $d_{ij}$ for subject $i$ and combination $j$ ($i = 1, 2,\ldots, n$; $j = 1, 2,\ldots, J$). In our example, $n = 3$ patients and $J = 8$ combinations. The sum of $d_{ij}$ will be zero for each characteristic.

(ii) Note that, in our example, the number of combinations is 8 but the total number of levels of all the three characteristics is $2 + 2 + 2 = 6$. Calculate the standardizing value as $b$ = (total number of levels of the characteristics)/$\Sigma d_{ij}^2$. This value is 0.6957 in Table C.34 for patient 1.

(iii) Calculate standardized deviation $b^*d_{ij}$ and obtain $u_{ij} = \sqrt{|b^* d_{ij}|}$. This is called the part-worth utility and measures the utility of the level of the characteristic. The utility is obtained while ignoring the sign for square root, but the sign is put back. This is one of the many ways that part-worth utility is calculated.

(iv) Find the range of utility for each characteristic, $r$ = (max $u$ – min $u$) for that characteristic.

(v) Importance of the characteristic for this subject, $I = r/(\Sigma r)$. In Table C.34, for the size of hospital, this is $100 \times 1.1796/4.3728 = 26.98\%$.

Similar calculations are done for each subject. Their mean, standard deviation, etc., can be computed as usual for drawing inferences. For example, the mean of the importance of hospital size, doctor, and room will tell us the relative importance of these characteristics in determining the preference of the patients. There are

**TABLE C.33**
**Rank for Combination of Three Characteristics of the Treatment Facility by Three Patients**

| Combination No. | Hospital (Big/Small) | Specialist/ Generalist | Room (Shared/Single) | Rank Given to This Combination by | | |
|---|---|---|---|---|---|---|
| | | | | Patient 1 | Patient 2 | Patient 3 |
| 1 | Big | Generalist | Shared | 4 | 1 | 4 |
| 2 | Big | Generalist | Single | 1 | 7 | 7 |
| 3 | Big | Specialist | Shared | 6 | 2 | 1 |

several examples of useful applications of conjoint analysis to medical problems. Wilson et al. [2] used this to delineate patient preference attributes of multiple sclerosis disease-modifying therapies, and Espanol et al. [3] proposed improved immunoglobulin therapy for patients with primary immunodeficiency by conjoint analysis of attributes such as quality of life and views on treatment.

## consecutive sampling

Consecutive sampling is the process of taking a block of eligible subjects occurring together in some sense in a specified population as the sample. These may be those who consecutively report in an outpatient department of a medical facility, say, every Tuesday in a year; those living in consecutive dwellings in a specified area; those admitted in a hospital from, say, 1st of April to 30th of September of a year; etc. There is no bar in defining the eligibility; for example, you may say that all consecutive patients with complaints of pain in the abdomen of age at least 40 years would be selected. Inclusion and exclusion criteria will apply.

Questions are sometimes raised about the validity of this kind of sampling because consecutive subjects can be of similar nature. Whereas those living in consecutive houses may really not represent the cross-section of the population, generally those that consecutively come to a hospital are adequate representative of hospital patients since their order of arrival has little to do with the type or severity of cases if there is no epidemic. Thus, these can be considered as a random sample. Sansone et al. [1] studied borderline personality disorder in consecutive patients of age at least 18 years undergoing cardiac stress testing in a community hospital from June 6, 2010 to September 3, 2010. Hoffman et al. [2] have even taken a consecutive sample of reports of randomized trials on nonpharmacological interventions published in 2009 in six leading general medical journals for studying the adequacy of description of the interventions. Thus, this kind of sampling is widely accepted.

## consistency, *see also* internal consistency

As in common parlance, consistency is getting the conforming results across a variety of conditions, but it can have different meaning depending on the context. A high degree of agreement among observers, laboratories, and methods measuring the same characteristic is called consistency. Similar is intraobserver and intralaboratory consistency when the measurements of the same characteristic from time to time have a large degree of agreement. Variations would occur, but those must be minor, possibly negligible. A group of long-term heavy smokers having no or little incidence of pulmonary problems is an inconsistent result with our existing knowledge. A perfectly healthy person getting aberrant results on liver parameters is an inconsistent finding. A patient reporting acute pain one time and no pain another time in the same interaction with a medical care facility is an inconsistent response. Such inconsistencies are not impossible but need to be explained so that there is no suspicion about such findings. Inconsistency is different from incorrect reporting, such as a person with injury from a sharp object saying that it occurred due to falling on a flat floor just to avoid legal hassles.

The most common form of statistical consistency is the **reliability** of the results across different samples from the same population, which means they do not vary much. Sample summaries such as mean and proportion from sample to sample would be called consistent when the differences across samples are minor. The greatest assurance for this is a large sample and random selection. When the sample size is large and it is truly random, mean or proportion would

not differ too much from sample to sample. In other words, large random samples do provide reliable results. The measure of such consistency is the inverse of the **standard error (SE)** of the sample summaries. The larger the SE, the lower the consistency.

Consistency of quantitative measurements across observers, time, methods, etc., is measured by **intraclass correlation** and **limits of disagreement**. For details, see these topics.

Internal consistency of an instrument such as a survey questionnaire is considered an important property for its validity. This is explained under the topic **internal consistency**. Methods such as **item analysis** are used for this purpose and are evaluated by measures such as **split-half consistency**, **Cronbach alpha**, and **Kuder–Richardson coefficient**. These are described in detail separately.

In epidemiological studies, incidence, prevalence, remissions, case fatality, and cause-specific deaths are related with one another. This kind of consistency becomes important when information on different aspects of a disease is obtained from disparate sources. This is explained under the topic **epidemiological consistency**.

## CONSORT statement

The CONsolidated Standards Of Reporting of Trials (CONSORT) statement prescribes the format in which trial results should be reported. The objective is to provide complete details to the reader about the plan and execution of the trial so that the reader himself/herself can make judgment about the validity of the results. The statement is periodically revised to reflect new realizations about such reporting. This was developed in 1996 and revised in 2001 and 2010.

The basic premise of CONSORT is that it is important to properly report a clinical trial to the fraternity after so much of resources are spent on its planning and execution. A good trial such as a randomized controlled trial must also be reported in a format that could be appreciated by the readers. The features of CONSORT statement are the same as generally known, namely, the report of the trial should indicate why the study was undertaken, and it should include scientific background and explanation of rationale, structured review of all pertinent literature not leaving out the opposite view, selection of subjects and sample size, allocation of subjects and blinding, baseline data, transparency regarding analytic methods including those for missing data, noncompliance, etc. [1]. Though widely known, many researchers were not as comprehensive in their reporting—thus the need to develop such a standard format.

To help minimize confusion and promote clarity in reporting the methods and results, the CONSORT statement comprises a 25-item checklist and a flow diagram (Figure C.24). This list ensures clear and transparent reporting of key elements of clinical trials. However, there are some deficiencies. As of 2015, the flow diagram does not include information on blinding, although it contains information on randomization. Moreover, there is no exclusive mention of the number of cases actually followed up, although this can be deduced. CONSORT guidelines do not require much information on statistical errors. The statement outlines the minimum requirement, and one can always supplement to make reporting more complete and accurate.

## consumption units

In the context of food, consumption units rescale the calorie requirements of individuals relative to an adult male with average physical activity. The calorie requirement of an adult male who performs heavy physical activity is greater compared to that of a woman or a

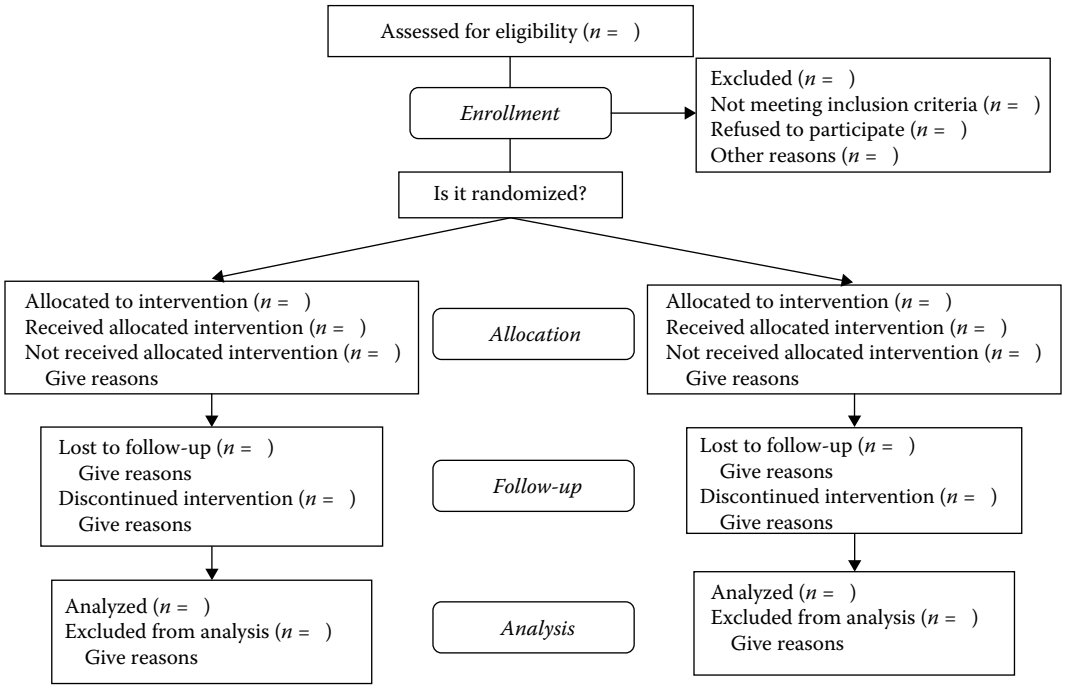

**FIGURE C.24** Flow chart of CONSORT statement.

child. Consumption units (CUs) for others are generally considered as follows: female adults who perform average physical activity, 0.9; lactating and prenatal women, 1.1; infants, 0.0; children 1–3 years, 0.4; children 3–5 years, 0.5; children 5–7 years, 0.6; children 7–9 years, 0.7; children 9–12 years, 0.8; and children 12+ years, 1.0. Note that the children units are for males; for female children, multiply these by 0.9.

These units can be used to find the total calorie requirement of a family or a group that has people of different age and sex. If a family has one male adult who performs average physical activity, one female adult not pregnant or lactating, one boy of age 4 years, and one girl of age 8 years, the total CU of the family is $1.0 + 0.9 + 0.5 + 0.7 \times 0.9 = 3.03$. If the average requirement of an adult male is considered to be 3000 calories, the total calorie requirement of the family is $3000 \times 3.03 = 9090$ calories. You can evaluate through diet survey whether the family is nearly consuming these calories or not. Such an assessment can be made for individuals also. This may be helpful in the assessment of food needs and health status. For the population of a country, the age–sex structure can be used to find the calorie requirement for the nation and can be assessed against availability of food. Conversely, food availability converted to calories per CU of one group of people can be compared with that of another group if the people are getting similar calories or one group outscores the other.

In an economic sense, such as requirement of income for a family comprising individuals of various age and sex, the kind of rescaling done for food may not be appropriate. For economic consumption, the following is recommended: 1.0 CU for the first adult in the household; 0.5 CU for other persons aged 14 years or older; and 0.3 CU for children under 14 years [1].

## content validity, *see* validity (types of)

## contingency coefficient, *see* association between polytomous characteristics (degree of)

## contingency tables

When a group of subjects is cross-classified into **mutually exclusive and exhaustive** categories, you obtain a contingency table. Categories are called mutually exclusive when only one of them is applicable to one subject. While measuring body mass index (BMI), categories such as –14, 15–24, 25–34, 35+ kg/m$^2$ are mutually exclusive because a person's BMI can be in only one of these categories. These are exhaustive too because no BMI can be beyond these categories. For example, a table giving the number of children with severe, moderate, and mild forms of a disease and no disease, attended to in a clinic, is a contingency table. Note that categories are necessary for representation of **frequencies** in a contingency table form. For a variable like heart rate (per minute), the categories could be (60–64), (65–69), (70–74), etc. For family size, each number by itself could be a category.

When the number of characteristics is two or more, a cross-classification can be done. A contingency table is called a one-way, two-way, or *K*-way table depending upon the number of characteristics on which the subjects are cross-classified. Table C.35 is a three-way table in which 1000 subjects coming to a cataract clinic are divided by age, gender, and the visual acuity (VA) in the worse eye. Totals collapse one or more characteristics and yield two-way tables, and further collapsing yields one-way tables. The last column of Table C.35 is a one-way classification of subjects by age, and the bottom row totals provide the two-way classification by VA and gender. When totals and columns P, which are the sum of M and F, are excluded, this table has 30 cells. The number of subjects in a cell is called the **cell frequency**. Since VA has three categories, age has five categories, and gender has two categories, the **order of the table** is $3 \times 5 \times 2$, which makes a total of 30 possible categories. Cells obtained by totals are not counted.

In Table C.35, gender is on the **nominal scale** while age and VA are **metric** but are categorized into groups. Such specifics of scale are considered when analyzing a contingency table. A table continues to be a contingency table when percentages are mentioned in place of the cell frequencies as long as the total $n$ is stated somewhere. When $n$ is known, the percentages can be readily converted to the respective frequencies.

A popular form of a two-way table is a $2 \times 2$ table that has two rows and two columns. These generally represent antecedent present/absent and outcome positive/negative. This kind of contingency table is commonly used for calculating **odds ratio** and **relative risk**. This can be extended to an $R \times C$ table that has $R$ rows and $C$ columns. The last three columns of Table C.35 form a two-way $5 \times 2$ table since this has $R = 5$ rows and $C = 2$ columns (excluding the totals). An $R \times C$ table is called a **square table** when $R = C$.

The primary interest in contingency tables is the association between two or more characteristics. This is explored almost

**TABLE C.35**

*Note:* F: female; M: male; P: person.

invariably by chi-square, but the actual calculations depend on the order of the table (see **chi-square—overall** for an overview of a large number of methods based on chi-square). For three-way tables, **log-linear models** are the method of choice, although these can also be analyzed by chi-square. **Three-way tables** are described separately in this volume.

### *Some Intricate Contingency Tables*

It is not uncommon in medical data that some cells in a contingency table have no frequency or zero frequency. It is important for the purpose of analysis to distinguish between observed zeroes and structural zeroes. An observed zero is one where some frequency could have occurred but happens to be zero in the sample. This is not much of a problem and is treated just like any other small frequency. A structural zero occurs when it is just not possible to have any subject in the cell. Both together are called **empty cells**.

Consider a study on multiple births—twins, triplets, and quadruplets. The births are classified by gender. The distribution may be as displayed in Table C.36. There are some observed zeroes in this table. In addition, note the × sign in some cells where no frequency is possible. Such tables are called **incomplete tables**. Special methods are required to analyze such tables. For a summary of such methods, see Kateri [1]. The present book excludes such incomplete tables, but observed zeroes are admissible for the methods discussed in this book.

### *Problems in Preparing a Contingency Table on Metric Data*

A problem frequently encountered in preparing a contingency table on all continuous and most metric variables is in deciding the number and width of intervals. When age in years is divided into (0–4), (5–14), (15–49), (50–69), and (70+) categories, the number of intervals is five and they are all unequal. Reporting of systolic BP (in mmHg) is mostly done in equal groups (120–129), (130–139), (140–149), etc.; and for diastolic BP in groups (70–74), (75–79), (80–84), etc. The choice mostly depends on commonsense evaluation of the utility of such groups in conveying the basic features of the data. Generally, the number of such groups should be between four and eight. The more groups the better for describing the variability, but this should also not take away the advantage of compactness of a contingency table. In the case of Table C.35, VA can be divided into (6/6–6/9), (6/9–6/18), (6/18–6/60), (6/60–3/60), (3/60–1/60), and (1/60–PL+) and (PL–), where PL is for perception of light. That certainly would give a better view of the subjects but would also make the table clumsier and less intelligible. Also, for cataract management, such detailed categorization may not be necessary.

All contingency tables give the distribution of subjects over various values of a measurement. Thus, these describe a frequency **distribution** although in an attenuated form. In this distribution, the values of a continuous variable would be grouped such as for age and VA in Table C.35. For a discrete variable, the values may appear as such, for example, 0, 1, 2, 3, 4, and 5+ for parity. The last category in this case is also a group. Ordinal and nominal groups may appear as such without any numeric assigned. A one-way contingency table describes a univariate distribution, a two-way table a bivariate distribution, and a three-way table a trivariate distribution. Table C.35 contains a trivariate distribution of cases coming to a cataract clinic by age, gender, and VA.

In contrast to contingency tables, in multiple response tables, the categories are not mutually exclusive. Details are presented under the topic **multiple response** tables.

**TABLE C.36**
**Distribution of Multiple Births (Twins, Triplets, and Quadruplets) by Gender**

| Number of Female Children | Number of Male Children 0 | 1 | 2 | 3 | 4 | Total |
|---|---|---|---|---|---|---|
| 0 | × | × | 17 | 5 | 0 | **22** |
| 1 | × | 25 | 6 | 2 | × | **33** |
| 2 | 12 | 3 | 0 | × | × | **15** |
| 3 | 4 | 0 | × | × | × | **4** |
| 4 | 1 | × | × | × | × | **1** |
| **Total** | **17** | **28** | **23** | **7** | **0** | **75** |

## continuity correction

Continuity correction is required when the distribution of a **discrete variable** is approximated by a distribution of a **continuous variable**. This helps in obtaining the approximate probability relating to a discrete variable since, in most cases, the probability relating to a discrete variable is relatively very difficult to obtain. Described below are three different situations where continuity correction helps in obtaining the probabilities.

The **Gaussian distribution** is meant for continuous variables. For a really continuous variable, $P(z > 2.33) = P(z \geq 2.33)$, that is, it does not matter whether or not the equality sign is used. Consider the following. A variable such as heart rate (HR) per minute is measured as discrete such as 70 or 71, but not as 70.4 per minute. Strictly speaking, when HR is measured, it is not necessarily exactly 70 per minute. While counting beats, it is possible that they are 70 in 59.7 s, and still 0.3 s remains. In other words, if these are counted for 10 min, the number may reach 704. Thus, a rate of 70.4 per minute is not impossible. In that sense, it is not wrong to say that the rate 70 really means that it is between 69.5 and 70.5. This is the correction for continuity in this case.

When this is acknowledged, HR between 65 and 70 (both inclusive) is actually HR between 64.5 and 70.5. Thus, to be exact, the probability that HR is between 65 and 70 (both inclusive) is actually HR between 64.5 and 70.5. If the mean in healthy subjects is 72 per minute and the standard deviation (SD) is 3 per minute, the probability that HR is between 65 and 70 is

$$P(64.5 \leq \text{HR} < 70.5) = P(\text{HR} < 70.5) - P(\text{HR} < 64.5)$$

$$= P\left(\frac{\text{HR} - 72}{3} < \frac{70.5 - 72}{3}\right) - P\left(\frac{\text{HR} - 72}{3} < \frac{64.5 - 72}{3}\right) = 0.30,$$

if the distribution of HR is Gaussian. Now, with the correction for continuity, nearly 30% of subjects in this healthy population are expected to have an HR between 65 and 70. This answer is more accurate than the 24% you would get without the continuity correction. Note how this correction can provide more accurate probability.

The other popular continuity corrections are Yates correction and the correction in the McNemar test. Both of these arise because they require the probability of Type I error by using the chi-square distribution, which is the distribution of a continuous variable, whereas the calculations are based on discrete values (frequencies) in the contingency tables. These corrections are described under the topics **Yates correction for continuity** and **McNemar test**, respectively.

## continuous variables (distribution of), *see also* discrete variables (distribution of)

A variable is continuous when it can take innumerable values in a specified range. The most glaring example in health and medicine is age. For an age between, say, 23 and 24 years, it could be 23.4 years or 23.9874 years depending upon how accurately you want to measure it. When called for, age can be in terms of years, months, days, hours, and minutes. However, this kind of accuracy is not needed since medical decisions do not change whether the age is 23 years 7 months or 23 years 8 months. In the case of neonates, possibly days are important, and in the case of a child less than 3 days, may be even hours are important. Similarly, hemoglobin level, cholesterol level, creatinine level, and duration of survival are continuous variables. On the contrary, family size, parity, and the number of patients coming to a clinic are not continuous—they are **discrete**. These cannot have a value such as 4.7.

All continuous variables are measured to only a necessary degree of accuracy. Age, in case of adults, is measured in terms of completed years; blood pressure (BP) to the counted mmHg; and hemoglobin (Hb) level to one decimal place of g/dL. This does not make them discrete despite, for example, the fact that measured diastolic BP values between, say, 86 and 88 (both inclusive) can only be 86, 87, and 88 and not innumerable. As mentioned under **variables**, many continuous variables are measured as continuous but are described in categories. If you have recorded the blood sugar level of 800 people, how do you report them? A frequency table with appropriate categories is the only way out. Such a categorical presentation of a continuous variable leads graphically to a **histogram** (Figure C.25a). In this figure, each category has Hb level width of 1 g/dL, and the number of categories is 8. When the width of categories is small, say just 0.1 g/dL in this example, the number of categories is large, and the number of subjects in the population is huge, the shape of the histogram approximates a curve (Figure C.25b). The smooth shape of this curve is called the distribution of the variable—in this case the hemoglobin level. It is called distribution as it tells how various values are distributed—which values are common, whether they are symmetric to a middle value, etc.

The shape of a distribution of a variable is best seen in a graph such as in Figure C.25b, but its mathematical properties are best studied when this is represented by an equation. Graph, however, is adequate to see the basic features of the distribution. The shape tells that the distribution is **left-skewed** (as in Figure C.25b) or **right-skewed** or symmetric, and also tells where the peak is and where it tapers off. The peak corresponds to the most common level, called the **mode**. Several other shapes such as **bimodal distribution**, **bathtub distribution**, and **uniform distribution** can also be identified by the figure alone. Among common distributions of continuous variables used for statistical inference are **Gaussian**, **chi-square**, **Student *t***, and ***F***. Mathematical formulation of these distributions helps in accurately working out the theoretical mean, variance, and such other parameters, and also the probabilities of any value bigger than or less than a specified value. Such probabilities are required primarily to find ***P*-values** for tests such as chi-square and Student *t*. Also, the properties of distributions also help in working out **confidence intervals** for various **parameters** of the distribution.

## contour-like diagram, *see* Lexis diagram

## contrasts (statistical)

Contrasts are the custom-made hypotheses constructed to test, for example, that the effect in control group in **one-way design** with three levels of a factor is less than the average of the effect of the other two levels. In terms of notations, this hypothesis is $\mu_1 < (\mu_2 + \mu_3)/2$, where the subscript 1 is for the control group. In null form, the hypothesis we seek to *reject* in this case is $H_0$: $\mu_1 \geq (\mu_2 + \mu_3)/2$. This **null hypothesis** can also be written as $H_0$: $\mu_1 - (\mu_2 + \mu_3)/2 \geq 0$. The contrast in this case is $\mu_1 - (\mu_2 + \mu_3)/2$. Conventionally, the contrast is tested as being equal to zero or not. Since there is no square, cubic, logarithmic, etc., term in this contrast, this is called *linear contrast*. We are generally interested in such contrasts only, and the following discussion is restricted to linear contrasts.

In the case of $K$ levels of a factor in one-way design, the general form of a contrast is $C = a_1\mu_1 + a_2\mu_2 + \ldots + a_K\mu_K$. In our contrast just mentioned, $K = 3$ and $a_1 = 1$, $a_2 = -½$, and $a_3 = -½$. The contrast can also be of the type $\mu_2 - \mu_3 = 0$. Note that the conventional null hypothesis in one-way **analysis of variance (ANOVA)** with three levels of a factor is $\mu_1 = \mu_2 = \mu_3$, but the contrast $\mu_2 - \mu_3$ is only for groups 2 and 3. In this contrast, $a_1 = 0$, $a_2 = 1$, and $a_3 = -1$. These coefficients that we are denoting by $a_k$'s ($k = 1, 2, \ldots, K$) are important for further analysis as many software packages require that these coefficients be specified. Also note that the sum of these coefficients is zero. Some consider this as a defining requirement for a function to be a contrast.

C

Under the usual conditions, the estimate of the contrast is obtained by replacing the population means μ's by their sample estimates $\bar{x}$'s. Thus, the estimate of the contrast $\mu_1 - (\mu_2 + \mu_3)/2$ is $\bar{x}_1 - (\bar{x}_2 + \bar{x}_3)/2$, and that of the contrast $\mu_2 - \mu_3$ is $\bar{x}_2 - \bar{x}_3$. In general, the estimate of the contrast $C = a_1\mu_1 + a_2\mu_2 + \ldots + a_K\mu_K$ is $\hat{C} = a_1\bar{x}_1 + a_2\bar{x}_2 + \ldots + a_K\bar{x}_K$. For finding the **confidence interval (CI)** of the contrast, we need its standard error (SE). This is given by

$$\text{standard error of the contrast: } \text{SE}(\hat{C}) = \sigma\sqrt{\Sigma\frac{a_k^2}{n_k}},$$

where σ is the variance of the residuals in the ANOVA, and $n_k$ is the sample size in the $k$th group. This is the usual SE we get for linear combination of sample means of independent groups. Independence of groups is an important requirement for the ANOVA. The CI for the contrast $C$ under Gaussian conditions is

$$100(1-\alpha)\%\text{ CI for contrast } C\text{: } \hat{C} \pm t_{1-\alpha/2} * s\sqrt{\Sigma\frac{a_k^2}{n_k}},$$

where $s$ is the estimate of σ and is the same as the √(MSE) in ANOVA, and $t$ is the Student $t$ at df = $(n_1 + n_2 + \ldots + n_K - K)$. When any $n_K$ is large, the value of $t$ is the same as the corresponding value of Gaussian $z$. If this CI contains 0, $H_0$ cannot be rejected.

Study of the contrasts raises several intricate issues at advanced level. (i) For two-way or higher-way designs, contrasts can involve **main effects** of the factors as well as the **interactions**. You may be aware how interpretation of the main effects becomes complicated when interactions are present. Contrasts become even more complicated. Just be careful in this setup. (ii) Even for one-way design, you can construct several contrasts. Their simultaneous consideration requires that they are independent, which is called orthogonality. Two contrasts are orthogonal when the sum of their cross-products is zero. The number of possible orthogonal contrasts is the one less than the number of groups. If you have $K = 3$ groups in one-way design, you can have only two orthogonal contrasts. (iii) Simultaneous consideration of two or more contrasts raises the issue of **experiment-wise** error rate (**Type I error**). For this, the procedure such as that of **Bonferroni** can be used. (iv) Contrasts can be preplanned or post hoc. While preplanned contrasts do not cause any problem, post hoc contrasts (those done after looking at the results) are more likely to be false positive. Interpretation of all post-hoc comparisons should be done as indicative rather than definitive. They can give rise to important hypotheses for planning subsequent studies.

## control charts, *see also* cusum chart

Control charts for any measurement typically plot the limits within which most of these values are expected to lie when they meet a desired goal. Observed values are assessed against these limits. Such charts are considered essential statistical tools for quality control of a product. In health and medicine, they are commonly used for quality control of the laboratories.

Laboratories differ in their methods, chemicals, skills of the staff, etc., and thus, results for aliquots of the same specimen may differ from laboratory to laboratory. Part of this variability can be eliminated by standardization across laboratories. Differences also occur within the laboratory from time to time. If such differences are substantial, it shakes the clinician's confidence in the values reported. Quality control helps to keep a check and maintain a high level of performance. This can be done with the help of a control chart.

For quality control in medical laboratories, a specimen with known composition is analyzed at least once everyday. Such a specimen is called a *control specimen*. This is preserved under standard conditions for repeated analysis. The daily readings for this control specimen are plotted on a graph called the *control chart*. This is prepared by adopting the following steps:

Step 1. At the initial stage, carefully analyze the control specimen at least 20 times under standard conditions. This will delineate the random error (that occurs due to **chance**) and should be small in this setup. They can occur due to the factors that vary in the operation of the method such as timing, temperature, humidity, staining, and actual measurement. However, this may be restricted to the factors operating in a short period of time. It fails to consider long-term variation such as in different seasons, even between night and day. For better control, the random errors should be studied separately "within day" and "between days." Also the random error must be estimated for the same solution (aqueous, serum, etc.) as proposed for final use.

Step 2. Calculate the mean and standard deviation (SD) of these 20 readings. Because the same specimen is being repeatedly analyzed, the distribution pattern would be **Gaussian** and SD would be small.

Step 3. The tolerance range is (mean – 2SD, mean + 2SD). The justification for the tolerance range is that this leaves out nearly 2.5% of the highest values and 2.5% of the lowest values of a Gaussian distribution. Thus, a useful property of this range is that, on average, only 1 in 20 samples is expected to fall outside the range, if no systematic error is committed.

Step 4. Draw the lines corresponding to mean, (mean – 2SD), and (mean + 2SD) on a chart as in Figure C.26. Your control chart is ready.

Step 5. Plot the readings for the control specimen on this chart every morning before using the laboratory for other incoming specimens. If a reading on any day is outside the tolerance range, consider this as an indication that the laboratory requires scrutiny. Take corrective measures as revealed by this scrutiny before starting the analysis of other specimens.

Consider the following data on serum glucose level on repeated analysis of a control specimen with a known level of 80 mg/dL.

| Repetition number | 1 | 2 | 3 | … | … | 20 |
|---|---|---|---|---|---|---|
| Serum glucose level (mg/dL) | 78 | 80 | 84 | … | … | 82 |

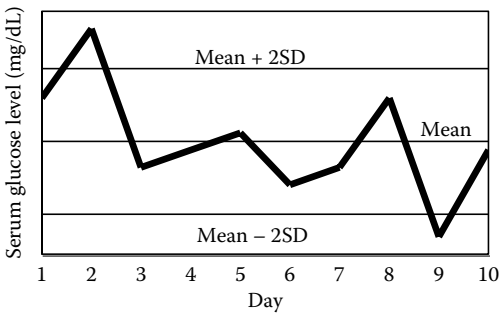

**FIGURE C.26** Control chart and the observed values.

The data for intermediary days are not shown. Suppose mean = 80.5 mg/dL and SD = 1.1 mg/dL. The lines corresponding to mean, (mean – 2SD), and (mean + 2SD) are shown in Figure C.26. This completes the first four steps just outlined. Step 5 is taking readings of the control specimen on each day. Suppose these readings for 10 days are as shown in the above table. These values are plotted on the control chart (Figure C.26). Any reading above or below the respective tolerance limits is considered a potential error and is investigated further for reasons that produced that kind of unusual value. In most such cases, an assignable reason can be identified and corrective steps can be taken before actual specimens from patients are analyzed. In this example, the value on day 2 is unacceptably high, and the value on day 9 is unacceptably low. When corrective steps are regularly taken to minimize the occurrence of such outliers, the laboratory's performance is considerably improved. Future help is provided by, what is called, a **cusum chart**.

Walter Shewhart invented control charts in 1924 to aid industrial production and management [1]. Scientists subsequently found useful applications in several fields including health and medicine.

## controls

Control is the mechanism to keep a system under check. In medical research, controls serve the purpose of a comparison against which the performance of the test group is evaluated. In this setup, controls provide the baseline, and test regimen delineates the gain or loss over this baseline. Selection of an appropriate control group is critical for the success of most analytical studies. They should ideally have same characteristics as the cases except for the antecedents under investigation as risk factors.

The most prominent use of controls is in the clinical trials, and we will come to this in a while. First consider observational studies such as **case–control** and **cohort studies**. Details are given later but realize for now that in case–control studies, one group has the disease, called the case group, and the other is without that disease, called the control group. Relevant risk factors are investigated among **antecedents** in both groups, and the factors more commonly present in one relative to the other are identified as possibly associated with the disease, either as aggravating or protective factors. In cohort studies, sometimes, but not always, a group with exposure and a group without exposure are followed up for the development of the disease. In this setup, the group without exposure is called the *control group*. Note how same nomenclature can be adopted for entirely different groups in different setups—without disease in case–control studies and without exposure in cohort studies.

Notwithstanding the strong argument made above for some kind of controls, there might be situations where they are not needed. If a treatment is being tried for a rapidly fatal disease such as tuberculous meningitis, where is the need of a control group? Saving of some cases is enough evidence of efficacy. Drugs with dramatic effects such as penicillin did not need a control. The utility of Pap smear was established without recourse to a controlled trial. However, such instances are becoming increasingly rare, and need for controls is widely accepted.

There is a debate whether surgical trials need a group with sham surgery as **placebo**. Perhaps evidence is not enough that sham surgery has the same psychological benefits as a placebo in a drug trial. Nevertheless, a sham surgery group can be adopted for a setup where it is not too expensive and is harmless to the participants.

### *Types of Controls*

A control is usually perceived to be the one that does not possess the factor of whom the effect is to be studied. Thus, this is a subject without the disease or without the exposure. While that is true in all setups, to be clear, for example in a case–control setup, the group that does not have the disease under study but has another disease can also be a good control. This depends on what you plan to study. In a study on antecedents of cardiovascular disease versus those of malignancy, any one of these groups can serve as control. No group is without disease in the setup. This is called an active **control**. This is more clearly defined in clinical trials where active control is not the placebo group but is a group receiving the existing treatment. Active controls help to assess the efficacy and side effects of the test regimen in comparison with those of the existing therapy.

In a **before–after study**, the preintervention values serve as control. Thus, there is self-control whatever its limitations may be. In contrast to this, **parallel controls** are a separate group of subjects that get an active or inert (placebo) treatment. Experiments in the laboratory and clinical trials where before–after study is not feasible or does not serve the purpose will have a parallel control group. This increases the requirement of subjects but many times is an essential "evil" for reaching a valid result.

Parallel control can be concurrent or historical. **Historical controls** comprise the group that was previously assessed. This kind of control group could be particularly considered when existing treatment is the control. This group may be derived from previous clinical trials or records such as registries or databases. This reduces the requirement of the subjects as well as the cost. Ethical issues regarding recruiting and exposing subjects to the control regimen are avoided. Historical controls may be appropriate for a disease that has a relatively stable natural history, and understanding of prognostic aspects has not changed. They must come from the same milieu from which the cases are coming. This must be verified by comparing the background characteristics. Generally, it is extremely difficult to locate a historical control group that matches with your current case group.

Despite demonstrable equivalence, the results are rarely accepted as definitive when based on historical controls. The flaw is that some factors may have changed over time. Known changes can be accounted for in the interpretation of results, but there might be some obscure changes that could affect the results. Diagnostic techniques and evaluation procedures may have improved over time. Lack of **randomization** also compromises the credibility of results in this setup. Historical controls may not have been monitored with the same keenness as concurrent controls would. If all this is fairly assured, examine the possibility of multiple controls. Multiple controls in this setup may help increase the confidence if the results replicate in each group of controls. In any other setup also, multiple controls help to increase the statistical **power** to detect a specified effect when present.

In contrast to historical control, **concurrent control** is a group that is studied at the same time as the study group. This helps to keep similarity in time such as both the groups available in 2015 since historical controls studied, say, 10 years ago may have been unwittingly overexposed or underexposed due to medical and other advances during the interregnum. Because of several other problems just enumerated, most clinical trials will have a concurrent control group.

An external group can also be used for comparison in some situations. An adequate number of nondiabetics may not be available in a

C

diabetes clinic for assessing the development of coronary incidents. *External controls* can be included in such a situation; however, they should come from the same milieu and should preferably be matched for all the factors except the exposure. In a rare situation when an appropriate external group is also not available, comparison can be done with the outcome rates in the general population. For example, incidence of birth defects in babies born to women of age 45 years or older can be compared with that in the births to women of childbearing age in the general population. The actual control group in this setup should be births to women of age less than 45 years, but a separate incidence of birth defects in them may not be easily available. The incidence in births to women of age less than 45 years may not be much different from that in all women of childbearing age since births after that age are rare. However, in many situations, the rate in the general population is not comparable with the rate in the unexposed group, and a great degree of precaution is required in using such a general group as control.

If the control subjects are in their homes, it is difficult to know if they have received some other therapy that can affect their status as controls. In the prostate cancer detection project reported by Concato et al. [1], the control subjects are those who are under routine care. But some of these may be screened outside the study and treated. Thus, their survival rate would not be sufficiently "pure" to be compared with the survival of those who were screened by the test procedures. In a field situation, *contamination* in a control group can occur if the control group is in close proximity with the unblinded test group and learns from the experience of the latter. The neighboring area may not be the test area of the research, but some other program may be going on there that has spillover effect on the control area.

### Controls in Observational Studies

The basic premise in the selection of controls in a case–control study is that the controls must come from the same group of people from whom cases have developed. For example, they could be patients from the same hospital but suffering from another disease, or peer workers, neighbors, relatives, and friends if that does not mask the relationship. Imagine a group that could have given rise to the cases and select the controls from the same group. In any case, the choice should be such that all **confounders** are ruled out as much as possible. For this, matched controls are advocated. Matched controls are those who are deliberately chosen to have the same characteristics as the cases with the exceptions as mentioned for **matching** in this volume. It has been observed, though, that matching confounders in case–control studies does not necessarily remove its confounding effect. You still have to **adjust** this in the analysis to remove its confounding effect. However, matching in case–control studies does increase the efficiency of the analysis in terms of rejecting the **null hypothesis** when false. A comprehensive discussion on selections of controls in case–control studies is available in a series of articles by Wacholder et al. [2–4].

In a prospective study, quite often, the control group comes from within the cohort, since some subjects are naturally exposed and some are not. For valid comparison, the exposed and unexposed groups must be similar at baseline, particularly with regard to the factors that can influence the outcome. If the objective is to study the effect of recently acquired central obesity on the electrocardiogram changes over time, factors such as age, gender, personality traits, stress conditions, and smoking need to be matched between the study group (with central obesity) and the control group (without central obesity). If complete matching is not possible, as would generally happen in practice, statistical methods are used to do the required adjustment at the time of analysis. Such an adjustment can become incomprehensible if done for a large number of factors.

It is sometimes impossible to find a group that is completely nonexposed. An example is exposure to dichlorodiphenyltrichloroethane (DDT). Even people in remote locations, such as Canada's Baffin Island, harbor traces of DDT. In such cases, the comparison effectively would be between the less exposed and the more exposed.

### Control Group in a Clinical Trial

As in other experiments, clinical trials can have one or more treatment regimens, but a parallel control group is almost invariably required except in crossover and before–after setup. Trials with parallel control group are also called *reference-controlled* trials. Real controls are those that are similar at baseline but follow the natural course of disease without any intervention. In practice, however, the reference control group is either treated with an existing regimen or administered a placebo. Randomization is a great strategy that could insulate against imbalance between the case and control groups.

The placebo is important because some subjects tend to behave or respond differently when no treatment is given compared with when a sham treatment is given. This may happen due to activation of mu-opioid reception in the brain by the *expectation* of relief [5]. The placebo should look exactly like the therapeutic agent under trial, perhaps with same taste, and should be given in a parallel dose. See the topic **placebo** for more details, particularly for situations where placebo can be justified.

The control group in a clinical trial should undergo the same medicinal rituals, such as dietary regulations, as the treatment group. This is more easily said than done. There are procedures for which a placebo group is nearly impossible. Examples are renal dialysis and fitting of an artificial limb. If a parallel group is a control, then appearance, schedule of administration, discomfort, etc., may cause differential compliance. Such a trial cannot be **double blind** as discussed separately. Finding a strategy that minimizes bias in such cases can be a challenging task. Whatever bias creeps in will have to be tackled at the time of analysis of data, and this too may not be easy.

In **crossover trials**, the availability of natural **controls** is automatic because the same experimental unit is used twice. This tends to reduce the impact of experimental error. The benefit of randomization is also available. Fewer subjects are required in this design relative to a parallel design with a separate control group. It is not necessary to recruit all subjects at a particular point of time. Period has a relative meaning. Some patients may have completed both periods before others are even recruited. But a big problem with crossover trials is the carryover effect and the limitation that the disease under study must bounce back to its original severity after the washout period.

## convenience sample, *see* sampling techniques

## Cook distance

This is one of the three methods to check whether any value is an outlier or not in the sense of unusually affecting the results, particularly for ANOVA. The first is called *leverage*, which is the proportion of the total sum of squares (TSS) contributed by the value under suspicion. For this, calculate TSS with and without that value and find how much is the contribution. If each observation is contributing equally, this would be TSS/*n*, and a substantial difference from this would indicate unusual contribution, indicating that this is an outlier. The second is called *Studentized residual* and is obtained as $\frac{r}{\sqrt{\text{MSE}}}$, where $r$ is the residual for the value under consideration, and MSE is the **mean square due to error**. If this exceeds, say, 5, conclude with confidence that this is an outlier. The third is

$$\text{Cook distance: } D_i = \frac{\Sigma_j(\hat{y}_j - \hat{y}_{j(-i)})^2}{K * \text{MSE}},$$

where $\hat{y}_j$ is the predicted value of $y_j$ ($j = 1, 2, \ldots, n$), $\hat{y}_{j(-i)}$ is the predicted value when the suspected $i$th observation is excluded, and $K$ is the number of parameters in the model. This measures the scaled change in the predicted value and in a way combines the first two. Cook distance is commonly used to assess if an observation is an outlier. Most statistical software packages have provision to calculate Cook distance and to test its statistical significance with the help of *F*-test. When significant, the $i$th value is most likely an outlier.

## COREQ (reporting of qualitative research)

An abbreviation for consolidated criteria for reporting qualitative research, this provides a checklist for conducting and reporting such research. A necessity for this arises because many vital aspects of health defy hard measurement and need special care. Among these are opinions, satisfaction, perspective, and contextual circumstances. Many medical decisions, both by the patients and the clinicians, are based on such soft aspects rather than hard facts such as risk factor, efficiency, and side effects. **Qualitative research** focuses on such hard-to-measure aspects. This research tries to find the why and how of decisions instead of what and when.

Most qualitative research is descriptive and exploratory rather than analytical. Techniques such as focus group discussion and consensus among opinion makers are used in this kind of research. Many consider this as anecdotal and not sufficiently scientific. Whatever its worth, such suspicion underscores a definite need to develop guidelines on how qualitative research should be conducted. Poses and Isen [1] cited several articles suggesting different methodological standards for this kind of research for clinical and health decisions, which further underscores the need for such guidelines.

COREQ is a 32-item checklist for reporting of qualitative research and is a big help also in conducting this kind of research as it includes several vital aspects of interviews and focus groups. The details have been provided by Tong et al. [2]. Items included in the checklist comprise settings, respondent validation of findings, description of the deviation of themes, etc., in addition to the usual sampling method and the method of data collection. The authors have divided these into three domains, namely, research team and reflexivity, study design, and data analytics and reporting. Following these guidelines can make research more complete, transparent, and usable.

Alnahedh et al. [3] used the COREQ checklist to report their findings on an exploratory qualitative study to gauge understanding and assess opinions about evidence-based predictions in a sample of Australian and Saudi Arabian optometrists. Hole et al. [4] used the COREQ tool to appraise the quality of papers included in their review of the patients' experiences of rehabilitation after stroke influences their outcome.

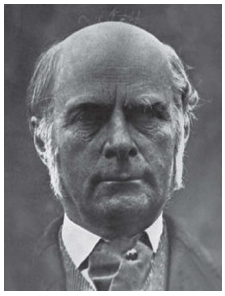
## correlation (the concept of), *see also* correlation coefficient (Pearsonian/product–moment)

Correlation between two variables is the tendency of one moving with the other. Note that the correlation indicates only the tendency and does not imply any definite relationship. Francis Galton introduced the concept of correlation in 1888 [1].



Francis Galton

Conventionally, the term *correlation* is used for quantitative measurements. The corresponding term for qualitative measurements is **association**. Correlation is called positive when both variables tend to move in the same direction and negative when they tend to move in reverse direction. Height and weight have positive correlation, whereas age and lung functions in adults have negative correlation. Possibly lung functions have no correlation with kidney functions.

As explained for a **correlation coefficient**, a correlation is generally considered linear, but it is possible for two variables to be

C

strongly correlated without being linearly related. Relation of weight with age in children is not linear (see **growth charts**), but the two are strongly related. Relation between age and forced vital capacity (see **linear regression**) over the age from 0 to 80 years is also strong but not linear (it is parabolic). For more examples, see **regression (types of)**. The correlation coefficient is an inadequate measure of the strength of relationship.

There is a tendency in public discourse to interpret a correlation as **cause–effect relationship**. This can be true in some cases, but mostly this is far from truth. A strong correlation between heights of siblings in a family exists not because one is the cause of the other but because both are affected by parental height. Similarly, correlation between visual acuity and vital capacity in subjects of age 50 years and above is not of the cause–effect type but arises because both are products of the same degeneration process. No one expects vision to improve if vital capacity is improved by some therapy. Maternal mortality rate declined in Mexico between 1960 and 2015, and the proportional mortality from coronary diseases increased. These two have a strong negative correlation, but they do not have a cause and effect type of relationship. Counterfactuals provide useful armory to refute causality. These are examples of what is called the **spurious correlation**—the correlation between two variables that, in fact, have no direct relationship—it arises due to a third intervening factor that might be related to both.

Two variables are said to have **nonsense correlation** when the correlation defies logic. Would you imagine that persons with depressed moods can have an elevated risk of lung cancer? But this can occur because of a third intervening factor, namely, smoking [2]. Depressiveness seems to modify the effect of smoking on lung cancer either by a biologic mechanism or by affecting smoking behavior. This example illustrates how a seemingly nonsense correlation can sometimes lead to a plausible hypothesis. Another example is the parental age gap influencing the sex ratio of the firstborn children [3].

A correlation in a sample of subjects does not necessarily imply that a correlation really exists. Your sample might exhibit some correlation purely because of sampling fluctuations. This is called *incidental correlation*. Before dismissing it as incidental, make sure that no hidden factor is working to cause this correlation.

The degree of correlation in quantitative data is measured by either a product–moment correlation coefficient or a **rank correlation coefficient**. The latter is also called **Spearman correlation**. Both are described separately in this volume. The product–moment is also called the Pearsonian correlation coefficient. This coefficient is so pervasive in statistics parlance that it is simply called *correlation coefficient*. This has many positive features but also has some negative features. Artifacts in the data such as a wide range of values and outliers can also give rise to statistically significant correlation with no medical significance. See **correlation coefficient** for details. This coefficient has been devised separately to measure canonical, intraclass, intraobserver, interobserver, auto, multiple, and partial correlations. Additionally, there are also **point-biserial correlation** and **tetrachoric correlation**, which are described separately in this volume. Also see **attenuated correlation**.

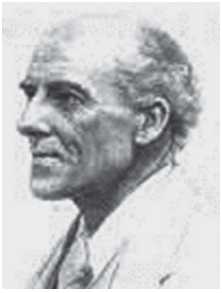
## correlation coefficient (Pearsonian/ product–moment)

The correlation coefficient is the most widely used and abused measure of the degree of correlation between two variables. Note that its objective is to measure the strength of correlation. Among its several forms, the one called product–moment is the most common. This is also called Pearsonian after Karl Pearson, the person who proposed this coefficient somewhere around 1893 [1]. This section is restricted to the product–moment correlation coefficient. Others are described separately as mentioned at the end of this section.



Karl Pearson

The product–moment correlation coefficient is obtained between paired quantitative values. The units of study may be persons such as correlation between age and systolic level of blood pressure measured for $n = 80$ persons, blood samples such as between prostatic specific antigen values obtained by two methods on $n = 45$ blood samples, areas such as between infant mortality rate and life expectancy in a group of $n = 193$ countries, or any such entity. For two quantitative measurements $x$ and $y$ on $n$ units, this is calculated for a sample as

product–moment correlation coefficient:

$$r = \frac{\Sigma(x-\bar{x})(y-\bar{y})}{\sqrt{\Sigma(x-\bar{x})^2}\sqrt{\Sigma(y-\bar{y})^2}} = \frac{s_{xy}}{s_x s_y},$$

where $\bar{x}$ and $\bar{y}$ are the respective means; $s_x$ and $s_y$ are the standard deviations (SDs) of $x$ and $y$, respectively; and $s_{xy}$ is the **covariance**. If you want to calculate this for a population, replace $s$ by $\sigma$, but this opportunity seldom arises in practice. In that case, this is denoted by $\rho$. $s_{xy}$ is the product–moment from which this correlation derives its name. You do not need to calculate it yourself unless you want to understand the underlying procedure—any statistical software will easily calculate this for you. The formula is just for your information and for you to realize that this correlation coefficient is covariance divided by the product of the SDs.

The crucial quantity in the product–moment correlation coefficient is the covariance in its numerator. This measures how much $x$ varies linearly when $y$ varies. The magnitude of covariance also depends on the magnitude of $(x-\bar{x})$ and $(y-\bar{y})$, i.e., on the individual variation in $x$ and $y$. The variation is measured by $\sqrt{\Sigma(x-\bar{x})^2/n}$ and $\sqrt{\Sigma(y-\bar{y})^2/n}$. These are the respective SDs. To make the covariance independent of such variation, it is divided by the product of SDs. This finally gives the formula of the product–moment correlation coefficient. The correlation coefficient thus obtained also becomes dimensionless and very easy to interpret. This correlation coefficient is not affected if you add any constant to

all values of $x$ or all values of $y$ (or both), and is also not affected if you multiply all values of $x$ by any positive constant or all values of $y$ (or both). In other words, the correlation coefficient between $ax + b$ and $cy + d$ is the same as that between $x$ and $y$, where $a$, $b$, $c$, and $d$ are any positive constants. Any of them can be zero. Also note that it is symmetric in the sense that $x$ and $y$ can be exchanged without affecting the correlation coefficient.

Now note the following for a correlation coefficient:

- The correlation coefficient is a pure number without any unit and ranges from –1 to +1. A value close to zero indicates that the two variables are linearly uncorrelated. That is, a change in the value of one is not accompanied by any linear change in the other. The scatter can then be random along a horizontal line with no slope. An example is cholesterol level and Hb level, which are generally uncorrelated. A value close to +1 indicates a strong positive relationship. Body temperature and heart rate have a strong positive correlation. A value close to –1 indicates a strong negative correlation. Homocysteine and transthyretin have a strong negative correlation among vegetarians. A perfect $r = \pm 1$ would mean that the scatter of $y$ with $x$ forms an exact straight line (see Figure C.27a,b). Such extreme correlation would seldom occur in health or medicine.
- Generally speaking, a correlation coefficient greater than 0.9 in absolute value can be considered strong, between 0.9 and 0.6 moderate, between 0.6 and 0.4 weak, and between 0.4 and 0 almost nonexistent. An illustration of scatter plots in weak and strong correlation is shown in Figure C.27. These are just rules of thumb for many applications in health and medicine, but in situations where no correlation was suspected, even a correlation of 0.2 can have great medical relevance as explained slightly later.
- An interpretation of $r$ is that $r^2$ measures the extent of variation accountable by linear relation between $x$ and $y$. Note, for example, that $r = 0.3$ means $r^2 = 0.09$. That is, for this $r$, only 9% of the total variation in $y$ is attributable to the linear variation in $x$. This explains why a correlation coefficient 0.3 is considered to indicate weak correlation.
- The magnitude of the correlation coefficient becomes unusually high when only extreme values (very high and very low) of $x$ and $y$ are observed, and becomes low when only a small range of values are observed. Thus, it is not desirable to deliberately restrict the observations of $x$ and $y$ to a narrow range or observe only extreme values. The distribution of observed values of at least one of them should be fairly spread out. Sometimes just one high value of $x$ and $y$ can yield a high value of the correlation coefficient.
- As stated earlier, the product–moment correlation $r$ measures only the *linear* component of the relationship, and this line must have some slope (small or big, negative or positive). If all age groups are combined for the relation between age and forced vital capacity (FVC), you will most likely get a scatter nearly evenly spread in all four quadrants (see **covariance**). Now the negative products $(x - \bar{x})(y - \bar{y})$ will mostly cancel out with positive products. Thus, the covariance will be nearly equal to zero. When all ages between 0 and 80 years are considered together, these data will give a small value of the product–moment correlation coefficient. This should not be construed to mean that there is no relationship between age and FVC. The relationship, in fact, is strong and can be expressed by a nice parabolic curve, although not by a straight line. The product–moment coefficient of correlation does not measure nonlinear relationships. Thus, a low value of the correlation coefficient needs to be interpreted with caution. Two variables can be heavily interdependent but may not appear correlated by this measure. This may sound like a paradox but is clear when the concept of correlation is correctly understood as concerned only with a linear form of relationship. The right criterion for measurement of the degree of relationship is the **coefficient of multiple correlation** $R^2$ when a curvilinear form is considered and the **coefficient of determination** $\eta^2$ when a nonlinear form of the parameter is considered.
- Sometimes weak correlations too can be medically important. One such example is the correlation between prostate volume and urethral resistance parameters in patients with prostatism [2]. This correlation was found to be less than 0.4 and indicated that urethral resistance is determined mostly by factors other than the volume of the prostate, or may be that they are not linearly related. This is a significant finding. Another example of weak correlation is that between age and FVC just mentioned. The *linear* relationship, as measured by the correlation coefficient, is weak, but they actually have a high degree of relationship of a curvilinear form. A third example is the correlation of systolic BP of persons with the level seen in their children. This correlation is weak in many populations but is definite. Such a correlation indicates that parents do have an influence on the level of systolic BP of their offspring, although the influence is minor.

See the explanations given for the concept of **correlation** to understand that it can be spurious, incidental, or even nonsense. This does not indicate a cause–effect relationship, neither does it measures

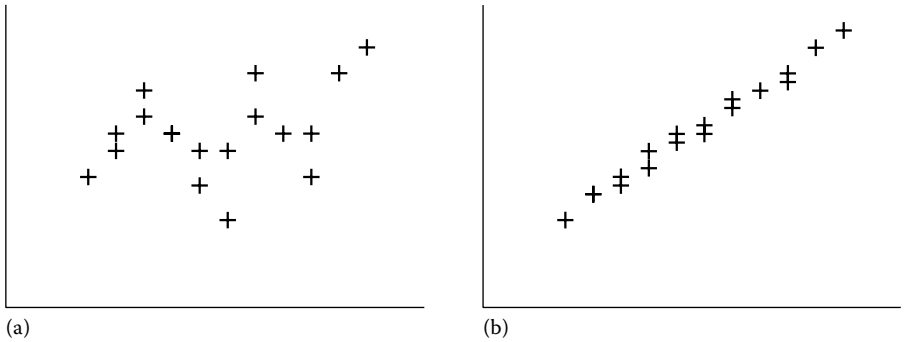


**FIGURE C.27** Scatter plot in the case of (a) weak and (b) strong correlations.

**agreement**. Modifications of the product–moment correlation coefficient are available that are used to find **intraclass correlation**, **autocorrelation**, **canonical correlation**, **multiple correlation**, and **partial correlation**. **Confidence interval for correlation coefficient** is also discussed separately, and for its test of significance, see **comparison of two or more correlation coefficients**.

Other correlation coefficients are **rank correlation**, **point-biserial correlation**, and **tetrachoric correlation**. These are not exactly product–moment correlations, but their modifications are separately described under the respective topics.

## correlation matrix

Correlation matrix is a square arrangement of **correlation coefficients** between pairs of a large number of variables. This is used in a **multivariate** setup where the characteristic under study has several variables. For example, liver function is a characteristic that may be assessed by bilirubin level (Bil), albumin level (Alb), alanine transaminase (ALT), aspartate aminotransferase (AST), and total protein (TP). These five variables together measure liver function in this example. Suppose these are measured for $n = 40$ subjects. Now you can calculate the correlation between Bil and Alb, between Bil and ALT, etc. These correlation coefficients can be arranged as follows:

| | Bil | Alb | ALT | AST | TP |
|---|---|---|---|---|---|
| Bil | 1 | 0.67 | 0.35 | 0.47 | 0.18 |
| Alb | 0.67 | 1 | 0.59 | 0.41 | 0.32 |
| ALT | 0.35 | 0.59 | 1 | 0.83 | 0.24 |
| AST | 0.47 | 0.41 | 0.83 | 1 | 0.21 |
| TP | 0.18 | 0.32 | 0.24 | 0.21 | 1 |

This is the correlation matrix of liver function variables. This matrix has order 5, which is the number of the variables measuring liver function. Note that all the values in the diagonal are always 1 as the correlation of a variable with itself is always 1. Also note that the correlation coefficient between ALT and Alb is the same as between Alb and AST—thus, this is always a symmetric matrix. For this reason, it is not necessary to write it as a full matrix. Only the upper half triangle or lower half triangle is enough.

The correlation matrix provides an overall view of the correlations among variables of a multidimensional characteristic in a compact form. This can help in deciding which variables to be pursued with vigor or what action to take next. In statistics methods, correlation matrix is helpful for procedures such as running the regression, in estimation of the parameters, and in tests of significance in situations where several variables have to be considered together.

The correlation coefficients in a correlation matrix are mostly obtained by product–moment method, but they can also be, for example, rank correlations.

## correlogram, *see* autocorrelation

## correspondence analysis

This analysis is done to find the categories or combination of categories of one **qualitative** variable that have significant relation with specific categories of another qualitative variable in the same **contingency table**. Thus, this method is similar to the **principal component analysis** for **quantitative** variables and is used more as an exploratory tool than for conclusions. The contingency table should be large either in terms of many rows and many columns in a two-way classification or in terms of cross-classification of many qualitative variables. Simply stated, correspondence analysis uses the cellwise decomposed values of the overall value of **chi-square** in a large contingency table to locate which cells are contributing more to the value of chi-square—thus more associated than others. The full method is mathematically intricate, but we explain its essential features in a simplified manner in this section so that you understand where it is or can be used, and for which purpose. The method was developed by Benzécri in 1973 [1] and described fully by Greenacre [2].

Consider the distribution of 1000 trauma cases by the major part of the injury and the severity at the time of reporting to a trauma center (Table C.37). The table gives the observed numbers in the left panel and the contribution of each cell to the value of chi-square in the right panel. These are calculated as usual by $(O - E)^2/E$, where $O$ and $E$ are the observed and expected frequencies, respectively, under

**TABLE C.37**
**(a) Distribution of Trauma Cases by Major Part Affected and Severity of Injury; (b) Contribution of Cells to the Value of Chi-Square**

**(a) Observed Frequencies**

| Major Part Affected | Severity at the Time of Reporting | | | | | |
|---|---|---|---|---|---|---|
| | Mild | Moderate | Serious | Critical | Fatal | Total |
| Head | 30 | 87 | 68 | 123 | 49 | **357** |
| Neck | 3 | 11 | 12 | 20 | 7 | **53** |
| Chest | 18 | 42 | 59 | 41 | 78 | **238** |
| Abdomen | 22 | 20 | 18 | 35 | 47 | **142** |
| Arm | 43 | 44 | 9 | 9 | 2 | **107** |
| Leg | 28 | 32 | 19 | 21 | 3 | **103** |
| **Total** | **144** | **236** | **185** | **249** | **186** | **1000** |

**(b) Contribution of Each Cell to Chi-Square**

| Major Part Affected | Severity at the Time of Reporting | | | | | |
|---|---|---|---|---|---|---|
| | Mild | Moderate | Serious | Critical | Fatal | Sum |
| Head | 8.9 | 0.1 | 0.1 | 13.1 | 4.6 | **26.7** |
| Neck | 2.8 | 0.2 | 0.5 | 3.5 | 0.8 | **7.8** |
| Chest | 7.7 | 3.6 | 5.1 | 5.6 | 25.7 | **47.7** |
| Abdomen | 0.1 | 5.4 | 2.6 | 0.0 | 16.0 | **24.2** |
| Arm | 49.4 | 13.9 | 5.9 | 11.7 | 16.1 | **97.0** |
| Leg | 11.7 | 2.4 | 0.0 | 0.8 | 13.6 | **28.6** |
| **Sum** | **80.7** | **25.6** | **14.1** | **34.7** | **76.9** | **232.1 = $\chi^2$** |

the null that there is no relationship between the major part affected and the severity of the injury.

This table has 6 rows and 5 columns (excluding the totals)—and thus has 30 cells. The overall value of chi-square = 232.1, which is highly significant ($P < 0.001$) for $5 \times 4 = 20$ df. This helps to conclude that the severity of injury almost surely depends on the part affected. As a first step in correspondence analysis, we examine the contribution of each row to the value of chi-square given in part (b) of the table. Arm injuries with a sum of 97.0 have large contribution to chi-square followed by chest injuries with a contribution of 47.7. These two injuries do not follow the general pattern of severity. In the second step, note for within arm injuries that the contribution of mild injuries is relatively large. If you want to know whether it is unusually high frequency or unusually low frequency contributing to chi-square, two options are available. The first one is that you go back to the observed frequency table and note that the cell frequency for mild injury in arm is high. This tells that mild severity is much more common in these data when arm is the major part affected. The second option is to calculate $(O - E)/\sqrt{E}$ in place of $(O - E)^2/E$, which will have negative and positive sign, and will help to know that the frequency is unusually low or unusually high in any cell. These results can be shown in a *mosaic plot* (Figure C.28).

This initial correspondence analysis also tells that the first row (Head) in the second and third columns (moderate and serious) in Table C.37 is not contributing much to the overall value of chi-square. One can subjectively say on the basis of the total that the contribution of the second, fourth, and sixth rows and of the second and third columns also is not high. Thus, these rows and columns can be deleted from this table without substantially affecting the relationship. This reduces the dimension of the table and possibly makes it more intelligible. This dimensionality reduction is similar to what we try to achieve by principal component analysis for quantitative data. For details, see Greenacre [2].

The steps mentioned so far are essentials of correspondence analysis, but this analysis does not end there. It goes on to compute quantities called singular value and inertia, and column and row coordinates, which finally lead to a correspondence analysis plot that displays the association between different categories in a contingency table. The method can be extended to multiway tables; in this case, this is called *multiple correspondence analysis*.

## covariance

Covariance between a variable $x$ and a variable $y$, when both quantitatively measured for the same group of $n$ subjects, is the average of the product of their deviations from the respective means. In terms of notations,

$$\text{sample covariance between } x \text{ and } y\text{: } s_{xy} = \frac{\Sigma(x-\bar{x})(y-\bar{y})}{n-1}.$$

This is the average of the products of $(x-\bar{x})$ and $(y-\bar{y})$, which are the deviations from the respective means. You can see that when $x$ is replaced by $y$, the numerator becomes $(y-\bar{y})^2$ and this becomes the variance of $y$. This explains the prefix *co-* in covariance—it is for how variation in one variable $x$ is related to the variation in $y$ when both belong to the same subjects. As in the case of the sample **variance**, the divisor $(n - 1)$ is used for samples instead of $n$. For an illustration of the calculations, see Table C.38, where the covariance between creatinine and blood urea measured for 5 persons is +0.2. In this case, the plus or minus sign is important. Covariance measures the extent and direction of the *linear* relationship between two variables, but it is incomplete because it is very much affected by the variations in $x$ and $y$ and by the units of measurement. For a complete measure, it is divided by the respective standard deviations and that yields, what is called, the product–moment **correlation coefficient**.

An explanation for covariance is as follows. Consider the scatter diagrams in Figure C.29 between age ($x$) and forced vital capacity (FVC) ($y$). Figure C.29a is for the age group 10–24 years, Figure C.29b for 25–39 years, and Figure C.29c for 40–79 years. Figure C.29d gives the joint scatter of all the age groups combined. Quadrants are drawn by lines corresponding to the mean of $x$ and the mean of $y$ in each case. In Figure C.29a, FVC is increasing as age increases from 10 to 24 years. Both $x$ and $y$ are moving in the same direction. This is an indication of positive correlation between $x$ and $y$. Most points are in the first and third quadrants. In the first quadrant, both $(x-\bar{x})$ and $(y-\bar{y})$ are positive, so their product is also positive. In the third quadrant, both $(x-\bar{x})$ and $(y-\bar{y})$ are negative, so their product again is positive. Thus, the *covariance* would be a positive quantity, signifying a positive relationship.

In Figure C.29b, FVC is neither increasing nor decreasing when age is between 25 and 39 years. The points are almost equally scattered in the four quadrants. In the second quadrant, $(x-\bar{x})$ is negative but $(y-\bar{y})$ is positive. In the fourth quadrant, $(x-\bar{x})$ is positive

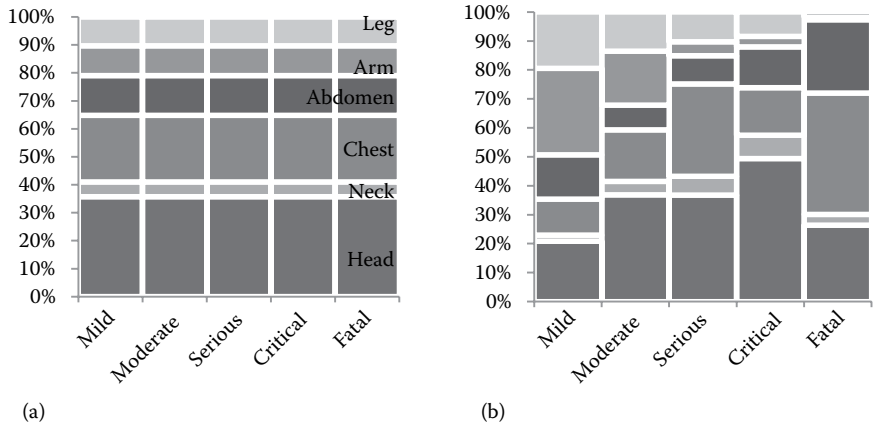

**FIGURE C.28** Mosaic plot of (a) the expected under the null of no association and (b) the observed frequencies in Table C.37.

| $(x-\bar{x})$ | –0.3 | +0.4 | –0.1 | +0.1 | –0.1 | |
| $(y-\bar{y})$ | –6 | –2 | +2 | +3 | +3 | |
| $(x-\bar{x})(y-\bar{y})$ | +1.8 | –0.8 | –0.2 | +0.3 | –0.3 | $\frac{\Sigma(x-\bar{x})(y-\bar{y})}{n-1} = +0.8/(5-1) = +0.2$ |

*Note:* $(n-1)$ used in place of $n$ for sample.

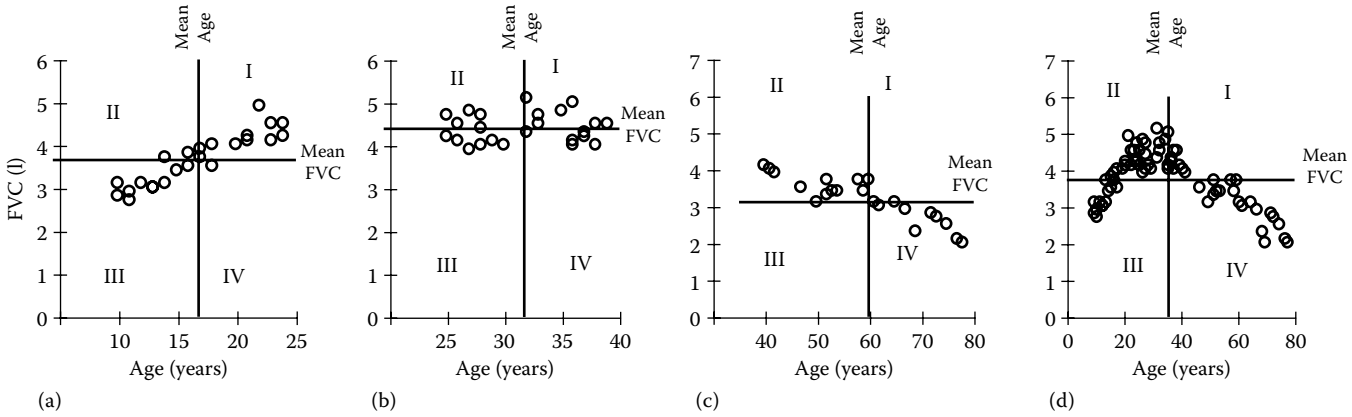

**FIGURE C.29** Scatter of forced vital capacity (FVC) by age. (a) For the age group 10–24 years; (b) for the age group 25–39 years; (c) for the age group 40–79 years; and (d) combined for all the age groups.

but $(y-\bar{y})$ is negative. In both cases, the product $(x-\bar{x})(y-\bar{y})$ is negative. The sum of negative products in the second and fourth quadrants would mostly cancel out with the sum of positive products in the first and third quadrants, thus giving a final sum nearly equal to zero. Thus, the covariance between $x$ and $y$ in Figure C.28b is nearly zero. In Figure C.29c, FVC decreases as age increases from 40 to 79 years. This inverse relationship yields a negative correlation. Most points are in either quadrant II or quadrant IV. They give negative products. The covariance in this case is negative. The illustration in all three cases indicates that covariance does measure the direction of the relationship. When all these are combined (Figure C.29d), the sum total is close to zero.

Beside its profound use in correlation coefficients, covariance is used in other setups as well. For example, it is used in analysis of covariance where the effect of a quantitative covariate on an outcome is studied.

In a multivariate setup, covariances between pairs of the variables can be expressed in a matrix, called the **covariance matrix**.

## covariance matrix, *see* dispersion matrix

## covariates

Covariate is a variable that is not of any direct interest for the study but affects the outcome of our interest. If our interest is in studying the relationship between use of tobacco and education in adults, you may like to have age as a covariate since it affects use of tobacco. Age is not the one of your interest but is included to get a clearer picture of the relation between use of tobacco and education. If the interest is in studying the effect of a hematinic on hemoglobin (Hb) level, you may like to have preexisting Hb level as a covariate since the effect of hematinic depends on the preexisting level. Preexisting level of Hb is not of any interest but is required to find the net effect of the hematinic.

Although it is customary to use the term covariate for a quantitative variable, it can be used for a qualitative variable also. Quantitative can be **categorical** divided into two or more categories, and qualitative can be **binary** or **polytomous**; it can be **ordinal** or **nominal**. There is no restriction. However, the method of analysis changes depending on such scale of the covariate.

A large number of statistical methods are available for adjusting the effect of one or more covariates on the results. First is the analysis of covariance (ANCOVA). This is used for adjusting for a quantitative covariate when the **dependent variable** is also quantitative. The **independent variables** of interest generally are qualitative. Details are under **analysis of covariance (ANCOVA)**. The second is ordinary least squares **regression** where also the dependent is quantitative. In this case, the independents also are mostly quantitative. Both these methods generally require a **Gaussian distribution** of the residuals. The third is **logistic regression** where the dependent is qualitative, mostly binary, and the independent could be qualitative and quantitative. The fourth is **Cox regression** where the dependent is the **hazard rate** and is generally applied to durations such as survival duration.

All these methods can be used to study the effect of several covariates together but require that the covariates are not much related with one another. Such multicollinearity adversely affects both reliability and validity of the results. In all these regression methods, quantitative covariate can be entered as such, but if it is

nominal, then recoding in terms of **indicator variables** would be needed. Many statistical software packages would automatically do this once you specify that the covariate is nominal. Some software packages may erroneously call nominal as categorical, forgetting that categorical can be quantitative (metric) also. If the covariate is quantitative categorical such as age categorized into 15–24, 25–34, 35–44, etc., examine if it would be wise to enter this as 1, 2, 3, etc., or as midpoints 20, 30, 40, etc. If so, enter these values. For ordinal covariates also, examine if some kind of **scores**, including linear scores 1, 2, 3, etc., are legitimate, and enter those scores. Else, use indicator variables. However, realize that indicator variables consider categories as nominal and ignore the order.

You may also like to make a distinction between a covariate and a **confounder**. For the relationship between smoking and hypertension, cholesterol level is a covariate but not a confounder since cholesterol level has no relationship with smoking. But sex is a confounder as sex affects smoking as well as hypertension. Statistical methods stated in the preceding paragraph do not distinguish between a covariate and a confounder. However, this distinction helps in proper interpretation of results.

## Cox–Mantel test, *see* log-rank test (Mantel–Cox test)

## Cox proportional hazards models, *see* proportional hazards; *see also* Cox regression

## Cox regression

Cox regression is a form of regression model where the dependent or the outcome is the hazard of developing the outcome. This is especially applicable to durations such as survival duration but can be used for other setups also where outcome depends on time. To understand this, be clear about the concept of **hazard**. Cox regression is a voluminous topic. We explain its essentials in this section. The method was developed by David Cox in 1972 [1].

David Cox

The hazard of developing an outcome depends not just on time but also on several other factors. In a clinical setup, the hazard of a serious side effect may depend on the characteristics of the person such as age, gender, and nutritional status, as well as on the type of regimen, type of domiciliary care, alertness, competence of the attending physician, etc. Since many factors are involved, one of which is time, it is sometimes helpful to obtain the hazard as a function of various regressors. One such model is

$$\text{Cox regression: } h(t) = h_0(t)e^{b_1x_1+b_2x_2+\cdots+b_Kx_K},$$

where $h(t)$ is the estimated hazard at time $t$ for given values of the regressors, now better understood as covariates ($x_1$, $x_2$, …, $x_K$), and $b_1$, $b_2$, …, $b_K$ are the estimates of the corresponding **regression coefficients**. $h_0(t)$ is the baseline hazard at time $t$ when all $x$'s are zero. These coefficients measure the hazard ratio on a logarithmic scale relative to the baseline, as is odds ratios do in a **logistic model**, and are treated nearly the same way. For example,

$$\begin{aligned} b_k &= \ln(\text{hazard with } x_k/\text{baseline hazard}) \\ &\quad - \ln(\text{hazard without } x_k/\text{baseline hazard}) \\ &= \ln(\text{hazard with } x_k/\text{hazard without } x_k) \end{aligned}$$

A positive value of any $b_k$ indicates that higher values of $x_k$ increase the hazard of the outcome or indicate worse prognosis. A negative value indicates that the corresponding covariate reduces hazard. The first component on the right-hand side of the above equation, namely, the $h_0(t)$, is the estimate of the time-dependent baseline hazard that is present in any case even when all $x$'s are zero. This is considered the same for all subjects. In some cases, this can be understood as the hazard of death at time $t$ for a healthy subject (no risk factor) because of the time factor that in any case operates on all life forms. The hazard ratio $h/h_0$ can be interpreted as the relative death rate when the hazard of death is under study. The covariates $x_1$, $x_2$, …, $x_K$ could be continuous such as age, polytomous such as type of treatment, or dichotomous, such as gender, and of course would vary from person to person. The difference [$\ln h(t) - \ln h_0(t)$] is the combined effect of all the covariates.

Because of the presence of time-dependent $h_0(t)$ in the Cox regression, the usual method of maximum likelihood cannot be used to compute the $b$'s. Special methods are needed. For details, see Kleinbaum and Klein [2]. The following comments contain some useful information about Cox regression that may help to understand it better:

1. The term *hazard* is generic and not restricted to death. It can be used for any other event of interest such as appearance or reappearance of symptoms or even for a favorable event such as discharge from the hospital, cessation of smoking, or resumption of daily activities. The coefficients are interpreted accordingly.
2. The Cox regression also assumes that the covariates affect the hazard in a multiplicative manner. This means that when two factors are simultaneously present, the hazard multiplies instead of increasing additively. Multiplicability amounts to additivity in logarithm terms. This condition, too, is generally satisfied in many situations.
3. In clinical studies, the variables $x_1$, $x_2$, …, $x_K$ may contain not only the personal characteristics of the patient such as age, gender, and nutritional status but also the treatment indicators such as dosage of drug, type of treatment, and kind of care provided. These may change over time. For example, drug dosage may be heavy in the beginning and moderate later on. Such flexibility is not available in the usual quantitative regression. However, when any $x$ is time-dependent in a Cox regression, the estimation of the $b$'s becomes complex. While using statistical software yourself, or trying to understand the results of someone else's, ensure that the right package for time-dependent covariates has been used when such covariates are present. If a time-invariant model is used for time-dependent covariates, the results can be misleading.

C

4. Consider a simple situation where there is only one $x$ in the Cox regression such that $x = 0$ for standard treatment and $x = 1$ for experimental treatment. The Cox model sometimes assumes that the difference between the logarithms of hazards in the two treatment groups is constant over the follow-up period. This has been seen to be true in many applications. This makes it a *proportional* hazards model. See **proportional hazards** for details.

The following example illustrates one application of the Cox model. Ahmad and Bath [3] obtained data from a nationally representative sample of 1042 community-dwelling people in the United Kingdom of age 65 years or more. Their survival time since 1985 was recorded with censoring in 2000. Data pertain to 460 independent variables on cognitive impairment, physical health, physical activity, psychological well-being, etc. Six Cox models were run that were asked to select 1, 2, 4, 8, 12, and 16 most important variables, respectively, to predict survival time. Besides age, the analysis found handgrip strength as an important marker of frailty in predicting early death. Pain in joints causing difficulty in carrying bags and self-rated activity compared to peers were important predictors of long-term mortality.

Not many researchers test goodness of fit of Cox model. For test of this hypothesis, the deviance $-2\ln L$ is used as in the logistic regression. The test for the overall model is provided by the difference in deviance of the full model and the deviance for just $h_0(t)$, which measures the effect of time only. This will tell whether all covariates together are of any help or not in explaining the hazard. To assess the utility of any particular covariate, calculate $-2\ln L$ with and without that covariate and refer the difference to chi-square with 1 df. Statistics similar to square of the multiple correlation coefficient ($R^2$) in quantitative regression can also be used for this purpose. For testing significance of individual covariates, the **Wald test** is preferred as it gives slightly better results. In this case, this is just $[b/\mathrm{SE}(b)]^2$ and referred to **chi-square** at 1 df.

As an illustration of how the Cox model works, consider the hazard of complications in case of peritonitis with different APACHE scores. If the coefficient $b$ for APACHE is 0.0487, what does it imply? This means that if APACHE score increases by 1, the hazard ratio (relative to APACHE score = 0) of complication is exp(0.0487) = 1.050. If APACHE score increases by 8, the hazard ratio becomes exp(8 × 0.0487) = 1.476, i.e., about 1 ½ times. In place of continuous APACHE, consider a binary variable such as gender. If $b$ for gender is 0.675 and the coding is 1 for men and 0 for women (so that women is the reference category), the hazard ratio of men to women is exp(0.675) = 1.96. Thus, men have nearly twice as much hazard of developing complication in peritonitis as that of women. For these two risk factors, the model would be

$$h(t) = h_0(t)\ [\exp(0.0487)*\mathrm{APACHE}]*[\exp(0.675)*\mathrm{gender}] \text{ for all } t.$$

As in the case of logistic, any unusually large coefficient in Cox model or large SE should be regarded as wrong. It can arise either due to strong multicollinearity or due to an extremely small number of subjects in a particular subgroup. Such instances highlight the importance of scrutinizing the data and exploring their suitability for a particular analysis. As in the regression models, the covariates in Cox model also should not have high multicollinearity.

## Cox Model in Survival Analysis

The duration of survival after organ transplantation may depend on the age of the patient, coexisting diseases, and the drug regimen followed. Because of the highly **skewed distribution** of duration of survival and **censored observations**, the conventional regression approach is not applicable. Two approaches are available to study the effect of covariates on survival duration.

One approach is the parametric models such as the **exponential**, **Weibull**, and **log-normal**. These can be extended to include covariates. For example, the exponential cumulative hazard model would look like

$$\text{Exponential model with covariates: } F(t) = 1 - e^{-(\beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_K x_K)t},$$

where $x_1$, $x_2$, …, $x_K$ are the covariates. Similarly, other models can also be parameterized to include the covariates. These models work well when the cumulative hazard function indeed follows the modeled pattern. A priori, this is difficult to assess, although the **goodness-of-fit** can be tested once the data are available.

The second approach is the Cox model. This has found wide acceptability. The Cox model is semiparametric since it is nonparametric for time and parametric for covariates. We do not have to worry about the specific shape of the distribution of survival time under certain conditions. The following is an introductory discussion. For details, see Lee and Wang [4].

The Cox proportional hazards model lets you get away with not specifying the underlying survival function. This can be helpful as the underlying hazard function may not be of our interest. For example, many epidemiology studies want to know, "Does exposure decrease the time until event X?" The interest is in the difference in patients who have exposure and who do not have exposure. In that case, the underlying hazard does not really matter, and the risk of misspecifying it is worse than the consequences of not knowing it. Knowing exact hazard is not important—only the ratio of the situation when the factor is present to the situation when it is absent is required.

The Cox model for survival provides better estimates of the hazard at any point of time than the **Kaplan–Meier method**. The log-rank test associated with Kaplan–Meier is for the difference in the survival pattern but does not provide the magnitude of difference. Cox model delineates the magnitude through hazard ratio. Hazard ratio associated with a covariate is given by the exponent of its coefficient in the model, and provides the estimate of the independent effect of that covariate after adjusting the effect of other covariates present in the model. The estimate would come from an appropriate software package.

Time invariance of covariates is quite a strict condition in the context of survival. Most baseline values of all covariates can be incorporated as covariates because they remain the same. Generally, lifestyle and physiological variables change over time, while background characteristics such as gender, blood group, ethnicity, and urban/rural residence remain stable. If you are not sure, check that interaction between the covariate and time has statistically not significant coefficient. If significant, abandon the usual Cox proportion hazards model in favor of its extension for **time-dependent covariates**. See Thomas and Reyes [5] for details.

For Cox survival model, all polytomous covariates are converted to a series of binary classes by using indicator variables. Most statistical software packages would do this once you specify that a particular covariate is polytomous.

## Cronbach alpha

Cronbach alpha is a measure of internal consistency of a multiple-item instrument such as a survey questionnaire or a recording schedule, or any other multiple-item test. This was first proposed by Lee Cronbach in 1951 [1].

Lee Cronbach

Internal consistency is said to be present when the items provide information that does not contradict one another—not because the respondent gave wrong information but because the items are not properly constructed. For details, see **internal consistency**. One method to check this is the **split-half** coefficient, and the second method for assessing internal consistency is

$$\text{Cronbach alpha} = \frac{M\bar{r}}{1+(M-1)\bar{r}},$$

where $M$ is the number of items in the test, and $\bar{r}$ is the average of $M(M-1)/2$ correlations between each pair of $M$ items. For this purpose, the product–moment **correlation coefficient** is used. Thus, this alpha is applicable only when the responses to various items are scores on a metric scale. For this, the items may be on a **Likert scale** that provides such scores or of any other type such as the graded response on activities of daily living (ADL) (e.g., ability to dress in infirm people graded from 0 for complete inability to 5 for complete independence). A basic assumption is that the variances of the scores on individual items are equal. If this is not the case, the measure stated in the preceding equation needs modification as indicated by Carmines and Zeller [2].

The formula shows that the Cronbach alpha depends on the number of items in the test. When $\bar{r}$ is 0.3, alpha = 0.68 for $M = 5$, and alpha = 0.87 for $M = 15$ for the same $\bar{r}$. Thus, the Cronbach reliability of a test can be increased simply by increasing the number of items, provided that the average correlation does not deteriorate. The reason for such behavior is not too hard to find. Cronbach alpha assumes that the items included in the test are a random sample from a universe of many possible items. The higher the number of items, the better the representation.

The following comments give some more information regarding Cronbach alpha:

- Cronbach alpha is based on all items of the test and thus is a better indicator of reliability than the split-half coefficient. The latter is based on only half the items. Also, split-half is based on the sum total of the scores on the items in the half-test, whereas Cronbach alpha considers each item separately and uses the average correlation.
- Cronbach alpha measures how well the items are focused on a single idea or an entity or a construct. All items are supposed to be focused on the same entity such as disability in the ADL example. But it does not tell you how well the entity is covered. A high value of this alpha is possible even when the breadth of the construct is covered only partially.
- Cronbach alpha measures the internal consistency component of **reliability** of an instrument as a whole and not of individual items. However, correlations of individual items with one another can be examined to find whether or not any particular item is adequately related to the others.
- Cronbach alpha can also be viewed as the correlation between the test and all other possible tests containing the same number of items on the same entity or construct. In the ADL example, the questions can be on being able to sit on a chair instead of walking around or can be on being able to climb stairs. If the test is reliable, the alpha will not materially change when an item is replaced by another equivalent item.
- All measures of reliability, including Cronbach alpha, range from 0 to 1. Thus, these measures are easy to interpret. A value less than 0.4 indicates poor reliability, between 0.4 and 0.6 a toss-up, more than 0.6 is generally considered acceptable, and a value more than 0.8 excellent. Use your judgment for values on the borderlines of these cutoffs.
- If the response to items is binary (yes/no, true/false, or present/absent type), then Cronbach alpha reduces to what is called the **Kuder–Richardson coefficient**. For further details, see Carmines and Zeller [2].
- All measures of internal consistency, including Cronbach alpha, are affected by the length of test, homogeneity of test items, heterogeneity of the subjects in the sample to whom the test was administered, and objectivity of the test items.
- In case needed, Spearman **rank correlation** can be used in Cronbach alpha in place of product–moment correlation coefficient.

The following example illustrates how Cronbach alpha is computed. A questionnaire consisting of four items on knowledge of acquired immunodeficiency syndrome (AIDS) was administered to 80 students of grade VII. These are as follows:

Item 1: Knowledge about mode of spread of human immunodeficiency virus (HIV) infection
Item 2: Knowledge about its prevention
Item 3: Knowledge about social handling of AIDS patients
Item 4: Knowledge about symptoms of AIDS

**TABLE C.39**
**Correlation between Items of Knowledge about AIDS**

| | Item | | | |
|---|---|---|---|---|
| **Item** | **1** | **2** | **3** | **4** |
| 1 | | 0.87 | 0.62 | 0.45 |
| 2 | | | 0.75 | 0.33 |
| 3 | | | | 0.36 |

Each item is graded on a four-point scale from 0 for no or completely wrong knowledge to 3 for perfect knowledge. Suppose the correlations are as shown in Table C.39. These give $\bar{r} = 0.563$. Thus,

$$\text{Cronbach's alpha} = \frac{4 \times 0.563}{1 + 3 \times 0.563} = 0.84.$$

The internal consistency, thus, is "excellent," despite the fact that the fourth item has poor correlation with the other items. Low correlation of this item with others is an indication that knowledge of symptoms is probably not part of the same entity that is being measured by the other three items.

## crossover designs/trials, *see also* crossover trials (analysis of)

A design is called crossover when the same groups of subjects are administered two or more regimens one after the other in one sequence in one group and in another sequence in the other group. In a simple 2 × 2 situation, this means that one group of subjects receives AB sequence (regimen A followed by regimen B) and the other group receives BA sequence. Since the subjects are the same in each group, this design helps to control between subjects variation that would occur if the groups of subjects are different and thus can provide substantially more believable results when the stringent conditions under which it is applicable are fulfilled. Crossover design has pronounced applications to clinical as well as laboratory experiments. Thus, the following discussion is mixed for laboratory and clinic setups.

Medicine is an incomplete science as it is today; many drugs work for a limited period. They have to be administered again, else the disease returns with the same intensity. Some drugs do have some **carryover effect**, but in others, there is practically none. When all traces of their effect vanish, say 2 or 3 days after the last ingestion, the same subject can be used again to try the other drug, provided the condition of the subject reverses to what it was. This is called the steady state. In the case of humans, epilepsy, migraine, enlarged prostate, and end-stage renal failure are examples of such diseases. In some patients, hypertension and diabetes require daily medication; otherwise, the disease returns to the baseline. Yet, a high-cholesterol diet consumed by older subjects for a long time when they were young because of lack of awareness might still have a carryover effect that persists despite a change to a low-cholesterol diet. **Cross-sectional studies** of the type envisaged by crossover design fail to take care of such confounders.

In the case of animals, the experiment could be for the effect of cocaine versus saline on behavior in terms of distance traveled in 30 min following the injection separately in long-sleep and short-sleep mice. In this experiment, some mice may receive cocaine on day 1 and saline on day 2, and others saline on day 1 and cocaine on day 2. The process of trying two regimens on the same subject after providing a time gap (called the **washout period**) for complete disappearance of the carryover effect of the first regimen is called crossover (Figure C.30).

You can see that crossover is more suitable for quantitative outcomes rather than binary (yes/no) response. Nonetheless, it can be used for such binary response as well. Suitability of crossover also depends on the regimen. Quickly reversible regimens are obviously more suitable than long-acting regimens such as steroids. Crossovers are difficult to implement for multidose trials.

An important prerequisite of a successful crossover experiment is the absence of carryover effect. The carryover effect need not be just physical; it can also be psychological if that affects pharmacological outcome. Also, a drug may have caused damage to the liver that would affect metabolization of future drugs for a long time. If a patient receives regimen A followed by regimen B, the effect seen after regimen B would be the direct effect of regimen B plus the residual effect of regimen A received earlier. This produces bias. The problem confounds further if the carryover effect of regimen A is different from the carryover effect of regimen B.

As just mentioned, the time gap required for carryover effect to vanish is called the washout period. This generally should be at least four times the half-life of the regimen. **Half-life** is the period at which half of the peak concentration of drug is available in the body and the other half is eliminated or metabolized by the body after the time when the peak is reached. Nothing should occur during the washout period that can affect the outcome. Absence of the carryover effect can be statistically tested in a crossover design. If carryover effect is significant, think of an alternative such as **Balaam design** where AA and BB sequences are also included in addition to AB and BA sequence.

In a crossover experiment, the subjects are divided into two equal groups by **randomization**—one group receives drug A followed by drug B, and the other receives drug B followed by drug A. Allocation can be done by tossing a coin or by any other random method. It is desirable to continue observation till the end of the washout period of the second drug. This provides confidence regarding the drug exiting the system. However, this sequence itself

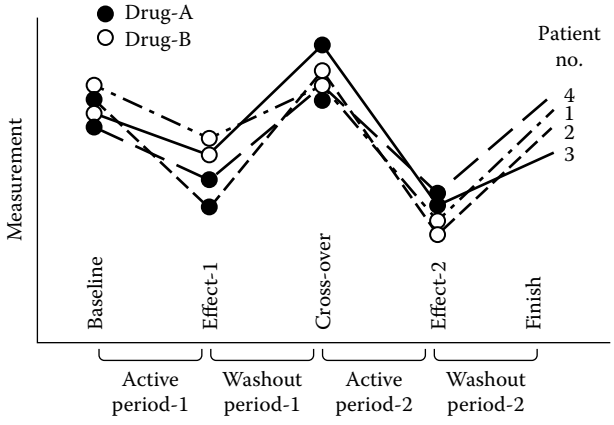

**FIGURE C.30** Representation of a crossover design.

can cause differential effect. This can particularly happen when the intervening period is favorable to one regimen than the other. For example, when lisinopril is given first and then losartan after a 2-week washout gap to nondiabetic hypertensive patients for insulin sensitivity, the first drug may still be in the system. This may not happen when losartan is given first. Crossover design is not appropriate for such regimens that have significant sequence effects.

The advantage of crossover is the availability of natural controls because the same experimental unit is used twice. This tends to reduce the impact of experimental error. The benefit of randomization is also available. Fewer subjects are required in this design relative to a **parallel** design with a separate control group. It is not necessary to recruit all subjects at a particular point of time. Period has a relative meaning. Some patients may have completed both periods before others are even recruited.

There are many cautions for using a crossover design. Besides the basic requirement of no carryover effect, crossover is recommended when the effect of the intervention can be assessed quickly so that the patient can be crossed over without a large time gap to deny opportunity for confounders to appear. If baseline condition can affect the outcome, all the subjects in the trial should be homogenous. Crossover is not a suitable design for cyclic diseases such as asthma and arthritis because they have natural remission periods. As for any design, there should not be any concomitant medication or comorbidity that can affect the outcome. Note that in this design, the subjects must stay in the experiment twice as long as otherwise needed in an experiment with parallel control group. This can cause higher dropouts. Crossover should not be used when substantial dropout is anticipated because then the statistical analysis becomes complex and the reliability steeply declines. However, periods in the case of crossover are not necessarily calendar periods. It is possible that one subject receives first-period treatment in the month of June and the second period in the month of July, and the second subject is recruited in August for the first-period treatment. Also, the entire trial should not be modified midway in any manner, such as for dosage, period, and sequence, because that could complicate the analysis.

Crossover is relatively easy when the treatment can be rapidly started and stopped. However, crossover strategy with random allocation of the order of therapy and adequate washout period as discussed earlier is essential for valid results from such self-control designs. A crossover design cannot be adopted if cure or death is the outcome. In addition, regulatory agencies seldom approve crossover because of the possibility of carryover effect even if demonstrated to be absent. Also, side effects and tolerability are difficult to study in a crossover setup since the administration is for a short period. Thus, crossover is not recommended for phase III trials. But this design can be easily used in phase II, particularly for identifying the right dosage. The conventional crossover is two regimens–two periods–two sequences strategy. But it can be extended for multiple periods and multiple regimens. For further details, see Senn [1].

Here are some examples that illustrate situations where a crossover strategy can be used. In rats, the ability of drugs to lower brain stimulation reward (BSR) thresholds often correlates well with high abuse reliability. Gill et al. [2] implanted bipolar electrodes into the medial forebrain bundle of male mice for assessing BSR thresholds after intraperitoneal alternative saline and cocaine in a crossover design. For an example involving humans, consider a representative group of 90 patients with essential hypertension. To study the effect of different drugs, they can be given atenolol, propranolol, and acebutalol for 6 days each after a gap of 3 days in between as a washout period for the drug to exit the system and for the disease to reappear at the same level. In this example, one patient is used three times. The order in which a patient receives the drugs is randomized. If the conditions are favorable, you can have four or five regimens in a trial.

Particularly in a crossover and in **repeated measures studies** without parallel control in general, the results are obtained by comparing the average within subject responses at different time points. In the usual experiments with a separate control group, the results are obtained by comparison of averages across groups. Crossover, just as **before–after experiments**, has smaller variability because the subjects are the same, and such experiments require fewer subjects to detect the same effect than the design with parallel control group.

For small cell frequencies in a crossover design, the statistical significance of the difference between treatments A and B can be investigated by using the Fisher exact test on the discordant pairs. The concordant pairs are ignored. This is discussed under **crossover trials (analysis of)**.

## crossover trials (analysis of)

As mentioned for **crossover designs/trials**, crossover could be a very efficient strategy for trials on regimen that provide temporary relief. In this design, one group receives regimen A and then B (AB sequence), and the other group receives regimen B and then A (BA sequence). The two groups contain different sets of individuals; thus, the groups are independent. The primary objective of a crossover trial is to test the significance of the difference in effects of the regimens. Primary difficulty in analyzing data from crossover designs arises from duplicity of factors. If there are three patients, two periods, and two treatments, a crossover could yield only six observations instead of $3 \times 2 \times 2 = 12$ in a conventional design. Two factors determine the third. If patient 1 gets the AB sequence, the observation for this patient in period 2 must be under treatment B. This section describes the method of analysis of data from crossover trials—first when the outcome is quantitative and second when it is binary.

### *Analysis of Data from Crossover Trials with Quantitative Response (Gaussian Conditions)*

Consider a trial on $n = 16$ chronic obstructive pulmonary disease (COPD) patients who were randomly divided into two equal groups of size 8. The first group received treatment A and then treatment B, and the second group received treatment B and then treatment A. Abbreviate these treatments as trA and trB. An adequate washout period was provided before switching the treatment so that there was no carryover effect. The response variable is forced expiratory volume in one second ($FEV_1$). The data obtained are in Table C.40.

*Test for Group Effect*: In the case of crossover trials, the groups identify the sequence, and the group effect is the same as the sequence effect. If the sequence does not affect the values, the mean difference between trA and trB should be the same in the AB group as in the BA group. A significant effect means that trA has different effect when in period 1 than when in period 2. Thus, this

C

**TABLE C.40**
**$FEV_1$ (L/s) in COPD Patients in a Crossover Trial**

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| **Group I—AB Sequence** | | | | | | | | | |
| Subject no. | | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| Period 1 | trA | 1.28 | 1.26 | 1.60 | 1.45 | 1.32 | 1.20 | 1.18 | 1.31 |
| Period 2 | trB | 1.25 | 1.27 | 1.47 | 1.38 | 1.31 | 1.18 | 1.20 | 1.27 |
| **Group II—BA Sequence** | | | | | | | | | |
| Subject no. | | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| Period 1 | trB | 1.27 | 1.49 | 1.05 | 1.38 | 1.43 | 1.31 | 1.25 | 1.20 |
| Period 2 | trA | 1.30 | 1.57 | 1.17 | 1.36 | 1.49 | 1.38 | 1.45 | 1.20 |

is also called treatment–period interaction. Note for crossover that group effect = sequence effect = treatment*period interaction. In this example,

| **trA – trB Values** | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Group I (AB) | +0.03 | –0.01 | +0.13 | +0.07 | +0.01 | +0.02 | –0.02 | +0.04 |
| Group II (BA) | +0.03 | +0.08 | +0.12 | –0.02 | +0.06 | +0.07 | +0.20 | +0.00 |

Since the patients in Group I are different from the patients in Group II, equality of means in these groups can be tested by the two-sample **Student *t*-test** under **Gaussian conditions**. In this case, for these differences, the means, variances, and pooled variance are

$\bar{x}_1 = 0.03375$ $\bar{x}_2 = 0.06750$

$s_1^2 = 0.0023125$ $s_2^2 = 0.0048786$ $s_p^2 = 0.0035955.$

Thus, for two independent samples,

$$t_{14} = \frac{0.03375 - 0.06750}{\sqrt{0.0035955(1/8 + 1/8)}} = -1.126.$$

This is not statistically significant ($P > 0.05$). Thus, the evidence is not enough for the presence of sequence effect. The practical implication is that there is no sequence effect, although this can be ascertained only when the sample is large and the power is high. If a sequence effect is present, the reasons should be ascertained and the trial done again after eliminating those causes. In most practical situations where a crossover trial is used, the sequence of administering the drugs does not make much difference. The real possibility is that of a carryover effect that can also make a dent in the sequence effect.

*Test for Carryover Effect*: If a positive carryover effect were present in any regimen, the performance of that regimen in period 2 would be better than its performance in period 1. Thus, the presence of a carryover effect can be assessed by comparing the performance of each regimen in the two periods. In the preceding example, this is obtained by comparing trA values in period 1 with trA values in period 2, and similarly for trB. It is possible that only one of the regimens has a long-term effect so that carryover is present for that regimen and the other has no such effect. Two two-sample *t*-tests would decide whether one or both have a carryover effect. In this example, these are as follows:

**trA**

| | | | |
|---|---|---|---|
| Period 1 | Mean = 1.325 | SD = 0.1386 | Pooled variance |
| Period 2 | Mean = 1.365 | SD = 0.1387 | 0.019224 |

$$t_{14} = \frac{1.365 - 1.325}{\sqrt{0.019224(1/8 + 1/8)}} = 0.577.$$

**trB**

| | | | |
|---|---|---|---|
| Period 1 | Mean = 1.298 | SD = 0.1391 | Pooled variance |
| Period 2 | Mean = 1.291 | SD = 0.0952 | 0.014206 |

$$t_{14} = \frac{1.291 - 1.298}{\sqrt{0.014206(1/8 + 1/8)}} = -0.117.$$

*P*-values associated with these values of *t* show that the carryover effect is not statistically significant for any of the treatments in this example.

*Test for Treatment Effect*: The two tests just mentioned are preliminaries. The primary purpose of the trial, of course, is to find whether one treatment is better than the other. This can be done only when the sequence (or the group) effect is not significant.

(a) *If there is no carryover effect*, the procedure is as follows. Consider two groups together as one because the sequence is not important and there is no carryover effect. Calculate differences trA–trB and use the paired *t*-test on the joint sample. In this example, these differences are

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| +0.03 | –0.01 | +0.13 | +0.07 | +0.01 | +0.02 | –0.02 | +0.04 |
| +0.03 | +0.08 | +0.12 | –0.02 | +0.06 | +0.07 | +0.20 | 0.00 |

These give mean difference = 0.0506 and $s_d = 0.06049$. Thus,

$$t_{15} = \frac{0.0506}{0.06049/\sqrt{16}} = 3.346.$$

This gives $P < 0.01$. Thus, statistically the treatment difference is highly significant.

(b) *If the carryover effect is present*, crossover is not a good strategy. You may then increase the washout period and ensure that no carryover effect is present. If the data from a crossover trial are already available and the carryover effect is found to be significant, then analyze as usual by Student *t* after ignoring the second period. Thus, half of the data (and efforts) will become redundant and the advantages of the crossover design lost. Remember the following for crossover designs:

- It is easy to say that a washout period will eliminate a carryover effect. In fact, it can rarely be dismissed on a priori grounds. A psychological effect may persist even in case of blinding of the subjects. Thus, a crossover design should be used only after there is fair assurance that a carryover effect is practically absent.

- The test for a carryover effect is based on variation between subjects and thus has less power. A small but real effect may not be detected unless a big trial with a large number of subjects is done. Then the advantage of the economy of subjects in a crossover design may be lost.
- Details are given under **multiple comparisons** but carrying out so many statistical tests on the same set of data increases the total chance of Type I error. To keep this under control to, say, less than 5%, you should carry out the three *t*-tests at the 2% level each.
- The preceding is an easy method based on the Student *t*-test. This is not so elegant. Quantitative data from crossover trials can be analyzed more meticulously by using the analysis of variance method. For this, see Everitt [1]. Neither methodology is fully standardized.

### *Analysis of Data of Crossover Trials with Binary Response*

The concern now is with crossover experiments in which the response or the outcome is binary. This is a yes/no, present/absent, or relieved/not relieved type of response. In such cases, the number of subjects with different responses in a crossover trial can be listed as in Table C.41. In this table, for example, $b_2$ is the number of subjects who were not relieved by drug B but were relieved by drug A when the sequence of administration was B followed by A. Other notations also have similar meaning.

The analysis of binary data from crossover trials is not fully standardized. One of the methods is as follows. For finding statistical significance in this case, the concordant pairs in the first and last columns are ignored. Since the response with drug A is the same as with drug B in these two types of pairs, they cannot help in deciding which drug is better. The decision is based on the discordant pairs in the second and third columns. The frequencies in these two middle columns are analyzed as a usual 2×2 table. For large $n$, the chi-square criterion is computed and the inference drawn as per the procedure for chi-square. The relevant numbers for this setup are given in Table C.42. This table will indicate whether the response with one treatment is different from the response with the other treatment. If $(a_2 + b_3)$ is large relative to $(a_3 + b_2)$, then drug B is more effective. If $(a_3 + b_2)$ is larger, then drug A is more effective. The prerequisite for validity of this test, however, is that there is no effect of different sequence of drug administration and no carryover effect.

It is helpful to investigate whether sequencing (A precedes B, and B precedes A) alters the response. This can be done by making another 2×2 table (Table C.43) that gives counts of relieved subjects in the two groups. Again, only discordant pairs are counted. Chi-square is computed for large samples and an inference drawn as usual. If sequence effect in Table C.43 is significant, crossover is not a suitable strategy. Redo the trial with some other design. If interaction is to be statistically tested, prepare a table, such as Table C.44, and calculate chi-square as usual.

These three procedures are stated in reverse order. In practice, do ③, then ②, and then ①. If the presence of interaction is detected by ③, it is not worthwhile to do ② or ①. In this case, find out why the interaction is occurring and do the trial again after taking steps to remove the likelihood of interaction. The following example illustrates the calculations.

A new drug A for relief from urinary problems in subjects with enlarged prostates was compared with an existing drug B. Each was given for 1 month to 50 subjects in sequence BA and to another 50 subjects in sequence AB. There was a washout period in between as needed in a crossover design. The results are shown in Table C.45.

For the purpose of comparison, the first and last columns are ignored. The frequencies in the discordant cells are small, and so the

**TABLE C.41**
**Format of Binary Response in a Crossover Trial**

| | Response[a] | | | | |
|---|---|---|---|---|---|
| **Group (Sequence)** | **(0, 0)** | **(0, 1)** | **(1, 0)** | **(1, 1)** | **Total** |
| Group I—sequence AB | $a_1$ | $a_2$ | $a_3$ | $a_4$ | $\boldsymbol{n_1}$ |
| Group II—sequence BA | $b_1$ | $b_2$ | $b_3$ | $b_4$ | $\boldsymbol{n_2}$ |

[a] 0 = no relief; 1 = relief.

**TABLE C.42**
**Relevant Numbers for Analyzing a Crossover Design**

| | | Response | |
|---|---|---|---|
| | | **(0, 1)** | **(1, 0)** |
| ① | Group I—sequence AB | $a_2$ | $a_3$ |
| | Group II—sequence BA | $b_2$ | $b_3$ |

**TABLE C.43**
**Numbers for Testing Sequencing Effect in a Crossover Trial**

| | | **Relieved with A** | **Relieved with B** |
|---|---|---|---|
| ② | Group I—sequence AB | $a_3$ | $a_2$ |
| | Group II—sequence BA | $b_2$ | $b_3$ |

**TABLE C.44**
**Numbers for Testing Interaction in a Crossover Trial**

| | | Response | |
|---|---|---|---|
| | | **(0, 0)** | **(1, 1)** |
| ③ | Group I—sequence AB | $a_1$ | $a_4$ |
| | Group II—sequence BA | $b_1$ | $b_4$ |

**TABLE C.45**
**Crossover Trial with Small Frequencies in Some Cells**

| | Response[a] | | | | |
|---|---|---|---|---|---|
| | **(0, 0)** | **(0, 1)** | **(1, 0)** | **(1, 1)** | **Total** |
| Group I—sequence AB | 2 | 1 | 7 | 40 | **50** |
| Group II—sequence BA | 7 | 5 | 2 | 36 | **50** |

[a] 0 = no relief; 1 = relief.

Fisher exact test would be used. The given configuration and more extremes are as follows:

| | | | | | |
|---|---|---|---|---|---|
| 1 | 7 | 8 | 0 | 8 | 8 |
| 5 | 2 | 7 | 6 | 1 | 7 |
| 6 | 9 | 15 | 6 | 9 | 15 |

No other extreme configuration is possible because marginal totals have to remain the same, and one cell frequency is already zero in the second configuration. Therefore, from **multinomial distribution**,

$$P = \frac{8!7!6!9!}{15!1!7!5!2!} + \frac{8!7!6!9!}{15!0!8!6!1!}$$

$$= 0.0336 + 0.0014$$

$$= 0.035.$$

This is less than 0.05. Since it is a one-tailed probability, the conclusion too would be **one-sided**. In this case, there are seven subjects in sequence AB that had relief from drug A but not from drug B and five subjects with relief from A but not from B in sequence BA. Of a total of 15 discordant pairs, 12 favor drug A and only 3 favor drug B. A small *P*-value shows that this is statistically significant. Thus, the conclusion is that the new drug A is significantly better than the existing drug B. For such one-sided conclusions, one-sided α is used.

## cross-product ratio, *see* odds ratio

## cross-sectional studies

**Observational studies** where both antecedent and outcome are elicited together are called cross-sectional studies. For example, one format for studying the effect of anemia on gestation period in pregnancy is that a group of deliveries are chosen irrespective of maternal anemia and gestational age, and both are elicited. This is a cross-sectional study since both antecedent and outcome are observed at the same time. Both are responses in this setup, and none is a factor. The presence or absence of either antecedent or outcome is not a consideration at the time of selection of subjects in this kind of design, but the objective still is to investigate the **association** as required for any **analytical study**. Although this kind of format is regularly used for descriptive studies, such as for estimating the prevalence of a health outcome, the term *cross-sectional study* is appropriate for analytical studies where the objective is to investigate antecedent–outcome relationship. They can be used to generate hypothesis regarding etiology. Cross-sectional descriptive studies are better understood as surveys. Cross-sectional studies are not surveys.

A cross-sectional study is categorized as analytical because it also intends to investigate associations and differences. However, the validity of conclusions would depend on the proportional representation of various levels of responses. Thus, it is important that a cross-sectional study is done on a randomly selected sample of adequate size, obtained from the target population without recourse to any consideration of presence or absence of antecedent or outcome. If this is compromised, the conclusions based on a cross-sectional study could be biased.

Cross-sectional studies are done where the distinction between antecedent and outcome is blurred. Consider cleft lip and thalassemia in children; neither is a known cause of the other, yet dependence of one on the other can be investigated for generating a hypothesis. Such studies are analytical in this sense and do not remain purely descriptive. For studying the association between blood group and gender, if male and female subjects are selected and tested for their blood group, it could be difficult to categorize it either as a prospective or as a retrospective study, though it might merit to be called a case–control study if one gender is regarded as case and the other as control. When the antecedent and the outcome are not identifiable, the study may be called descriptive rather than analytical—thus not really cross-sectional. It would only indicate the blood group profile in the two genders without aspersions on the exposure–outcome type of relationship. Such a study would continue to be of a descriptive type until one is identified as an antecedent or at least as a suspected antecedent for the purpose of the investigation. A study on evaluation of concordance between two or more methods is also cross-sectional.

Cross-sectional studies are more appropriate for assessing the relationship between fairly stable entities, such as gender and hypertension, which do not change during the course of the study. Note that a cross-sectional study provides a one-time snapshot of the status of the characteristics, and not a long-term perspective.

In a cross-sectional study, **confounding factors** can also be investigated at the same time. For example, in a study on determinants of the increase in serum cholesterol with age in adults, a group of subjects could be elicited for sex, diet, body mass index, etc., in addition to age and serum cholesterol level. All measurements would be considered valid for the date of investigation, although assessment of diet in this case could be based on the food intake during the previous 3 days. The investigation might have the objective of determining the role of age in increasing the cholesterol level, but the design is such that the role of sex, obesity, and diet can also be investigated with the same validity. Statistically, any characteristics in a cross-sectional study can be considered dependent on the rest; the only restriction is the plausibility or justifiability of the relationship obtained.

The first step for sampling for a cross-sectional study is, as usual, to identify the target population for which the results would generalize. Then decide which sampling method would be appropriate. For age- and sex-related disease such as hypertension and diabetes, stratification by age and sex might be useful. For a community-based study in a large population, a **multistage sampling** involving selection of counties and households can be adopted, or a **cluster sampling** might be more convenient. In a clinical setup where subjects come in queue, **systematic sampling** could be adopted.

Consider the following example. A study was conducted on 137 extremely obese subjects (mean BMI = 46.9 kg/m$^2$), and their diabetes status and obstructive sleep apnea (OSA) were elicited [1]. Thus, this is a cross-sectional study. Among subjects with normal glucose tolerance, 33% had OSA. This was 67% in prediabetic subjects and 78% in type 2 diabetes patients. Thus, the association between OSA and diabetes status in extremely obese subjects was clear. This continued to be so after age, sex, BMI, etc., were adjusted. This cross-sectional study excluded the role of various confounders, yet the conclusion rightly is of association and not cause–effect.

### *Merits and Demerits of Cross-Sectional Studies*

The following paragraphs describe the demerits of cross-sectional designs before describing the merits because, for such studies, demerits should be considered first when investigating antecedent–outcome relationship.

Cross-sectional studies give a snapshot view and cannot measure risk. They may turn out to be a poor choice in situations in which either the antecedent or the outcome or both are rare. If the outcome of interest is testicular cancer or the antecedent under investigation is exposure to synthetic estrogen, then a cross-sectional study is not appropriate. An extremely inadequate number of subjects with the characteristics of interest may render the entire exercise futile.

There are other demerits too. The analysis can certainly be extrapolated to evaluate the net relationship between any two characteristics, keeping the others constant, but it should be clear that a cross-sectional design investigates the presence and not the appearance of the condition. Transient cases or rapidly fatal cases may inevitably remain underrepresented in this kind of design. The causes that determine the appearance are confounded with those influencing the duration of the disease, and it may be difficult to draw a clear inference about either set of causes. Dropouts or migrants tend to be excluded in a cross-sectional study.

The other serious difficulty in a cross-sectional study is that it cannot be ensured that the antecedent has actually preceded the outcome. This might have important implications for a causal inference. A firm conclusion on cause–effect can rarely be drawn from cross-sectional studies, and this is a major limitation for such studies to be truly analytical. The concept of a control group is not relevant to cross-sectional studies. The biases seen in other observational studies are largely applicable to cross-sectional studies as well. However, information bias or memory lapse could be practically absent in this setup.

Caution is required in interpreting the results of a cross-sectional study. Such a study might reveal, for example, that the prevalence of hypercholesterolemia increases with age, but the fact could be that it is not age-induced but is due to the changes in the diet pattern of younger subjects resulting from increased awareness of the harmful effects of a high-cholesterol diet. Such awareness was less common 30 years ago and practically absent 50 years ago. A high-cholesterol diet consumed by older subjects for a long time when they were young because of lack of awareness might still have a carryover effect that persists despite a change to a low-cholesterol diet. Cross-sectional studies fail to take care of such confounders.

It follows from the preceding discussion that the cross-sectional design is particularly well suited for acute conditions with a short latent period or for chronic diseases that are stable and nonfatal. As already stated, this design can be recommended for situations in which the distinction between antecedent and outcome is blurred. In disease–anxiety syndrome, disease can cause anxiety and anxiety can cause disease—thus either could be an antecedent. Also, a cross-sectional study is generally considered a rapid and inexpensive way to provide clues for further and more valid investigations.

For analysis of data from a cross-sectional study, any one of the characteristics that can plausibly be considered as the outcome can be considered dependent on the others. **Logistic regression** or the usual **multiple regression** can be used to find the joint or net effect of each of the independent factors in the model. In the case of cross-sectional studies, the assessment is generally made in terms of **odds ratios** for qualitative dependent. Sometimes the **prevalence rate** ratio is used.

Type 2 diabetes and pre-diabetes are associated with obstructive sleep apnea in extremely obese subjects: A cross-sectional study. *Cardiovasc Diabetol* 2011;10:84. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3206416/

## *C*-statistic, *see also* receiving operating characteristic (ROC) curve

*C*-statistic is the area under a **receiving operating characteristic (ROC) curve**. This curve plots the **sensitivity** of a quantitative medical test against (1 – **specificity**). *C*-statistic measures the performance of the test in terms of combination of sensitivity and specificity. Thus, an understanding of these concepts is necessary to understand *C*-statistic. In brief, sensitivity of a test is the true positive rate that measures its ability to show positive result among those who are known to have disease, and (1 – specificity) is the false positive rate that measures the dubious ability of a test to show positive result among those who are known not to have that disease. The maximum value of *C* is 1.0.

A test such as serum omentin-1 can be considered as an inflammatory activity marker in Crohn disease [1]. This can be measured for the established cases as well as the healthy controls. Thus, sensitivity and specificity can be obtained for different levels of serum omentin-1. When these are plotted, the **area under the ROC curve** was $C = 0.87$. This was higher than $C = 0.76$ for *C*-reactive protein (CRP), indicating that serum omentin-1 has better performance than CRP as an inflammatory marker in Crohn disease. As in medical literature, we use the term *C*-statistics and AUC interchangeably in the context of ROC curves. This is also called *C*-index.

### *Area under the ROC Curve*

The primary utility of ROC curve lies in the area under the curve (AUC), denoted by statistic *C*. The larger the AUC, the better the overall performance of the medical test to correctly identify diseased and nondiseased subjects. The closer the ROC curve to the left and top border (see Figure C.31), the larger the AUC and the more valid the test in terms of sensitivity and specificity. In this figure, test A is better than test B, and test B is better than test C. If the test is lousy, for every true positive, as the level (e.g., of serum omentin-1) increases, you are likely to encounter a false positive. The ROC curve tends to flatten in this case, and nearly a diagonal line is obtained.

Because of inherent variations and uncertainties in all biological phenomena, no test can be perfect. It is considered excellent if *C* is 0.90 or more and good if *C* is between 0.80 and 0.89. An area

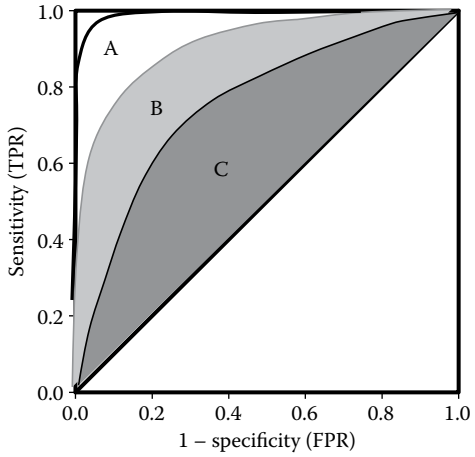

**FIGURE C.31** Three ROC curves with different areas under the curve.

of 0.50 corresponds to the diagonal and indicates that the test is absolutely not helpful. In a rare case, if this area is less than 0.50, conclude that the test is misleading. In this case, reverse the definition of positive and negative, i.e., in place of higher values signifying the presence of disease, examine if lower values will correctly pick up the disease.

As is true for sensitivity and specificity, validity of ROC and AUC depends on the "gold" being really so. If the gold is suspect, a high AUC does not necessarily mean a good test. Also, for ROC to be valid, the test must not be affected by what gold is. All other constraints for sensitivity–specificity also apply. AUC measures the performance with regard to combination of sensitivity and specificity and fails to balance the differential risks of misdiagnosis and missed diagnosis effectively. Note that these risks cannot come from the present data and should come from experience of the clinicians.

While statistically comparing two tests, the decision regarding which test is better depends on AUC. Thus, this area should be obtained by using an appropriate method. Statistical software packages provide nonparametric and parametric methods for obtaining the area under the ROC curve. The user has to make a choice. The following details may help.

**Nonparametric methods** are distribution-free and the resulting area under the ROC curve is called empirical. First such method uses trapezoidal rule. If sensitivity and specificity are denoted by $s_n$ and $s_p$, respectively, the trapezoidal rule calculates the area by joining the points $(s_n, 1 - s_p)$ at each interval value of the continuous test and draws a straight line joining the $x$-axis. This forms several trapezoids, one corresponding to each interval, and their area can be easily calculated and summed. This method is illustrated under the topic **area under the curve**, although that is area under the (drug) concentration curve. Another nonparametric method uses Mann–Whitney statistics, also known as **Wilcoxon rank-sum** statistic. Both these nonparametric methods of estimating AUC have been found equivalent [2].

Parametric methods are used when the statistical distribution of test values in diseased and nondiseased is known. **Binormal distribution** is commonly used for this purpose. This is applicable when test values in both diseased and nondiseased follow a normal distribution. In this case, the relevant parameters can be easily estimated by the means and variances of test values in diseased and nondiseased subjects. For details of how to obtain the area, see Zhou et al. [3].

The choice of method to calculate AUC essentially depends upon availability of statistical software. The binormal method produces a smooth ROC curve, and further statistics can be easily calculated but gives biased results when data are degenerate and when the distribution is bimodal. When software for both parametric and nonparametric methods is available, conclusion should be based on the method that yields greater precision of the estimate of AUC.

### *Issues in C-Statistic*

Equal AUCs of two tests represent similar overall performance of tests, but this does not necessarily mean that both the curves are identical. They may cross each other. Figure C.32a has hypothetical ROC curves of two medical tests A and B applied on the same subjects to assess the same disease. Tests A and B have nearly equal area but cross each other. Test A performs better than test B where high sensitivity is required, and test B performs better when high specificity is needed.

In cases where ROC curves for two tests cross each other and in some other situations, the interest may be restricted to specific values of sensitivity or specificity. You may be interested in a test with high sensitivity as for a disease with grave prognosis (cancer). Then the interest will be in test A and that too for specificity ≤ 0.65 or (1 – specificity) > 0.35. In that case, the area of interest is 3+4 as shown in Figure C.32b. This is called partial area under the curve. Some software packages calculate this also, and if you want, for easy interpretability, you can standardize it to 1 by considering the total area = 1 of rectangle from (1 – specificity) = 0.35.

Variance of AUC can also be obtained by using parametric and nonparametric methods. The formulas are complex. Software will give you this easily. This variance can be used to obtain the **confidence interval** assuming Gaussian pattern.

Formulas of sample size for testing hypothesis on comparing AUC with a prespecified value and for comparison of two on the same subjects or different subjects are available. See Zhou et al. [3] for details.

We have provided the details of *C*-statistic for binary groups, namely, with disease and without disease. Sometimes, the groups are **polytomous** such as with none, mild, moderate, and serious disease. In this situation, *C*-statistic can be used to see if a medical test is able to discriminate mild from moderate cases and moderate from serious cases. One alternative is to calculate *C*-statistics for mild versus moderate and another for moderate versus serious cases using

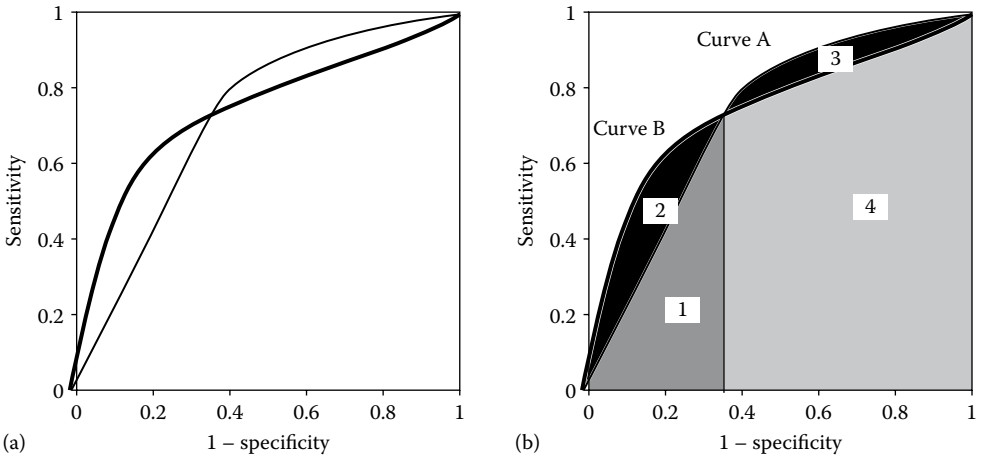

**FIGURE C.32** (a) Two ROC curves crossing each other but with nearly the same area. (b) Illustration of partial area under the ROC curve.

the binary procedure as stated in this section. But a *polytomous discrimination index* is also available based on *C*-statistic [4]. An example of such application is the study on discriminating between primary invasive and metastatic ovarian tumors, and between borderline and metastatic tumors [5].

## cubic clustering criterion

Cubic clustering criterion (CCC) is used to decide when to stop a hierarchical clustering process so that the clusters obtained are externally isolated and internally homogeneous. For these terms, see **hierarchical clustering**. Hierarchical clustering is the process of merging most similar to less similar entities (group of units) into clusters in stages and sequentially obtaining from $n$ clusters containing one unit each to one cluster containing all the units. However, this process requires identifying a stage when it is considered that the clusters are optimal grouping of units in the sense that the similar ones are clustered together and the dissimilar ones are in the other clusters. CCC is one of the measures calculated at each stage of clustering process and is used to get a feeling of where such natural clusters have been formed. Thus, this helps to determine the number of natural clusters. CCC was developed by SAS Institute [1].

The expression and the method of computing CCC are complex and are explained by Sarle [1]. This is based on the **multiple correlation** coefficient $R^2$. A larger value of CCC indicates better clustering. Thus, the stage where CCC is the highest can be considered best for obtaining optimal clusters. However, this criterion fails if the units are correlated, and in that case, other criteria should be used such as semipartial $R^2$, pseudo-$F$, and pseudo-$t^2$ statistic. Gerlinger et al. [2] have used all of these including the CCC to find the number of clusters of women on sex hormones by studying their menstrual diaries. They found four clusters with desirable patterns and two with undesirable patterns—a total of six clusters.

## cubic splines

This method uses cubic polynomials to extract a smooth pattern out of a scatter plot. The method is generally used in a setup where the usual methods of linear, quadratic, exponential, logarithmic, and such other regression functions fail to adequately represent the full pattern. Perhaps the most common use of cubic splines in health and medicine is in obtaining smooth growth curves of children such as for various percentiles of height, weight, and head circumference versus age.

A spline is an extension, say a wiggly shaped pipe, used to join another wiggly shaped pipe such that they can function together. Each pipe may have a different shape. For our purpose, these pipes are curves; for example, a cubic spline will draw a cubic curve, whereas a linear spline will draw a line. In statistics, a spline is a numeric function that defines polynomial for different pieces of the data range with a high degree of smoothness at connecting points. When the scatter does not have a uniform pattern over the entire range, it is split into smaller parts within which the scatter points can be adequately represented by a line or a curve (Figure C.33). In this figure, the entire scatter is divided into five parts. This is said to have four *knots* demarcating the parts—in this case at $x = 22$, 24, 29, and 31. Lines show linear splines, and the serpentine curve shows cubic splines. Note how cubic splines have extracted a smooth shape out of the scatter and how they are smoothly connected with the next at each knot. Cubic splines can take a lot of different shapes—Figure C.33 shows just one of them. The number of knots depends on the natural bents in the scatter. Generally, three knots for small samples and five to six knots for large samples are considered adequate. Location and the number of the knots can be left for the data to decide.

To understand how a smoothing problem can be challenged, consider centile curves that are often used to delineate norms of medical

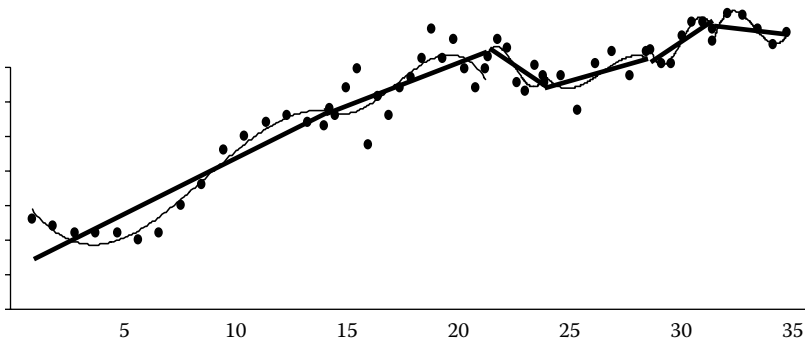

**FIGURE C.33** Linear and cubic splines with five knots.

C

parameters in a population. For these, estimation is done for many points in time. For example, for weight curve, one would obtain, say, 97.5th percentile for age 1 year, age 2 years, age 3 years, etc., to be able to obtain the centile curve. It is fair to expect that these percentiles at different ages would follow some kind of smooth trend. But, unfortunately, that would not be so in the data, mostly due to sampling fluctuations. These percentiles would, in all probability, follow an irregular pattern as are the **BCPE method**–based hypothetical estimates in Figure C.34. These are 95th percentile of aortic cross-sectional areas at the ascending aorta at different ages, similar to those obtained by Voges et al. [1].

In Figure C.34, observed values are shown by the solid line, linear trend by the dashed line, polynomial of degree 4 by the dotted line, and polynomial of degree 2 by the spaced dashes. The difficulty is to ascertain that flattening at age 15 years in this figure is real (does the aorta area really increase slowly between age 10 and 15 years?) or that it is just because of sampling fluctuation—another sample may not give this trend. If this flattening is genuine and we ignore this in our trend, important information regarding a slowdown just before age 15 years is lost. For delineating norms, no genuine information can be sacrificed. Also, a similar slowdown is noted after age 25 years. None of the four trends in Figure C.34 seems adequate to provide a real picture. Biological knowledge suggests that the aorta area increases rapidly till age 20 or 25 years and then the increase slows down, particularly in those who have a relatively large area for their age (say, those on the 95th percentile). Thus, a flattening between 25 and 30 years seems real but not between age 10 and 15 years. This is resolved by smoothing as it can provide the contextual shifts where needed.

It would be unrealistic that one age gives a high aorta area and the next a relatively low area unless there is a biological explanation. Extracting a realistic trend from erratic values without sacrificing useful information is a great statistical challenge. Eyeball trend can be fitted, but that lacks scientific basis and could vary from person to person. Thus, we take the help of methods such as cubic splines. This is done after suitably dividing the range of $x$-values (age, in our example) and fitting separate splines for each division.

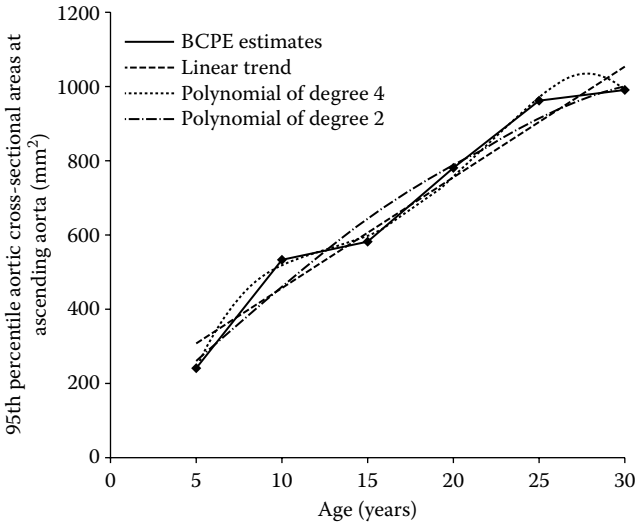

**FIGURE C.34** Erratic trend in plotted points: 95th percentile aortic cross-sectional areas at ascending aorta and the fitted polynomials. (From Indrayan A, *Ind Ped* 2014;51:37–43. http://www.indianpediatrics.net/jan2014/jan-37-43.htm, last accessed May 4, 2015.)

The calculations are intricate, and software help will be required for using cubic splines as a smoothing tool. For example, *GAMLSS* [3] software for growth curves uses cubic splines for smoothing the curves. But cubic splines seem to have not made much inroad to the popular statistical software yet. There is functionality SRS1 that adds cubic spline to MS Excel spreadsheet.

## cumulative frequency, *see* ogive

## curvilinear regression, *see also* regression (types of)

This is a **regression** of $y$ on $x$ (or set of $x$'s) that graphically yields a curve instead of the usual straight line. A curvilinear regression is obtained when quadratic (square), cubic, logarithmic, or exponential type of terms is added among the regressors. Another term for this is **polynomial regression**.

For simplicity, we explain this with one dependent and one independent variable. Linear regression in this case is $y = a + bx$. It becomes curvilinear when

$$\text{curvilinear regression of power } K\text{:}$$
$$y = a_0 + a_1x + a_2x^2 + a_3x^3 + \ldots + a_Kx^K.$$

Depending upon the maximum degree of $x$, this is called polynomial regression of degree $K$. When $K = 2$, this is called quadratic or **parabolic curve** because of the shape it gets; for $K = 3$, it is called cubic; for $K = 4$, it is called quartic; etc. Each power of $x$ is considered as a new variable in this regression, although this may raise the question of **multicollinearity**. Figure C.35 shows a linear regression by a line, a quadratic regression by a thick curve, and a cubic regression by a dotted curve. A linear regression is a straight line with no turn, a quadratic will have one turn, a cubic will have

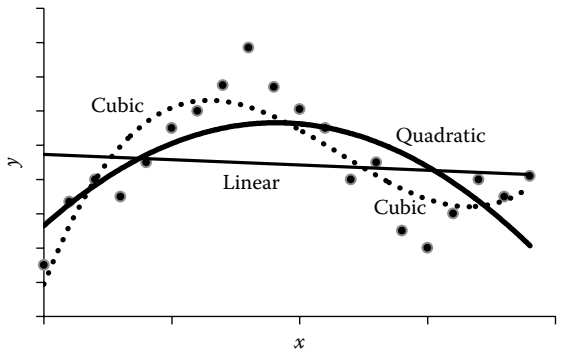

**FIGURE C.35** Linear and two curvilinear regressions with one regressor ($x$).

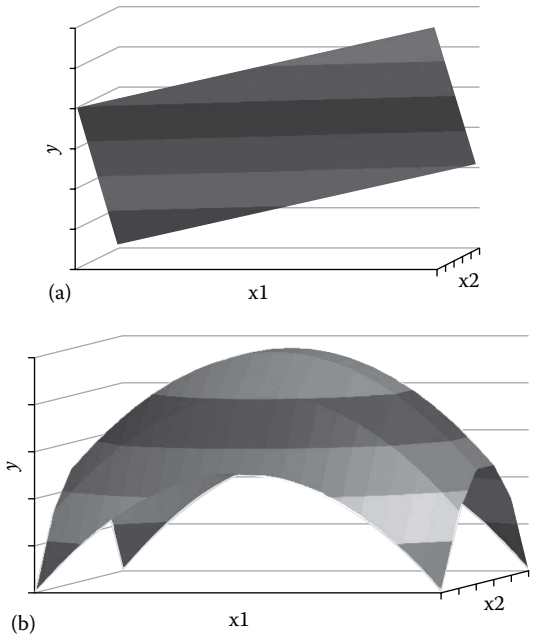

**FIGURE C.36** Regressions with two regressors: (a) linear and (b) curvilinear.

two turns, etc. A linear regression is appropriate when $y$ is increasing at a constant rate for each unit increase in $x$ such as between body temperature and pulse rate; quadratic is appropriate when $y$ shows an increase for an initial value of x and then levels off of or decreases (or vice versa); and cubic is appropriate when $y$ shows an increase then decrease, and then increase again. Regression of total glomerular filtration rate plasma on creatinine level is quadratic [1], and that of chronological age on dental age is cubic [2]. Polynomials can be fitted sequentially—first try linear then examine quadratic, and then go to cubic, etc. However, the regression coefficients will also change: the regression coefficient of $x$ in a quadratic equation will not be the same as in a linear equation.

Let us extend this concept to two regressors. A linear regression with two regressors will graphically give a plane (Figure C.36a). When quadratic terms are introduced, the plane bends as in Figure C.36b. Because of the complexity, this kind of regression is rarely used in health and medicine.

Exponential and logarithmic regressions also come under the ambit of curvilinear regression. For their shape, see **exponential curve**. This kind of relationship is frequently seen for bacterial growth over time (exponential growth) and for drug concentration in the body (exponential decay). Graham [3] has explored exponential regression of incidence of complete moles per 1000 viable conceptions on follicle stimulating hormone and luteinizing hormone in women of England and Wales. Kim et al. [4] used exponential regression for estimating the mean rate of annual endothelial cell loss for patients with no ocular surgery, those with pharmacoemulsification only, and those undergoing keratoplasty with cataract surgery.

## cusum chart

A cusum chart is a tool of quality control similar to a **control chart**, but it depicts the cumulative sum of the differences from the standard. For quality control in a medical laboratory, a control specimen with a known standard value is analyzed each day, and the difference from this known standard is plotted. A control chart is for detecting the outliers, which are considered beyond tolerance, and cusum chart is for plotting trend. Sometimes this plot reveals an increasing or decreasing trend, indicating a need to revisit the functioning of the laboratory. Some subtleties of the daily change in the values are revealed much better by a cusum (cumulative sum) chart as in Figure C.37 for the data in Table C.46. This table gives differences of the values in the control specimen from the known standard each day and the cumulative differences.

Even though no trend is discernible in this plot and no value is possibly outside control limits, all values are on the positive side of zero. This shows that there is some tendency to overestimate the value. Thus, it is worthwhile to examine the laboratory procedures and functioning for possibility of a positive bias. This drift is more easily detected by a cusum chart than by the conventional control chart.

Wolfe et al. [1] used a cusum chart to monitor the rate of reexploration for excessive bleeding after cardiac surgery in adults. They observed that the cusum chart has become an important part of the quality feedback of clinical care outcomes. Sibanda and Sibanda [2] have illustrated its use in clinical monitoring of clinical outcomes using routinely collected data. Thus, cusum chart has applications outside laboratory also.

## cyclic model/trend

Cyclic trend is periodic high and low values of a variable at regular intervals. Basically this represents repetition. A model that represents a cyclic trend is called a cyclic model. Sometimes this is called an *oscillating model*.

Intraday circadian rhythm is well known for sleep, blood pressure, and body temperature. They follow a 24-h cycle. Menstrual bleeding and everything associated with it follow a 4-week cycle in most women. Incidence of seasonal diseases such as dengue, viral fever, and heat stroke follows a 1-year cycle. Asthma and inflammatory polyarthritis are cyclic as they have natural remission periods, although the period may differ from person to person. The highest point attained during each cycle is called *peak* and the lowest is called *trough*. The gap between one peak to the other peak is the periodicity of the cycle. This may remain constant or may increase or decrease with time. The distance of peak (or trough) from the middle is called the amplitude provided that the trend is symmetrically up and down (it goes up as much as it comes down). Cyclic trend may also be accompanied by increasing or decreasing or any other **secular trend**. In Figure C.38a, the secular trend is increasing but also leveling off with time. Many experts distinguish between seasonal and cyclic trends—a peak within each year is seasonal, and a peak every few years is cyclic. For example, a country may have a 6-year cycle for influenza.

Although regular cycle is typical of a cyclic trend, this may not be so in some cases. Figure C.38b shows body temperatures recorded in a person who was diagnosed with a case of nodular sclerosing Hodgkin's lymphoma similar to the one reported by Good and DiNubile [1]. Note the peaks and troughs.

For fitting a cyclic model to any data, first attempts are made by using the sine function, which is known to oscillate. In its simplest form, this takes the equation

$$y = a^*\sin(bx - c) + d,$$

where $y$ is the variable under study, $x$ is the time, constant $a$ defines amplitude, $b$ depends on periodicity, $c$ depends on the horizontal shift, and $d$ depends on the vertical shift. In a more complex situation, all these may depend on the value of $x$, i.e., they vary with time. For details, see Hyndman and Athanasopoulos [2]. The other method is **autoregressive moving average (ARMA)** model used in **time series**. Elementary information on this method is available in this volume under these terms.

## DALYs, *see* disability-adjusted life years (DALYs)

## data analytics, *see also* data mining

Data analytics is developing actionable insights by analyzing a set of data for preconceived notions using appropriate statistical methods, and its communication to the target audience. Thus, data analysis is just one component of data analytics. More important is developing insights—this could mean looking at the analysis critically and locating the right signals that could help in making decisions. Communication is mostly in terms of data visualization and tabulation that summarizes the data in a meaningful manner.

In other words, data analytics is the investigation of meaningful patterns in the data about which you have suspicion, mostly using tabulation and graphics, and communicating them. Data analytics merely tries to find the suspected statistical pattern in the data, for which statistical methods such as regressions can be used to discover the patterns. Data analytics would confirm or deny a suspected relationship, or would place a quantitative value on the extent to which this relationship exists and in what types of cases. This is more about associations and correlations than causation. Thus, the results of such analysis may not be supported by well-designed clinical trials. A natural prerequisite for data analytics is that the data are recorded in a structured format that can be systematically analyzed. Analytics relies on optimal combination of computer programming and data analysis methods that can quantify the anticipated outcome. After some trials of this nature, it is possible to develop computer programs that would drive fully automated decisions on specific aspects of a data set.

An associated term is **predictive analytics**, which is concerned about future projections, resembling statistical **regressions**. For example, when sufficient past data are available in records, a profile of cases with successful stent implants can be predicted with considerable precision. This can rule out certain types of cases, which can lead to savings in cost and inconvenience. The success of this exercise depends on correct records and their systematic organization. These aspects should be considered at the time of developing the database structure as much as possible, and corrective steps taken when something is found amiss while undertaking the analytics. In case a method such as regression is used, all the requirements for its application must be validated. All predictions assume that the past trends will continue at least for some time in the future, if no suitable adjustments are made for the anticipated changes in the future.

Statistical methods referred to in the context of data analytics are not probability-based inferential methods from a sample to the target population but just analysis without recourse to **estimation** or **testing of hypotheses**. Confidence intervals for the predicted values and ***P*-values** relating to a **null hypothesis** are excluded unless some random sampling is done. Analytics would be mostly tabulation and graphics, but statistical methods such as regression are not excluded. Realize that the inference methods from sample to population are the core of statistical science that are not used in data analytics. Although data analytics, in its pure form, is intensive data analysis that does not lead to any probabilistic conclusions, many would like to consider the data on hand as some kind of sample and include statistical methods too within the fold of data analytics. That could make the two subjects indistinguishable.

There is a thin line between data analytics and **data mining**. Analytics requires that you have some preconceived ideas, howsoever vague, about the kinds of relationships that can possibly arise, and the analysis is geared to investigate those relationships. Data mining, on the other hand, is like groping in the dark in the hope of laying a hand on gold at a place that you suspect will have treasure. It is trying to discover the patterns about which possibly nothing is known beforehand. Data mining allows you to search through enormous quantities of data without having any idea what you are specifically looking for. When a huge data set is available, a relationship may be accidentally found through data mining between the variables $x_j$ and $x_k$ in a specific type of cases that was not visualized earlier. It discovers relationships simply by performing extensive analysis in a networked manner.

Data analytics is a newly emerging science in medicine but has a lot of promise. For example, according to a study in 2013, only a small number of oncology providers in the United States (7%) possess the analytic tools and capabilities, although there is an expectation that a majority of oncology providers (60%) will have developed such capabilities within the next 2 years [1]. Google surprised the world in 2009 when they were able to track the spread of influenza in the United States faster than the Centers for Disease Control (CDC) just by finding a correlation between online searches and whether they had flu symptoms [2]. Watch out for more such surprises as data analytics gets more respectability and is used more often. Online data are piling up at an exponential speed and waiting to be exploited.

## database systems

It is necessary first to describe what is meant by a database. A database is an organized collection of data, structured in such a manner that it may be accessed easily by a wide variety of application programs. Medical care facilities are increasingly creating large clinical databases on the patients they serve. For example, the Centers for Medicare and Medicaid Services [1] collect information on all Medicare patients' hospitalizations, surgical procedures, and office visits. These databases are primarily created to facilitate health care delivery but can be used for research through **data mining** and structured investigations. The Genome Database is another popular example of a medical database. Smaller databases are regularly generated by empirical studies that are currently the core of medical research publications.

The general format of a medical database is all the information for any one subject arranged in different mutually exclusive columns (called fields) in one row (called record), and one dedicated row for each subject. If your sample has 220 subjects, the database will have 220 rows. All the information in each column will be in a predefined format. For example, if you have a column for sex, the entries could

**TABLE D.1**
**Example of a Brief Database of Breast Cancer Patients**

| Sl. No: | ID | Present Age (Years) | Age at Detection (Years) | Nipple Discharge | Extent of Ulceration | Months of Itching | Family History |
|---|---|---|---|---|---|---|---|
| 1 | | 43 | 42 | 1 | 0 | 0 | 1 |
| 2 | | 51 | 46 | 0 | 2 | 40 | 0 |
| 3 | | 39 | 39 | 0 | 1 | 1 | 2 |
| Notes | | Age at last birthday | In completed years | 0 for no, 1 for yes | 0 for no, 1 for small, 2 for large, 3 for extensive | 0 for no itching, months if yes | 0 None<br>1 Mother<br>2 Sister<br>3 Other |

be Male or Female, or M or F, or 0 or 1, but you cannot have a mixture—M for one person and Male for another person. Table D.1 is a simple example that illustrates the essentials of a database. Note how no/yes type of information is noted in the same column.

Now for database *systems*. More fully known as database management systems, these are tools for efficiently creating and managing large databases that can persist over a long period of time [2]. These are computer-based systems, organized for systematic management of large structured collections of information that can be used for storage, modification, and retrieval of data. Querying is a special feature that lends respectability to a database. Thus, systems include some elements of **data analytics** that databases by themselves do not. Access to a database is usually restricted so that only authorized people can enter, delete, or modify the data, and query the data. However, when a database is complete, as for tobacco surveys in different countries, data can be placed for public access [3]. Anybody can download the data and use them the way they want, but the database at the access site remains undisturbed.

Database systems let you organize any type of information, including patients, prescriptions, laboratories, images, and outcomes. Sometimes, a separate database is prepared for special cases, such as for deaths, and a unique code is provided to link this to the master database. The information stored in a database can be in the form of numerical data, text, photos, PDF files, sound files, illustrations—pretty much any information can be stored on a computer. However, in this book on biostatistics, we have restricted ourselves to numerical and textual data. Textual data will be for qualitative variables. There must be linkage between different records belonging to the same subject, concerned hospital, etc., so that they can be analyzed with the proper perspective.

There are a large number of examples of useful research from hospital databases. A recent example is identifying cases of physeal fractures of the distal radius that could not be classified according to the Salter–Harris system but were fully classified by a modified nomenclature [4]. But hospital databases generally do not represent the general population, and one has to be careful in extrapolating the results.

## data collection, *see also* data quality

Data collection is the process of gathering and measuring information on variables of interest in an established systematic fashion that enables one to answer stated research questions, test hypotheses, and evaluate outcomes [1]. Data collection can also be done for administrative purposes, but our concern is with research endeavors, particularly in health and medicine.

Systematic data collection requires methods that could achieve the objective and tools that are adequate for the purpose. These are described here.

### *Method of Data Collection*

Medical data are mostly obtained by observation, by interview, by examination, or by investigations. Data on some behavioral variables are obtained by observation only. This may be important in the case of psychosomatic disorders. The primary methods in a clinic are interview and examination, but realize that an interview may or may not reveal the full truth, and the data obtained by examination are most reliable in the sense that they can be largely believed to be correct. This is even truer for laboratory and imaging investigations, which form the core of diagnostic tools these days. Some of these methods are very expensive to adopt or just not available in a particular setup, and the clinician may have to resort to interview and physical examination, or to a test of lower quality. This can compromise the credibility of data.

For example, a patient with liver disease can be identified either by asking the individual whether the disease has already been diagnosed, or by looking at health records, or clinical examination, or carrying out some biochemical tests. Visual acuity in a subject can be assessed just by noting the power of the spectacles worn, if any, or by a proper visual examination by an optometrist. Each method of eliciting information has merits and demerits in terms of **validity** and **reliability** on one hand, and cost and time on the other. These factors have to be assessed in the context of the problem at hand and the resources available. Factual data, based on examination, are often given more weight than data obtained by the other methods. Note, however, that knowledge, opinion, and complaints as revealed by interview and observation, particularly for symptoms, have an important place in the practice of medicine.

Comprehensive documentation of the collection process before, during, and after medical maneuvers is essential to preserve data integrity. In a research setup, the documentation needs are identified at the time of writing the protocol and adhered to during the conduct of the research.

### *Tools of Data Collection*

The tools of data collection include various instruments used to collect data. These can be **questionnaires, schedules, and proformas**, besides existing **medical records**. All these can be newly developed or can be modifications of existing ones. Each has its own merits and demerits, as discussed under these respective topics in this volume. We are not discussing them all over again here, but we leave a note that perhaps more important than the structure and content of these tools are the instructions to complete the forms and faithfully following these instructions.

## data dredging, *see also* data snooping

The term *data dredging* is used for two unethical practices. First is playing with the values you have actually observed. Because of availability of software packages, it is now easy to reanalyze data after deleting some inconvenient observations. Valid reasons for deleting observations include the presence of known outliers, but this can be misused by excluding some data that do not fit the hypothesis of the investigator. It is extremely difficult to get any evidence of this happening in a finished report. The integrity of the workers is not and cannot be suspected unless evidence to the contrary is available. Thus, data dredging can go unnoticed. Also, there is hardly any penalty if the data dredging was discovered.

Second, data dredging also refers to the practice of examining comparisons within a data set not specifically planned prior to the start of the study. Also called *data fishing*, data dredging is a form of data mining practice in which large volumes of data are explored for any possible relationships between data. These relationships are not those that were planned. The traditional scientific method, in contrast, begins with a hypothesis, and the data are examined for whether they support or contradict the hypothesis. Data dredging is sometimes described as seeking more information from a data set than it actually contains. This is also called *P-hacking* since hidden significant ***P*-values** are filtered after intensive search and analysis of the data. You may be aware that at a 5% **level of significance**, 1 in 20 *P*-values is likely to be significant by chance alone.

Howsoever unethical it may sound, the second type of data dredging can sometimes lead to unexpected findings. Thus, it has rewards along with the perils. To rule out that this finding is coincidental, a full-fledged study can be planned focused on that aspect so that a more reliable conclusion based on accepted scientific principles can be reached. Or, other similar data sets can be examined if they also give you the same conclusion.

While not much can be done to avoid the first type of data dredging except to call on the integrity of researchers, the second type can be avoided by investing more time and intellect at the time of planning the study. However, this kind of data dredging, when properly acknowledged, may be acceptable to generate a hypothesis for further investigations.

## data entry

This is the process of typing data values recorded in a questionnaire or schedule onto a **database**. A database will generally have a standard format—thus, data entries are made in a uniform format and in a structure that is amenable to computer analysis. This looks like a simple process but can jeopardize the analysis and findings if not done with sufficient care. The difficulty arises on two counts: first, many data forms, when filled manually, may have errors or illegible writing, and second, the data entry operator may be careless and not enter correct data as recorded in the form.

Numeric entries, dates, and text entries should be properly identified, and there must be uniformity across entries. This would require, for example, that "Male" should not be entered as "male" or "M" in other places. Also, as much as possible, there should not be any blanks. They should be clearly demarcated as Nil, No, None, Not available, Not applicable, Not answered, etc. In the case of nested studies, the level of the informant needs to be properly tracked. For example, if you have collected data from patients and doctors and hospital-level information, such as availability and utilization of staff, all these cannot be entered in the same worksheet. A separate worksheet may be required for each type of respondent, but the linkage codes may have to be provided so that the correct analysis can be done.

Substantial improvement in data entry can be ensured by planning. All steps needed for correct entries should be listed, and the data entry operators should be trained. Range checks and other consistency checks are performed to enhance the quality of entries. *Range check* means that the value or the response for a question must be within a plausible range. For example, parity can almost never be 17, and if such an entry occurs due to carelessness or otherwise, it will be immediately detected when the database flags such out-of-range entries. Large-scale medical investigations generally follow a system of dual entry of data and their cross-validation. The errors are resolved by going back to the form, and in some cases, this may even require recontacting the respondent for clarification.

Gadgets are now available that will record your response electronically and at the same time will also check for consistency. This automatically transfers data to a database format. Thus, some of the problems of data entry are eliminated. But some remain. In fact, such e-forms can provide unnecessary assurance of quality, and the investigator can become complacent in the hope that inconsistent responses will always be noticed. It is rare that all kinds of inconsistencies can be anticipated, least of all those incorporated in the program. Thus, such forms have to be devised with substantially more care and after a thorough discussion on entries that can be wrongly entered, and how to correct them in what manner. This can partly address the problem of wrong reporting too by providing checks and balances, flagging the responses requiring further probing in case any inconsistency or suspicion arises.

Use of SMS, Twitter, and a web page for surveys is becoming increasingly common. Even if their selective use and the resulting bias are ignored, such browsing has its own set of problems. Internet or mobile phone connections may terminate midsession, causing disruptions. Thus, there must be provisions for saving the information as entered. Then there are data security issues that can threaten data integrity and force you to devise steps to ensure that the responses are not used without authorization.

## data management

Data management can be considered as the mother of all data-related activities. In its broad sense, it includes planning for the collection of data; preparation of tools for data collection; and the actual process of collection of data, data collation and cleaning, and data analysis. This also includes the development and execution of policies and procedures around the data. The ultimate purpose is to have a system that can meet the information needs of an organization or of a project. In the context of a research endeavor, **data management** is the process of controlling the information generated during the project. Any research will require some level of data management,

and funding agencies are increasingly requiring scholars to plan and execute good data management practices [1].

The core of data management is data collation. This primarily starts after the data become available and comprises activities such as data scrutiny for incompleteness and misreporting, data entry such that all the data are properly transferred to the worksheet, cleaning for possible errors in entry, and arranging data in a manner such that they can be easily compiled and tabulated. Thus, the structure of the **database** in which the data are entered is important. Any data transformation, such as weight and height into body mass index, should be clearly specified and should be built-in. Complete data must have a backup that can be used in case a crash occurs. All the rules must be laid out and implemented with regard to when the entered data can be changed, who can access them, and what possible analysis is targeted. Policies for data security and data sharing should also be devised and publicized among the stakeholders. A policy for the preservation of the database should also be framed.

Data management is an essential part of the empirical research process. This provides a backbone for the research so that it can stand up to any review and be able to answer any question that might come up at a later stage. This helps the investigators in becoming accountable for their research. Data management is easy for small-scale research but can be challenging for large-scale endeavors, particularly in a **multicentric study** or when several workers are involved. All may have to follow a uniform format that is designed beforehand at a central place, although extra entries can be planned to meet the special constraints or needs of different centers.

## data mining

Data mining is discovering the patterns among different variables in a huge **database** about which possibly nothing is known beforehand. This is like a treasure hunt in a suspected forest. Data mining allows you to search through enormous quantities of data without having any idea of what you are looking for specifically. This uses the statistical method of **pattern recognition** to discover any buried relationships. When a huge database is available, a relationship may be accidentally found through data mining between the variables $x_j$ and $x_k$ in specific types of cases that were not visualized earlier. A popular perception is that it discovers relationships simply through brute-force analysis and neural network learning techniques. Thus, this is also sometimes called *knowledge discovery*, a name that has given it much respectability. The term that denigrates it is *data fishing.*

Big data are both large $n$ and large number of variables in a repository. In fact, they are enormously large compared with, say, a clinical trial setup. Contrary to the common belief, such a large $n$ does not reduce the bias but instead tends to magnify it if present. That, however, does not deter conclusions for the kind of subjects we have in our database. There is no attempt to extrapolate these results to any larger population except possibly those who are likely to become part of the same database in near future.

On a practical plane, data mining is exploring a database from several different perspectives, and analyzing its different dimensions with different angles, summarizing the analysis in several different ways, and critically looking at the results to identify some useful relationships. The art is in catching patterns that are not otherwise visible, nor even suspected. Once such unanticipated patterns are identified, they are tested for validity and further collated to convert into information and, subsequently, into knowledge. Remember, though, that data mining is not searching for credible evidence for something that was suspected. The only suspicion to begin with is that some useful relationships are hiding, without knowing the nature of these relationships.

The following quote sums up the latest about data mining very well. "Data mining and knowledge discovery techniques have greatly progressed in the last decade. They are now able to handle larger and larger data sets, process heterogeneous information, integrate complex metadata, and extract and visualize new knowledge. Often these advances were driven by new challenges arising from real-world domains, with biology and biotechnology a prime source of diverse and hard (e.g., high volume, high throughput, high variety, and high noise) data analytics problems" [1].

There is a thin line between **data analytics** and data mining. Analytics requires that you have some preconceived ideas, howsoever vague, about the kinds of relationships that can possibly arise, and the analysis is geared to investigate those relationships. Since a relationship was already suspected, data analytics would confirm or deny it, or would place a quantitative value on the extent to which this relationship exists and in what types of cases. In the case of data mining, no such hint on a preconceived relationship is available. A large number of variables are investigated for a possible relationship in the hope that accidentally, some useful pattern would be discovered. Both data analytics and data mining lack a probabilistic base and do not intend to generalize to the "population" from the sample—thus, hard-core statisticians, who are trained for probabilistic conclusions, are reluctant to join the fun. Statistical methods used in data mining are mostly restricted to cross-tabulations, and graphics although methods such as regression are also used to find relationships.

The big data deluge is occurring these days due to accumulation of data with online entries. In our context, medical records in hospitals are the warehouses of such data. They are very likely to contain useful information on the patterns and relationships between at least some of the large number of variables such a database generally has. They may conceal fascinating stories that need to be extracted and told. But discovering these patterns is a difficult process. A statistical tool called *mutual information* [2] provides a way to identify patterns without much reliance on the prior assumptions. This tool quantifies the relationship between two variables of any type. Data visualization is an important part of this process.

Data mining today is being increasingly used by large hospitals with a consumer focus. They integrate clinical data and laboratory and radiological investigation data with transactional data, and try to identify groups that have a similar usage pattern. That could possibly determine which services are amenable to promotion. This could also lead to substantive medical research, such as which signs and symptoms happen together more often in cases of a specific type, or which groups of patients happen to respond to particular therapy. For example, Raschi et al. [3] mined a database of more than a million reports to assess the association of drug-induced liver injury with antimycotics in a postmarketing setup. However, doubts are raised about the conclusions reached from data mining and other studies based on the existing data. Among nearly 50 health claims arrived at by examining existing data (including the data mined) for possible associations, not a single one could stand up when a follow-up controlled experiment was done to confirm that finding [4]. This could be partly due to the absence of **random allocation**, which tends to equalize not just the known but also the unknown factors in a clinical trial setup, and due to the fact that the existing data may not be representative of the general class of subjects. Thus, uncertainty lingers with regard to the conclusions reached by data mining.

## data (nature of)

Data are the result of measurements of the object(s) of interest. Raw data are those that are yet to be processed; once analyzed, the results can become the raw data for the next step, if appropriate.

Blood glucose level and urea clearance are measured in terms of quantities; blood group is a quality recorded as O, A, B, or AB. Age can be measured in terms of years, months, days, and hours but is often categorized into years as 0–4, 5–14, 15–49, etc., particularly for reporting. Disease severity and extent of malnutrition are quantities but are generally measured as none, mild, moderate, or serious. Thus, the nature of data varies from measurement to measurement. The statistical analysis methods depend on the nature of the data you want to analyze.

A scale is a tool on which measurements are made. It can be quantitatively calibrated in the usual sense, or it can be qualitative. Not all measurements are necessarily in terms of quantities. Cancer sites are a quality but are still a measurement, statistically speaking. They are known only by their name: they are nominal in nature. They could be dichotomous with just two categories or polytomous with multiple categories. Such measurements are analyzed by using proportions instead of means. Methods such as odds ratio and chi-square test are prominent in this setup. Compare nominal characteristics with those that can be exactly measured in terms of a quantity (such as heart rate) on what is known as a metric scale. Sometimes, the metric scale is divided further into interval and ratio scales. In an interval scale, there is no absolute zero: body temperature, for example. In a ratio scale, a zero point can be meaningfully designated. For example, survival of 6 years is twice as much as survival at 3 years. In an interval scale, a statistically important quantity is the difference, whereas in a ratio scale, it is mostly the ratio. Both of these can be apportioned into intervals to give rise to **categorical data**. Another type of scale is the ordinal scale, made up of categorical variables in which the different levels of the variables are ordered. All these **scales of measurement** are discussed in detail under this topic.

The levels of measurements represent a successive increase or decrease in the characteristic conveyed by the variable. For example, severity of pain has the following levels: no pain, minimal pain, moderate pain, and severe pain. Note that the difference between any two consecutive levels does not necessarily represent increments of the same magnitude in this case. One should analyze ordinal data with special methods (e.g., **chi-squared test for trend**) and not with methods used for nominal variables.

Data on multiple or single measurements on subjects that are absolutely unrelated with one another are called **univariate** and are analyzed accordingly one at a time. Age, sex, and body mass index in adults are such measurements. If the measurements depend on one another, they are called **multivariate**. Liver functions such as bilirubin, albumin, and globulin are related and thus are multivariate. Repeated measurements of, say, creatinine levels in kidney patients over a period of time also are factually multivariate. These should be analyzed together by multivariate methods.

There are other aspects of the nature of data that are relevant to statistical methods. The data can be opinion based or factual. Clinical signs assessed by a qualified physician are factual, whereas symptoms told by the patient are opinions. The answer to "How are you feeling today?" is opinion, but measurement of blood pressure, heart rate, etc. is factual. One would naturally like to depend more on factual data than opinion-based data as opinion can quickly change and is subjective. Similarly, there are **hard data and soft data**. These also have to be handled differently, as mentioned under that topic.

## data quality

Data quality is a multifactorial entity comprising several aspects that together determine the fitness of data for the intended purpose. Most important of these is the **validity**—does it correctly reflect what it is supposed to? If the data are not valid, they cannot lead to right conclusions. Inaccurate or incomplete but valid data are considered better than accurate or complete but invalid data. It is better to have an approximate answer to the right question than to have a correct answer to a wrong question! Other aspects are completeness, **reliability**, freedom from errors, consistency, being up-to-date, and accessibility. Last is **accuracy**. We are using the term *accuracy* to mean being correctly measured to several digits and not as a replacement for validity, which many researchers seem to believe. Some may want to include adequacy of the data also in terms of sample size among data quality parameters, but let us keep that separate from this topic.

The importance of the quality of data can hardly be overemphasized. If the quality is poor, one cannot hope to come to valid decisions. This is like **garbage-in garbage-out** syndrome, where no amount of meticulous analysis helps. Some aspects of data quality such as **missing values** and **outliers** can be addressed to an extent by statistical methods before the data are analyzed, but there is no way to restore quality. Thus, it is important that steps are taken from the beginning so that high-quality data are available. This may require correct assessment of what data are to be obtained to achieve the stated objectives, proper identification of the subjects, adequate design of the form of recording so that the right information is elicited and recorded, detailed instructions and training for interview and examination of the subjects, use of standardized laboratory and radiological investigations, continuous monitoring and periodic appraisal, and a system of scrutiny. Another term for data quality is *data integrity.*

Obtaining correct data from subjects could be a challenge in some medical research situations. Sometimes, people deliberately hide information, and many times, they forget. Information on extramarital sex in the context of sexually transmitted diseases can be erroneous because of the stigma attached to such issues in some societies, and information on the source of injury can be misreported to avoid legal hassles. In the case of retrospective investigation into antecedents that occurred far away in time, it may be difficult to get the correct information because of memory lapses. Scrutiny of data also does not help much in these situations as the correct status is not

known. However, data scrutiny is an important step to detect inconsistencies, such as a person with male sex recorded as pregnant or a woman of age 65 years recorded as pregnant. These are examples of errors (as per the present knowledge) that may have occurred either at the time of recording in the case sheet or at the time of entry in the database. Scrutiny can also help in retrieving some of the missing data.

Most et al. [1] describe *quality assurance* and **quality control** as two approaches that can preserve data integrity and ensure the scientific validity of study results. Assurance includes activities we undertake before the collection of data to prevent corruption of the data, and control comprises activities we undertake during the process of collection of data and thereafter. Most of the steps we have listed in a preceding paragraph pertain to assurance. Besides identification of the appropriate variables and training, constant vigilance may be required to ensure that no violation of the protocol occurs. You may also have to identify steps to be taken in case aberrations occur. Scrutiny and double data entry are the steps for quality control. Feedback from this exercise may go to the data collection stage so that such errors do not recur.

## Data Safety and Monitoring Board

Also known as the Data Monitoring Committee, the Food and Drug Administration (FDA) of the United States defines the Data Safety and Monitoring Board (DSMB) as a group of individuals with pertinent expertise that reviews on a regular basis accumulating data from one or more ongoing clinical trials and who are interested in the trial but are strictly neutral to the results. The committee advises the sponsor regarding the continuing safety of trial subjects and those yet to be recruited to the trial, as well as the continuing validity and scientific merit of the trial [1]. The committee is supposed to be objective in its assessment, and report to the sponsors rather than the investigators.

A DSMB is primarily set up for a clinical trial because the intervention could be harmful and data quality is of prime concern, particularly for large-scale trials. All clinical trials should be designed to accommodate ethical concerns. This is true in at least two ways. Firstly, the researcher should assess the risks and benefits of treatment for the individual participants on an ongoing basis. Secondly, the researcher must make arrangements to constantly monitor the trial and determine if the evidence is strong enough to require a change in clinical practice, either with those participants already in the trial or new patients.

In many trials, such awareness regarding safety and efficacy comes about through the services provided by a DSMB. As mentioned, this committee oversees the ongoing trial with regard to treatment efficacy and safety. The board regularly meets at predetermined intervals, such as once in 6 months, and reviews the progress. They are provided unblinded data so that an **interim analysis** can be done. They can review external evidence as well if needed to support their decision. If there is strong evidence that the treatment is efficacious before the trial is due to stop, the DSMB will recommend early termination of the trial. In some cases, the trial may still be recommended to continue to monitor long-term side effects despite convincing evidence of efficacy. Interim analysis may also suggest increasing or decreasing the sample size, altering the method of allocation, changing the criteria for recruiting the subjects, or any other modification that, is in the interest of science in their opinion (see **adaptive designs for clinical trials**). Also, if serious unanticipated toxicities or side effects are discovered, the trial must be halted. Mortality and irreversible morbidity receive special consideration. The trial can also be stopped if sufficient evidence emerges that the intervention is not going to serve the intended purpose, called *futility*. There might be other logistic reasons for terminating the trial midway.

DSMB members should be completely independent of the study investigators, with no conflict of interest, either scientific or financial. Their neutrality is intended to control the adverse impact of sharing the premature information that could be sensitive to the integrity of the trial. They are typically drawn from experts in the fields of clinical, statistical, epidemiological, laboratory, data management, and ethical concerns. They will have a scientific interest in the trial, to the extent that they are looking to see a valid, well-performed trial, but will not have any interest in the success or failure of the regimen under trial. Only then can they be assumed to be neutral. However, due to a lack of subject-matter expertise of the DSMB members, they may be not as meticulous. Investigators learn quite a bit while running a trial but cannot share this practical knowledge with the DSMB. Thus, their contribution may lack scientific merit. But the advantages far outweigh these minor hiccups.

A DSMB should have standard operating procedures as decided amongst themselves before a formal meeting on substantive issues is convened. They must have the facility to record all the deliberations so that a proper review can be undertaken when needed. Conclusions of the deliberations are communicated to the sponsors in such a manner that the integrity of the trial is not compromised.

## data snooping, *see also* data dredging, data mining

Data snooping is excessive unplanned analysis of data with the objective of discovering some kind of relationship or interesting finding. Planned analysis, howsoever extensive, is not snooping. This is only unplanned analysis, which is generally carried out after seeing the data. This may look like **data dredging**, and indeed, you may find overlapping usage. Dredging has an element of dishonesty, even cheating, that snooping does not have. It also can be confused with **data mining**, but data mining applies to huge data sets and rarely has probabilistic implications. Data snooping may involve repeated statistical tests of hypotheses and many confidence intervals that involve extrapolation to a target population with probabilities attached to each of them.

When considering **multiple comparisons** in **analysis of variance (ANOVA)**, there are a variety of possible tools, but many choose the **Bonferroni procedure** or the **Tukey test**. These procedures are valid only for *preplanned* comparisons. Sometimes, the idea of testing statistical significance between two or more groups arises after seeing the observed data, and this is what we are calling data snooping. Although multiple comparisons are often described as post hoc tests because they are generally done only after the $F$-test between the groups reveals significance, the tests indicated by data are also post hoc, but they are of a different type. Tests done after looking at the data distort the chances of statistical error, particularly the Type I error. Thus, they are considered indicative and

not definitive, and help generate a hypothesis for subsequent testing by another study.

## death certification, *see also* cause of death

A death certificate is a legal document that confirms that the person named has died. His/her age and sex and place of death are also mentioned. Other personal details can also be mentioned so that the person is uniquely identified. These can be parents' names, social security number, or any such identification. The certificate is helpful in claiming inheritance, insurance, etc. However, over the years, **cause of death** has become an integral part of death certificates, and this has made them an important source of information on how people are dying, at what age-sex, and where. This has great significance for developing a strategy to control deaths by certain causes and of specified age and sex. For example, you can find how many deaths of what age and sex are occurring due to fatal accidents on the road, how many due to suicides and homicides in which areas, and how many infants are dying due to asphyxia. However, the requirement of specifying the cause varies from area to area. For example, in the United States, natural causes can be assigned, although those are not medical causes. When properly recorded, such information can trigger a series of steps for the control of the dominant preventable causes.

A death is certified by a qualified person who can (i) correctly assess that the death has indeed occurred and (ii) properly identify the cause of death. Generally, only medically qualified personnel have this capability, although many who are medically qualified also may not be fully capable of correctly identifying the cause of death. The international recommendation is to record direct cause, antecedent cause, and other significant condition contributing to the death [1]. For details, see the topic **cause of death**. Although the death and its cause are certified by a qualified professional, the certificate is issued by the local registrar who is officially assigned by the government to do this job. This is mostly issued by the municipal agencies. The certificate would ordinarily contain the details of the informant; the demographic details of the deceased; the date, time, and place of death; the cause of death; and the signature and title of the registrar.

In the United Kingdom, at present, there is no legal definition of death, although guidelines do exist for the diagnosis of death in more complex situations. There has been recent guidance on the diagnosis and confirmation of death from the Academy of Medical Royal Colleges. The guidance is mainly concerned with confirmation of death in the hospital and in circumstances where the diagnosis of death may be more difficult (patients on ventilators, for example) [2].

## death rates, *see also* mortality rates

Death rate is the number of deaths per unit of population per unit of time. The unit of time is mostly years so that most death rates are obtained per year. However, the unit of population changes depending upon the interest. Computationally, death rate is a ratio with the number of deaths in the numerator and the concerned population in the denominator. The unit of time makes it a rate that signifies the speed of occurrence. For example, the number of deaths during a year divided by the estimated size of the population midway through that year is the most common form of death rate. Frequently, this ratio is multiplied by a convenient base (such as 1000) to avoid small decimal fractions: then this becomes the annual death rate per 1000 population.

The terms *death* and *mortality* are interchangeable, but some professionals maintain a thin distinction between death rate and mortality rate. Death rate has the concerned population (exposed + unexposed) in the denominator, whereas mortality generally has only the exposed population. For example, **infant mortality rate** is the number of deaths of infants out of those born live. There are several types of death rate. More commonly used among them are as follows.

### Crude Death Rate

If the death rate is calculated for a population covering all ages and sexes, it is called a crude death rate (CDR). This is the number of deaths in an area in a year per 1000 population counted at midyear, i.e.,

$$\text{crude death rate} = \frac{\text{number of deaths in 1 year}}{\text{midyear population}} * 1000.$$

The CDR ranged from a low of 1.4 per 1000 population in Qatar to a more than 10-fold high of 16.2 in Congo in 2012 [1]. Thus, this rate varies widely from country to country.

A problem with the CDR is that it disregards the age structure of the population. For this reason, it is called *crude*. If people in an area are predominantly old, a high CDR is not as bad as in an area where the population is predominantly young. Thus, a CDR of 8 per 1000 population in Sweden should not be construed to mean that the health status is nearly the same as in India, where the CDR is nearly the same. In India, only 8% of the population are of age 60 years or more, whereas in Sweden, it is more than 20%. The death rate among old people is bound to be high, and therefore, the CDR naturally becomes high. A valid comparison is obtained when the rate is recomputed by assuming the same age structure in the two countries. This is one form of standardization. The other brings the age-wise death pattern to a common base. The details are under the topic **standardized death rates**. Both types of standardizations require age-specific death rates (ASDRs).

### Age-Specific Death Rate

When the numerator and the denominator in the equation mentioned earlier are restricted to a particular age group, we get the specific death rate for that age group. For example, the ASDR for age group 65–74 years is the deaths that occur in this age group per 1000 persons of age 65–74 years. Such a rate provides an adequate comparison of the health status in two areas or at two different times for that particular age group. In 2006, the ASDR in the age group 5–14 years was 1.0 in Peru but only 0.08 in Sweden per 1000 population of that age. The rate in Peru was more than 10 times that in Sweden in this relatively healthy age group. This legitimately highlights the qualitative difference in deaths in these two countries.

### Proportional Deaths

It is useful for health authorities to know the extent of deaths occurring because of various causes. The number one killer in the United States is vehicular accidents, whereas in Indian rural areas, it is respiratory diseases. Similar statements can also be made for the age

groups contributing to deaths. Such proportional deaths can be measured in several different ways. The most common are as follows:

$$\text{Proportional deaths due to cause A} = \frac{\text{deaths due to cause A}}{\text{total deaths}} * 100$$

$$\text{Proportional deaths in age group C} = \frac{\text{deaths in the age-group C}}{\text{total deaths}} * 100.$$

For example, proportional deaths due to cancer = 100*(total deaths due to cancer)/(total deaths by all causes). For age group 60+ years, proportional deaths = 100*(deaths in the age group 60 years and above)/(total deaths in all age groups). Multiplication by 100 puts it in terms of percentage. Both of these can be computed for any cause or any age group, and the denominator in both is total deaths. Although this is calculated for any particular time period, such as the year 2015, proportional deaths are not per year: this is not a rate. The proportional deaths for any cause are different from the cause-specific death rate.

### *Cause-Specific Death Rate*

A cause-specific death rate is the number of deaths from a specified cause for a population during a specified time period per thousand or per million population. The numerator is typically restricted to deaths of people residing in a specific geographic area to which the denominator belongs. For example, if there were 137 homicide deaths in New Mexico during the calendar year 2015 and estimated midyear population was 2,010,787 in that year, then cause-specific death rate due to homicides in New Mexico in 2015 is (137/2,010,787)*1,000,000 = 68 per million population.

$$\text{Cause-specific death rate (due to cause A)} = \frac{\text{deaths due to cause A in a year}}{\text{midyear population}} * 1{,}000{,}000.$$

This is basically the same as the CDR but is restricted to a particular cause of death. The sum of specific death rates for all causes would be the same as the CDR. Cause-specific death rates may be adjusted for the age and sex composition, or other characteristics of the population. When that is done, for instance, in the case of age adjustment, it is called an age-adjusted rate. If the rates in two areas are to be compared, then a **standardized** cause-specific death rate is computed.

## death spectrum

Death spectrum is the eyeball picture of the causes of deaths that tells what percentage of deaths is occurring due to various causes in an area.

The health care profession is making every effort to prevent mortality from any cause. Few realize that the probability of death is 1—it can only be postponed and not denied. In the end, there will be some cause of death. In fact, various causes tend to compete with one another because the total probability is 1. Depending upon the biological, environmental, and demographic factors, the causes of death only change hands. If I do not die of tuberculosis, I may die of cancer, or in an accident. If one does not die in infancy, he/she may die at the age of 100 years. Perhaps the duration of survival is more important than the cause of death.

Over quite a while, the spectrum of causes of death has undergone a dramatic transition. Because of various health-promoting steps, infant deaths have substantially decreased, and correspondingly, deaths due to chronic ailments such as cancers, diabetes, and coronary artery disease have increased. This transition is the direct result of better health and increased longevity.

Since death is a certainty, this raises the question of whether some causes of death are more desirable than others. Medical science seems to have completely ignored this issue. The thrust all around is to control all the causes. This simply is not possible. It is time to debate which causes should in fact be promoted for death in *old age* and which should be controlled. Indrayan [1] has emphasized this aspect and opined that more people prefer sudden death in old age instead of a protracted slow death, which necessarily will be painful. There is no condition yet that would bring slow death but would still not be painful. A disease such as Alzheimer disease may not cause physical pain but does cause an intense psychological trauma. In Indrayan's opinion, myocardial infarction (MI) could be the most desirable cause of death in old age since it causes sudden death in many cases. But sudden death has negative features also. The person does not get time to meet near and dear ones, to pass on messages, to settle accounts, etc. Since the concern here is with death in old age, one can counterargue that the person should do all this at the time of reaching old age, say at 80 years or earlier, and not when death becomes inevitable.

If the contention that MI is the most desirable cause of death in old age is accepted, all research around the world will have to be reoriented. The risk factors for such deaths in old age have to be identified not for controlling death but for nurturing these factors during early life so that the chances of death by this desirable cause increase and, correspondingly, for other painful causes such as cancer decrease. Perhaps a choice should be available to individuals to die suddenly or slowly. The choice will be exercised not at the time of death but during one's lifetime by controlling risk factors of one type and promoting the other types that increase the chance of death by the promoted factors.

All of this is for deaths in old age only. Deaths at a young age by any cause, including MI, have to be averted as much as possible. Thus, there is a need to differentiate between risk factors of death in old age from the preferred cause and risk factors of death in young age—the former to be nurtured and the latter to be controlled. This kind of orientation is currently missing from medical research.

## deciles, *see* quantiles

## decision analysis/tree

Decision analysis is the formal process of making decisions after critically analyzing all available evidence for and against those decisions. It may involve several stages that act as mediators to reach a decision. These stages together form what is called a decision tree. We always make decisions in life, but the decision analysis formalizes the process so that nothing important is missed and we have more confidence in the decision we make. In health and medicine, decision analysis is an important component of **evidence-based medicine**.

In many situations, the cost of a false-positive conclusion is more than that of a false-negative one, and in some situations, it is vice versa. In the case of diagnosis, misdiagnosis of severe schizophrenia, requiring admission to a psychiatric ward, can cause severe strain on the patient, his/her family, and the medical care system. A false-positive diagnosis is more costly than a false-negative diagnosis in this case. The false-negative diagnosis would be caught in subsequent examinations if the problem persists. On the other hand, a missed diagnosis of leukemia is much more expensive in terms of loss of years of life than a false-positive diagnosis, which can possibly be rectified later on. Decision analysis in this case will consider these kinds of aspects. The chance of error cannot be eliminated, altogether but efforts can be made to keep both types of errors to a minimum. This is done by using a sufficiently valid test or by a combination of tests where feasible. The fact, however, is that errors do occur. The question is what type of error is more affordable considering the monetary cost, pain, and the risks involved. An approach can be evolved for each patient separately to minimize such costs.

Two important components of decision analysis are probabilities of various outcomes as available in the literature or record, and value judgment regarding the consequences of the action to be taken at different stages. The probabilities are assessed in terms of prevalence, incidence, risk, sensitivity, specificity, predictivity, etc. They must have an effective interface with clinical acumen so that they are examined in the context of the actual condition of a patient. Judgments regarding advising a test or not, treating or not treating, treating by medication or by surgery, discharging from the hospital or not discharging, etc. are subjective assessments based on the experience and knowledge of the physician. The final outcome depends on a judicious mix of these probabilities and judgments. A decision tree helps to visualize various possibilities and to act accordingly (Figure D.1). The value of a decision tree is substantially enhanced when utility is assigned to each possible outcome. This utility can be either to the patient, such as 0 for death and 1 for full recovery, or to society. Assigning these utilities to various judgments may be challenging in some situations. Once this is done, a decision tree maps all the pertinent courses of action and their consequences. For details, see Hunink et al. [1].

Medical decision trees generally assume the following process of patient management.

Patient → test → positive and negative predictivity → diagnosis → management strategy based on risks and benefits → efficiency of the services → outcome

Out of these, strategy based on risks and benefits is the key for evidence-based decisions. Risks and expected benefits can be assessed as follows. The most favorable situation is that there is no disease and it is correctly excluded. The patient is spared the unnecessary pain of undergoing the therapy and psychologically feels relieved, and there is no further cost (of treatment). The second most satisfying situation is that the presence of disease is correctly diagnosed, it is properly treated, and recovery is full. In between, there are several possibilities. The spectrum of possibilities is given in Table D.2.

The options provided in Table D.2 assume that the decision to treat or not to treat is guided solely by the test result—start treatment if the test is positive and no treatment if the test is negative. Similarly, no treatment is done when the diagnosis is ruled out by the test. However, test predictivity is never completely assured, and the test can mislead. Diagnosis may be missed, and a misdiagnosis can occur. If a clinician can start treatment despite a negative test and not start treatment despite a positive test, the possibilities are many more. Figure D.1 shows all such possibilities. The probabilities in this figure are positive **predictivity** of 85% and negative predictivity of 90%. The prevalence of disease among those with the reported complaints is assumed to be 70%. An oval indicates

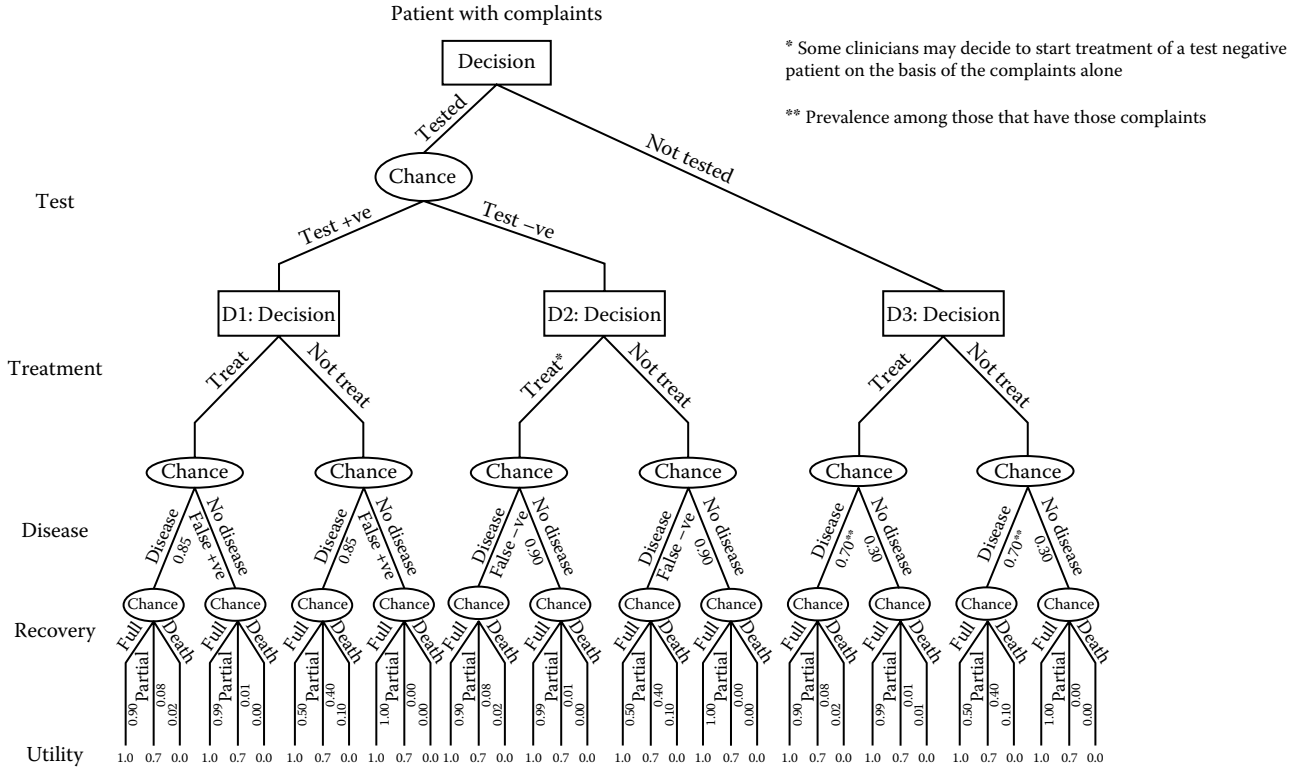

**FIGURE D.1** Example of a decision tree.

D

**TABLE D.2**
**Cost Involved in Various Situations of Disease, Diagnosis, and Treatment**

| Situation | Test | Test Outcome/ Clinical Diagnosis | Actual Status of Disease | Treatment Done | Recovery | Cost |
|---|---|---|---|---|---|---|
| 1. | Done | Test positive (Correctly diagnosed) | Present | Yes | Full | Test + treatment ① |
| | | | | | Partial | ① + disability |
| | | | | | Nil (death) | ① + loss of life |
| 2. | Done | Test positive (Misdiagnosis) | Absent | Yes | Full | Test + treatment ① |
| | | | | | Partial[a] | ① + disability |
| | | | | | Nil[a] (death) | ① + loss of life |
| 3. | Done | Test negative (Diagnosis missed) | Present | No | Full | Test ② |
| | | | | | Partial | ② + disability |
| | | | | | Nil (death) | ② + loss of life |
| 4. | Done | Test negative (Correctly excluded) | Absent | No | Full | Test ② |
| 5. | Not done | Disease diagnosed (Correctly diagnosed) | Present | Yes | Full | Treatment ③ |
| | | | | | Partial | ③ + disability |
| | | | | | Nil (death) | ③ + loss of life |
| 6. | Not done | Disease diagnosed (Misdiagnosed) | Absent | Yes | Full | Treatment ③ |
| | | | | | Partial[a] | ③ + disability |
| | | | | | Nil[a] (death) | ③ + loss of life |
| 7. | Not done | Disease ruled out (Diagnosis missed) | Present | No | Full | Nil |
| | | | | | Partial | Disability |
| | | | | | Nil (death) | Loss of life |
| 8. | Not done | Disease ruled out (Correctly excluded) | Absent | No | Full | Nil |

*Note:* Unlikely scenarios of administering the treatment when the test is negative or when the diagnosis is ruled out, or of treatment not done despite positive test or despite diagnosis of the disease, are excluded.

[a] Can occur due to side effect of treatment.

a **chance node**, where the outcome depends on probability, and a rectangle indicates a judgment node (more formally, **decision node**), where the clinician has to make a call.

A probability is assigned to each grade of recovery in different situations on the basis of the available evidence. If the evidence is not adequate, subjective probabilities based on experience are used. In Figure D.1, only three grades of recovery are shown for illustration—full, partial, and nil, where the last means death. For example, in the case of disease being present and treated, the probability of full recovery is 0.90, of partial recovery, 0.08, and of death, 0.02 in this example. When the disease is present and not treated, due to missed diagnosis or otherwise, the probability of full recovery is 0.50, of partial recovery, 0.40, and of death, 0.10.

The last row of the figure shows the utility assigned to various outcomes. This obviously is 1 for full recovery and 0 for death. For an intermediary outcome such as recovery with disability, an assessment can be made considering its lifelong implications. In this example, partial recovery is assigned a utility of 0.7. Also, 1 minus the utility can be interpreted as the cost. But a utility of 1.0 indicates that the cost of treatment is not factored in.

Depending on predictivities, the cost involved, the probabilities of various grades of recovery, and the utility assigned to various outcomes, it is possible to work out the expected benefit of different decisions. For this, the process of folding bottom-up is followed. The following is in terms of multiplication of probabilities and utilities, and their addition. Cost is not adequately factored in.

For example, the expected benefit of treatment when a test is positive is as follows.

a. When the disease is indeed present,

$$1.0 \times 0.90 + 0.7 \times 0.08 + 0.0 \times 0.02 = 0.956.$$

b. When the disease is actually not present (test is false positive),

$$1.0 \times 0.99 + 0.7 \times 0.01 + 0.0 \times 0.00 = 0.997.$$

Note how the probabilities and utilities are multiplied and added to compute the expected benefit. Since the just-calculated probabilities are $P(a) = 0.956$ and $P(b) = 0.997$, in this example, the expected benefit of treatment when the test is positive

$$= 0.956 \times 0.85 + 0.997 \times 0.15 = 0.962.$$

Similarly, the expected benefit of no treatment when the test is positive:

$$\begin{aligned} &= (1.0 \times 0.50 + 0.7 \times 0.40 + 0.0 \times 0.10) \times 0.85 \\ &\quad + (1.0 \times 1.0 + 0.7 \times 0.0 + 0.0 \times 0.00) \times 0.15 \\ &= 0.78 \times 0.85 + 1.0 \times 0.15 = 0.813. \end{aligned}$$

Clearly, in this example, when the test is positive, the expected benefit of treatment is much more than of no treatment. This takes care of decision node D1 in Figure D.1.

Now consider the expected benefit in the situation when test is negative.

c. When the disease happens to be present (the test is false negative),

$$1.0 \times 0.90 + 0.7 \times 0.08 + 0.0 \times 0.02 = 0.956.$$

d. When the disease is indeed not present,

$$1.0 \times 0.99 + 0.7 \times 0.01 + 0.0 \times 0.00 = 0.997.$$

The expected benefit of treatment when the test is negative

$$= 0.956 \times 0.10 + 0.997 \times 0.90 = 0.993.$$

Similarly, the expected benefit of no treatment when test is negative

$$\begin{aligned} &= (1.0 \times 0.50 + 0.7 \times 0.40 + 0.0 \times 0.10) \times 0.10 \\ &\quad + (1.0 \times 1.00 + 0.7 \times 0.00 + 0.0 \times 0.00) \times 0.90 \\ &= 0.78 \times 0.10 + 1.0 \times 0.90 = 0.978 \end{aligned}$$

Note that even when the test is negative, expected benefit of treatment is more than of no treatment in this example. This is based on the positive and negative predictivities, as already specified, and utilities and probabilities of various grades of recovery, as in Figure D.1. When these values change, the expected benefit also changes, and the decision to treat or not to treat would also change accordingly.

In case no test is done because of exigencies of situation or otherwise, the expected benefit of treatment

$$\begin{aligned} &= (0.0 \times 0.90 + 0.7 \times 0.08 + 0.0 \times 0.02) \times 0.70 \\ &\quad + (1.0 \times 0.79 + 0.7 \times 0.01 + 0.0 \times 0.01) \times 0.30 \\ &= 0.956 \times 0.70 + 0.997 \times 0.30 = 0.968 \end{aligned}$$

and the expected benefit of no treatment

$$\begin{aligned} &= (1.0 \times 0.50 + 0.7 \times 0.40 + 0.0 \times 0.10) \times 0.70 \\ &\quad + (1.0 \times 1.00 + 0.7 \times 0.0 \times 0.00) \times 0.30 \\ &= 0.78 \times 0.70 + 1.0 \times 0.30 = 0.846 \end{aligned}$$

Thus, when the prevalence of disease among patients with those complaints is 70% and all other values as in this example, the expected benefit from treatment is more than no treatment when the test is not done.

All these results are as you would intuitively expect. If the utility of partial recovery were only 0.2 and not 0.7, or if the prevalence of disease in this group were only 10%, the results would change. You may want to do this as an exercise.

The example illustrates the kinds of complexities involved if somebody really wants to make decisions on the basis of a decision tree such as in Figure D.1. The calculations apparently look complex but can be implemented easily with the help of a computer-based small spreadsheet. By changing values of various utilities and probabilities, the spectrum of expected benefits can be calculated, which can help decide what action to take in the best interest of the patient.

This discussion is focused on one particular application of decision trees, namely, in diagnosis and treatment. However, there are several other applications. Bayati et al. [2] developed a decision algorithm to guide decisions about postdischarge interventions in cases of heart failure and concluded that this could reduce the cost of rehospitalization by 18.2%. Su et al. [3] used this approach for an algorithm to diagnose gastric ulcer using mass spectral data. They did not consider treatment options. Lunt et al. [4] evaluated a decision tree format for classification of rheumatoid arthritis. These two approaches do not consider the utility or the cost, as illustrated in our example, and are similar to the **expert systems** described under that topic.

When resources permit, examine whether a tree diagram can help minimize the role of chance in decisions and in objective assessment of the outcome for various options that can be exercised in patient management.

## degrees of freedom (df's) (the concept of)

We explain the concept of degrees of freedom (df's) with the help of an example. In Table D.3, four categories of blood group are listed, namely O, A, B, and AB. However, the frequency in only three of them can be freely chosen; the fourth is automatically determined by the total. If the frequencies chosen for O, A, and AB are 70, 20, and 10, respectively, then the frequency in group B has to be 50 because the total is 150. If the frequencies chosen for O, A, and B are 60, 30, and 20, respectively, then the frequency in the group AB has to be 40. Thus, there is freedom to choose only three out of four cells. This is the df. For $K$ cells in a one-way **contingency table**, when the sample values have no restriction other than that the total is fixed, the df = $K - 1$. In a $2 \times 2$ contingency table, when the row and

**TABLE D.3**
**One-Way Contingency Table**

| | Blood Group | | | | |
|---|---|---|---|---|---|
| | **O** | **A** | **B** | **AB** | **Total** |
| Observed frequency | 57 | 36 | 51 | 6 | **150** |

total columns are fixed, only one of the four cells can be chosen at will—all others will be automatically fixed. In general, in an $R \times C$ contingency table ($R$ is the number of rows and $C$ is the number of columns), the df = $(R - 1)(C - 1)$. The method of **chi-square** uses such df's all the time.

The preceding explanation is for frequencies. The concept can be easily extended to values. Suppose you measure the diastolic blood pressure (BP) level of a person three times and you are told that the average is 133 mmHg. If the measurements at two of the three times are 134 and 131, the measurement the third time has to be 134 mmHg for the average to be 133. You have freedom to choose only two of these three numbers; the third is automatically fixed because of the given mean. Thus, when you have $n$ measurements and the mean is fixed, the df's are $(n - 1)$. When additionally, the value of the standard deviation is also fixed, it can be shown that the df's are $(n - 2)$. This kind of df is used by the **Student *t*-test**.

The ***F*-test**, commonly used in analysis of variance, has a pair of df's—one belonging to the numerator and the other to the denominator. The purpose, as you can see, is to find the number of independent values. The distribution of chi-square, $t$, and $F$ depends on this number, the df. This is similar to BP distribution depending on age—different age groups have different BP distributions.

## Delphi method

The Delphi method is a procedure by which experts are brought to a consensus in stages by gradually eliminating the isolated differential opinion. The consensus and the isolated differential opinion are shared among the experts without identifying the names of the experts. They are asked to revise their opinion in view of the consensus, finally reaching a conclusion, which is generally agreeable. The consensus arrived at may or may not be shared by the experts who did not participate in the exercise or whose opinion was eliminated after being found not in line with those of the majority.

For example, the Delphi technique was used by Henson [1] to explore differences in expert opinion and to provide more reliable estimates of the incidence of food-borne *Salmonella* in the United Kingdom. The first step in this Delphi study was to run a workshop in which seven experts on *Salmonella* infection examined the issues to be covered in the Delphi survey. These experts wrote the precise wording to be used in the Delphi study questions and identified 62 experts to be part of the study; 42 of them agreed to participate. Five Delphi rounds were then conducted by means of questionnaires over 7 months, with three of them exploring the experts' judgments. The first question was "What would you estimate to be the total number of persons ill due to infection with nontyphoid *Salmonella* in the United Kingdom from all sources (food and nonfood) over the course of 1 year?" Second, "What proportion of experts thought the infection was food-borne?" Third, "Could the proportion of cases be related to the type of food?" For each question, experts were asked to describe how they produced their estimates, and any difficulties they encountered in doing so. The results of the first and second rounds were fed back to the participants, inviting them to revise their estimates of incidence. Importantly, the process narrowed the range of estimates for the incidence of infection as experts reflected on the median and range of responses to the incidence questions. Henson concluded that this Delphi study "provides a good summary measure of expert opinion in an area which is characterised by great uncertainty."

Zhao et al. [2] used the Delphi method to assess the validity of a medical test on prehospital stroke symptom coping in China, and Juanola Roura et al. [3] derived recommendations for early referral of patients with spondyloarthritis in Spain using the Delphi method.

## Demographic and Health Surveys

Demography is the study of the human populations by statistical methods. The Demographic and Health Survey (DHS) program provides decision makers and program managers with the information necessary to plan, monitor, and evaluate population, health, and nutrition programs [1]. Under the DHS program, large-scale surveys are undertaken of nationally representative samples of households in several countries around the world, mostly developing countries that lack vital data, on aspects such as fertility, education, nutrition, family relations, behavior, and child mortality. A report on the findings is quickly brought out so that relevance is not lost. This program is supported by the United States Agency for International Development (USAID).

The survey process is guided through procedures and manuals developed within the DHS program. To be sure that data reflect the scenarios that they intend to describe, and that data are comparable across countries, a number of steps are undertaken, such as an almost-uniform questionnaire, common training, and the same definitions. The program also collects geographic information of the surveyed countries. Using geographic information systems, DHS data can be linked with health data, health facility locations, and local infrastructure such as roads, rivers, and environmental conditions. Regarding health issues within a country, analysis of DHS data gives a more in-depth understanding than available elsewhere for developing countries. Synthesis of information across DHS surveys can be essential to informing policy and programs.

Many countries repeat the DHS, typically every 5 years. Some countries have carried out many surveys; among them, Bangladesh did this survey in the years 1993–1994, 1996–1997, 1999–2000, 2004, 2007, 2011, and 2014. This country is practically repeating the DHS every 3 years. Since each survey is based on a nationally representative sample and since the estimates are derived using a proper weighting method for differential representation of population by age and sex, the estimates are fairly comparable across years, and a trend indeed can be obtained. Since the survey methodology is nearly the same in each country, the data are comparable across countries also.

## demographic cycle

Also known as *demographic transition*, this cycle depicts how a general population moves from an initial phase of high fertility/high mortality to a low fertility/low mortality phase over a period of, say, 100 years as development takes place. Figure D.2 shows this cycle.

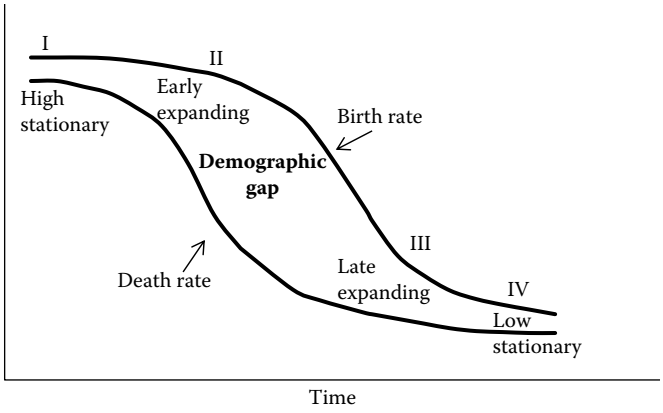

**FIGURE D.2** Demographic cycle.

The initial phase of the cycle is called high stationary as both fertility and mortality are high and the population is stable. As people become aware about health, the death rate quickly starts to come down, but the birth rate remains high. The gap increases, and the population starts expanding—this is called the early expanding phase. This is phase II of the demographic cycle. As the death rate settles down to a low level, the difference between the birth rate and the death rate—called the *demographic gap*—widens before narrowing down in phase III of the cycle. In this phase, the birth rate also relents, and the gap shrinks, although it still remains substantial. In the last phase (phase IV), called the low stationary phase, both the birth and death rates become low, and the population stabilizes.

Note a few more points about the demographic cycle. First, the death rate is easier to control than the birth rate. People easily accept advice on nutrition and treatment of diseases than on fertility control. This is paradoxical in view of the general perception that deaths are not in our hands but births are. The experience is just the reverse—we can easily control deaths but not so easily births. Second, some countries have taken 100 years in reaching from phase I to phase IV in a natural course, but countries like China have provided an unusual example of completing the cycle in just about 30 years. Some countries are still in the midst of this cycle. Third, some countries have shown a trend of reaching negative growth in phase IV, with the death rate exceeding the birth rate. This is expected in countries where fertility is low and a higher number of deaths has become inevitable due to a sizeable old-age population. According to the World Bank estimates for the years 2010–2014, Albania, Latvia, and Japan are in this club.

The demographic cycle depends much on the health of the people. Healthier people die late in life and, generally, reproduce less. Health infrastructure and health awareness play a crucial role in determining the phase of the cycle and its duration.

## demographic indicators, *see also* demographic cycle, population pyramid

Demographic indicators are those that measure the state of the population. Main among them are

- **Fertility indicators** and **mortality indicators**, including **expectation of life** and marital status
- Population growth and levels of migration
- Level of urbanization and population density
- Age-sex distribution, **dependency ratio**, and education levels
- Amenities available and their utilization (housing, water/sanitation, schools, health centers, doctors/nurses, communication, etc.)

In addition, some people include occupation, income, and expenditure pattern also under demographics. Many of these indicators are discussed as separate topics in this book.

Whereas fertility and mortality are directly related to health and medicine, other indicators also have a bearing on health. For example, age-sex distribution determines health needs—a predominantly geriatric population has different needs than a predominantly pediatric population. Urbanization affects not just the availability of amenities but also awareness and keenness to utilize those amenities. Density of population affects housing and pollution. And so on.

To get a sense of what information demographic indicators can provide, note the following from a United Nations (UN) report on ageing. "Globally, the number of older persons (aged 60 years or over) is expected to more than double, from 841 million people in 2013 to more than 2 billion in 2050. Older persons are projected to exceed the number of children for the first time in 2047. Presently, about two thirds of the world's older persons live in developing countries. Because the older population in less developed regions is growing faster than in the more developed regions, the projections show that older persons will be increasingly concentrated in the less developed regions of the world. By 2050, nearly 8 in 10 of the world's older population will live in the less developed regions" [1].

The working-age (15–64 years) population contributes most to development. Over the next few decades, infant mortality rates will be on the decline, and fertility rates will fall. Thus, with children more likely to survive into productive adulthood and fewer children being produced, the share of the working-age population will increase. The dependency ratio will decrease. This will build what is called the *demographic dividend*. When properly harnessed, this can handsomely contribute to the economic growth of nations. Those who are of working age will, on average, be more productive also. These people are more likely to save (while dependents will not), resulting in more productive investment. This has already occurred in many East Asian countries, fondly called "the East Asia miracle." The demographic dividend is also known as the *demographic bonus*.

### *Stable and Stationary Population*

A population becomes stable when its fertility and mortality rates remain unchanged for a substantial period, say, at least 5 years. This results in an unvarying age distribution: the population grows at a constant rate. The *stable population* theory provides a widely useful framework connecting a fixed set of rates to the resulting population dynamics. This allows us to trace causes and consequences of population change, to develop methods for estimating rates, and to make predictions regarding the future population. A *stationary population* is a special case of a stable population. If fertility and mortality rates remain equal over a long period of time, such a population is said to be stationary. The technical measure of a stationary population is that the **net reproduction rate** (NRR) is 1. Crudely, NRR is the number of daughters born to an average woman in her lifetime after discounting for mortality rates of the women at different ages. Under the stationary state, the population replaces itself, and there is no growth. In practice, this will happen after several years of zero population growth.

On the other end of the spectrum are populations with negative growth. In these populations, deaths exceed births, mostly because

of ageing of the population and low fertility. Albania and Latvia are current examples, and Japan has also started to show this trend [2]. Negative population growth can also occur due to large-scale deaths by widespread epidemics such as the scourge of AIDS that afflicted some sub-Saharan African countries early this century. The adult population declined, but total population did not decline in these countries due to high fertility in this region.

## demography

This is the science of population—its structure, pattern, trend, and everything else that concerns the population but not individuals. Thus, counts of people done by census or otherwise, population growth, migration, fertility and mortality, family size, age-sex structure, possibly occupation and education patterns in different segments of population, housing, etc. come under the ambit of demography. We have separately discussed these various components of demography. In particular, see **death rates**, **fertility indicators**, **demographic cycle**, **demographic indicators, mortality rates**, **population pyramid,** and education indicators.

## dendrogram, *see also* cluster analysis

A dendrogram is an agglomerative diagram representing a hierarchy of categories based on degree of similarity or number of shared features among various characteristics. In statistics, this is a graphical representation of hierarchical groups, which are usually generated through a mathematical process such as **cluster analysis**. The purpose of a dendrogram is to display the relationships among distinct units by grouping them sequentially from smaller to bigger clusters.

The method to draw a dendrogram is as follows:

- Write down all of the units and their values that you want to depict in a dendrogram.
- Choose the clustering method. An overview of these methods is under the topic **cluster analysis**, and each of the hierarchical agglomerative methods is discussed in detail under respective topics. This puts like units into small groups, similar small groups into larger groups, etc., in stages until all units are in a single cluster.
- Ask the computer package to provide you the complete dendrogram depicting the agglomerative process. This will look like Figure D.3, either in this form or in transposed form. Also see the topic **cluster analysis** for another dendrogram. Minami et al. [1] analyzed basic amino acids and their derivatives in water using a turn-on fluorescent sensor array. The dendrogram obtained is in Figure D.3. Height in this diagram measures the distance between units or groups of units. As you can see from this dendrogram, lysine and histidinol were closest to each other (look at the height of the bar and joining in the first stage) followed by histidine and lisinopril (slightly bigger height of the bar and joining in the second stage). Thus, this dendrogram represents the hierarchical clustering process of the amino acids. The authors concluded that the sensor array can discriminate amino acids from the corresponding amines that are produced by the action of amino acid decarboxylases.

## dependence and independence (statistical), *see also* dependent and independent variables (in regression)

In statistics, events are said to be independent if the occurrence of one event does not affect the probability of occurrence of the other event. On the other hand, if the occurrence of one event does affect the occurrence of another event, the events are said to be dependent.

In the toss of a coin, getting heads in one toss is independent of what you get in the other tosses. If the first toss is tails, this has absolutely no effect on the second toss; the probability of getting heads or tails remains ½ regardless of the outcome of the previous tosses. Similarly, the sex of an unborn child does not depend on the sex of the past or future children. Events that do not affect each other are said to be independent.

With independent events, you can calculate the probability of both events occurring in succession simply by multiplying the probabilities of each event. Returning to the sex of children, the probability of getting a boy (B) followed by a girl (G) is

$$P(\text{BG}) = P(\text{B})*P(\text{G}) = 0.5 \times 0.5 = 0.25,$$

where $P(\text{BG})$ is the joint probability of a boy and a girl. This is the same as that of two boys or of two girls. Statistically, this is written as $P(\text{B}\cap\text{G})$ and read as B intersection G. This intersection in effect means B and G occurring together.

Statistically independent events are sometimes confused with mutually exclusive events. The fact is that if two events are independent, then they cannot be mutually exclusive, and vice versa. That is to say that it is impossible for mutually exclusive events to occur together. A subject in a study cannot be both male and female at the same time, nor can the subject be aged 40 and 50 years at the

same time. These are mutually exclusive events and not independent events. However, one person can be male and the other female. These are independent but not mutually exclusive. On a more practical plane, hypertension and diabetes are neither independent nor mutually exclusive since the presence of one increases the chance of the other and they can occur together at the same time in one person.

The idea of independence can be readily extended to more than two events. For example, the events A, B, and C are independent if and only if $P(\text{ABC}) = P(\text{A})*P(\text{B})*P(\text{C})$. This can also be extended from events to variables. A variable $x$ is considered statistically independent of another variable $y$ when $P(xy) = P(x)*P(y)$ for *all* admissible values of $x$ and $y$. If the age distribution of males in a population is the same as that of females, age and sex would be independent variables in the sense, for example, that $P$(male of age 40–45 years) = $P$(male)*$P$(age 40–45 years). This would not be so if, for example, males are mostly young and females mostly old. Intuitively, two variables are independent of each other if any specific value of one does not alter the chance of any value of the other.

There is an interesting dependence feature of the variables jointly distributed as **multivariate Gaussian**. In this setup, each variable is dependent on the others in a linear fashion. If all their product–moment correlation coefficients are 0, the variables would be independent. However, if two variables each have univariate Gaussian distribution and their correlation is 0, they are not necessarily independent. Their relationship can be nonlinear.

The terms *independent* and *dependent variable* are also used with a different meaning in the context of regression. For this, see the topic **dependent and independent variables (in regression)**.

## dependency ratio

Dependency ratio is generally defined as

$$\text{dependency ratio} = \frac{\text{population of age} < 15 \text{ years} + \text{population of age} \geq 65 \text{ years}}{\text{population of age } 15-64 \text{ years}} * 100.$$

As per this definition, the populations of children (age < 15 years) and the elderly (age ≥ 65 years) are considered to be dependent on the working-age, generally healthy population (age 15–64 years). The dependence is not necessarily only economic but might be social and psychological. The age groups at the two ends can be chosen differently according to the local context.

To be exact, the aforementioned formula gives the *total* dependency ratio. This can be divided into child dependency and old-age dependency ratios. The total dependency ratio in 2013 was 100 in Angola and only 30 in Bahrain [1]. It is generally believed that the higher this ratio, the less is the social health. This may be economically true, but interpretation of a high ratio needs to include the wisdom of the elderly as well as the contribution of children's presence to the well-being of the family.

Use of the dependency ratio is critical in terms of obvious economic consequences. But what is not generally appreciated by the population at large (although the experts realize it) is the demographic bonus (see **demographic indicators**) brought about by the transition as a population moves from the high fertility/high child mortality stage to the low fertility/low child mortality stage. A phase comes in this transition when the percentage of the adult population swells and the dependency ratio substantially declines. When all of the adult population is put to productive work, economic progress can be fast because there are few people to support, reflecting tremendous improvement in overall health. This is what turned around some countries and is now known as the East Asia miracle.

1. The World Bank. *Age Dependency Ratio (% of Working-age Population).* http://data.worldbank.org/indicator/SP.POP.DPND?order=wbapi_data_value_2013+wbapi_data_value+wbapi_data_value-last&sort=asc

## dependent and independent variables (in regression)

The terms *dependent* and *independent variable* have tremendous significance in a regression setup. The general form of regression is given by the following equation:

$$\hat{y} = f(x_1, x_2, \ldots, x_K).$$

This tries to express a variable $y$ in terms of variables $x_1, x_2, \ldots, x_K$. The variable $y$, whose estimated value appears on the left side of this equation, is called the dependent, the **outcome**, the response, or the target variable. The variables $x_1, x_2, \ldots, x_K$, which appear on the right side, are called independent or **explanatory variables** or input variables, sometimes **covariates**. These are also sometimes called determinants or **predictors** of $y$. Depending on the context, these can be **concomitant** or **confounding variables**. In general, $x_1, x_2, \ldots, x_K$ are the **regressors**. These sometimes define the intervention or specify what can be possibly manipulated. Note that there are at least seven different names for the same set of variables.

In a survey, the independent variables are the underlying variables, and the dependent variable is the target variable that is to be ultimately studied. In a clinical setup, the dependent variables may be prognostic or outcome variables. In an experiment or a trial, the independent variables define the initial state, and the dependent variable measures the subsequent or the final state. The *independents are considered fixed and known in a regression setup*, although they may actually not be fixed. Only $y$ is considered stochastic. The regression given by the aforementioned equation is interpreted as the value of $y$ for given values of $x$'s.

Independent variables are the antecedents in terms of time, and the dependent is the outcome. There may be situations where it is difficult to distinguish between independent and dependent variables. For example, between gender and blood group, which is the dependent variable? In general, *independents are those that come first in time* and possibly can be manipulated to alter the outcome. If the postulated dependence does not appeal to your conscience, try reversing the order and see if it makes more sense.

A variable can be either qualitative or quantitative. There might be a qualitative variable that occurs in one of two possible states, often coded in statistical software as 0 or 1. This is a **binary variable**, also known as dichotomous or yes/no data. Frequently found binary variables in medical investigations are of the type dead/alive, depressed/not depressed, treated/not treated, etc. Such binary dependents often require specialized techniques such as **logistic regression** for their analysis. When dealing with two categories, definitions should clearly split the subjects into two categories. For example, there might be a third sex to male/female dichotomy, and you should be able to decide the category of such subjects if dichotomy is to be retained, or whether they are to be excluded. Sometimes, the distinction is not so clear: for example, married/single. Where to put divorced people, unless the categories are currently married or currently single?

In case the dependent variable is quantitative, ordinary quantitative **regression** is used to find the relationship between the dependent variable and the independent set of variables. If the dependent is qualitative but polytomous (many categories), there are two possibilities. One is that this is **ordinal** and the other is **nominal**. In both situations, logistic regression can be extended to cover these possibilities when they are dependent. Note that the nature of the independent variables—qualitative or quantitative, binary or polytomous, or mixed—does not affect the broad method since the independents are considered fixed in a regression setup whether it is logistic or ordinary quantitative regression or any other type, but the method is different for a qualitative dependent than for quantitative dependent. A special case of regression is **analysis of variance (ANOVA)**, where the dependent is quantitative and all the independents are qualitative. If the independents are a mixture of qualitative and quantitative variables and the dependent is quantitative, **analysis of covariance (ANCOVA)** is the first method that comes to mind. Both of these are extended to multivariate quantitative dependent by **multivariate analysis of variance (MANOVA)** and multivariate analysis of covariance (MANCOVA).

In some situations, the logarithm of expected frequencies in a **contingency table** can be expressed in terms of additive factors relating to the variables under study. The name **log-linear** is used for these models. These are useful only when no variable is considered dependent on the other or others and can be used only for contingency tables. No distinction is made between outcome and antecedent in this setup. Thus, this model is best suited for data obtained from cross-sectional studies. The dependent variable in these models is the number of subjects in a cell of the contingency table. The objective is to find whether the categories of different variables, individually or jointly, are especially contributing to determining the cell frequency.

## descriptive analysis/statistics, *see also* exploratory data analysis

This term is used for the summary of all the background or current information of the subjects of a study. These would be mostly in terms of counts and percentages; means, medians, standard deviations (SDs), and ranges; and graphs and diagrams. Even if you have a small-scale study with just 60 cases, it is not helpful to the reader to see the entire database—instead, a summary in terms of descriptive statistics is helpful.

Consider a study on 60 patients with liver cirrhosis where their age and sex, nutritional intake, enzyme levels, family history, etc. are noted. All these can be summarized in the form of tables and graphs that may contain information on age distribution (number of subjects in different age groups), nutritional intake into suitable categories, the mean and SD of enzyme levels for various age-sex groups, histograms and bar diagrams, etc. Descriptive statistics provide an overview of the kind of subjects you have studied. These statistics do not include any analysis such as correlations, regressions, confidence intervals, or tests of hypothesis. This analysis is subsequently done in light of the findings revealed by descriptive statistics.

Besides communicating the basics of the subjects, descriptive statistics are also used to explore the data. For example, descriptive statistics will tell you whether you can use the usual parametric statistical procedures, such as the Student *t*-test and ANOVA, or you need to use nonparametric methods. This would depend on the nature of the statistical **distribution** of the values you have measured. The choice of descriptive statistics also depends on the nature of the distribution. If the distribution of, say, enzyme levels is highly skewed in your subjects, median and interquartile range may be more appropriate descriptors than mean and SD.

## descriptive studies

Studies that seek to assess the current status of a condition in a population of people are called descriptive studies. These are also named **prevalence studies**. These studies are mostly cross-sectional as they do not envisage any follow-up nor go into the past. The focus is only what is currently present at the time of contact. Consider the power of the following results from a 2010 National Health Interview Survey in the United States, which was a descriptive study:

- Most (82%) US children aged 17 years and under had excellent to good health.
- Fourteen percent of children had ever been diagnosed with asthma.
- Eight percent of children aged 3–17 years had a learning disability, and 8% had attention deficit hyperactivity disorder.

The importance of descriptive studies is not fully realized, but it is through such studies that the magnitude of problems is assessed. They also help to assess what is normally seen in a population. Unfortunately, even body temperature among healthy subjects is not known with precision for many populations. Thus, there is a considerable scope for carrying out descriptive studies. Such studies can provide baseline data to launch programs, such as breast cancer control or rehabilitation of elderly people, and can measure progress made.

A descriptive study can generate hypotheses regarding the etiology of a disease when the disease is found to be more common in one group than another. In some situations, a descriptive study can be designed to test a hypothesis regarding the status of a parameter, such as whether at least 30% of patients with abdominal tuberculosis come with the complaints of abdominal pain, vomiting, and constipation of long duration, or whether the prevalence of non-insulin-dependent diabetes is 10% among married females of age 50 years or more whose husbands are diabetic.

A **case study**, which generally describes features of a new disease entity, is also descriptive. It is anecdotal in nature. A story can have a definite impact, and it is easily understood. But be wary of *anecdotal evidence*. It can be interesting and can lead to a plausible hypothesis, but anecdotes are sometimes built around an exciting event and used by the media to sensationalize reporting. You must verify anecdotes even for forwarding a hypothesis. A series of such cases form **case series**. They summarize common features of the cases or may highlight the variation. This, too, can lead to a hypothesis. Initial case series of HIV positives in the United States, almost exclusively among homosexual men, led to the suspicion that sexual behavior could be a cause of HIV.

**Surveys**, too, are descriptive studies although this term is generally used for community-based investigations. When repeatedly undertaken, they can reveal time trends. Complete enumeration, such as a population census, is also descriptive. A descriptive study generally has only one group since no comparison group is needed for this kind of study. Its design is mainly in terms of a sampling plan so that a representative sample of subjects is available. Those who are aware of statistical errors realize that no Type I or Type II error arises in descriptive studies unless we test a hypothesis, such as the presence of correlation between two characteristics.

## design effect and the rate of homogeneity

Design effect is the factor by which the **variance** (Var) of the estimate is affected due to sampling other than the **simple random sampling** (SRS) of the same size. In other words,

$$\text{design effect: deff} = \frac{\text{Var(Other sampling)}}{\text{Var(SRS)}}.$$

For clarity, note that the variance of the estimate is the square of its **standard error (SE)**. When sampling other than SRS (such as stratified, cluster, or multistage) is used, the variance of the estimate of, say, the mean or proportion generally is more than what you get from SRS. Design effect is the ratio by which this is inflated. The design effect would be mostly more than 1, although sampling designs other than SRS can be constructed to give lesser variance.

Design effect is mostly talked about in the context of **cluster random sampling** (CRS). In this method of sampling, groups of units are selected in place of individual units. This can reduce the cost of travel since in this method, you will have a cluster of units in one place. These groups almost invariably will have some trait in common. They may reside close to one another, may belong to one particular class of students, may be those patients who come to consult a particular physician in a clinic, may be admitted in specific wards in a hospital, etc. Because of this affinity, the units within a cluster are likely to be more similar than the units belonging to different clusters. It is this feature that makes CRS less efficient than SRS. If you take SRS of size 100 units and CRS also of size 100—in this case, say belonging to five clusters—the CRS would not represent the same cross-section of units that an SRS would. It may sound ironical, but the CRS sample will have a larger variance.

If the data obtained by CRS are analyzed by using the regular methods that do not recognize design effect, due to clustering of units, and treat positively correlated units as independent, you may reach wrong conclusions. Bland [1] has found this quite common in analyzing clinical trials where cluster randomization was used for selection or allocation of subjects but was ignored at the time of analysis.

Many consider a design effect of 2.0 as standard for CRS, but it actually depends on the rate of homogeneity in units within a cluster and the cluster size. The rate of homogeneity measures the extent of **affinity** among the units belonging to the same cluster. The statistical measure for this for quantitative data is the **intraclass correlation coefficient** (ICC), denoted by $\rho_I$. We are avoiding mathematics in this book, but it can be shown for CRS that

$$\text{design effect: deff} = 1 + (m - 1)\rho_I,$$

where $m$ is the cluster size. This reduces to 1 when $m = 1$ because then CRS is the same as the SRS. As the cluster size increases, the deff also increases. Deff varies from variable to variable in the same study depending upon whether that the variable has more affinity in within-cluster units or less affinity.

From this formula, you can see that clustering may have a large design effect if the ICC is large or if the cluster size is large. Any one of these conditions needs to be met for large deff. For example, if the ICC is 0.001 (a very small correlation) and the cluster size is 500, deff = $1 + (500 - 1) \times 0.001 = 1.5$. The implication is that we would need to increase the total sample size by 50% to achieve the same power as an unclustered (SRS-based) design. Generally, the cluster size chosen is 30–70 and is determined by how much a particular team can cover in a day or in any specified time of stay in that cluster. The number of clusters is determined by first deciding on the total sample size based on the design effect, and then the number of clusters is (total sample size)/(cluster size).

Where do we use deff? We can use this in at least four different ways. (i) Wherever feasible, form clusters in such a way that the ICC is small. This means that the units of the clusters should not be alike but instead should be different as much as possible. This will not be feasible in many practical situations. (ii) If we calculate the required sample size ignoring clustering, we must multiply it by the design effect to get the sample size required for the clustered sample. (iii) Deff can help us to balance the cluster size and the number of clusters. These two together determine the total sample size. If the total sample size is 200, you can have 5 clusters of 40 each, 10 clusters of 20 each, etc. In general, try to select as many clusters as possible of small size to get a good representation of the cross-section of the units. (iv) If we analyze the clustered data as if there were no clusters, the variance of the estimate must be multiplied by deff; hence, the SE must be multiplied by the square root of deff.

1. Bland JM. Cluster randomised trials in the medical literature: Two bibliometric surveys. *BMC Med Research Methodol* 2004;4:21. http://www.biomedcentral.com/content/pdf/1471-2288-4-21.pdf

## design of experiments, *see* experimental designs

## designs of medical studies (overview), *see also* experimental designs

The design of a study is the preplanned scheme under which the subjects are selected and the data are collected. Depending on the scheme, several names are given to the designs. An overview of various designs followed in medical studies is in Figure D.4. In place of designs, these can also be called types of medical studies.

Medical studies primarily have two designs: **descriptive** and **analytical**. Descriptive ones could be **sample surveys**, **case series**, or **census**. A **case study** is a particular form of case series. Surveys could be based on random sampling or nonrandom sampling. Each of these could be one of the several types as explained under the topic **sampling techniques**. Analytical studies could be observational or experimental. **Observational studies** are also sometimes called epidemiological as there is no human intervention. These could be **prospective** (also called follow up), **cross-sectional**, or **retrospective**. Prospective studies could be **longitudinal**, **cohort**, or other, whereas retrospective ones could be **case–control**, **nested**, or no-control studies. Thus, *retrospective* and *case–control* are not synonymous terms. **Experimental studies** in medicine are mostly carried out in the laboratory on animals or biological specimens. **Clinical trials** are experiments on human beings: the regimen under trial could be a therapeutic agent, diagnostic modality or tool, prophylactic regimen, or screening tool. **Field trials** done in communities can be for a prophylactic regimen or screening tool. The design of all these different types of "experiments" should specify whether there is a control group, whether the subjects would be **randomized,** and whether any **blinding** would be done. Also, note the possible layouts toward the bottom of Figure D.4, which could be **crossover**, **repeated measures**, **one way**, **two way**, **factorial**, etc. All these designs are explained in detail under the respective topic.

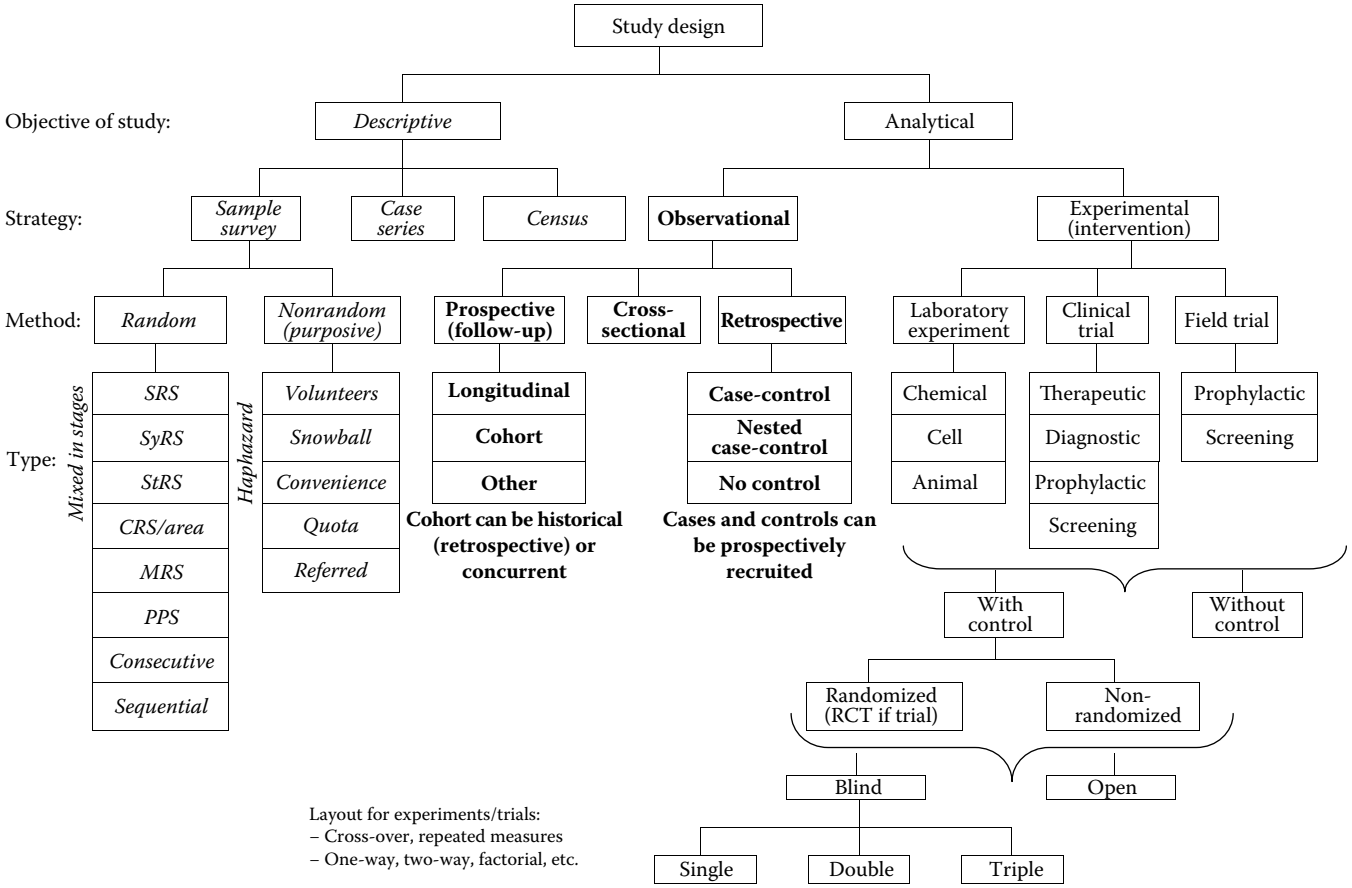

**FIGURE D.4** An overview of designs for medical studies.

## deterministic variables, *see* variables

## deviance

Deviance in statistics is the difference a variable or a set of variables makes to the log-likelihood of the sample for **qualitative** data. The **likelihood**, $L$, under a specified model is the probability of obtaining the values observed in the sample when the model is correct. A probability is necessarily a small number, i.e., less than 1, and your high school math tells you that the logarithm of a number less than 1 is negative. It is helpful to use $-2\ln L$ instead of $L$ because it is positive and the distribution of $-2\ln L$ for large $n$ has been found to follow **chi-square** under the null hypothesis $H_0$ in fairly general conditions. This can be obtained for any set of variables as in the case of **logistic regression** and again after adding or deleting one or more variables. The difference in the two values of $-2\ln L$, say between $-2\ln L_0$ and $-2\ln L_1$, is the deviance for the added variables. Since it is in logarithmic terms, the difference actually is the $-2\ln(L_0/L_1)$, where now the term in parentheses is the **likelihood ratio**. Thus, deviance is –2 times the log-likelihood ratio. This measures the contribution of the added variables to the fitness of the model—and thus can be used to assess the adequacy of the model.

In the case of logistic regression, for example, the $H_0$ is generally is that there is no relationship between the dependent and the regressor variables. With $K$ regressors, if this $H_0$ is true, all the regression coefficients $b_1, b_2, \ldots, b_K$ should be close to 0 and $\hat{\lambda} = b_0'$. Compare this with the fitted model $\hat{\lambda} = b_0 + b_1x_1 + b_2x_2 + \cdots + b_Kx_K$. Denote the likelihood for the reduced model $\hat{\lambda} = b_0'$ by $L_0$ and for the aforementioned fitted model by $L_1$. The value of $-2\ln L_0$ for the reduced model would invariably be more than $-2\ln L_1$ for the fitted model. The difference between these two, which we are calling deviance, also follows a chi-square distribution with $K$ degrees of freedom (df's). This is also called the model chi-square. Most standard statistical software packages give the value of $-2\ln L$ for the model under consideration. For example, if $-2\ln L_0 = 83.18$ for the reduced model and $-2\ln L_1 = 61.01$ for the fitted model with $K = 3$ predictors, then model chi-square = 83.18 − 61.01 = 22.17. At $K = 3$ df's, this is highly significant ($P < 0.001$). So $x_1$, $x_2$, and $x_3$ (together) in this example are useful in understanding the model.

The following comments explain some of the implications:

- If the model is a perfect fit, then the likelihood is 1 and $-2\ln L = 0$. The higher this value, the less adequate the model. Note again that being the probability, $L < 1$, and thus, $\ln L$ is always negative, and $-2\ln L$ is always positive.
- One measure of the adequacy of a full logistic model is the extent of decrease in the value of $-2\ln L$ *relative* to the value for the reduced model. This can be calculated as follows:

$$\text{contribution of the model: } C = \frac{(-2\ln L_0) - (-2\ln L_1)}{-2\ln L_0},$$

where $L_0$ corresponds to the reduced model and $L_1$ to the fitted model as before.

- The role of $-2\ln L$ for qualitative data is similar to that of $R^2$ (square of the **multiple correlation coefficient**) in the case of a quantitative dependent, but it has a negative meaning. In the case of $R^2$, a larger value is better, but in the case of $-2\ln L$, a smaller value is better. Also, $-2\ln L$ does not fall between 0 and 1 as $R^2$ does.
- All models can be improved by adding more regressors. This will invariably decrease the value of $-2\ln L$. But this deviance may or may not be statistically significant. To test this, the difference in deviance is again referred to chi-square to obtain a *P*-value. A nonsignificant decrease indicates that adding those regressors is not helpful. Similarly, one or more regressors can be dropped in search of a more parsimonious model. A nonsignificant change in deviance justifies dropping a regressor from the model because the model still works almost just as well without those regressors.
- Also, as always in a regression setup, an increase in the number of parameters decreases $-21\ln L$ and improves fit in absolute terms, but sometimes, the df's increase relatively faster, and statistical significance declines.

Although several criteria such as generalized $R^2$, likelihood ratio, and the Wald statistic are available to check the statistical adequacy of a logistic model, the log-likelihood and the deviance seem to have better appeal and wider applicability. For other criteria, see Hosmer et al. [1].

1. Hosmer DW, Lemeshow S, Sturdivant RX. *Applied Logistic Regression*, Third Edition. Wiley–Interscience, 2013.

## deviations, *see* variation (measures of)

## df, *see* degrees of freedom (df's) (the concept of)

## diagnosis errors

There are two types of diagnosis errors—first, misdiagnosis, which occurs when a person does not have a particular disease but is diagnosed to have one, and second, missed diagnosis, when a person has a disease but it is missed.

Clinicians these days examine a great deal of evidence before reaching a diagnosis. This evidence is in terms of clinical features, laboratory investigations, images, records, etc. Despite this, errors are not uncommon. In place of a differential diagnosis, let us restrict our discussion to the presence or absence of a specific disease. If the disease is actually not present but wrongly diagnosed as present, this is called misdiagnosis. Misdiagnosis can mean a great deal of inconvenience, cost, and side effects to a person who is actually unaffected and an unnecessary load on the health care system. Misdiagnosis is obviously a more serious error than missed diagnoses, which occur when the disease is present but is missed. Both are errors in most situations, but a missed diagnosis is likely to be detected in a subsequent encounter because the patient is likely to come back with complaints.

Tools such as laboratory tests are an integral part of modern medicine. Fine-needle aspiration cytology (FNAC) is done to detect breast cancer, Pap smear for cervical cancer, Western blot for human immunodeficiency virus (HIV) infection, and chest x-ray for tuberculosis. Often, the sign–symptom syndrome functions as a *test* to form the basis for establishing a diagnosis. Generalized maculopapular rashes and fever with cough are considered indicative of measles, and prolonged acute chest pain indicates myocardial infarction (MI). However, such tools used for evaluation and management of health and disease are seldom perfect. These examples might have convinced you that all tests are flawed to a degree. These produce correct results in many cases but fail, fully or partially, to perform well in some cases. Healthy individuals are occasionally classified wrongly as ill (giving rise to false alarm). Some individuals who are really ill may not be detected, increasing complacency. All such errors need to be controlled because there is a cost involved—cost of unnecessary treatment, cost of side effects, inconvenience, progression of disease, even death of some patients.

The ability of a tool or of a procedure to perform its assigned function correctly is called its **validity**. A valid diagnostic test would correctly detect the presence as well as the absence of the disease. Some tests are more valid than others, although they may be more expensive. Rectal sonography is considered more efficacious than prostate-specific antigen (PSA) values for detecting prostate cancer. Scintigraphy gives better results than an electrocardiogram (ECG) for MI. However, **gold standards** that give perfect results all the time are practically nonexistent, and most of them are expensive in terms of time and effort. No medical test is valid in an absolute sense. Errors in classification such as misdiagnosis and missed diagnosis occur no matter what test is used.

The true diagnosis is evaluated on the basis of more refined methods—the current gold standard—that may be far more difficult to adopt. Often, the real diagnosis emerges after the passage of time, for instance, on response to therapy or upon autopsy. Sometimes, a surrogate is used as a gold standard, such as histological evidence for cancer. If the gold itself is a bit shoddy, a good **sensitivity and specificity** may give a false sense of security, and diagnostic errors can go unnoticed.

## dietary indices

These indices are used to assess nutrition intake. Most dietary studies have interest in food intake also beside nutrients. Generally, three methods are used for this purpose at an individual level. First is multiple 24-hour recall, second is 1-week diet record, and third is the food-frequency questionnaire (FFQ). All three methods elicit dietary intake and then convert that to nutrition intake, such as calories, protein, and carbohydrate, on the basis of the available standards for each intake. A large number of other questionnaires, scoring systems, and recording tools are available for this purpose. If the target is a specific group, such as adolescents, you may be able to find a method specifically tailored for this segment of the population. Patients of different diseases will require a different format altogether.

D

As the name implies, the 24-hour recall method is asking people what they consumed in the past 24 hours. This can be done for a dispersed or contiguous 2 or 3 days to get a cross-section and then averaged per day. In the second method, families are asked keep a record of consumption for one full week. These are apportioned per person considering an adult male (moderate worker) as the reference. For example, a child of age 5 years may be 0.6 unit—meaning thereby that the food needs of a child of age 5 years is 60% of that of an adult male (see **consumption units**). The third method, FFQ, typically asks about diet over the past month, generally in terms of groceries purchased and consumed. When properly adjusted, this method may be epidemiologically more relevant as it provides a long-term perspective of the effect that a diet is most likely to have on health parameters. But this may not be able to provide accurate information on occasional intakes, such as in parties and restaurants. The other two methods include this consumption.

Some biomarkers, such as urinary and plasma measurements, are more sensitive to recent intake, and their correlation with diet may be exaggerated when assessed with a 1-week record. If a 1-week record is used, the biomarkers should be assessed remotely in time. Natural week-to-week variation in 1-week dietary record lowers the validity of this method. This is true for 24-hour recall also.

Even if done several times, 24-hour recall cannot provide information on dietary intake in the long term. But 24-hour recall generally provides more accurate information as the recall lapse is minimal. This method can be focused on individuals rather than the family.

You can see that one method is advantageous in one setting and another in different setting. Some associations may be better detected by one method than the other. Choose the method that meets your objective most appropriately.

In an attempt to analyze associations of dietary indices with biomarkers of dietary exposure and cardiovascular status, Truthmann et al. [1] investigated if the dietary factors in adolescence predict cardiovascular risk marker values in adulthood in Germany. The authors concluded: "Overall, the indices, even the simpler ones, seem to have a similar general capability in predicting biomarkers of dietary exposure. To predict risk of cardiovascular disease, the dietary indices may have to be more specific."

## difference-in-differences approach

This is a commonsense approach for the analysis of data arising from before–after quantitative measurements in two groups. When the same subjects are measured before the intervention and after the intervention, the quantity of interest is the change in the outcome from baseline. Values obtained before the intervention are the baseline values. This change can be measured either in absolute values or in terms of percentage over the baseline values. When this is done for two groups, such as in the control and the test group, the interest many times is to find that change in one group is different from the one seen in the other group. That is, the objective is to compare the difference (from *before* to *after* values) in group 1 with the differences observed in group 2. If the difference between these differences is nearly 0 on average, or for most subjects, the conclusion would be that the change in one group is not significantly different from the change in the other group. This naturally leads to a difference-in-differences approach.

Suppose a test group is measured before and after the treatment under test as well as a control group before and after a placebo. If the corresponding population means are $\mu_{1T}$ (before treatment), $\mu_{2T}$ (after treatment), $\mu_{1C}$ (before placebo in the control), and $\mu_{2C}$ (after placebo in the control), then the actual treatment effect is

$$\text{mean difference in differences: } (\mu_{2T} - \mu_{1T}) - (\mu_{2C} - \mu_{1C}),$$

assuming that *after* values are higher and the interest is in absolute change. If this difference in differences is found to be significant, the estimate of the treatment effect is obtained by substituting the corresponding sample means.

As for several other statistical methods, the difference-in-differences method assumes that the two groups under comparison are equivalent either by randomization or by matching. If that is not so, it would be difficult to say that the difference is the true effect.

In the usual setup, the statistical significance of this difference in differences can be checked by the **Student *t*-test** for two groups. This would utilize only the change and not the actual values. This test has the same requirement of independence of groups, Gaussian distribution, sample size, etc., as stated for a two-sample *t*-test. Otherwise, a nonparametric test can be used.

There is another useful method based on **regression**. This method uses **indicator variables** that are sometimes useful in including one or more qualitative variables in the regression. The regression approach is as follows. Consider the regression equation

$$y = b_0 + b_1x_1 + b_2x_2 + b_3x_1{}^*x_2,$$

where $x_1 = 0$ for the control group, $x_1 = 1$ for the treatment group, $x_2 = 0$ for *before* values, and $x_2 = 1$ for *after* values. These are the indicator variables. Plug in these values and obtain the following.

*Before* values: treatment group $y = b_0 + b_1$; control group $y = b_0$; difference = $b_1$
*After* values: treatment group $y = b_0 + b_1 + b_2 + b_3$; control group $y = b_0 + b_2$; difference = $b_1 + b_3$
Difference in differences = $(b_1 + b_3) - b_1 = b_3$

Thus, $b_3$ is an estimate of the actual treatment effect compared with the controls. This is the regression coefficient of the product $x_1{}^*x_2$, which is now called an **interaction**. If the interaction is significant, the treatment effect obtained by the difference-in-differences approach is significant. This significance can be tested as for any **regression coefficient**.

A word of caution is in order while working with differences. Since both *before* and *after* values are subject to sampling fluctuations and inadvertent measurement errors, the differences have higher variance. Thus, the sample size required for statistical inferences from differences is higher than the sample size required for inferences from the directly measured values.

## digit preference

It is well known that almost all of us have a special love for digits 0 and 5. This is often subconscious but quite common. Measurements are more frequently recorded ending with these digits. A person aged 69 or 71 is very likely to report one's age as 70 years. In the context of age, this is called *age heaping*. In other setups, if digit 0 is preferred, 78, 79, 80, 81, and 82 can be recorded as 80. For example, this can happen in self-reporting of weight in kilograms.

This can also happen with readings on a visual analog scale or mercury sphygmomanometer. It is quite common in recording of birth weight.

The net effect of the digit preference is that the values ending with 0 or 5 have higher frequency (spikes) than what are actually present. This can cause bias in the results. The counts at the preferred digits are composed of the actual values at these values plus the misclassified cases from the nearby values due to the preference pattern. According to Nagi et al. [1], besides 0 and 5 as the most preferred digit for reporting of age, the multiples of 2, that is, 2, 4, 6, and 8, are preferred over odd digits. The digits 1 and 9 are the least preferred. This may be due to their heaping with the nearest 0. This is depicted in Figure D.5 for reported age at death.

Another manifestation of digit preference is in forming intervals for quantitative data. Blood glucose level categories would be 70–79, 80–89, 90–99, etc., and not 64–71, 72–79, etc. Intervals 105–114, 115–124, 125–134, etc. for blood pressure (BP), for example, or 108–112, 113–117, 118–122, etc. are better to ameliorate the effect of digit preference, but the conventional intervals ending with 0 or 5 are almost invariably used. Such intervals tend to further aggravate the effect of digit preference since such categories put a value of 119 in one interval and a very close value of 120 in another interval. Actual values equal to 119 but preferred to be reported as 120 unnecessarily go in the next interval.

You can see how digit preference can distort the statistical distribution of values. If not taken into account, the results can be biased. For example, if your definition of hypertension is BP <140/90 mmHg, people with systolic BP of 138 or 139 mmHg and diastolic BP of 88 or 89 mmHg would unnecessarily go into the hypertension group in the case of digit preference. Broad et al. [2] have discussed this phenomenon of misclassification.

Nagi et al. [1] have also investigated the social and economic correlates of age heaping, and Jena et al. [3] have done this for self-reported smoking of cigarettes. In general, digit preference happens either because of approximation done by the subjects themselves at the time of inquiry, such as stating smoking 20 cigarettes a day instead of a more exact 18, or because of the observer's bias, such as in recording a systolic 130 mmHg instead of the exact 132 mmHg.

As an approximation, one can think of redistributing the excess values of the preferred digit to the neighboring values as the observed pattern of the distribution. For example, in Figure D.5, a trend can still be seen, and the frequencies on the vertical axis can be adjusted to follow the general pattern. For a more adequate solution, see Carlo et al. [4].

## direct standardization, *see* standardized death rates

## disability-adjusted life years (DALYs)

The difference between ideal health and achieved health is called the *health gap*. It defines the need and delineates the shortfalls. Among the many indices that measure the health gap, the one that looks important for a society is the **burden of disease** measured by disability-adjusted life years (DALYs) lost. Broadly speaking, this is computed as the sum of the *years of life lost* (YLL) due to premature mortality and the *equivalent* YLLs due to various disabilities in life. The disability can be due to disease, injury, or any other condition. The details are as follows.

Ideal health is that everybody lives for 100 years (even more!) without falling sick for a single day. Practically, this does not look feasible by any stretch of the imagination. Perhaps the next best hope is that the **expectation of life** becomes as much as the highest actually seen in a population, and this is attained without being sick. This is the basic premise on which the concept of DALYs lost is based. Note that life expectancy is the population average, and individual lives vary.

Japan has the highest life expectancy in the world. Life tables for males and females prepared by the World Health Organization (WHO) corresponded fairly well with the Japanese experience. Any death contributes to life years lost according to the remaining life expected as per their life table. Thus, a death even at the age of 90 years means 4 years lost because this is the expectancy at age 90 years in the Japanese model. Deaths of people at different ages add up to the YLLs, with a modification as shortly described.

The second component of DALYs comes from the disability arising from illnesses and impairments. Disease severity is assigned a **disability weight**, which in turn is converted to equivalent years in full health lost, by using a concept such as person trade-off. For details, see WHO's *National Burden of Disease Manual* [1]. This method of calculation has now been revised, but the basic concept remains the same. Essentially, this means that 1 year of paraplegia counts several times more than 1 year of suffering from hypertension. Death is given a weight of 1.0, and a state of complete restriction of movements (bedridden) but no other restrictions (as in the

case of fracture) can be given a weight of 0.6. Perfect health gets disability weight = 0. Lifetime duration of diseases together in terms of equivalent years forms what is called *years lost due to disabilities* (YLDs). That is, for a particular disease A in the year X,

YLD for disease A in the year X = (prevalence of the disease A in the year X) × (disability weight) × (average duration of disease A in the year X until remission or death).

This can be restricted to a particular age and sex, and adjusted for comorbidities.

The sum of YLLs and YLDs is called DALYs lost. This is considered a comprehensive measure of the health gap or burden of disease, and is generally calculated per 1000 population for any particular year. A big advantage of this measure is that it can be calculated separately for each disease or adverse health condition. The sum total of DALYs lost by all diseases must be the same as the total DALYs obtained from the age-specific death rates. This is an important self-check mechanism because otherwise, when disease-wise incidence, prevalence, and mortality are calculated, each disease overestimates itself probably to show that it is a more important health condition, and the sum total can far exceed the total burden of disease. Note that the total mortality is easy to work out on the basis of the age-sex-specific death rates and would be fairly valid as this information is largely available for each country. Disease-wise calculation is not so valid yet because of a lack of disease-wise information for different ages and sexes in most parts of the world. The **Global Burden of Disease (GBD)** study done by the Institute of Health Metrics and Evaluation (IHME) has computed DALYs lost for more than 200 health conditions for each of the 187 countries around the world. They have used statistical models to estimate the missing information. Some of the results of this study are available in their publications [2,3] and their website [4].

The earlier calculation of DALYs as done by WHO from 1990 to 2008 valued life around age 25 years much more than at childhood or at old age, i.e., nearly 1.4 compared with 1.0 at the age of 10 years and 55 years, and 0.4 at the age of 90 years. Future years lost were discounted for equivalence with the current year. This kind of adjustment has been dispensed with in GBD 2010 because of severe criticism of age weighting and discounting. Also, these calculations used incidence instead of prevalence in calculation of YLDs. That was termed *incidence perspective*, while the present is based on *prevalence perspective*. The latter more correctly reflects the current situation.

According to 2010 estimates, an average of 360 DALYs were lost in the world per 1000 population. This implies that more than one-third of life in full health is lost due to early mortality and various diseases during the lifetime. YLLs contributed nearly two-thirds of this loss, and YLDs, nearly one-third.

If the world average is considered, nearly 54% of DALYs lost in 2010 were because of noncommunicable diseases such as neuropsychiatric conditions, cardiovascular disease, and malignancy; nearly 35% because of communicable diseases and nutritional and perinatal conditions; and nearly 11% because of injuries. The spectrum differs widely from country to country.

The concept of DALYs is criticized because the unavailable information that has to be estimated by modeling, expert panels, and such other presumptive methods is substantial. Nevertheless, it remains the most comprehensive measure of burden of disease in a population. It should not be used as a summary measure of *comprehensive* health, because social and many aspects of mental health are not included in this measure.

## disability-free life expectancy, *see* life expectancy (types of)

## disability weight, *see also* disability-adjusted life years (DALYs)

The term *disability* can be defined as the deviation from optimal health in any domain, and disability weight is the measure of this departure. This reflects the general population's judgment about the extent of "healthlessness" rather than that of the patients. Depending on how these are calculated, the disability weights are also referred to as *quality-adjusted health weights* and *health state valuations*. These are extensively used to estimate the **burden of disease** in different segments of a population by a metric such as **disability-adjusted life years (DALYs)**.

Essentially, this means that 1 year of paraplegia counts several times more than 1 year of suffering from hypertension. Death is given a weight of 1.0, and a state of complete restriction of movements (bedridden) but no other restrictions (as in the case of fracture) can be given a weight of 0.6. Perfect health gets disability weight = 0.

Disability weights were originally worked out by a method called person-trade-off as reported by selected health professionals, but this was later judged unethical [1]. The Global Burden of Disease (GBD) study in 2010 undertook a comprehensive reestimation of disability weights, this time based on population surveys in five countries. The investigators found strong evidence of consistent results across countries with different cultural environments in this survey—providing evidence of robustness of these estimates. This study estimated disability weights for 220 health states using lay descriptions and with explicit caveats that it does not represent loss of well-being [1]. The questionnaire used in this exercise used a clear-cut choice between two states for the respondent to answer who is healthier. However, there are problems with this approach as well, particularly with long-term or permanent disabilities. For details, see Ref. [1].

## disconcordance, *see* concordance and disconcordance

## discrete variables (distribution of), *see also* continuous variables (distribution of)

It is first necessary to describe what is meant by a discrete (as opposed to **continuous**) variable. Some variables can take only a small number of values. Gender has only two possible values, and severity of disease generally has five values: none, mild, moderate, serious, and critical. Some other variables can take any of a large number of values, such as systolic blood pressure (BP) ranging from 100 to 200 mmHg. BP can be 132.7 mmHg if an instrument giving such accuracy is available. On the other hand, the parity of a woman can be 1 or 2 but never 1.6. A variable that can take only a finite, generally small, number of values in a range is called discrete. The number of deaths in a hospital in a day, blood group, and diagnosis are other examples of discrete variables.

It is common in medicine that discrete variables take only non-negative *integer* values, but the definition does not require it to be so. Shoe size can be 7, 7½, 8, 8½, etc. but is still discrete. It can take only these four values between 7 and 8½. Compare this with a variable such as age. If needed, age can be measured accurately as 7.2613 years. Although recording of age in terms of completed years is often considered adequate, particularly for adults, theoretically, age can take an infinite number of values between 7 and 8½. Thus, this is not a discrete variable.

Now for the distribution. For this purpose, discrete variables can be divided into several types, as shown in Table D.4. The last column of this table also names the corresponding discrete distribution.

All the distributions named in the last column of Table D.4 are described in detail in this volume under their respective topics. But these are not the only ones. If $r = 1$ in a negative binomial (number of "failures" before the first "success"), this leads to what is called a *geometric distribution*. You may occasionally find reference to *hypergeometric distribution* in medical literature. This is similar to a binomial distribution but arises when the probability of success changes from one occasion to another. The simplest is **uniform distribution**, when each of the possible $K$ values has the same chance of occurrence, i.e., each value has probability $1/K$.

Most discrete distributions tend to behave like a continuous distribution under limiting conditions. For example, the binomial distribution becomes nearly **Gaussian** when $n$ or $\pi$ (the probability of success in one attempt) or both are large such that $n\pi$ and $n(1 - \pi) \geq 8$. The probabilities for a discrete distribution are easily obtained by simple algebra; otherwise, statistical tables are also available. Statistical packages in any case give you the required probability for established distributions. However, **confidence intervals (CIs)** for the **parameters** of a discrete distribution are not so easy. For example, for binomial probability $\pi$, the **Clopper–Pearson interval** is used for finding the correct CI.

## discriminant analysis/functions

This section is divided into several subsections.

### *Discriminant Analysis*

The procedure to find the combinations of variables that best separate given groups is called discriminant analysis. Consider a setup where the classification structure of $n$ observations is known and this information is used to assign other observations whose classification is not known. Suppose you have information on clinical features and laboratory investigation for 120 thyroid cases. On the basis of extensive information and the response to therapy, they are divided into three groups, namely, the hyperthyroid, euthyroid, and hypothyroid patients. Assume that this division is almost infallible and there is practically no error. This is feasible in this case because the response to therapy is also known. The problem is to classify a new subject into one of these three groups on the basis of clinical features alone. This exercise would be useful when the facility for evaluation of thyroid functions is restricted. Response to therapy in any case would be available only afterward. What would be the best clinical criteria for classifying a new case with the least likelihood of error? The answer is obtained by discriminant analysis.

There are riders, though. The usual discriminant analysis is used when we have one or more continuous independent variables.

**TABLE D.4**
**Common Discrete Variables in Health and Medicine and Their Distribution**

| Features of the Characteristic | Examples | Variable | Statistical Distribution |
|---|---|---|---|
| Dichotomous (binary)—same probability of occurrence every time | Success/failure, yes/no, alive/dead, with disease/without disease, etc. | Number of "successes" in $n$ independent events | Binomial |
| Dichotomous (binary)—same probability of occurrence every time | Success/failure, yes/no, alive/dead, with disease/without disease, etc. | Number of failures one has to encounter before a prefixed number $K$ of successes are obtained | Negative binomial |
| Polytomous—mutually exclusive and exhaustive | Severity of disease (none/mild/moderate/serious/critical), blood group (O/A/B/AB), main cause of death (cardiac/cancer/kidney/etc.), parity (from 0 to a maximum, say, 7), etc. | Number of subjects in different groups | Multinomial |
| Count of cases where each occurs independently of the previous occurrence | Number of attacks of migraine in a year in one person, number of trauma deaths in a ward in 1 month, number of patients coming to an epilepsy clinic in a day, etc. There is no upper limit on this number. | Number of times an event occurs in a particular duration/place | Poisson |

The dependent, of course, is categorical and defines the groups. It is a multivariate technique that considers the latent dimensions in the independent variables for predicting group membership in the categorical dependent variable.

### Discriminant Functions

The combinations of variables that best separate the groups are called discriminant functions. They may not have any biological meaning. These functions are considered optimal when they minimize the probability of misclassification. If there are $K$ groups, the number of discriminant functions required is $(K - 1)$. The first is obtained in such a manner that the ratio of the between-groups **sum of squares** to the within-groups sum of squares is at a maximum. The second is obtained in such a manner that it is uncorrelated with the first and has the next largest ratio, and so on. If there are only two groups, only one discriminant function is needed. The nature of these functions is similar to the multiple regression equation, i.e.,

$$D_k = b_{0k} + b_{1k}x_1 + b_{2k}x_2 + \ldots + b_{Jk}x_J; k = 1, 2, \ldots, (K-1), \quad \text{(D.1)}$$

where $J$ is the number of $x$ variables on the right side. They are all considered **stochastic** in this setup, as opposed to regression, where they are considered fixed. The function in this equation is **linear**, but other forms can also be tried. The $x$ variables are **standardized** so that any particular $x$ or few $x$'s with large numerical values do not get an unfair advantage. The method used to obtain the function as represented in this equation is complex. Therefore, it is best to leave it to a software package.

If $J$ measurements $(x_1, x_2, \ldots, x_J)$ are available for each subject, it is not necessary to use all $J$ of them. Simple discriminant functions with fewer variables are preferable provided they have adequate discriminating power. This power is measured by the percentage of correct classification done by the discriminant function. Relevant variables can be selected by a stepwise procedure similar to the one explained for regression. See **stepwise methods** for details. This procedure also helps to explore which variables are more useful for discriminating among groups. Sometimes, just one variable may be enough to distinguish the groups.

### Classification Rule

When values of $x_1, x_2, \ldots, x_J$ for any particular subject are substituted in the function in equation D.1 mentioned in the preceding section, the value obtained is called the *discriminant score*. These scores for various sets of $x$'s are used in the **Bayes rule** to classify the cases. The probability required to use this rule depends on the distribution form of the variables. A **multivariate Gaussian distribution** is generally assumed. The rule also requires specification of the prior probability of a subject belonging to various groups. It is not necessarily equal. In some situations, it is known from experience that subjects come more frequently from one group than from others. This is generally estimated by the proportion of cases in different groups in the sample, provided there is no intervention that could distort sampling. If in 120 consecutive thyroid cases coming to a clinic, 30 are found to be hyperthyroid, 70 euthyroid, and 20 hypothyroid, then the estimates of prior probabilities are 30/120 = 0.25, 70/120 = 0.58, and 20/120 = 0.17, respectively. If the subjects are deliberately chosen to be in a certain proportion in your sample, such as being equal, then the prior probabilities are specified in accordance with the actual group prevalence in the target population. For example, you may wish to have 50 cases each of hyperthyroidism, euthyroidism, and hypothyroidism for your discriminant analysis, but the prior probabilities would continue to depend on their respective proportion in all the incoming cases that are slated to be the subjects for future classification. Many published reports seem to ignore this aspect and assume equal probabilities. Then the results can be fallacious. Also, do not try to temper prior probabilities to get a better classification.

In the case of two groups, the threshold for classification is

$$d = \frac{D_I + D_{II}}{2} + \frac{\ln(\text{prior probability of group II/prior probability of group I})}{D_I - D_{II}},$$

where $D_1$ is $D$ in Equation D.1 evaluated at the mean of the $x$'s in group 1 and $D_2$ is $D$ evaluated at the mean of the $x$'s in group 2. The labeling is such that $D_1 > D_2$. If $D > d$ for a particular subject, then that subject is assigned to group 1; otherwise, to group 2. This is called the classification rule. If the prior probabilities are equal, the second term on the right-hand side of this equation becomes 0.

### Classification Accuracy

The exercise of classification is first used on existing cases. For each case, a predicted class is obtained on the basis of the discriminant score for this case. Its actual class is already known. A cross-classification of cases by actual and predicted classification thus obtained is called a *classification table*. (See the example given later in this section.) This is used to find the percentage correctly classified, called the *discriminating power*. For discriminant analysis to be successful, this power should be high, say exceeding 80%. If a set of discriminant functions cannot satisfactorily classify the cases on which it is based, it certainly cannot be expected to perform well on new cases. When the percentage correctly classified is high, it is still desirable to try the discriminant functions on another set of cases for which the correct classification is known. It is only after such external validation that the hope for its satisfactory performance on new cases is high.

Introna et al. [1] studied the right patella of 40 male and 40 female Italian skeletons with respect to seven measurements: maximum height, maximum width, thickness, height and width of external facies articularis, and height and width of the internal facies articularis. Through a stepwise procedure, they found that only two measurements, maximum width and thickness, could discriminate gender correctly in 83.3% of cases. It was concluded that gender can be predicted by patellar dimensions when no other suitable remains of a human skeleton are available for gender determination. The prior probabilities in this example are 0.5 each because the two genders have the same proportions in the population. The following example gives the full details of the discriminant analysis in another context.

There is a considerable overlap between discriminant functions and logistic regression. The outcome in both is qualitative and must be mutually exclusive. Both represent the outcome as a function of the independent variables. Logistic regression can be used with a wide variety of data, but it serves best when the outcome is binary. Discriminant functions have no such restriction. But they work best when the independent variables have Gaussian distribution. Logistic regression has no such requirement.

### Example

Consider 5-year survival in cases of cervical cancer investigated as depending on age at detection (AGE) and PARITY. Suppose data are available for $n = 53$ cases, of whom 33 survived for 5 years or

more but 20 died before this. Can AGE and PARITY be effectively used to predict whether the duration of survival is going to be at least 5 years? Suppose the data summary is as given in Table D.5.

The difference between the groups in mean age at detection of cancer is not significant ($P > 0.50$), but the difference in mean parity is ($P < 0.05$). The ratio of survivors to nonsurvivors in this group is 33/20 = 0.623/0.377. Assuming that the same ratio will continue in the future, these can be used as prior probabilities for running the discriminant analysis. Then the following discriminant function is obtained:

$$D = -0.327 - 0.0251(\text{AGE}) + 0.774(\text{PARITY}).$$

For classification of subjects, we need the threshold $d$. This is obtained as follows from the equation given earlier. Substitution of group means in the discriminant function $D$ gives the following:

For nonsurvivors: $D_1 = -0.327 - 0.0251 \times 43.2 + 0.774 \times 2.6 = 0.6011$

For survivors: $D_2 = -0.327 - 0.0251 \times 42.6 + 0.774 \times 1.4 = -0.3127$

Thus,

$$d = \frac{0.6011 - 0.3127}{2} + \frac{\ln(0.623/0.377)}{0.6011 + 0.3127} = 0.1442 + \frac{0.5023}{0.9138}$$

$$= 0.69.$$

If $D > 0.69$ for a particular subject, then assign the subject to group 1 (surviving less than 5 years); if not, to group 2. The discriminant function in this case can be represented by a line, as shown in Figure D.6. This shows that the chance of survival for at least 5 years is less if age at detection and parity are high. Some points in this figure overlap.

Variations and uncertainties play their role, and many subjects are misclassified. The actual numbers are shown in Table D.6. Only 40 (75.5%) out of 53 could be correctly classified. As many as 8 (40%) out of 20 nonsurvivors are classified as survivors by this discriminant function. When the search is restricted to linear functions, no better discrimination criterion can be achieved. For better discrimination, either look for nonlinear functions or include more variables in addition to AGE and PARITY. Perhaps a more plausible conclusion is that AGE and PARITY by themselves are not sufficient to predict 5-year survival in cervical cancer cases. You can take the view that correct classification in three-fourths of the cases on the basis of such mundane variables as AGE and PARITY is good enough for practical applications. If this view is accepted, the discriminant function must be externally validated before it is used on new cases.

**TABLE D.5**
**Age and Parity in Cases of Cervical Cancer by 5-Year Survival**

| 5-Year Survival | Number of Subjects | AGE, Mean (SD) | PARITY, Mean (SD) |
|---|---|---|---|
| No | 20 | 43.2 (6.55) | 2.6 (1.43) |
| Yes | 33 | 42.6 (6.84) | 1.4 (1.27) |

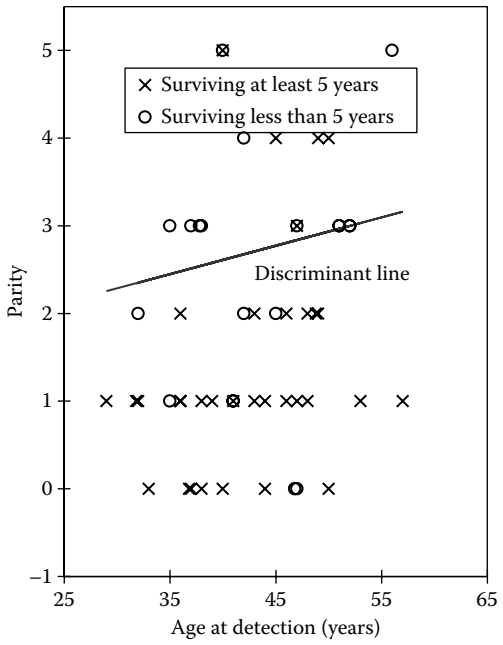

**FIGURE D.6** Scatter and discriminant line for surviving less than 5 years and at least 5 years.

**TABLE D.6**
**Classification Table Based on Discriminant Function in Our Example**

| | Predicted Group | | |
|---|---|---|---|
| **Observed Group** | **Survivors[a]** | **Nonsurvivors** | **Total** |
| Survivors[a] | 28 | 5 | **33** |
| Nonsurviors | 8 | 12 | **20** |
| **Total** | **36** | **17** | **53** |

[a] For 5 years or more.

### *Additional Points*

Note the following regarding discriminant functions:

- Discriminant functions divide the universe of subjects into sectors corresponding to different groups. Each sector defines the group to which a subject is most likely to belong.
- You might be aware that **logistic regression** is used when the target variable is binary. We have included a comment on this earlier in this section. Logistic regression for polytomous dependent variables exists, but that also generally considers two categories at a time. Discriminant analysis can be used for all categories together when the target variable is polytomous. The interpretation of a discriminant function, even when there are two groups, is not exactly the same as that of a logistic regression, but it serves the purpose of predicting the category. The associated probability can also be calculated. For the calculation of these probabilities, see Everitt and Dunn [2]. Most statistical software packages calculate these probabilities.
- Discriminant analysis is sometimes used to find whether or not a particular variable or a set of variables has sufficient

discriminating power between groups. Kilcoyne et al. [3] studied the renin–angiotensin system in 146 Black patients with essential hypertension in the United States. They divided these patients into low-, normal-, and high-renin groups. It was observed that none of the variables they studied, including incidence of cerebrovascular and cardiovascular events or age, had adequate discriminating power.

- As stated earlier, the foregoing discriminant analysis assumes that the variables are jointly multivariate Gaussian. This necessarily implies that the distribution of each variable is Gaussian. Mild deviations do not do much harm. In our example, the parity distribution is not Gaussian, yet the result may still be valid for large $n$. If many variables are binary, then the foregoing procedure is questionable. In that case, use a logistic discriminant function. This is briefly discussed by Everitt [4].
- The other important requirement for discriminant analysis is equality of the **dispersion matrices** in various groups. This is checked by the **Box *M* test**. If the dispersion matrices are really very different, the linear discriminant function is not adequate in separating the groups. A more complex, quadratic discriminant function [4] may be helpful in this case.

## disease spectrum

The term *disease spectrum* is used in at least three ways. This can be illustrated by considering pain as an example. First, one can think of characteristics of pain, such as the nature of pain (e.g., throbbing pain), regularity (e.g., intermittent or continuous), the extent of pain (e.g., local or generalized), etc. Second, one can consider the magnitude of pain as mild, moderate, severe, etc., or 7 on a 10-point scale. Prognostic severity, such as stage of cancer, also comes under this category. A third possible use of disease spectrum can be the description of the progression of infection from susceptibility to virulence. This is illustrated in Figure D.7.

This figure makes it seem as though a large percentage of exposed cases are infected and a substantial portion manifest the disease, but actually, these proportions are small in practice for most diseases.

Susceptibility is proneness to a disease. An effectively immunized person against diphtheria, pertussis, and tetanus (DPT) is not susceptible to these diseases for at least 1 year. A child is not susceptible to myocardial infarction. Susceptibility is a property of the host. Infectiousness is the property of the agent that causes infection. The measles virus is highly infectious for a susceptible person, but HIV is not. Infectivity is the actual performance in terms of the percentage infected when exposed. An infection may or may not manifest as disease. The percentage of susceptible persons who get the actual disease after the exposure can be called the pathogenicity of the disease. Out of those diseased, many will have a mild episode and recover easily. The percentage that have the severe form of disease requiring hospitalization and have a risk of death can be called the virulence of the disease. Cholera is highly pathogenic but less virulent, whereas rabies is less pathogenic but more virulent. AIDS is less infective but very pathogenic and highly virulent. At the end of this spectrum is mortality, which is the ultimate for virulence. Mortality can be measured per 1000 population or as percent affected. The latter is called the **case fatality**.

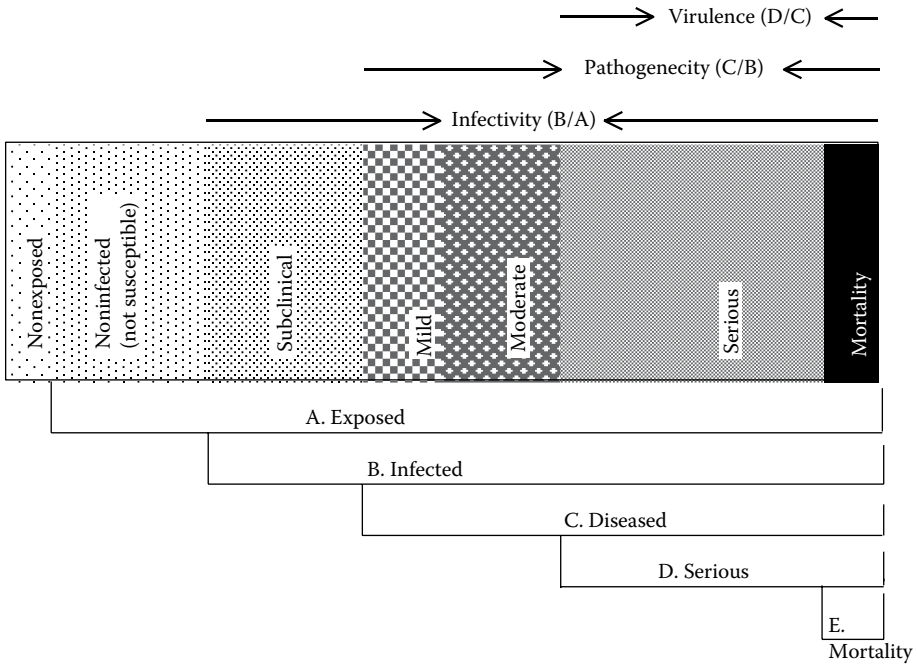

**FIGURE D.7** Disease spectrum.

The following indicators can be calculated to delineate the spectrum of a disease:

$$\text{Infectivity} = \frac{\text{number of subjects infected}}{\text{number of subjects exposed}} * 100$$

$$\text{Pathogenicity} = \frac{\text{number of subjects manifesting the disease}}{\text{number of subjects infected}} * 100$$

Virulence

$$= \frac{\text{number of subjects with serious disease (including mortality)}}{\text{number of subjects with disease}} * 100.$$

The terms *pathogenic* and *virulent* are borrowed from the field of infectious diseases but can be used for chronic diseases as well, as long as the meaning is explained. Division of cases into such a spectrum can help in choosing treatment strategies and in prognostic assessments. This also helps in their biostatistical classification.

The disease spectrum is likely to be very different during times of epidemics than in normal times. Another related concept is transmissibility. If an infected person is able to infect at least one person on average during the entire period of infectivity, then the infection will be sustained or increase. This is called the **reproductive number** of the infection. In countries where hepatitis B infection is on the rise, this rate is more than 1. If the reproductive rate is less than 1, expect that the infection will die down or stabilize at a low level.

## DisMod, *see* epidemiologically consistent estimates

## dispersion, *see* variation (measures of)

## dispersion matrix

In a multivariate setup, the variables have not just variances but also **covariances**. If these variables are ($x_1$, $x_2$, …, $x_K$), the covariance will be between $x_1$ and $x_2$, between $x_1$ and $x_3$, etc. A dispersion matrix (also called the **variance–covariance matrix** or just *covariance matrix*) is the arrangement of these variances and covariances in a square format such that the element in the $i$th row and $j$th column is the covariance between $x_i$ and $x_j$. This is denoted by $\sigma_{ij}$. Note that the "covariance" between $x_i$ and $x_i$, $\sigma_{ii}$, is the same as the variance of $x_i$. Thus, a dispersion matrix takes the following form:

$$\begin{pmatrix} \sigma_{11} & \sigma_{12} & \cdots & \sigma_{1j} & \cdots & \sigma_{1K} \\ \sigma_{21} & \sigma_{22} & \cdots & \sigma_{2j} & \cdots & \sigma_{2K} \\ \vdots & \vdots & & \vdots & & \vdots \\ \sigma_{i1} & \sigma_{i2} & \cdots & \sigma_{ij} & \cdots & \sigma_{iK} \\ \vdots & \vdots & & \vdots & & \vdots \\ \sigma_{K1} & \sigma_{K2} & \cdots & \sigma_{Kj} & \cdots & \sigma_{KK} \end{pmatrix}$$

You can see that the dispersion matrix is the multivariate analog of the variance. Elements in the matrix give an indication as to how much dispersed values of each variable are and how much these are dependent on one another. Covariance is the measure of their linear dependence. The dispersion matrix is estimated by the sample analog of the variances and the covariances. When the variables are uncorrelated, the off-diagonal elements in the dispersion matrix are 0. In samples, they may be small values. A special form of this is the correlation matrix. A Pearsonian **correlation coefficient** is obtained when these variances and the covariances are divided by the multiplication of the respective standard deviations. In that case, all the diagonal elements of this matrix are equal to 1, and the off-diagonal elements are the Pearsonian correlation coefficients. For more details, see the topic **correlation matrix**.

Dispersion matrices are required in several multivariate methods such as **multivariate regression**, **multivariate analysis of variance (MANOVA)**, and **discriminant analysis**. Specifically, equality (homogeneity) of dispersion matrices in different groups is a requirement for a valid MANOVA test. Methods such as the **Box *M* test** are used for testing their homogeneity.

## distribution-free methods, *see* nonparametric methods/tests

## distributions (statistical)

Statistical distribution of a variable describes which values are more common than others, which values are unlikely, which values do not occur, how much their variability is, whether or not they are symmetric with respect to any particular value, how much the asymmetry is, etc. For example, see the distribution of hemoglobin (Hb) values in women in Figure D.8. This shows that the most common values seen in these women are 12–13 g/dL. Values like 7–8 and 14–15 g/dL are least common; perhaps not even 1 in 50 women has such low or high values. None has a value less than 7 g/dL or more than 15 g/dL. It also shows that values below 12–13 g/dL are more common than values above, etc. Thus, the distribution is not symmetric.

The statistical distribution characterizes all the features of the data and helps us to determine what type of analysis should be done and which statistical methods should be used to derive valid inference. In short, the distribution is the backbone of the statistical methods. Mathematical formulation of these distributions helps in accurately working out the theoretical mean, variance, and such other parameters, as also the probabilities of any value bigger than or less than a specified value. Such probabilities are required primarily

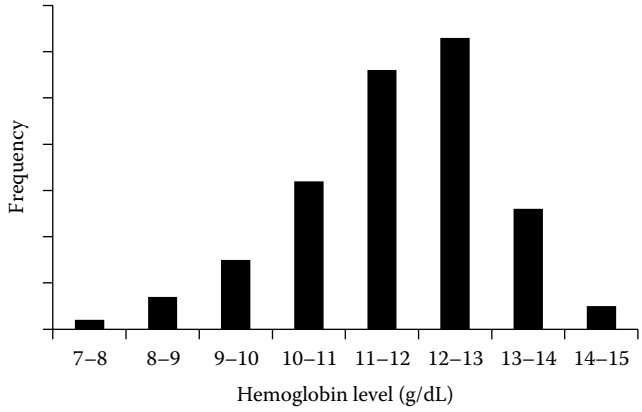

**FIGURE D.8** Illustrative distribution of Hb values in women in a developing country.

to find ***P*-values** for tests such as chi-square and Student *t*. Also, the properties of distributions of statistical summaries help in working out **confidence intervals** on the concerned parameter.

Because of the two broad natures of the variables—discrete and continuous—the distributions also have these two broad categories. Distributions of the discrete variables are called discrete distributions. These are described under the topic **discrete variables (distribution of)** in this volume. There you will find mention of hypergeometric, negative binomial, and uniform distributions. Major discrete distributions, namely, the **binomial**, **Poisson**, and **multinomial**, are presented separately under the respective topics. Similarly, major **continuous variables (distribution of)** are **Gaussian**, **chi-square**, **exponential**, **Weibull**, **Student *t***, and ***F***. All these also are discussed in detail in this volume under the respective topics.

Besides whether the distribution is discrete or continuous, other considerations while looking at any distribution for a statistical method are **skewness** and sometimes **kurtosis**. These features are measured as deviations, if any, from the **Gaussian** (normal) distribution—a central distribution for statistical theory and practices. When there are significant deviations, the distribution is generically termed non-Gaussian. When the distribution is highly skewed and sample size is not large, generally, **nonparametric methods** are preferred over Gaussian distribution–based methods. Many popular statistical methods such as Student *t* and ANOVA ***F*** are Gaussian based; so are the statistical tests and confidence intervals for many parameters. These would not be applicable if the distribution were highly skewed and the sample size were small. For conditions that allow use of a Gaussian distribution, see the topic **Gaussian conditions**.

The preceding discussion is restricted to what are called univariate distributions, since only one variable is being considered, but the distributions can be multivariate also where several variables are considered together. See the topic **multivariate distributions** for details.

## diurnal variation

These are the variations that occur at different times of the day in some medical parameters. These generally occur due to the dramatic effect of the day-and-night cycle on our physiological processes, as evidenced by the alternation of duration of activity and sleep. Theoretically, one might argue that there is a distinction between **circadian rhythm** and diurnal variation, but practically, there is no difference.

Thyroid-stimulating hormone (TSH) levels show a strong diurnal variation with low levels in the early morning and high levels in the evening. The variation could be on the order of 50%. Loss of this variation in TSH levels and other such parameters may be the expression of gradual alteration of the integrated function of the neuroimmune–endocrine system in subjects suffering from neoplastic disease [1]. The clinical onset of both myocardial infarction and stroke occurs more frequently in the early morning than at other times of day [2]. Diurnal variation in mood is a prominent symptom of depression [3].

Statistically, diurnal variations contribute to the uncertainties in interpretation of values, as illustrated by Goede et al. [4] for TSH. Indeed, many studies seem to ignore or forget about such variation, possibly leading to less valid conclusions. For measurements that show diurnal variation, the assessment in a research setup should be done at the same time of the day in all the subjects, and this time should be clearly mentioned in the article. In clinical practice, too, the assessment that a value is decreased or increased should also be done keeping diurnal variation in mind.

## donut diagram

Make a hole in a **pie diagram** and get a donut. Both have the same functionality and the same requirement. The total must be a meaningful quantity just as for a pie diagram. A donut comparison of age distribution of males and females in cases of mild hypertension is shown in Figure D.9. This shows that females are nearly one-half of males, as depicted by the size of the donuts in this figure. Note how the large percentage of those aged 35–44 years in females is shown relative to males.

The Slide Team [1] gives an excellent description of how donut diagrams can help in effective PowerPoint presentations.

## dose–response (type of) relationship

It may not be exactly true for a treatment regimen, but most toxic substances (such as insecticides) exhibit the property that higher dose results in higher response—in the case of insecticides, the response is mortality. The same property is exhibited by most anesthetic agents, where the response is the duration or effectiveness in causing sensory loss. While these may sound like extreme examples, many interventions show some pattern of change in response as the

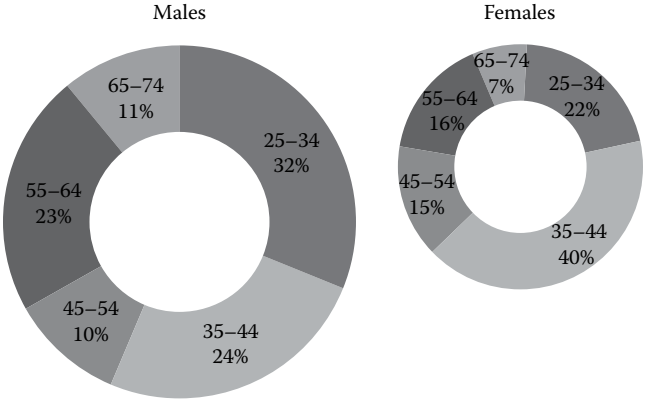

**FIGURE D.9** Donut diagrams showing age distribution of male and female cases of mild hypertension.

intensity or the amount of intervention is increased or decreased. This pattern of change is called the dose–response relationship. This could be positive (response increases with higher dose), negative (response decreases with higher dose), or none at all (response remains the same with changed dose). The relationship could be linear (each unit of additional dose brings about the same additional response) or multiplicative (each unit of additional dose has, say, twice as much effect as the previous dose), or can have any other pattern. For example, Ekwaru et al. [1] found that the dose–response relationship between vitamin D supplementation and serum 25(OH) D followed an exponential curve, and this is characterized by a multiplicative effect.

As always, for simplicity and parsimony, attempts are made to linearize the relationship between dose and response if it is not already linear, and transformations are used many times for this purpose. For example, log(dose) is used in place of dose, and square root of response is used in place of response. These transformations are called dose and response metameters, respectively. The relationship is examined by the methods used in **bioassays**, such as **parallel-line assays** and **slope-ratio assays**.

A dose–response relationship occurs in many other medical setups. This kind of relationship is known for the effect of radiation exposures and the effect of noise or air pollution. McCarthy-Jones and McCarthy-Jones [2] have observed mediation by body mass index and anxiety/depression in a dose–response manner for the majority of physical health disorders in women. Feng et al. [3] found a dose–response relationship between maternal parity and risk of congenital heart defects in offspring. A large number of such examples are available in the medical literature.

When investigating whether an association or a correlation indicates a cause-and-effect kind of relationship, there are a good number of criteria to consider, as enumerated by Indrayan [4]. One of these criteria is a dose–response kind of relationship in the sense that if the cause is present in a higher amount or at greater intensity, then the chance of an effect should also be high. The more you smoke, the higher your risk of lung cancer.

## dot plot

Generically, a dot plot is a graphical display of data using dots in place of lines, bars, or curves. In this sense, all **scatter diagrams** are dot plots. But the most common use of dot plots in health and medicine is in representing a frequency **distribution**, particularly of a **discrete** variable (Figure D.10). In Figure D.10, we have used diamond as a dot, but you can have any other shape. Most common

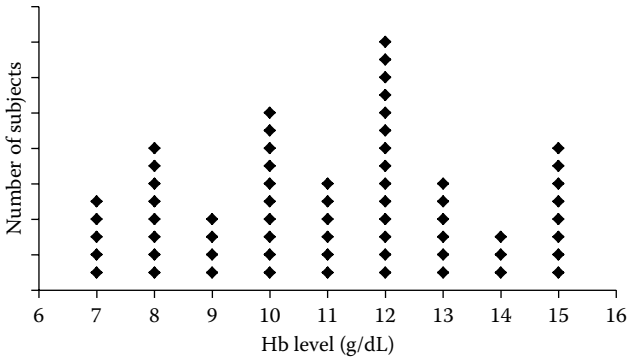

**FIGURE D.10** Dot plot of Hb level.

is the circle. Each observation is represented by a dot against the appropriate point on the horizontal scale. Thus, there are as many dots as the number of subjects. If the total number of subjects is large, each dot can represent, say, 10 subjects to avoid congestion. When a dot is representing more than one subject, this should be clearly specified. In this case, you can have a proportionate dot at the top to represent, say, seven subjects.

In Figure D.10, the hemoglobin (Hb) level actually is **continuous** but shown as discrete, where values between 6.5 and 7.4 g/dL are represented by 7 g/dL, between 7.5 and 8.4 g/dL by 8g/dL, etc. For such data, a dot plot is an alternative to a **histogram**, and the same interpretation applies. For example, you can talk about variability and **skewness** of the distribution on the basis of a dot plot of a continuous variable. But the dot plot suits well when the "values" on the $x$-axis are **qualitative**. These can be values such as site of injury, blood group, and state of residence. For such qualitative data, a dot plot is an alternative to a **bar diagram**.

## double blind trials, *see* blinding

## double sampling, *see* two-phase sampling

## dummy variables, *see* variables

## Dunnett test

Many times, the interest in multigroup experiments is in comparing each group with a particular reference group, and comparison between other groups is not required. Quite often, the reference group is the control group. For example, you may want to compare maternal serum copper concentration in normal pregnancies with pathological conditions such as threatened abortion, blighted ovum, and pyelonephritis. The Dunnett test is used for multiple comparisons where all the comparisons are with a particular reference group. This is given by

$$\text{Dunnett test: } t_d = \frac{\bar{x}_k - \bar{x}_0}{\sqrt{2\text{MSE}/n_h}},$$

where $\bar{x}_k$ is the mean of the $k$th group under comparison ($k$ = 1, 2, …, $K$) and $\bar{x}_0$ is the mean of the reference group. Thus, under this notation, there are a total of $(K + 1)$ groups in the experiment, including the reference group. Here $n_h$ is the **harmonic mean** of $n_0$ and $n_k$, the respective sizes of the reference and the comparison group.

The harmonic mean arises from $1/n_1$ $1/n_2$, occurring in the denominator of a two-sample **Student *t***. MSE is the **mean square error** that comes from the ANOVA table. The test is valid only under **Gaussian conditions**. Thus, either the sample size in each group should be large, or the values should follow a Gaussian distribution. The value of Dunnett $t_d$ is compared with its distribution at $(n - K)$ degrees of freedom (df's). You may find the value of $t_d$ for different df's in tables in some statistical books; otherwise, good software will provide the *P*-value directly.

In such comparisons, the result of the reference group is expected to be much more reliable since all the comparisons are with this group. Statistically, this means that the reference group should have larger $n$, generally, $n_0 = \max(n_k\sqrt{K})$ for all $k$. If not, the reference group values should have less variation from person to person than in other groups under comparison.

The Dunnett test was developed by Charles Dunnett in 1955 [1].

## Durbin–Watson test

The assumption of **independence** of **residuals** is the most serious requirement for the validity of the analysis of variance (ANOVA) ***F*-test**. This is checked by the Durbin–Watson test. Residuals are the values unaccounted for by the model under consideration. The test was proposed in the years 1950–1951 [1,2].

Independence is threatened particularly in situations where observations are taken and the value of an observation depends on what it was at the preceding time. This is called autocorrelation or **serial correlation**. This happens in almost all repeated measures where, for example, a patient is assessed repeatedly after surgery. This can happen even after the time factor is properly accounted for, because of other factors that may also change results but are not accounted for.

The Durbin–Watson test checks that the residuals from a regression are statistically independent [1]. The residual at time $t$ is denoted by $e_t$ ($t = 1, 2, \ldots, T$). Generally, $T$ is the same as the number of observations $n$. The test statistic is

$$\text{Durbin–Watson } d = \frac{\Sigma_{t=2}^{T}(e_t - e_{t-1})^2}{\Sigma_{t=1}^{T} e_t^2}.$$

You can see that this statistic considers only the autocorrelation of lag 1. That is, this investigates the correlation between $e_2$ and $e_1$, $e_3$ and $e_2$, etc. If you suspect a correlation of $e_3$ with $e_1$, of $e_4$ with $e_2$, etc. (i.e., of lag 2), then the formula will accordingly change.

The rule of thumb for the Durbin–Watson test is that if $d$ is substantially less than 2, there is evidence of a positive serial correlation. If $d$ is less than 1.0, there could be a real problem. Small values of $d$ indicate that successive error terms are, on average, close in value to one another, or positively correlated. The value of $d$ becomes smaller as the serial correlation increases. If a test for negative autocorrelation is required, the test statistic to be used is $(4 - d)$ [3].

Most statistical packages routinely perform the Durbin–Watson test and give a *P*-value. If $P < 0.05$, you should reanalyze the data after controlling the factors that might be causing serial correlation. A strategy such as that of working with differences of successive values might be adopted in some cases. If $P \geq 0.05$ for Durbin–Watson, the *F*-test can be used as usual to test differences among means in different groups or for regression.

## ecological fallacy

Ecological fallacy is interpreted in different ways by different researchers. This fallacy basically arises from wrong interpretation of group-based results to the individuals of these groups. Thus, this has three essential ingredients, and all of them must be present for an ecological fallacy to occur. These are the following: (i) the data must belong to groups and not to individual units, (ii) results are inferred for individuals, and (iii) when individual results become available, they contradict the group results [1]. If there is no contradiction, there is no fallacy. For example, it is generally believed that rice-eating vegetarian populations generally have better brains, whereas wheat-eating populations have better brawn. Extending this to the comparison of a rice-eating person with a wheat-eating person and saying that one will have a better brain and the other a better body, even in the sense of probability, can be fallacious. If some ancillary information on these two types of people is available to support this claim, then there is no problem. The problem arises when group results are directly extended to individuals *without* supportive evidence for the individuals, and the individual results are found to be contradictory.

This fallacy is primarily a fallout of **ecological studies**, where the units of measurements are at macro levels and not individuals, although, as explained shortly, this fallacy can also occur in other group studies. There are several variables that can be measured only at a macro level. Examples are environmental pollution and fluoride content in water supply at, say, a city level, and the type of cooking oil at a household level. These can seldom be measured at an individual level. Various community health indicators such as life expectancy and incidence of cardiovascular diseases (CVDs) are macro-level measures. When studied for many areas, these may have significant correlation. The units of study in this case are the areas and not individuals. A fallacy occurs when, for example, the results based on age at death and presence of CVDs in individuals do not provide the same kind of correlation.

In health and medicine, ecological fallacy is primarily considered a biostatistical error in interpretation when group results are used for individuals. Shah [2] studied suicide rates in the elderly (age 65+) and the prevalence of obesity (body mass index [BMI] ≥ 30 kg/m$^2$) in this age group in different countries of the world. They concluded that suicide rates in elderly females are independently associated with prevalence of obesity in different countries. The unit of study is country. They have cautioned against any extension to individuals, but if we do so, this can result in ecological fallacy.

Ecological fallacy is sometimes erroneously said to have occurred because individuals do not agree with the group means. This happens all the time and should not be termed any kind of fallacy. The nature of the mean is such that some values will always be higher, some always lower, and few, if any, will be exactly equal to the mean. In addition, the pattern in means in many cases will not match with the pattern in individuals. There are two glaring examples of this—one is the **Simpson paradox**, and the other is **regression**. Both are discussed in detail separately, but the following brief may be relevant to understand why these should not be termed *fallacies*.

Let us first understand regression. **Regression** is the relationship between the *mean* of the dependent $y$ and the given set of regressors $x$'s. Many times, it is forgotten that this relationship is for averages, and some researchers unnecessarily wonder why the results are not applicable to individuals. For individuals, something like **prediction interval** may be a better indicator of the uncertainties in the relationship. Now the Simpson paradox. This occurs when the picture obtained from the whole is different from what you get from the subgroups. This can happen when, for example, the case mix in the two groups is very different—one group has more serious cases, and the other group has more mild cases. For an example, see the topic **fallacies (statistical)**. This imbalance in the subgroups tends to provide a distorted picture of the whole. Marang-van de Mheen and Shojania [3] have discussed this in the context of standardized mortality ratios. **Standardization** of the two groups with respect to the case mix is a good remedy in such situations.

## ecological study, *see* ecological fallacy

## $ED_{50}$

$ED_{50}$ stands for "effective dose 50" and is used in pharmacology for the dose of a drug that is effective in 50% of cases or yields 50% response. Biostatistically, this is the **median effective dose** since this works in half of the cases and does not work in the other half. The concept of $ED_{50}$ works for a setup where increased dose is more effective, although it can also produce more side effects. Examples are anesthetic agents and other pain relievers. $ED_{50}$ can be used to compare the potency of one drug with another or to calibrate a drug for wider use. However, for this purpose $ED_{50}$ must be based on a trial on a random sample of the specified population of patients, and the trial must be conducted in standard conditions that can be fully specified and replicated. The "effect" should also be properly defined—it could be achieving the desired level of cholesterol, the ability to do some work, specified relief in pain, or any other such measurable end point.

Note that estimation of $ED_{50}$ is a kind of reverse biostatistical process. The general setup is to estimate the efficacy and its confidence interval of a given dose of a drug. Here, different doses are tried to find the dose that gives 50% efficacy. The confidence interval is obtained for the dose level and not for efficacy. This requires studying the dose–response relationship (Figure E.1) (sometimes after converting dose to log-dose and even response to log-response),

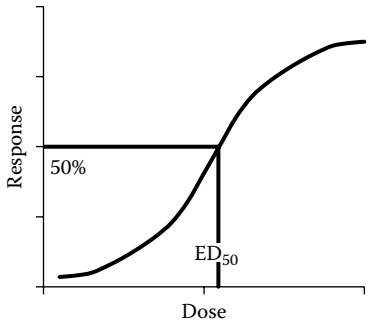

**FIGURE E.1** Dose–response curve and $ED_{50}$.

and the methods of **bioassays** are used. In Figure E.1, the response is symmetric on either side of $ED_{50}$, but for some drugs, this may not be so. In some cases, estimation of $ED_{50}$ requires that the factors influencing this also be considered, such as body mass index and severity of disease. This can also be done when needed.

You can see that $ED_{50}$ is not directly useful to clinicians for patient management. No clinician would want to use median effective dose on his/her patients. Clinicians probably will want to use the dose that is effective in 95% of cases if the side effects are negligible. This is called $ED_{95}$. Hang et al. [1] have described a study on estimation of $ED_{95}$, in addition to $ED_{50}$, of ketamine for prevention of postoperative hyperalgesia in patients undergoing laparoscopic cholecystectomy. $ED_{95}$ is worked out keeping in view its use in actual conditions.

$ED_{50}$ is primarily used to assess the potency of a drug in producing a change. Ramboer et al. [2] studied $ED_{50}$ of cetirizine and loratadine for inhibiting the wheal and flare response of the skin to the histamine pick test and concluded that on average, cetirizine is seven to nine times more potent than loratadine. This illustrates how $ED_{50}$ is used for comparing potency. Statistical methods are available to compare $ED_{50}$ of two regimens. These are based on **bioassays**.

A corresponding concept for poisons such as insecticides is the lethal dose 50 ($LD_{50}$)—the dose that kills half of the organisms or kills half of the subjects, such as rats in a laboratory.

## education indicators

Education is among the core indicators of **social health**. Many parameters of physical health are directly or indirectly affected by the level of education. Education creates awareness about health issues and thus affects health status. In clinics, the education level of the patient decides the level of interaction. In medical research, the education profile of the subjects provides the demographic structure of the subjects, which helps to assess whether or not the results can be applied to the other populations.

Education can be measured at the individual level as well as at the community level. At the individual level, years of schooling is a useful indicator as it incorporates different types of schooling into a single index. Sometimes, information on the kind of education (engineering, medical, law, etc.) is useful, and sometimes, occupation is used as a surrogate. However, our focus in this section is on community indicators.

At least four different types of indicators are used to assess the level of education in a community. For developing countries, where a substantial segment of the population is illiterate, the literacy rate can be a useful indicator. This is the percentage that is literate among people of age 6 years and above. Children younger than 6 years are supposed to be neither literate nor illiterate and thus are excluded from calculation. This gives

$$\text{literacy rate} = \frac{\text{literates among population of age 6 years and above}}{\text{total population of age 6 years and above}} * 100.$$

When calculated for age 15 years and above, this is called the **adult literacy rate**. When calculated for age 15–24 years, this is called the youth literacy rate. In the block years 2008–2012, the youth literacy rate among males of Chad was 53.6%, and among females, 42.2% [1]. This rate is showing a rapid rise all across the world, but in almost all countries, all education indicators are lower in females than in males.

The second indicator of education is the average years of schooling in the adult population.

$$\text{Average years of schooling} = \frac{\text{sum total of schooling of all individuals in a population (25+ years)}}{\text{total population (25+ years)}}.$$

To maintain validity, the age is restricted to 25 years and above for the numerator as well as for the denominator. It is presumed that all schooling will be over in practically all individuals in the population of this age. The years of schooling for each individual in a community are rarely available, and thus, this average is difficult to compute. As a middle path, the third indicator is

$$\text{percentage of adults with high school diploma} = \frac{\text{adults with high school diploma}}{\text{total adults}} * 100.$$

Adults can be defined according to local conditions. Information on the addition of high school diploma holders each year can be obtained from schools, boards, or councils awarding such a diploma. But keeping track of exits, by way of migration or death, can be difficult. To overcome this problem, the fourth indicator used is

$$\text{net enrollment ratio} = \frac{\text{children of age 6–16 years enrolled in a school}}{\text{total children of age 6–16 years in the population}} * 100.$$

*Net enrollment ratio* measures the extent to which children are using educational facilities. In place of 6–16 years, any other age group can be used. The enrollment figures can be easily obtained from schools, and the age structure of the population is generally available from other sources. Thus, this indicator can be easily computed.

Net enrollment ratio can be computed separately for primary, secondary, and tertiary schools by adjusting the age accordingly. There might be children in schools who are younger than 6 years and older than 16 years. When the numerator of this equation is relaxed to include such children also, it is called the *gross enrollment ratio.*

Since the age group in the denominator cannot be relaxed, the gross enrollment ratio can exceed 100, as occurring in Australia (104 in 2011) for primary education [2].

## effect modification, *see* interaction

## effect size, *see also* medically important effect (the concept of)

The effect size of an intervention is the measure of the change in outcome after that intervention. This is a quantitative measure of the magnitude of the effect of the intervention—thus, it is more than just statistical testing of a hypothesis that finds whether an intervention is effective or not. This answers "how much" the effect is, and thus, a meaning is attached to the effect.

If a regimen has increased the response from 36% in controls to 54% in the test group, the effect size is 18%. One can also say that the effect is 1½ times as much in the test group as in the controls. If an intervention has decreased a sickness in a community from 15% per year to 12% per year, the effect size is 3% per year. If a supplement has increased the hemoglobin level from an average of 8.3 g/dL in anemic subjects to 10.5 g/dL after 1 month, the effect size is 2.2 g/dL. The unit of measurement changes depending upon the kind of outcome. It can be measured in terms of odds ratio, correlation coefficient, or even the change in the value of the regression coefficient.

In cases where the effect size is measured by the difference in means in two independent groups, it is customary to make it independent of units by dividing this difference by the corresponding standard deviation (SD) if this can be assumed same for the two groups. Thus, in this case, effect size = $(\mu_1 - \mu_2)/\sigma$. This is estimated by $(\bar{x}_1 - \bar{x}_2)/s$, sometimes known as *Cohen d*. In cases where the SDs are different in the two groups, you can use either the average of the two SDs or **pooled SD**, as used in Student *t* for testing the difference between two independent samples. No standard guidelines are available. One can subjectively say that the effect size, when computed in SD units in this manner, is small if around 0.2, medium if around 0.5, and large if around 0.8. This would, of course, depend on the context and can exceed 1. Since this measure is independent of units, you can easily compare the effect size of one intervention with another intervention. The usual precautions, such as adequate sample size, unbiased averages, and comparable group composition, are applicable to the estimation of effect size.

For correlation also, the same cut points (0.2, 0.5, and 0.8) can be used to subjectively interpret the effect size. No such guidelines are available for proportions because sometimes an increase of just 1% from 0.01 to 0.02 can be substantial, as in the case of the chance of death becoming twice as much in a disease that can have severe implications, and sometimes even a difference of 10%, as in the case of opinion in favor of a regimen increasing from 60% to 70%, may not have much health implication.

Effect size and its confidence interval is the core quantity in **meta-analysis**. This is because in meta-analysis, results from diverse studies meeting the preset criteria are combined to provide a pooled estimate. For this, it is necessary that the effect size be measured in comparable units.

## efficacy and effectiveness

The efficacy of a regimen is its positive response rate in ideal conditions, and effectiveness is the positive response rate in actual conditions. Much of the medical literature fails to distinguish between the two, but these can be very different.

**Clinical trials** are generally done in ideal conditions that do not exist in practice. The subjects are carefully chosen with strict inclusion and exclusion criteria, administration is done in standard conditions, efforts are made for full compliance, patients get full attention, the results are adjusted for dropouts and other missing observations, and the response is carefully assessed by experts. The actual performance of the regimen in practice may differ. Efficacy of a treatment is what is achieved in a trial that simulates optimal conditions, and effectiveness is what is achieved in practical conditions when the treatment is actually prescribed. For clarity, the latter is sometimes called use effectiveness.

Effectiveness could be lower than efficacy because of lack of compliance to the regimen due to cost or inconvenience, inadequate care, nonavailability of the drugs, etc. These rarely occur in a trial. Experience suggests that nearly three-fourths of patients do not adhere to or persist with the full prescriptions. Thus, the results for patients and maneuvers adopted during a trial do not translate to patients at large. Consequently, such external validity of trial results is not high. But clinical trials do establish the potential of a regimen to effect a change. Effectiveness, on the other hand, is a suitable indicator to decide whether or not to adopt that regimen in practice, or what to expect. For further details, see Singal et al. [1].

The concept of effectiveness as opposed to efficacy has given rise to what are called **pragmatic trials**. As explained under that topic, pragmatic trials are conducted under actual field conditions.

## empiricism

Empiricism can be roughly equated with evidence available from sensory experience. Inherent in this is just not the experience but also the change that comes with time as more experience is accumulated. A hypothesis, for instance, better health leads to more happiness, remains just a thought till such time that it is really seen or experienced by at least a segment of the population. Thus, evidence is an integral part of empiricism. In contrast, mathematics and some other physical sciences are based on theories and lemmas. They are deductive and not empirical. Deductive science holds that the mind can directly perceive truth without going through the process of sensual experience. Empiricism is based on induction from sensual learning.

Empirical evidence could arise from experiments, trials, natural occurrences, observations, records, etc. It refers to the actual facts as currently present or occurred in the past. Empiricism emphasizes the tentative and probabilistic nature of knowledge. Thus, probability, and hence statistics, plays a key role in empirical conclusions.

Empiricism is sometimes contrasted with rationalism, although there is no conflict. The observations must stand up to reason and should have an adequate rational explanation. After all, it is the logic of reasoning that separates humans from other species. Research results are more acceptable when the accompanying evidence is compelling, stands to reason, and inspires confidence. Without logic, research is reduced to storytelling.

### *Medical Empiricism*

Medicine is a delicate science. It is concerned with vital aspects of life such as health, disease, and death. Thus, it brooks no error. Ironically, no theories are available that can make it infallible, and there are no lemmas and no theorems. It must depend on evidence provided by observations and experience. Medicine is largely an inductive science and has very little space, if any, for deductive methods. It is individualized yet participatory in the sense that if a treatment regimen has worked in Mr. Somebody and nine others of his clan, there is a high likelihood that it would work in the eleventh also of that type. Past experience and present evidence provide insight into the future. Such empiricism is the backbone of medical science. Empirical research helps in the quantitative assessment of the plausibility of complex issues. In dealing with a new case, or an old case with a new set of conditions, past knowledge and experience are applied, and it is hoped that they will work in the new setup also. Very often, they do, but sometimes, they do not. There is no assurance, and miscues occur.

Much of medical research is on cause and effect. Mental illumination, stipulated in theories, may provide a clue on what really may be going on, but this is not accepted in medicine without support from actual observations. Only then can you hope to convince colleagues to accept your theory. Thus, there is no escape in medicine from the evidence base and empirical process. For example, even when genomics has a wide role, the decision of what treatment to administer in a given gene structure would still depend on gaining experience.

## empty cells, *see* contingency tables

## endogenous and exogenous factors and variables

Factors working within the system under study are called endogenous, and those working from outside are exogenous. If you are studying the cardiovascular system, kidney functions are exogenous, whereas heart rate, cardiac output, and arterial pressure are endogenous. Exogenous variables are not necessarily independent—they can affect the endogenous variables, albeit in an indirect manner. They do not have a direct causal link.

Treatment for a disease will generally be directed to controlling the endogenous factors, and separate regimens may be needed to control the effect of exogenous factors. For example, for vaginal candidiasis, the oral cavity and anus could be endogenous sources of reinfection as they are from the same woman, while infection coming from sex partners is exogenous [1]. For prostate and breast cancer, genomic variations are endogenous, and lifestyle is exogenous [2]. Thus, the terms have wide and varied usage. Biostatistical usage is based on entirely different considerations, as explained next.

Classification of factors as endogenous and exogenous as stated in the preceding paragraph is for medical purposes. For biostatistical modeling, both medically endogenous and exogenous variables can be included in the same model. Endogenous and exogenous classification in biostatistical modeling depends on the model you are working on. When working on how total bilirubin level is affected by age, sex, body mass index, and dietary content in healthy people, all these are endogenous to the study. If later on it is realized for some reason that the pulse rate should also be included, this is exogenous since this is not related to any of the variables already under investigation. In a **regression** of an outcome $y$ on a set of independents $(x_1, x_2, \ldots, x_K)$, all these variables are endogenous to this model. However, $y$ may be affected by another variable $x_i$; this is exogenous for this model if it is not causally related to any of $(x_1, x_2, \ldots, x_K)$.

Whether the variables are endogenous or exogenous has important implications for some statistical methods, such as **path analysis** and **structural equation models**. Both investigate how exogenous variables affect endogenous variables, although in structural equation models, the relationship between latent factors and their indicators is also investigated. In these analyses, particularly in structural equation models, the observed variables are endogenous, and the underlying constructs that cannot be directly observed are exogenous.

## enrollment ratio, *see* education indicators

## ensemble methods

Ensemble methods help in scientific aggregation of predictions of the same outcome by multiple models. Models can differ with respect to the variables used for prediction; case mix; statistical method (logistic, discriminant functions, regression tree, etc.); and the algorithm (agglomerative or divisive in the case of cluster analysis, backward elimination or forward selection in the case of regression, etc.). It is natural to expect that this aggregation many times would yield a prediction that is better than any of the constituent models when the right ensemble method is used. "Better" would be mostly in terms of **reliability** and, in some cases, even **validity** of the prediction, perhaps also generalizability. But the ensemble methods are mostly used for models based on huge data sets. It is desirable that the ensemble results on a new data set are tested to confirm that they really work better than any of its constituents.

A simple ensemble method is to take average of the predictions by specific inputs to diverse models. This has the same merits and demerits as any other mean. Different models may be based on different sample sizes and different methods, and it is necessary to carefully examine whether or not the average can be used. The other method is *bootstrap aggregation*, forming the acronym *bagging*. As explained for the topic **bootstrap**, this generates replicates of the data set by repeated sampling from the original data set with replacement. In this case, the bootstrap samples have the same size as the original data set. Then the model is built on each of these bootstrap samples. Suitable aggregation methods are used to get the ensemble estimates. Ghafourian and Amin [1] found boosted regression trees to be the most appropriate ensemble method for prediction of plasma protein binding of drugs. These methods are too mathematically complex for inclusion here. For more details on ensemble methods, see Rokach [2].

## epidemic curve

A graph showing the number of new cases occurring each day or any other time period from the beginning to the end of an epidemic is called an epidemic curve. Time is plotted on the horizontal axis and the number of cases on the vertical axis. Even though this could be a bar diagram, it is interpreted as a curve because it shows trend over time.

In the case of an epidemic of infectious diseases, the number of cases gradually rises, reaches a peak, and then starts to decline. The shape of the curve depends on whether it is a common-source epidemic or a propagated epidemic. An infectious disease epidemic in a population that has a common source (such as contaminated water for cholera) would look like Figure E.2a. A sharp peak occurs a couple of days later than the incubation period, but tapering off may not be as sharp, because of varying time taken in recovery. The Bhopal gas tragedy in India and the Minamata disease outbreak in Japan caused by eating fish containing high concentrations of methyl mercury are well-known examples of common-source epidemics.

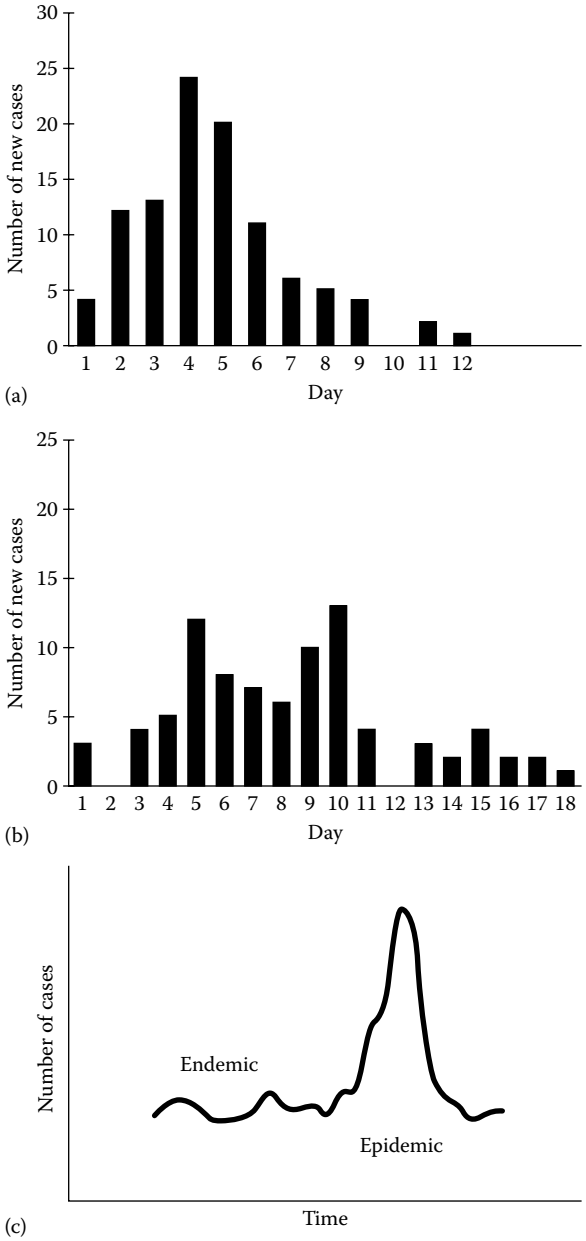

**FIGURE E.2** Epidemic curves: (a) common source; (b) propagated; (c) endemic versus epidemic levels.

A propagated epidemic results from person-to-person transmission (e.g., of hepatitis A and polio). It shows a gradual rise, sometimes intermittent peaks, and a very gradual fall (Figure E.2b). The speed of spread depends upon herd immunity, opportunities for contact, and the **secondary attack rate**. If you want to see actual epidemic curves, see Chen et al. [1] for the epidemic of shigellosis in China and Barnea et al. [2] for influenza-like illness in Israel.

An epidemic of a disease is said to exist when the occurrence is clearly in excess of the usual occurrence. The term was originally used for infectious diseases such as influenza and cholera but is now used for conditions such as deaths in vehicular accidents in vacation times. A steep rise in cases over the endemic level is shown in Figure E.2c. It helps to identify the time of start and finish of an epidemic. This is the real epidemic *curve* and not a bar diagram.

## epidemic models, *see also* infectious disease models

In the context of biostatistics, the epidemic model is the equation that describes the number of new (incident) and/or existing (prevalent) cases at various time points during an epidemic. It is a mathematical formulation of the **epidemic curve**. This formulation smoothens the random fluctuations and can be used to estimate the precise time of the start and end of the epidemic, the time of peak incidence, and the rate of increase and decline. Any cyclical or seasonal components can also be included in the model. If the disease reaches an endemic stage, that also can be identified. More practical use of such models is in projecting the number of cases while the epidemic is still going on and in estimating the effect of interventions undertaken to modify the course of the epidemic.

While there is quite some overlap between epidemic models and **infectious disease models**, they must be regarded as distinct entities. Infectious disease models incorporate the number or proportion of the population immune, susceptible, and exposed; infectives; infectivity; recoveries; etc. On the other hand, in our opinion, epidemic models are simply for the number of cases at different stages of an epidemic that can possibly be estimated by empirical processes where some of these parameters can also be used. For example, Chin and Lwanga [1] used the following **gamma function** as an epidemic model (they called it an epidemiological model) for estimation and projection of adult AIDS incidence:

$$y = \frac{1}{(p-1)!} t^{(p-1)} e^{-t},$$

where $y$ is the incidence at time $t$ and $1/p$ is the steepness of the curve and $(p-1)$ is the duration to reach peak ($p \geq 1$). The larger the $p$, the slower the progress of the epidemic. On the basis of data from some countries, they estimated it as $p = 5$ years (Figure E.3). This estimate is based on empirical observations and not on the incubation period, force of infection, number of susceptible, etc. Time $t = 0$ is the time

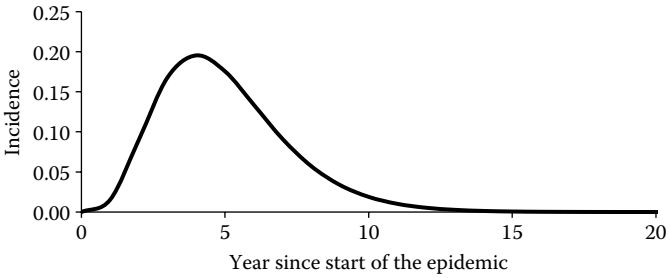

**FIGURE E.3** Graphical representation of an epidemic model for AIDS cases.

when the epidemic started. This model is fit for person-to-person transmission and assumes that the epidemic will ultimately relent. The peak of the epidemic is at time $(p - 1)$, in this case, at 4 years. If the data suggest that the peak will be reached in 8 years, you can choose $p = 9$ in this model.

The model presented in the preceding paragraph shows that the infections steeply increase in the beginning, reach a peak, and then gradually decline as the susceptible pool is depleted. Another approach for epidemic modeling, distinct from infectious disease models, could be time series fitting, as done by Lee and Wong [2] for pandemic influenza A in Hong Kong and surrounding areas. Both these approaches exploit the time trend instead of the susceptible–infections–recoveries route of the infectious disease modeling.

## epidemiologically consistent estimates

You may be aware that the number of cases of any disease present (prevalence) in a community is affected by how many new cases are occurring (incidence), what the duration of illness is, at what rate the cases are getting cured (remission), and how many are dying (case fatality). This is explained in Figure E.4. All these can be woven into an equation under certain stability conditions, and one can be determined by the others. Also, age at onset, remission, and duration are related to age-specific mortality for that disease. When all these fall into the expected pattern, they are called epidemiologically consistent.

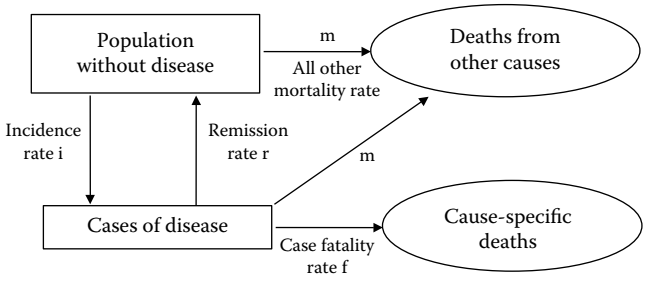

**FIGURE E.4** Interrelations for epidemiologic consistency of data. (From Mathers CD et al. [Eds.]. *National Burden of Diseases Studies: A Practical Guide*, Edition 2.0. Global Programme on Evidence for Health Policy. World Health Organization, available at http://www.who.int/healthinfo/nationalburdenofdiseasemanual.pdf, 2002.)

Quite often, different rates are estimated from disparate sources, such as prevalence and age-specific mortality from a cross-sectional survey; incidence from one cohort study; and remission, duration, and case fatality from another longitudinal study. There is a great likelihood in this case that various rates are not internally consistent. Age-specific mortality may not be the same as expected on the basis of age at onset, duration, and case fatality, or prevalence may not be the same as expected from the incidence, duration, remission, and mortality estimates. A software package called **DisMod** II, available from the World Health Organization (WHO) website [2], can be used to check the internal consistency of these estimates with some limitations. In case they are not internally consistent, more reliable rates should be used to generate consistent estimates of the other rates. This package can also be used to generate estimates of rates that are not available at all. The generated rate would be epidemiologically consistent but may not be plausible in terms of the knowledge of the experts. In that case, iterations may be needed in terms of reentering a new set of known rates so that the final estimates are not only internally consistent but also plausible.

A new version of DisMod has arrived, called DisMod-MR. This is based on a meta-regression approach and uses the systematic review of different studies to come up with a set of more valid estimates. Details of this method have been provided by Vos et al. [3].

## epidemiological studies

Although epidemiology is concerned with distribution, dynamics, and determinants of health status (including disease) in a population, all **observational studies** are customarily termed epidemiological studies. This is in contrast to **experiments**, where a human intervention is deliberately introduced to study its effect on a group of subjects. Experiments include all kinds of clinical and field trials whether for diagnostic, screening, prophylactic, or preventive purposes. Epidemiological studies are sometimes understood as nature's experiments in situations where intervention is not deliberate. If somebody is or was a smoker, you can study the effect of smoking without deliberately introducing smoking. It is generally assumed that epidemiological studies would be analytical since they would be concerned with an antecedent–outcome relationship; that really is not so. **Descriptive studies** are also considered epidemiological as they are concerned with the distribution of various factors in a group of subjects. Disease surveillance also falls under this term.

The primary format of epidemiological analytical studies is **prospective**, **retrospective**, or **cross-sectional**. A prospective study could be a cohort study, a longitudinal study, or a repeated measures

study. A retrospective study could be case–control, nested case–control, or a study without any control group. **Ecological studies** also come under the umbrella of epidemiological studies. In addition, as just mentioned, descriptive studies and disease surveillance are also epidemiological.

Because of a lack of controlled conditions, the evidence available from epidemiological studies is considered indicative rather than definitive. Various biases can occur that could make any epidemiological study result suspect. In biostatistical terms, they provide evidence on associations but not cause–effect relationships. For concluding cause–effect, a large number of other rather strict conditions must be satisfied (see **cause–effect relationship**).

There are instances in the medical literature where trials are also called epidemiological studies. If that is so, almost any medical study would be epidemiological. We advise you to guard against such "generalizations." In fact, clinical trials and laboratory experiments are the most common example of nonepidemiological studies.

## epistemic uncertainties, *see also* aleatory uncertainties

Uncertainties arising from our limitations are called epistemic. Knowledge gaps are wider than generally perceived. One paradigm says that what we do not know is more than what we know. Unfamiliarity breeds uncertainty, and this is part of the epistemic uncertainties. A long way down from the art of healing based on esoteric knowledge, the realization of epistemic gaps in medicine is recent. In the context of health and medicine, this type of uncertainty was first highlighted by Indrayan [1] in 2008.

Besides incomplete knowledge, epistemic uncertainty also includes (i) ignorance, e.g., how to choose one treatment strategy when two or more are equally good or equally bad, such as between amoxicillin and cotrimoxazole in nonresponsive pneumonia; (ii) parameter uncertainty regarding the factors causing or contributing to a particular outcome, such as etiological factors of vaginal and vulvar cancer; (iii) speculation about unobserved values, such as the effect of high levels of $NO_2$ in the atmosphere; (iv) nonavailability of the exact quantitative effect of various factors, e.g., diet, exercise, obesity, and stress on raising blood glucose level; and (v) confusion about the definition of various health conditions, such as hypertension—whether the blood pressure cutoff should be 130/85 or 140/90 mmHg.

Another kind of epistemic uncertainty arises from nonavailability of the proper instrument. How do you measure blood loss during a surgical operation? Swabs that are used to suck blood are not standardized. In some surgeries, blood can even spill onto the floor. Even a simple parameter such as pain is difficult to measure. A visual analog scale (VAS) and other instruments for this are just approximations. Stress defies measurement, and behavior/opinion-type variables present stiff difficulties. If the measurement is tentative, naturally, the conclusion, too, is tentative. The following is a brief description of some sources of epistemic uncertainties.

### *Inadequate Knowledge*

Notwithstanding claims of far-reaching advances in medical sciences, many features of the human body and mind, and their interaction with the environment, are not sufficiently well known. How the mind controls physiological and biochemical mechanisms is an area of current research. What specific psychosomatic factors cause women to live longer than men is still shrouded in mystery. Nobody knows yet how to reverse hypertension, which can obviate the dependence on drugs. Cancers are treated by radiotherapy or excision because a procedure to regenerate aberrant cells is not known. Treatment for urinary tract infections in patients with impaired renal function is not known. Such gaps in knowledge naturally add to the spectrum of uncertainty.

The preceding paragraph discusses universal epistemic gaps. In addition to these is the incomplete knowledge of a particular physician. This can arise at two levels. First is that the physician does not know enough, although medical science knows. Second is that the physician knows but is not able to recollect at the time of facing a patient. Both can result in misdiagnosis or missed diagnosis, or improper prescriptions.

### *Incomplete Information on the Patient*

When a patient arrives in a coma at the casualty department of a hospital, first steps for management are often taken without considering the medical history of the patient or without waiting for laboratory investigations. An angiography may be highly indicated for a cardiac patient, but initial treatment decisions are taken in its absence if the facility is not available in that health center. Even while interviewing a healthy person, it cannot be ensured that the person is not forgetting or intentionally suppressing some information. Suppression can easily happen in the case of sexually transmitted diseases (STDs) because of the stigma attached to them. An uneducated person may even fail to understand the questions or may misinterpret them. Some investigations such as computed tomography (CT) and magnetic resonance imaging (MRI) are expensive, and lack of funds may sometimes lead to proceeding without these investigations even when they are highly indicated. Thus, information remains incomplete in many cases despite best efforts. Clinicians are often required to make a decision about treatment based on such incomplete information.

### *Imperfect Tools*

A clinician uses various tools during the course of practice. Examples are signs–symptoms syndrome, physical measurements, laboratory and radiological investigations, and intervention in the form of medical treatment or surgery. Besides his/her own skills in optimally using what is available, the efficiency of a clinician depends on the validity and reliability of the tools he/she uses. Validity refers to the ability to measure correctly what a tool is supposed to measure, and reliability means consistency in repeated use. Sensitivity, specificity, and predictivities are calculated to assess the validity of a tool. Reliability is evaluated in terms of measures such as **Cohen kappa** and **Cronbach alpha**. In practice, no medical tool is 100% perfect, so much so that even a CT scan can give a false-negative or false-positive result. A negative histologic result for a specimen is no guarantee that proliferation is absent, although in this case, positive predictivity is nearly 100%. The values of measurements such as creatinine level, platelet count, and total lung capacity are indicative rather than absolute, i.e., they mostly estimate the *likelihood* of a disease, not establish or deny its existence. Signs and symptoms seldom provide infallible evidence. Because all these tools are imperfect, decisions based on them are also necessarily probabilistic rather than definitive.

### *Chance Variability*

Let us go a little deeper into the factors already listed. Aging is a natural process, but its effect is more severe in some than in others. When exposed equally to heavy smoking for a long duration, some people develop lung cancer, and others do not. Despite consuming the same water deficient in iodine, some people do not develop goiter, whereas some do—that, too, of varying degrees. The incubation

period differs greatly from person to person after the same exposure. Part of such variation can be traced to factors such as personality traits, lifestyle, nutritional status, and genetic predisposition, but these known factors fail to explain the entire variation. Two patients apparently similar, not just with regard to disease condition but also for all other known factors, can respond differently to the same treatment regimen. Even susceptibility levels sometimes fail to account for all the variation. The unknown factors are called **chance**. Sometimes, the known factors that are too complex to comprehend or too many to be individually considered are also included in the chance syndrome. In some situations, chance factors could be very prominent contributors to uncertainties, and in some situations, they can be minor.

### *Epistemic Gaps in Research Results*

Most medical research is an attempt to fill in epistemic gaps. Descriptive studies tell us prevalence rates of health and disease in various segments of the population and their trend, which otherwise would not be known. The objective of analytical studies is to find antecedent–outcome relationships. However, realize that only those factors that are known or suspected to affect the outcome. Others are excluded or included as independents in the study. For example, blood group could be a contributory factor for a particular health condition but will not be included till such time that some evidence comes forth implying its possible role. Including limited factors in the study is pragmatic too, as nobody can include all factors. Genomic information is not included, as it is rarely known for the subjects of research. Thus, research remains incomplete, and we wonder why results are not applicable in practical conditions. The search for truth does not relent, although goal posts are continuously shifted upward as the new results appear.

Statistical models are always developed under certain conditions. First is the limited number of independent variables and their choice, which we have mentioned in the preceding paragraph. The most commonly ignored limitation is the linearity of the effect of the factors on the outcome. This is used for simplicity as the study of curvature is not only intricate, but also, the model loses its parsimony. After all, the purpose of generating models is to explain the phenomenon in an easily understood manner in the hope that the left-out portion is not high enough to cause much damage to the explanation. In some cases, this turns out to be too much to expect. Second is the measurements. Statistical methods assume that the values of each variable are exactly known without any error. This is hardly ever true. Thirdly, it is also assumed that the measurements available are indeed valid markers for the phenomenon under study. For malaria, you may include palpable spleen without considering its false positivity and false negativity. S large number of such epistemic gaps can be cited.

Some of the impact of epistemic uncertainties can be studied by **sensitivity analyses**. These consider alternative scenarios and see how the results are affected. The big question is what, if anything, can we do to reduce the impact of epistemic uncertainties on our medical decisions. Partial answers are provided by tools such as **etiology diagrams**, **expert systems**, and **scoring systems**. However, these tackle some aspects of epistemic uncertainties and not others. The solution for others is research and to realize that we are in imperfect world.

The counterpart of epistemic uncertainties is **aleatory uncertainties**. As described under that topic, aleatory uncertainties are mostly due to biologic, environmental, instrumental, and other variations, and to biases and errors. Biostatistics seems to be the best science to deal with aleatory uncertainties. For a discussion of aleatory and epistemic uncertainties, see the work of Sandomeer [2], although this is in the context of engineering applications.

## equipoises

Equipoise is the balance among the regimens under study so that none has an initial advantage over the others. This term is used in the context of clinical trials. As you can appreciate, equipoise breeds uncertainty, and this is considered a moral prerequisite for conducting any clinical trial. Equipoise is espoused as the essence of the **uncertainty principle** under which clinical trials are conducted. Uncertainty does not imply equipoise, but equipoise implies uncertainty. Uncertainty has much wider applications, and equipoise is just one source of uncertainty.

Among various equipoises discussed in the context of clinical trials, medically, the most important is **clinical equipoise**. This is the collective uncertainty among clinicians about the efficacy of the regimen under trial. For example, this exists for the use of vasopressin for management of septic shock. Lilford [1] cites the example of amniocentesis and chronic villous sampling for such clinical equipoise, although in his opinion, the latter is twice as risky for miscarriage. These two are suitable candidates for comparison in a trial. Similar equipoise exists between stenting and endarterectomy for carotid restenosis. The optimal route (intramuscular versus subcutaneous) of administration of influenza and pneumococcal vaccines in elderly patients is also under debate. However, the window of clinical equipoise is generally small as it is grabbed up fast for research, and the results one way or the other are available sooner than later.

When the concept is stretched further, it means not only uncertainty but also that the two arms of a trial are likely to result in *equal* efficacy on an a priori basis. It connotes equal uncertainty for the positive and negative outcomes of the trial. Practically, though, genuine uncertainty is enough without pressing for equal uncertainty. Clinical equipoise is the condition under which clinicians as a group would not object to their patients participating, and patients may rationally accept randomization. This equipoise *also* insulates against prejudiced assessment of the patients by the investigators. Previous evidence of benefit of a treatment may be flawed but can disturb the equipoise [2]. Sometimes, a trial is terminated early when overwhelming evidence emerges and the equipoise is disturbed.

In addition to the regimen, the groups of subjects also should be such that there is a priori uncertainty about the efficacy of the test therapy in them. This is one of the criteria for selection of cases for a clinical trial. This is called *patient equipoise* and helps to ensure that the patients are homogenous. Patient equipoise implies guarding against an unwitting tendency to include subjects who are likely to benefit from the drug under trial without declaring that the trial is restricted to such specific groups. Sometimes, health-conscious people agree to enter a trial, while in fact, participants should be fair representatives of the class of patients that are finally targeted to benefit from the regimen in the case that the trial is successful. The participants should be uncertain about the outcome of the trial so that the results are unbiased. Primarily, this is a statistical requirement for psychological homogeneity of the subjects at baseline.

The third is the *personal equipoise* of the clinician so that he/she does not feel uncomfortable about his/her own views and about the patients. A particular clinician may have a strongly positive or a very bitter feeling about a regimen even though clinical equipoise in terms of collective uncertainty may exist. A clinician who is convinced that

one treatment is better than another for a particular patient cannot ethically agree to randomization. Personal equipoise may be difficult to achieve, but efforts can be made by discussing evidence regarding the underlying uncertainties and trying to convince the particular physician that equipoise indeed exists. The term can also be used for an individual patient if he/she is undecided on which treatment to choose.

Cheng et al. [2] have discussed these three kinds of equipoise in the context of a trial for melioidosis, but they explain the concepts very well. Cook and Sheets [3] have also provided some details.

## equivalence and noninferiority trials, *see also* equivalence, superiority, and noninferiority tests

Equivalence trials aim to show that the effects of interventions differ by no more than a medically unimportant specified margin. For efficacy in clinical trials, these trials consider the possibility of lesser efficacy as well as of higher efficacy. If the specified margin is 3% and if the existing therapy has 70% efficacy, for equivalence, the efficacy of test therapy should be between 67% and 73%. If the efficacy is either more than 73% or less than 67%, the test regimen is not equivalent. Statistically, this is assessed in terms of probability. The chances of efficacy outside 67–73% should be negligible. Equivalence trials need two-tailed statistical tests and confidence intervals as discussed under the topic **equivalence**, **superiority**, **and noninferiority tests**.

Equivalence trials need far more care than the usual comparative trials. The kind of incentive available in showing that a difference exists probably is not available in equivalence trials. Thus, equivalence trials may lack natural internal checks. Inclusion and exclusion criteria should be stricter in such trials; otherwise, something like concomitant medication can tilt results toward equivalence. Also, make sure that equivalence is not due to mischievous execution of the study, such as a lot of dropouts and noncompliance to the regimen by either group, particularly in the group with the standard regimen.

As just stated, equivalence of a regimen can be concluded when its efficacy is different by not more than a specified margin. This can have serious implications. If an existing regimen has 79% efficacy and if a 3% difference is your tolerance, a regimen with 76% efficacy can be considered equivalent. This, however, means that the standard can slip over time. Now a new regimen could be evaluated for 76% efficacy in place of 79%. You may want to guard against such a fallacy.

In a therapeutic setting, the interest generally is in noninferiority rather than equivalence. Also, if the existing regimen already has 95% efficacy, superiority can be a faraway dream—only noninferiority is practical. If a new regimen has the potential to be almost as effective as the existing regimen but is cheaper or more convenient, the interest would be in noninferiority. Noninferiority trials aim to show that the effect of the new regimen is not worse than the existing regimen by more than a specified margin, and therefore, the new regimen can be advocated. Statistically, they need one-tailed procedures just like **superiority trials**, although the critical tail in noninferiority is on the right side. For superiority, it is on the left side of the distribution. For a short and crisp discussion about noninferiority trials, see Snapinn [1]. He argues that noninferiority and superiority can be assessed in the same clinical trial without statistical penalty. For further details of the design and analysis of noninferiority trials, see Rothman et al. [2].

## equivalences (types of) in clinical trials, *see also* equivalence and noninferiority trials

Equivalence in clinical trials is similar performance of different regimens under consideration in identical conditions. Performance can be measured in a variety of ways, and this gives rise to terms such as therapeutic equivalence and bioequivalence. These equivalences are different from group equivalences at baseline, which we try to achieve through randomization and matching.

**Therapeutic equivalence** considers only the success rate as the end point, such as efficacy. Many therapeutic equivalence trials are done for an alterative dose schedule or method of administration. For example, alendronate 35 mg once weekly may be therapeutically equivalent to 5 mg daily for prevention of osteoporosis. Innovative and generic formulations of beclomethasone dipropionate may be therapeutically equivalent in adult patients with moderate to severe asthma. Both give nearly the same efficacy, i.e., the efficacy does not differ by more than a clinically unimportant margin. Baker [1] argues that different mesalamine products may not be therapeutically equivalent, because they differ with regard to where the drug is released in the intestinal tract, and this may affect the outcome. Therapeutic equivalence is also called **clinical equivalence**. Note that this is equivalence on average and not individual equivalence.

**Bioequivalence** considers the entire course of the absorption process of the drug rather than just the end point. When the course of the disease or the improvement pattern over a period of time is the same for two regimens, they are considered bioequivalent. In the context of drug trials, this requires pharmacological studies, and the comparison may be in terms of peak concentration, time to reach their peak, half-life, area under the curve, etc. These are called **pharmacokinetic parameters**. Popovic et al. [2] studied spline function for the bioequivalence of a single 240 mg orally standard retard tablet of verapamil with single 5 mg intravenous dose. Bioequivalence studies can certainly be done on sick subjects using conventional designs but can be done on healthy subjects as well for some regimens using crossover designs. For statistical details of bioequivalence, consult Patterson and James [3].

Many consider bioequivalence to imply therapeutic equivalence. This really may be so in most cases. However, the reverse is obviously not true. A distinction should also be made between bioequivalence at the individual patient level and average bioequivalence in groups of patients. If the two regimens under comparison produce different responses in individuals, this is ignored in average bioequivalence, whereas in individual bioequivalence, this interaction is an important consideration. *Average bioequivalence* would imply that either of these regimes can be prescribed to newly incoming patients. Individual bioequivalence would mean that the patient can be switched from one regimen to the other in the midst of the ongoing treatment. For example, drug switchability can be from a brand-name drug to a generic drug while the patient is still under treatment, say for cost considerations.

Related terms are *equivalence trials*, *superiority trials*, and *noninferiority trials*. These are separately discussed in this volume under the topic **equivalence and noninferiority trials**. Statistical tests for these are discussed under the topic **equivalence**, **superiority**, **and noninferiority tests**.

## equivalence, superiority, and noninferiority tests

Equivalence tests are statistical procedures to find whether two regimens under trial are equivalent or not in their performance on average. Thus, these are for equivalence for prescription and not switching one treatment to the other midcourse. Such switching requires individual equivalence, which we are not considering here. Between the two types of **equivalences in clinical trials**, in this section, we mostly concentrate on therapeutic equivalence and later briefly mention **bioequivalence** also, which is for the entire course of the treatment. The thrust here is to test whether two groups are essentially equivalent with respect to a particular end point and the difference, if any, is of no medical consequence. Superiority and noninferiority are also discussed. To understand this topic, you should be familiar with the usual statistical **tests of hypothesis** and **confidence intervals**. The following procedures are valid under **Gaussian conditions** for both means and proportions.

### *Superiority, Equivalence, and Noninferiority*

One regimen can be considered medically equivalent to another regimen when the difference in efficacy and side effects between the two does not exceed a prespecified medically unimportant margin (see **medically important effect**). The margin could be in terms of percentage or in terms of means. Group 1 is superior to group 2 when the response in group 1 is higher by at least the specified margin, and group 1 is noninferior to group 2 when the response is lower by not more than the specified margin. This is illustrated in Figure E.5. This assumes that one is a test group and the other is a reference group. Both the groups are under trial. Horizontal bars are the 100(1 − 2α)% confidence intervals (CIs) for difference in efficacy in 10 different experiments, and the solid dot in the middle of these bars is the **point estimate**. Alpha (α) is the **level of significance**, and Δ is the prespecified unimportant margin. In this figure, experiments A and H provide unambiguous results—A has statistical significance and superiority, and H has statistical significance and inferiority. In experiment E, the interval contains 0, and the entire interval is within the limits of medical indifference. Thus, the difference is neither statistically significant nor medically significant. In experiments D and F, the interval does not contain 0, so that the difference is statistically significant but the interval again lies entirely within the limits of medical indifference; thus, the results are medically equivalent. These are the examples that illustrate that statistical significance does not imply medical significance. In experiments I and J, the CIs overlap with the limits of equivalence. In these two cases, since the CI is relatively large, a restudy with a larger sample is advisable.

Comments on the left side of Figure E.5 assume that the same margin Δ can be used for noninferiority, equivalence, and superiority, and also assume that higher values are in favor of the test regimen. A trial gives evidence of superiority of the test regimen when the lower limit of the CI for $(\pi_{test} - \pi_{ref})$ exceeds $+\Delta$, where $\pi$ is the efficacy; of noninferiority when the lower limit of the CI is

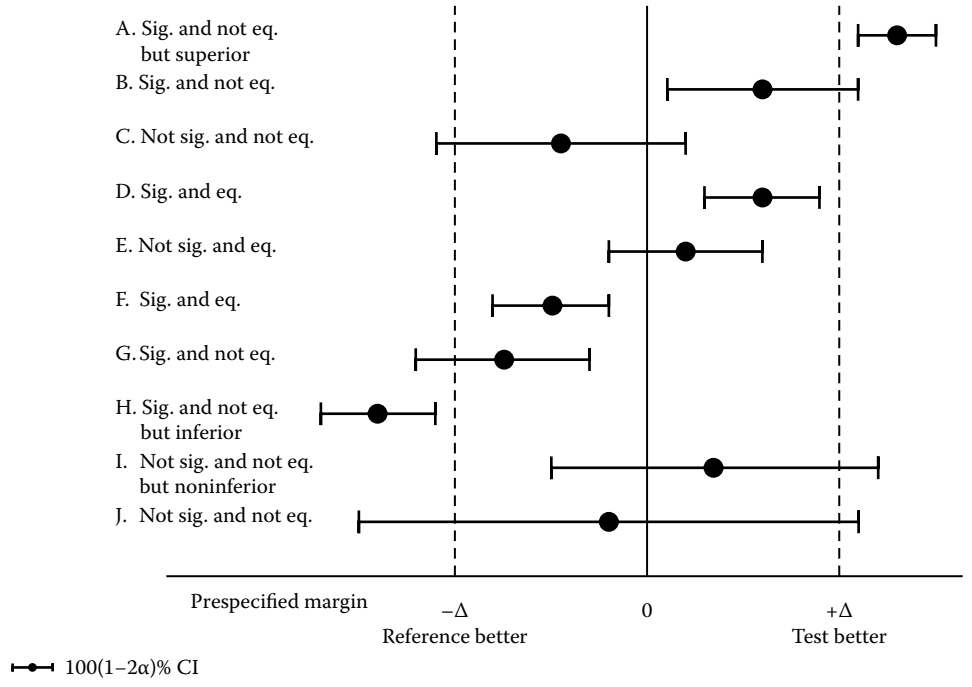

**FIGURE E.5** Statistical significance and medical equivalence. Eq., equivalent; sig., statistically significant.

more than $-\Delta$; and of equivalence when the entire CI is between $-\Delta$ and $+\Delta$. In case the efficacy of the reference group is already fairly known, there is no need to include that in the trial. In that case, the CI will be based on one-sample $100(1 - 2\alpha)\%$ confidence level and not on the difference. This may happen particularly in noninferiority trials since noninferiority is mostly tested against a known standard.

You can easily see that superiority or noninferiority is tested by specifying the medically relevant difference and conducting the usual one-tailed test. However, equivalence within a specified margin needs a little more consideration.

### *Equivalence*

For equivalence, the margin is specified for either side, generally saying that the difference does not exceed $\varepsilon\pi$, where $\varepsilon$ is the proportion of $\pi$ for equivalence. If the proportion of success in one group is $\pi = 0.50$ and 4% of $\pi$ on either side is considered to arise due to natural factors, then $\varepsilon = 0.04$ and $\varepsilon\pi = 0.04 \times 0.50 = 0.02$. The limits of tolerance for equivalence thus are 0.48 and 0.52. This is for therapeutic or clinical equivalence and not for bioequivalence.

In equivalence testing, the null hypothesis has a reverse nature: the difference is a priori specified $\Delta$ or more. Rejecting this null would mean equivalence, and the burden of rejecting the null is on the data as before. **Type I error** in this case is concluding that the difference is less when, in fact, it is $\Delta$ or more, and **Type II error** is concluding that the difference is at least $\Delta$ when, in fact, it is less. These are a kind of inverse of the conventional setups.

An approach to test equivalence is to perform **two one-sided tests (TOSTs)**. But an easier procedure is to obtain the CI for the difference between two groups at $100(1 - 2\alpha)\%$ confidence level instead of the usual $100(1 - \alpha)\%$ level. Since the difference on either side is admissible in an equivalence setup, the limits for confidence level $100(1 - 2\alpha)\%$ provide the lower and upper bound at $100(1 - \alpha)\%$ confidence. If this CI contains 0, the difference is not statistically significant at $2\alpha\%$ level of significance. If this interval is completely contained in $-\Delta$ to $+\Delta$, equivalence is concluded. Any difference less than $\Delta$ is considered trivial and within medical indifference. In exceptional cases, the difference for the lower bound can be different than for the upper bound. Thus, $\Delta_1$ and $\Delta_2$ can be separately specified. There is a convention to consider efficacy between 80% and 125% of the expected as the equivalence margin, i.e., a margin of one-fifth on either side. In some situations, this may be too wide for clinical decisions. Sample sizes with this threshold are provided by Liu and Chow [1].

Under this procedure, the difference between two proportions may be statistically significant, yet the two could be equivalent in terms of the difference not exceeding the medical tolerance. The reverse can also happen. Two proportions may not be statistically significantly different yet not equivalent.

The main difficulty in equivalence tests is not the statistical procedure but the specification of tolerance $\Delta$. This is primarily a medical decision, where biostatistics plays a secondary role. This limit depends on how much latitude can be given without compromising patient management and what variation is expected due to unforeseen and unknown factors, such as in obtaining exact measurements. By its very nature, this has to be fairly small and trivial so that it does not alter patient management. This is what makes two regimens clinically indistinguishable. Identifying such a limit could be a challenge in some situations and can force one to be inexact. See also our comments on determining the noninferiority margin later in this section.

Typically, tests for establishing equivalence need a larger $n$ than tests for establishing difference. This is because the clinically unimportant $\Delta$ chosen for equivalence is generally much smaller than the target clinically important difference in the usual comparative trials, and the formula also is slightly different.

There are other *if*s and *but*s attached to equivalence: (i) equivalence can be achieved also when both treatments are ineffective—thus, the reference under comparison must have established efficacy; (ii) unless special care is taken, equivalence in efficacy is oblivious of differences in patient compliance, side effects, and losses, which can be greater with one regimen than the other; (iii) if equivalence is found for a particular dose, it may not carry over to the other doses; and (iv) if both regimens have high efficacy, the difference could be masked, and equivalence can be fallacious.

Equivalence trials are affected much more than the usual comparative trials by violation of the **protocol**. Equivalence should be concluded only when both the per-protocol analysis and the **intention-to-treat analysis** reach to the same conclusion.

The following example illustrates equivalence testing in a simple situation. Wolf et al. [2] conducted an equivalence study in the United Kingdom comparing clonidine and midazolam as intravenous sedative agents in critically ill children. They had specified the dosages. The end point was adequate sedation at least 80% of the time. The margin of equivalence was prefixed at ±0.15. The difference in efficacy was 0.04 (clonidine had higher efficacy), and the 95% CI for the difference in efficacy was −0.13 to +0.21. Since the upper limit exceeds the equivalence margin, the two drugs do not provide equivalent sedation. Since the lower limit is within the equivalence range and upper limit higher, the authors took this to suggest that clonidine is noninferior (noninferiority $P$-value = 0.01) and possibly superior (superiority $P$-value = 0.10) to midazolam.

### *Determining Noninferiority Margin*

Noninferiority trials are done to find whether the test regimen can be as good as the one with established efficacy. The procedure for noninferiority testing is essentially the same as for equivalence trials, but the lower limit of the 95% CI should be more than $-\Delta$ in this case, and the upper limit can be any value (experiment I in Figure E.5). Interpret noninferiority with caution. It does not mean that the regimen is not inferior—only that it is not worse by more than the prespecified clinically unimportant margin. That is, any loss of efficacy has no clinical relevance. Such a regimen may have other benefits, such as convenience, cost, and safety. There are other implications too. If the clinically unimportant margin is 2%, a regimen with 86% efficacy is noninferior to one with 88% efficacy, and one with 84% efficacy is noninferior to one with 86% efficacy. Thus, the standard can progressively slip down. Thus, it is important to be judicious in choosing $\Delta$, especially for noninferiority trials.

The noninferiority margin is specified in advance and must always be justified for the specific regimen and disease you are considering. This margin does not depend on the size of the trial nor on the statistical power of the study. It primarily depends on natural variability in the difference between efficacies of the test and reference regimen that can arise from trial to trial. It also depends on what sacrifice in efficacy can be made in exchange for lower cost or fewer side effects that the regimen under test may have. A review of literature or experience might suggest what difference is clinically irrelevant. The following may also help in deciding on the noninferiority margin:

- Survey the practitioners who deal with that disease and find the range they consider unimportant considering other advantages of the regimen under investigation. This will take care of cost, convenience, acceptability, etc.
- If there are many regimens that are interchangeably used at present for treating the same condition, the difference

in their efficacies as reported in the literature can give a fairly good idea of what can be a clinically unimportant margin.
- Consider the natural variation you expect due to unavoidable errors in measurement and other assessments.
- If there is a definite safety advantage, a larger Δ can be chosen.

If the outcome of interest is death, it could be ethically difficult to specify clinically unimportant deaths. You may want to plan a superiority trial in this case, possibly with a relaxed significance level.

We have discussed equivalence and related tests for efficacy, which is measured in terms of proportion or percentage. Most clinical trials will require this kind of equivalence. However, in some rare cases, the outcome can be quantitative, such as the mean reduction in glycated hemoglobin (HbA1C) level by two different regimens. One regimen may be based on drugs and the other based on changes in lifestyle. The basic procedure remains the same, namely, finding the CI for a difference in differences in this case and examining if the lower and upper limits reach the specified threshold for medically unimportant margin. This is mostly based on Gaussian approximation and requires that the differences follow a **Gaussian distribution** at least approximately or that the sample size be large enough for the **central limit theorem** to operate.

In the case of bioequivalence, the parameter under consideration is mostly the **area under the curve**, although this is not a perfect measure. This parameter is quantitative, and the test can be done using the procedure just outlined in the preceding paragraph.

## errors (statistical), *see* measurement errors, Type I error, Type II error

## error sum of squares

Error in the context of error sum of squares (ESS) is the difference between the observed value and the value estimated or **predicted** by any model. The observed value for the *i*th subject is denoted by $y_i$ and the predicted value by $\hat{y}_i$. Thus,

$$\text{Error sum of squares: ESS} = \Sigma_i (y_i - \hat{y}_i)^2.$$

Note again that this is based on differences of the predicted from the observed value, whereas the usual sum of squares is based on the difference from the mean. ESS is a measure of the overall goodness of fit of the model. High ESS indicates worse fit relative to the model with low ESS. Many models, particularly **regression** models, are fitted in a manner such that ESS is the minimum. That the minimum may still be large is another issue. We explain this later in this section with the help of an example.

ESS arises in almost all statistical models. Models, by definition, are simplified versions of the intricate biological process—thus, the predicted value will seldom match exactly with the observed value. Errors will occur. Most models are fitted in a manner such that errors for some subjects are positive, for others negative, and their sum is 0. Thus, their sum fails to quantify the overall error. In place of the sum of their absolute value, it is mathematically easier to work with squares. ESS is the sum of these squares. This is also called **residual sum of squares** since the error $(y_i - \hat{y}_i)$ is also called residual, particularly in the context of the sample values.

ESS is easy to understand with the help of a simple example. Extension to complex models is immediate. Consider a study on total bone mineral density (BMD) in adult males affected by age (years) and serum C-peptide level (nmol/L). Let the **regression equation** be

$$\text{total bone mineral density (g/cm}^2\text{) } \hat{y} = 1.98869 - 0.28652*\text{serum C peptide} - 0.01155*\text{age}. \quad \text{(E.1)}$$

The observed values of total BMD for nine persons is in the first column of Table E.1, their serum C-peptide level is in column 2, and age is in column 3. When these values are substituted in the regression equation, the predicted values of total BMD are in column 4. The difference between the observed and the predicted value is the error, which is in column 5, and the square of this error is in column 6. The sum of these squares is the ESS, which is at the bottom of column 6. In this example, ESS = 0.057. You can see that the ESS will be high when the predicted values are very much different from the observed values. Thus, ESS measures the goodness of fit. However, ESS increases without bound as the number of observations increases—thus, a better measure is the **error variance**, where ESS is divided by its degrees of freedom (df's), which is based on *n*.

ESS is so important in modeling that the entire **least squares method** is based on ESS. This method finds estimates of the parameters (such as the **regression coefficients**) of the model such that the ESS is minimum. Least squares is the most popular method for this purpose. The regression coefficients in Equation E.1 are also based on the least squares method. You may want to try other values of the regression coefficients in Equation E.1 and see for yourself that ESS will increase. However, ESS will decrease if you include more predictors, say, body mass index (BMI) and creatinine level. ESS can also decrease if the form of regression is not restricted to

**TABLE E.1**
**Calculation of Error Sum of Squares**

| Total BMD ($y$) | Serum C-Peptide | Age | Predicted Value ($\hat{y}$) | Error ($y - \hat{y}$) | Error Square |
|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 5 | 6 |
| 1.32 | 0.83 | 32 | 1.3811 | −0.06108 | 0.003731 |
| 1.45 | 0.72 | 45 | 1.2624 | 0.18763 | 0.035205 |
| 1.15 | 0.82 | 56 | 1.1066 | 0.04340 | 0.001884 |
| 1.32 | 0.75 | 37 | 1.3462 | −0.02622 | 0.000687 |
| 0.99 | 0.64 | 63 | 1.0773 | −0.08728 | 0.007618 |
| 1.34 | 0.87 | 38 | 1.3003 | 0.03972 | 0.001578 |
| 1.43 | 0.95 | 26 | 1.4160 | 0.01397 | 0.000195 |
| 1.29 | 0.98 | 31 | 1.3497 | −0.05966 | 0.003559 |
| 1.18 | 0.67 | 49 | 1.2305 | −0.05047 | 0.002547 |
| | | | **Sum** | **0** | **0.057004** |

linear terms and is extended to include curvilinear and nonlinear terms. Such changes can indeed provide a better model in terms of better prediction, although there are two problems: (i) when more predictors or nonlinear terms are included, the parsimony is lost, and the model becomes difficult to understand, and (ii) one has to consider the statistical significance of "improved" prediction by such changes.

ESS is one of the several sums of squares used in statistics. Others are regression sum of squares, between-groups sum of squares, within-groups sum of squares, sum of squares due to a particular predictor, Type III sum of squares, etc. All these are explained under the topic **sum of squares**.

## error variance

Error variance is the **error sum of squares** (ESS) for a statistical model divided by the corresponding **degrees of freedom** (df's). ESS is the sum of squares of differences of model-based **predicted values** from the corresponding observed values. This measures how bad the model is at predicting values close to the observed values or how much of the total variation the model has failed to account for. The smaller the error variance, the better the model for prediction. Another popular name for error variance is the **mean square error (MSE)**.

The square of any real difference can never be negative and will be more than 0 for most values. For this reason, ESS increases without bound as the number of observations increases. ESS for 8 values is always more than or equal to ESS for 7 values, and ESS for 20 values is always at least as much as ESS for 19 values. Thus, a meaningful measure is obtained when it is divided by the number of observations. Since predicted values use the data to estimate the parameters of the model, such as regression coefficients, the number of independent observations is reduced to the df. Thus,

$$\text{error variance} = \frac{\Sigma(y - \hat{y})^2}{df}.$$

This, in fact, is the sample estimate of the error variance. The numerator is the ESS and explained under the topic **error sum of squares**, including the method of computation in a simple case. Two crucial differences between error variance and the usual variance are that (i) the error variance is based on the deviation from the predicted values, whereas the usual variance is based on the deviation from the mean; and (ii) the denominator in the error variance is the df's, and the denominator in the usual (sample) variance is $(n - 1)$. Because of these two differences, error variance varies from model to model, but the usual variance remains the same.

Error variance (or, call it MSE) has some very useful applications. Among others, it is used in constructing the **confidence interval** for the predicted value and for testing of the hypothesis on the **regression coefficients**.

## estimate

In statistics, an estimate is a sample summary value that can be used for an unknown value in the population. The sample mean $\bar{x}$ is an estimate of the population mean $\mu$, and sample standard deviation (SD) $s$ is an estimate of population SD $\sigma$. Simply stated, sample summaries are called statistics (as plural), and population summaries are called **parameters**. Whether these estimates are good or not is a different issue, and we will come to this slightly later in this section.

Two kinds of estimates are used in statistics. First is the point estimate, and second is the interval estimate. **Point estimate** is a single value, whereas **interval estimate** is the range within which the parameter value is likely to lie. The second is popularly called **confidence interval** and is discussed under that topic. We will not discuss it here. This section is restricted to the point estimate.

There is another term, *estimator*. This term is used when we use notations and not values. Although we mentioned that $\bar{x}$ is an estimate of the population mean $\mu$, actually, it is an estimator. *Estimator* is a generic term, whereas *estimate* is specific to a particular sample. When the value is used, an estimator becomes an estimate.

The term *estimate* itself signifies that there is uncertainty around it. Then what is a good estimate? When talking of quality, we turn to an estimator instead of an estimate so that we can talk in general terms.

The most important property of a good estimator is that its average over all possible samples of that kind is the parameter itself. In statistical terms, this average is called the *expected value*—expected in the sense of long-term perspective. For most estimators, the expected value can be theoretically obtained and examined whether or not it is the same as the parameter. When the expected value is the same as the concerned parameter, it is called an **unbiased estimator**, signifying that this has no bias in the long run. For example, $\bar{x}$ is an unbiased estimator of the population mean $\mu$ for almost any distribution provided that the sample is randomly drawn. It does not have to be Gaussian. This also underscores the importance of random sampling. On the other hand, the sample variance $s^2$ is an unbiased estimator of population variance $\sigma^2$ only when the divisor is $(n - 1)$. If the divisor is $n$, it is biased. That is the reason that $(n - 1)$ is used for sample variance. Also, beware that sample SD $s$ is not an unbiased estimator of $\sigma$ but is still accepted because the variance is considered the actual parameter, and not the SD. By the way, the sample median is not an unbiased estimator of population median if the distribution is **skewed**.

Just as a variable has a distribution, so does the estimator. When a large number of samples are drawn, each will provide an estimate, and those values will have a distribution in the sense that some values will be high, some low, and most around the middle in many situations. These values will have a variance and SD, although this SD is now called **standard error (SE)**. The second property of a good estimator (the first is that it is unbiased) is that it has minimum variance among all possible estimators. When there is only one such estimator, it is called unique. The estimator that is unique, is unbiased, and has minimum variance is called the *unique minimum variance unbiased estimator* (UMVUE). The sample mean is the UMVUE of population mean $\mu$ for most populations.

As a medical professional, you really need not worry about such technicalities. Statisticians take care of these properties, such as advising us to use $(n - 1)$ in the denominator for sample variance. The statistical estimators we use in medical and health sciences generally have these properties.

## estimator (unbiased), *see* unbiased estimator

## ethics of clinical trials and medical research

Three cardinal ethical considerations in medical research are that (i) the subject must be made fully aware of his/her role in the research and the possible consequences should be clear to all the parties involved; (ii) all possible steps are taken to safeguard the interest of the subjects; and (iii) expected gains must far outweigh the cost in terms of time, resources, and inconvenience. These, in brief, can be described as follows.

### Informed Consent

All subjects under investigation, even if it is just questioning, should be accurately told about the purpose of the research; what they would be asked; what invasive procedure, if any, would be used, as for taking a blood sample; what the interventions are, if any; what harm can possibly occur to the subjects; what compensations are available; what the safeguards are; what alternatives are available; how much time it will take; what the competency of the investigators is; how the results would help the subject, the researcher, and society; freedom to leave midway in case of follow-up; etc. After this explanation, the subjects are expected to sign the consent if they agree to participate. The consent must be completely voluntary, with no pressure. Consent is required even for surveys because they, too, invade private information and encroach on time. In the case of children and differently abled persons who cannot decide for themselves, the consent can be provided by the guardian or the next of kin. In the case of community studies, the consent can come from the appropriate representatives. For further details, see Ref. [1].

Note that informed consent to participate in medical research is very different from the user agreement signed when you create an account (as on Google or at a bank). That can seldom be called informed consent.

Realize that informed consent can preselect a biased group. In the case of clinical trials, they may be those who are inclined to take risks or those that are hopeless cases. Some patients or some clinicians may have strong preference for a particular therapy, and they may refuse randomization. Some eligible patients may refuse to participate when they are told that they could be randomized to placebo, the existing therapy, or an untested therapy. Some may refuse because it is a trial and not treatment per se. Considerable efforts may be needed to keep such refusals at a minimum.

Informed consent is taken after explaining the researcher's commitments. But how to ensure that the commitments made will actually be translated into actions? Most important of these is safeguarding the interest of the subjects. For this, it is necessary to properly study the possible consequences of the study on the subjects and other participants, such as those handling infectious and hazardous material. Before starting the study, the complete mechanism should be in place to deal with each of such possible consequences. Also, plan to compensate the subjects for their time and inconvenience. In some cases, free laboratory investigations, free checkups, etc. could be adequate, but in some cases, additional financial or other kinds of compensation can be provided. However, the compensation should be proportional to the expected discomfort and not excessive, which could be frowned upon as coercive or as unnecessary inducement.

In the case of clinical trials, ethical issues also exist regarding recruiting and exposing subjects to the control regimen. Control can be either on the existing regimen or on a placebo. Since a new regimen is under trial, that itself is a testimony that the existing regimen is not the ideal. Thus, legitimate questions can be raised about exposing subjects to this regimen. Placebo, in any case, is advised in certain specific situations, as described under the topic **placebo**. For example, placebo rarely can be used on subjects who are sick. Historical controls obviate this problem but are advised for a disease that has a relatively stable natural history and about which the understanding of prognostic aspects has not changed. In surgical trials, sham surgery is sometimes used as a control. This may be unethical many times because it exposes a patient to surgical risks.

It is obligatory for institutions carrying out research on human beings to have a functional *ethics committee* with powers to approve or disapprove a research project depending upon meeting the ethical requirements. This committee has at least some members who do not have stakes in that research. Human rights activists and legal experts also are included. These days, no research results are accepted unless the research has gone through the process of vetting by the institutional ethics committee. The funding agencies also are expected to pass every research project through their own ethics committee. Ethics of research on animals is also expected to be examined by an animal ethics committee.

### Ethical Cautions in Clinical Trials

Some important considerations in the ethics of conducting *a trial* on subjects, some of whom could be sick, can be reiterated as follows:

- Research should be carried out when sufficient reasons exist for that kind of research. This must be preceded by enough groundwork.
- Is the treatment regimen under test reasonably safe?
- Is there sufficient information that the treatment is likely to be beneficial?
- Have the subjects been informed about the potential benefits and possible side effects, and their consent obtained?
- Is it ethical to use a placebo on some subjects who are sick?
- Is it ethical to allocate the subjects randomly among various groups to receive different treatments? Are sufficient precautions built in to take immediate action in case an adverse reaction develops?
- Is it proper for a trial to be blind in any way?

The basic theme of all these considerations is that the science cannot compromise the interest of the individual subjects without taking them into full confidence.

It is now widely realized that researchers have an ethical obligation to make the full results of human research public. Several innovations are quickly occurring to meet this need. The World Health Organization is leading an international effort to promote registration of clinical trials at the time of initiation. The International Committee of Medical Journal Editors (ICMJE) has issued its own registration requirements [2]. These requirements include submission of the complete protocol, which would make it obligatory not just to publish but also not to miss out on any inconvenient findings.

### Biostatistical Ethics for Clinical Trials

Trials have the potential to harm the participants and society since an unproven modality or intervention is used, although the perception may be that it is beneficial. In an eagerness to complete the trial soon after problems surface, the findings may become statistically biased. Then the entire trial is questionable. When undetected inappropriate biostatistical methods are used, erroneous results are accepted, and this can cause irreversible damage to the patients and society. This can cause avoidable deaths of a number of people. An illustration of this is given by Baigent et al. [3]. Surgeons, for example, are trained for years, and even one death by mistake can be fought for millions in compensation. Biostatisticians are not so well trained—many studies are available that show that inappropriate methods have been used, and to save them from damage claims, they take umbrage under the probabilistic nature of the conclusions. Awareness is increasing to make biostatisticians accountable for what they advise or do. The following precautions can be advised.

First and foremost is equipoise. This includes clinical equipoise, patient equipoise, and personal equipoise. All these are

discussed under the topic **equipoise**. This is to ensure that there is no bias in conducting the trial and in the results. As mentioned earlier, the second is proper use of biostatistical methods. The entire effort of conducting a well-designed trial can go waste, including inconvenience to the patients, if the analytical methods are substandard. This, in fact, amounts to misuse of resources. Third is conducting a study on an adequate sample size. A smaller sample could mean wastage of resources since no reliable results can be obtained, and an unduly large sample also means wastage of part of the resources since results with adequate reliability could be obtained with a smaller sample. In the context of clinical trials, ethical issues are attached to interim appraisals also. These appraisals can help to stop the trial early either due to futility or due of availability of convincing results on efficacy early in the trial. Many trials do not follow this, although the trend is positive. Among various adaptations that can be undertaken midway, statistically most relevant is the **reestimation of the sample size** on the basis of the actual effect size found at interim stages. Reestimation requires intricate statistical inputs as this is done to preserve the level of significance and the power. Such adaptation does not cause much of ethical problems; rather, it seems to enhance ethics by keeping a provision to stop the trial early in case convincing evidence of efficacy or of futility appears. Care is taken that such appraisal does not undermine the integrity and validity of the trial.

## etiologic factors, *see also* causal diagrams

Etiologic factors are those that point to the origin. They are generally a set of factors or collection of factors that work together in tandem to produce a particular effect. In the context of health and medicine, they together are the contributors to a particular health outcome and can range from prenatal factors to current stresses in life. It is generally believed that a health condition is a by-product of host–agent–environment interaction. Host factors pertain to the affected person, such as genetic makeup, age, sex, parity, blood group, nutrition status, physiological and biochemical measurements, radiological investigations, and socioeconomic condition. Agent factors pertain to the causes, such as infections, injury, and side effects of regimens. The environment factors work as catalysts, such as water, pollution, traffic, availability of food, distribution mechanisms, health infrastructure, and social infrastructure.

Clearly, each health condition has its own etiologic factors. For example, Bektas-Keyhan et al. [1] found alcohol abuse, family history of cancer, smoking, and chronic mechanical traumas to be significant etiologic factors of tongue cancer, and Guagnozzi and Lucendo [2] discussed iron deficiency, vitamin $B_{12}$, and folic acid deficiencies, along with the effects of proinflammatory cytokines, hemolysis, drug therapies, and myelosuppression, as etiological factors in inflammatory bowel disease.

Identification of etiologic factors sometimes requires sustained investigations on patients in different setups, and statistical methods such as **regression analysis** are used to select a few significant ones out of many suspected factors. This kind of analysis also helps in exactly quantifying the effect on the outcome—what percentage is contributed to the "causation" by each. However, it may not be easy to attribute them as causes unless the much more restricted conditions mentioned for a **cause–effect relationship** are also satisfied. Perhaps the choice of variables to begin with and their correct assessment is the key to the identification of etiologic factors. Nonetheless, the etiology for a health condition may remain obscure till such time that we know enough about suspected contributors. This limitation falls under **epistemic uncertainties**: the etiology is still unknown for some diseases, such as fibromyalgia syndrome [3] and spontaneous coronary artery dissection [4].

## etiologic fraction, *see* attributable risk (AR) fraction

## etiology diagrams, *see* causal diagrams

## Euclidean distance

Euclidean distance is just about the most popular measure of the difference between two observations. In its most simple form, the distance between a value $x$ and a value $y$ is $(x - y)$. If you have two sets each of $K$ values, namely, $(x_1, x_2, \ldots, x_K)$ and $(y_1, y_2, \ldots, y_K)$, the

$$\text{Euclidean distance} = \sqrt{\sum_{k=1}^{K} (x_K - y_K)^2} \ .$$

Note two features for the Euclidean distance. First, it is applicable to quantitative variables only. Second, the number of elements in each set must be the same. If one set has five values and the other set has eight values, Euclidean distance cannot be calculated in this format, although some variations are available. As you can see, this measures how values in one set are different from the values in the other set. This is believed to have been first proposed by Greek mathematician Euclid in the third century BC.

Euclidean distance has a big limitation. It is disproportionately affected by the units of measurement. Consider values of hemoglobin level (g/dL), body mass index (kg/m$^2$), total cholesterol level (mg/dL), and plasma creatinine level (mg/dL). Let

these be (12.4, 23.7, 189, 0.6) for one person and (13.6, 21.8, 211, 0.8) for the second person. The Euclidean distance between these two is $\sqrt{(12.4-13.6)^2+(23.7-21.8)^2+(189-211)^2+(0.6-0.8)^2}$ = $\sqrt{489.09}$ = 22.12. Out of 489.09, as much as 484 (square of 189 – 211) is contributed only by the difference in total cholesterol level. This highlights how one value can severely affect the Euclidean distance. Thus, it is desirable that the values are **standardized** before calculating Euclidean distance. For statistical applications, when a series of values are available for many subjects, standardized values are (value − mean)/SD, where SD is the standard deviation. Each value is standardized using its own mean and SD. When such values are used, we can get what is called *standardized Euclidean distance*. This helps to give equal weight to different values in the set, and the distance becomes scale invariant. Beside internal homogeneity, the standardized distance can be compared even when the units are different. For other variants of Euclidean distance, see Greenacre [1].

Euclidean distance is one of the many measures of distance, and indeed the most popular one. Among others are Mahalanobis distance, which uses a **dispersion matrix** also in computing the distance, and Minkowski distance, which uses the $p$th power and $p$th root. Euclidean distance is its special case for $p = 2$. For these and other distances, see Ref. [2].

All these are for quantitative data. For binary data and ordinal and nominal data, other kinds of measures can be used [2].

## evaluation of health programs/systems

Evaluation of a health program is a systematic examination of its strengths and weaknesses, to identify the factors for its success or failure. The purpose is to find whether it is worth it to continue the program if it is ongoing and in what aspects it needs improvement. Thus, evaluation is not just the assessment of its present status against the initial objectives but, more importantly, the assessment of the contributors to its present status. The process of evaluation is expected to help put the program back on track if derailed and to provide guidance for improving it by developing better strategies. It also ensures that the conclusions are shared and acted upon. This can help in justifying further support and funding. In its comprehensive form, evaluation involves needs assessment, process evaluation, outcome measurement, and impact appraisal. For more details on meaning and steps in evaluation of health programs, see the Centers for Disease Control and Prevention (CDC) document in Ref. [1]. The World Health Organization (WHO) manual also provides the details, although in the context of road safety.

Successful evaluation engages stakeholders, gathers credible data from all parties involved (the recipients, the providers, and the executors), processes the data with immaculate care using the right methods, and reaches evidence-based conclusions. The input and output variables must be properly specified and adequately measured. You can see that the statistical methods play a crucial role in estimating the present status as well as in delineating the exact contribution of various factors.

Most evaluations follow a defined protocol just as research does so that the results obtained are objective, consistent, valid, and comprehensive. Many of these follow the protocol of before–after study, although that has limitations. Some may follow the method of qualitative research. However, the popular saying that "research seeks to prove and evaluation seeks to improve" characteristically defines the difference between research and evaluation. Thus same methods are not necessarily applicable.

## evidence-based medicine

Replacing clinical judgment with solid scientific evidence is considered a major step forward. Evidence-based medicine is the conscientious, explicit, and judicious use of current best **evidence** in making decisions about the care of individual patients [1]. It is the net result of individual clinical experience; best external evidence including **systematic reviews**; expectations of the patient; and the results of interview, examination, and investigations. Evidence-based medicine is the essence of "turning research into practice" as the attempt is to convert the information available from the research to answers relevant for patient welfare. The attempt is to effectively counter eminence-based decisions, which sometimes threaten the science of medicine. For a good critique of evidence-based medicine, see Jenicek [2].

Interest may have slowed down now in the middle of the second decade of the twenty-first century, but evidence-based medicine captured a lot of imaginations in the early 1990s. This paradigm requires medical decisions to be based on critical appraisal of documented risks and benefits of various aspects of the decision-making process, including interventions. Under this paradigm, we strive to critically appraise the best evidence available about diagnostic methods, effectiveness of treatment prognosis, or magnitude and causes of important health problems [3]. The underlying evidence is categorized from level 1, for strong evidence based on properly conducted **randomized controlled trials**, to level 7, for opinions based on experience [see Figure E.6 under the topic **evidence (levels of)**]. Note the low priority accorded to opinion, even if belonging to the experts. Experts, too, are supposed to back up their opinions with evidence under this paradigm. This is for unfiltered evidence. Filtered evidence is provided by systematic reviews, particularly **Cochrane reviews**.

Besides clinical acumen, evidence-based medicine requires expertise in retrieving, collating, and interpreting the evidence available in literature or records. It requires assessment of the validity and reliability of diagnostic procedures, efficacy and safety of medical intervention, and sensitivity–specificity of diagnostic markers. Converting these to delineate risks and benefits of different actions may be even more daunting, particularly since the available evidence may not be the best you would like to have. Developing such skills is not easy, and resources required for instant access to evidence may be woefully inadequate in most medical settings. This might be one reason that the interest in evidence-based medicine has not increased. **Epistemic uncertainties** due to a lack of reliable and valid evidence for many clinical situations may be another bottleneck. Also, evidence that evidence-based medicine works better than opinion-based medicine is slow to surface.

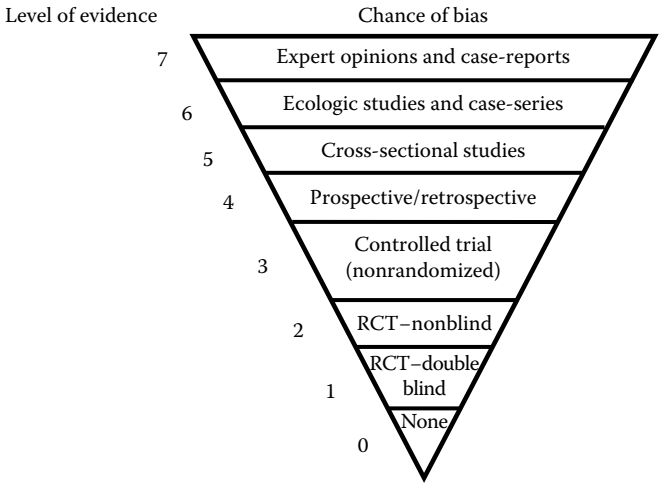

**FIGURE E.6** Level of evidence by different kinds of analytical research studies.

The intent is laudable, but the delivery so far has not been very convincing.

Although evidence is indeed the sheet anchor, patient preferences, expectations, and dilemmas get due consideration. Thus, many times, hard evidence does not translate into medical guidelines. External evidence may not be applicable to a particular patient. Consideration of a patient's needs highlights that evidence is used as a supplement and not as a replacement to clinical judgment. The purpose is to assist in arriving at a decision that is in the best interest of the patient considering the known risks and benefits. The accompanying argument must be convincing and flawless. The key is a balanced approach with the ultimate aim to reduce the areas of uncertainty and identify medical management steps that have the best likelihood of success. A glaring example often cited for non-evidence-based medical advice is that the babies should be laid to sleep on their stomach. It turned out that this carries increased risk of death while asleep. Skepticism about established beliefs is good for science, and these must be challenged as soon as new evidence emerges.

While it is true that no evidence is required for the evident, the practice of evidence-based medicine generally requires several steps, such as transforming your information requirements to framing questions, searching the literature and other evidence, evaluating the evidence and assessing its clinical applicability, and realizing its limitations. Reliability of evidence is judged by statistical methods. Statistical evidence in terms of the tests of hypotheses and confidence intervals is not the core but is ancillary in reaching an evidence-based decision. Also, our discussion is focused on the clinical setting but applies equally well to the community setting.

Among the biostatistical tools for evidence-based medicine, the best known is **decision analysis**. This takes care of the likelihoods at each step as well as the value judgments. The other is **classification and regression trees**. Details of both are provided in this volume under the respective topics. For further details, see Hunink et al. [4].

## evidence (levels of)

Scientific evidence is the objective information on a hypothesis. A large number of unidentified flying objects (UFOs) have been reported as cited, yet the "evidence" of this occurrence is considered weak despite some of these instances providing graphic details that are hard to deny. Physical plausibility requires that stronger evidence must emerge. So paramount is the role of evidence in science. However, various hues exist for evidence too, just as for many other concepts. For example, evidence could be against or in favor of the hypothesis, could be weak or strong, could be voluminous or scanty, and could be biased or unbiased.

In health and medicine, particularly in research, evidence typically is considered strong when obtained from experiments and trials. Properly conducted double-blind **randomized controlled trials** are supposed to provide almost infallible evidence regarding the efficacy of an intervention. This is called unfiltered evidence. Filtered evidence is available from **systematic reviews** that combine several studies of the same nature and come up with a joint conclusion. **Cochrane reviews** are regarded as the best resource for this purpose.

Other unfiltered evidence such as that provided by **observational studies** is relatively weak because of uncontrolled conditions. Expert opinion and case reports provide the poorest evidence among the various kinds of research studies. Level of evidence is fairly well depicted by Figure E.6. This is called a **bias pyramid** as it also depicts the likelihood of bias in different formats of **analytical studies** in health and medicine. This pyramid is an excellent educational tool for explaining how various designs stack up for controlling bias. This helps in fixing ideas and can provide substantial help in assessing the level of evidence available from a published or unpublished analytical study.

The underlying evidence can be categorized from level 1, for strong evidence based on properly conducted randomized controlled trials, to level 5, for opinions based on experience (see Table E.2). Note the low priority accorded to opinion, even if belonging to experts. Experts, too, are supposed to back up their opinions with the evidence under this paradigm. This hierarchy could be important for evidence-based medicine.

The volume of evidence comes from replications either in the same setup or from better-controlled studies in different setups. External evidence, whether supportive or not, is given more credence. Adequacy of evidence is judged by a lack of bias on one hand and statistical significance on the other. The idea is to plug **sources of uncertainty** as much as possible. However, **epistemic uncertainties** may remain, and those continue to pose a challenge to the veracity of evidence. Only when the results convert into actions and these actions yield results as per the expectations can we say that the evidence was adequate.

Beware of *anecdotal evidenc*e. Whereas it can provide important scientific leads, anecdotal evidence can hardly be believed to be the truth. Sometimes, an interesting event may happen in isolation because of other precipitating factors that cannot be generalized. For example, David et al. [1] discussed anecdotal evidence that

**TABLE E.2**
**Hierarchy of Study Designs by Level of Evidence for Cause–Effect Relationship**

| Evidence | Type of Design | Advantages | Disadvantages |
|---|---|---|---|
| Level 1 (best) | Randomized controlled trial (RCT)—double blind or crossover | Able to establish cause–effect and efficacy | Assumes ideal conditions |
| | | Internally valid results | Can be done only for potentially beneficial regimen |
| | | | Difficult to implement |
| | | | Expensive |
| Level 2 | Trial—no control/not randomized/not blinded | Can indicate cause–effect when biases are under control | Cause–effect is only indicated but not established |
| | | Effectiveness under practical conditions can be evaluated | Can be done only for a potentially beneficial regimen |
| | | Relatively easy to do | Outcome assessment can be blurred |
| | Prospective observational study | Establishes sequence of events | Requires a big sample |
| | | Antecedents are adequately assessed | Limited to one antecedent |
| | | Yields incidence | Follow-up can be expensive |
| Level 3 | Retrospective observational study—case–control | Outcome is predefined, so no ambiguity | Antecedent assessment can be blurred |
| | | Quick results obtained | Sequence of events not established |
| | | Small sample can be sufficient | High likelihood of survival and recall bias |
| Level 4 | Cross-sectional study | Appropriate when distinction between outcome and antecedent is not clear | No indication of cause–effect—only relationship |
| | | When done on representative sample, same study can evaluate both sensitivity/specificity and predictivity | |
| Level 5 | Case series and case reports | Help in formulating hypothesis | Many biases can occur |
| | | | Do not reflect cause–effect |

*Note:* Laboratory experiments excluded.

the records created by physicians alone have fewer errors compared with collaborative recording, but their research reveals that this is not necessarily the case. Michels and Frei [2] have talked about widely accepted negative and positive effects of vitamin C that have never been substantiated.

Also, beware of conflicting evidence. One result might lead you to believe that the effect of a regimen is positive and another that it is negative, one saying that the effect is definite and the other saying that it is doubtful. Chin and Ima-Nirwana [3] quoted from the literature to assert that there is conflicting evidence regarding the effect of α-tocopherol on bone. Davis et al. [4] have mentioned studies providing conflicting evidence regarding prognostic factors for morbidity and mortality in patients undergoing acute gastrointestinal surgery.

Statistical evidence is in terms of sample observations. This is used to draw **inference** regarding the population from which this sample has come. Credibility of statistical evidence depends primarily on the sample being representative of the population. This, in turn, depends on sample size and the **sampling techniques** used to draw the sample. Random sampling at least at one stage of the process of selection helps us to legitimately assign probabilities and to be able to use statistical methods. Statistical evidence can fall flat if the observed values are not valid or not reliable, and when inappropriate statistical methods are used for inference.

## exact confidence intervals (CIs), *see also* Clopper–Pearson interval

The usual 95% **confidence interval (CI)** for a parameter θ is obtained as $h \pm 1.96*\text{SE}(h)$, where $h$ is an estimate of θ and SE($h$) stands for **standard error (SE)** of $h$. When SE is not known, as in most practical situations, this CI is $h \pm t_{\upsilon}*\text{SE}(h)$, where $t_{\upsilon}$ is the value of Student $t$ at relevant df = υ and 95% confidence level. This is valid only when the **distribution** (**statistical)** of $h$ is Gaussian and is approximately correct for other distributions under **Gaussian conditions**. When the sample size is small and the underlying distribution far from Gaussian, we need to obtain what are called exact CIs. These are also recommended when the sample values are sparse or heavily tied (many values equal to one another). Exact CIs do not use any approximation and may be desirable in some situations even when Gaussian conditions hold true. Some statistical packages have

a provision to calculate exact CI for odds ratio, difference in proportions, and correlation coefficient, but popular exact CIs are for binomial $\pi$ and median $\tilde{\mu}$. The latter two are described next. Others are too complex for the level of this book. Besides the following methods, exact CIs are sometimes obtained by a **bootstrap** method. This method can be used for any underlying distribution.

### *Exact CI for Binomial $\pi$*

The most glaring example of a situation where exact CI is useful is for the parameter of a binary variable that follows a **binomial distribution**. In this, case the variable $x$ is the count of "successes" out of $n$ independent trials provided that the chance of success in each trial remains same. This chance is denoted by $\pi$ for the population and by $p$ for the sample. For example, $\pi = 0.5$ for the sex of an unborn child being female and $p = 34/80$ if you happen to see $x = 34$ female births out of $n = 80$ in a hospital. Quite often, $\pi$ will not be known, and you would like to find its estimate. If 17% of patients undergoing gastrointestinal surgery die within 7 days of the surgery in a hospital, what is the mortality rate in all such patients? The best point estimate is, of course, the observed $p = 0.17$ but what is the CI?

The exact CI for the binomial $\pi$ is obtained by using the exact binomial distribution in place of the Gaussian approximation. This is given as follows

$$\text{exact } 100*(1-\alpha)\% \text{ CI for } \pi\text{: [IDF.BETA}(\alpha/2,\ x+.5,\ n-x+0.5)]$$
$$[\text{IDF.BETA}(1-\alpha/2,\ x+.5,\ n-x+0.5)],$$

where IDF.BETA stands for inverse distribution function for cumulative binomial probability $\alpha/2$ corresponding to $x$ successes out of $n$ trials for the lower limit of the exact CI and probability $(1 - \alpha/2)$ for the upper limit of the CI. This is obtained by what is called a beta function. Addition of 0.5 to $x$ and $n - x$ is the **continuity correction** since a binomial distribution is a **discrete distribution**, whereas BETA function is based on a **continuous distribution**. The IDF.BETA function is available in most statistical packages, although the name can be different.

For $n = 12$ and $x = 2$, we get $p = 2/12 = 0.1667$ and the exact 95% CI is (0.0363, 0.4362) from this formula, whereas the approximate Gaussian CI is $0.1667 \pm 1.96 \times \sqrt{\frac{2}{12} \times \frac{10}{12} / 12}$, or (0, 0.3776). The lower limit is, in fact, less than 0 by this method but is stated as 0 since no $\pi$ can be negative. The exact interval just mentioned is slightly different from the popular **Clopper–Pearson interval**, which does not use continuity correction. You can see that there is a large difference between approximate Gaussian CI and the exact CI.

A similar exact CI is available for difference in proportions in independent and paired samples and for odds ratio [1].

### *Exact CI for Population Median*

Median is not a summation type of summary value, and a large sample does not help in achieving Gaussianity, as the **central limit theorem** does not generally operate in this setup. When the sample is from a Gaussian distribution, the 95% CI can still be obtained using sample median ± 1.96*SE(median), where SE(median) $\approx 1.253*\sigma/\sqrt{n}$, but not when the sample is from a non-Gaussian distribution, even when the sample size is large. Thus, the exact method for obtaining CI for a median is doubly important.

The exact CI for population median is obtained by using **nonparametric methods**. This would be more exact compared with the Gaussian CI but not fully exact. Nonparametric methods mostly require that the values observed in the sample are arranged in ascending order $X_{[1]}, X_{[2]}, \ldots, X_{[n]}$. The 95% CI for the population median (generally denoted by $\tilde{\mu}$) is in terms of the ordered values $X_{[k]}$ and $X_{[n-k+1]}$, where $k$ is largest integer such that the probability in between these two values is at least $(1 - \alpha)$. This is obtained by using binomial distribution with $\pi = ½$. The values of $k$ for different $n$ are given in Table E.3 for $(1 - \alpha) = 0.95$. With the exception of $n = 17$, the order of values in the table nearly agrees with the following:

$$\text{Lower limit} = \text{Integer part of } \left[\frac{n+1}{2} - 0.9789\sqrt{n}\right]$$

$$\text{Upper limit} = \text{Integer next to } \left[\frac{n+1}{2} + 0.9789\sqrt{n}\right].$$

In fact, these formulas work for $n = 6$ through $n = 283$ except for $n = 17$ and $n = 67$. Thus, you can use these for practically every situation—Gaussian, non-Gaussian, small $n$, and large $n \le 283$.

For illustration, the following are the numbers of diarrheal episodes (of at least 3 days' duration) during a period of 1 year in 12 children of age 1–2 years:

3 7 12 2 4 3 5 8 1 2 3 4

In this case, $\bar{x} = 4.5$ and $s = 3.12$. Of 12 observations, 8 are below the mean, and only 4 are above the mean. This indicates that there is

**TABLE E.3**
**Value of *k* for Different *n*—95% Confidence Interval (CI) for Median is $(X_{[k]}, X_{[n-k+1]})$**

| *n* | *k* | 95% CI |
|---|---|---|
| ≤5 | | 95% CI cannot be computed |
| 6 | 1 | $(X_{[1]}, X_{[6]})$ |
| 7 | 1 | $(X_{[1]}, X_{[7]})$ |
| 8 | 1 | $(X_{[1]}, X_{[8]})$ |
| 9 | 2 | $(X_{[2]}, X_{[8]})$ |
| 10 | 2 | $(X_{[2]}, X_{[9]})$ |
| 11 | 2 | $(X_{[2]}, X_{[10]})$ |
| 12 | 3 | $(X_{[3]}, X_{[10]})$ |
| 13 | 3 | $(X_{[3]}, X_{[11]})$ |
| 14 | 3 | $(X_{[3]}, X_{[12]})$ |
| 15 | 4 | $(X_{[4]}, X_{[12]})$ |
| 16 | 4 | $(X_{[4]}, X_{[13]})$ |
| 17 | 5 | $(X_{[5]}, X_{[13]})$ |
| 18 | 5 | $(X_{[5]}, X_{[14]})$ |
| 19 | 5 | $(X_{[5]}, X_{[15]})$ |
| 20 | 6 | $(X_{[6]}, X_{[15]})$ |
| 21 | 6 | $(X_{[6]}, X_{[16]})$ |
| 22 | 6 | $(X_{[6]}, X_{[17]})$ |
| 23 | 7 | $(X_{[7]}, X_{[17]})$ |
| 24 | 7 | $(X_{[7]}, X_{[18]})$ |
| 25 | 8 | $(X_{[8]}, X_{[18]})$ |
| 26 | 8 | $(X_{[8]}, X_{[19]})$ |
| 27 | 8 | $(X_{[8]}, X_{[20]})$ |
| 28 | 9 | $(X_{[9]}, X_{[20]})$ |
| 29 | 9 | $(X_{[9]}, X_{[21]})$ |
| 30+ | | Order value at $Int\left[\frac{n+1}{2} \pm 0.9789\sqrt{n}\right]$ |

a lack of symmetry, and the distribution is unlikely to be Gaussian. In ascending order, the durations are

$$X_{[1]} = 1, X_{[2]} = 2, X_{[3]} = 2, X_{[4]} = 3, X_{[5]} = 3, X_{[6]} = 3,$$
$$X_{[7]} = 4, X_{[8]} = 4, X_{[9]} = 5, X_{[10]} = 7, X_{[11]} = 8, X_{[12]} = 12.$$

Sample median = $(X_{[6]} + X_{[7]})/2 = (3 + 4)/2 = 3.5$. From Table E.3, for $n = 12$, the 95% CI is $(X_{[3]}, X_{[10]})$, i.e., in this case, (2, 7). There is a rare chance, less than 5%, that the median number of diarrheal episodes in the child population from which this sample was randomly drawn is less than 2 or more than 7.

When proceeding with the Gaussian pattern, the 95% CI for median would be $3.5 \pm 2.201 \times 1.253 \times 3.12/\sqrt{12}$ or (1.0, 6.0), where 2.201 is the value of Student $t$ at 11 degrees of freedom (df's) for 5% probability on either side. This Gaussian CI is not very different in this case but sometimes can be very different.

The CI obtained by the nonparametric method just described has *at least* a 95% confidence level. The ordered observations rarely allow the level to be exactly 95%. In some cases, it could be as high as 98%. If the CI is narrowed, the confidence level becomes less than 95%, and that is not allowed for a 95% CI. Also note that small samples can rarely provide precise information. This is illustrated by our example where the 95% CI for median is fairly wide and not able to provide much useful information.

1. Agresti A. Dealing with discreteness: Making 'exact' confidence intervals for proportions, differences of proportions, and odds ratios more exact. *Statistical Methods Med Res* 2003;12:3–21. http://www.stat.ufl.edu/~aa/articles/agresti_2003.pdf

## exact tests

Exact tests are those statistical tests of hypothesis that produce exact probability of Type I error (***P*-values**). These are in contrast to the approximate tests where the *P*-values are nearly the same as planned but not necessarily exactly the same. For example, the tests based on Gaussian approximation taking advantage of the **central limit theorem** for large $n$ are not exact. A $z$-test is exact only when the underlying distribution is exactly Gaussian. On the other hand, the **Fisher exact test** for association in a $2 \times 2$ table is an exact test for small frequencies irrespective of the underlying distribution. Exact tests generally require more intricate calculations. These tests are especially recommended when the sample size is small and the underlying distribution is far from Gaussian. Sparse data and heavily tied values (many observations have the same value) also require exact tests.

Besides the Fisher exact test and the similar **Barnard test**, this volume describes an exact binomial test for paired data in a $2 \times 2$ table under the topic **McNemar test** (where the approximate chi-square test is also described). This exact test for dichotomous data is the same as the **binomial test** for one-way tables. Among other exact tests are the **Zelen test** for equality of odds ratio in two or more independent samples, exact test for Pearson and Spearman correlations, tests for regression coefficient, tests for Cohen kappa coefficient, and Cochran test for trend in proportions. For example, Schlag [1] has discussed an exact test for correlation and slope parameter in simple linear regression, and Agresti [2] has reviewed algorithms for exact *P*-values for **contingency tables**. Most exact tests are mathematically complex and not described in this volume. Our advice is to fall back on reputed statistical software, choose the right option if available in the software package, and get the results of an exact test where needed. Some software packages provide the option to do **Monte Carlo simulations** to get exact *P*-values. Permutation tests are also considered exact tests.

## examination (health/medical) data/surveys

Medical data obtained after examination of a patient by a competent physician are just about the most reliable data on the condition of a patient. Data from laboratory and radiological investigation may be better in quality, but the data obtained from interviews and observations may not be so reliable. Generally, five kinds of medical examination data are available for processing, as described next. For the purpose of research, special care is taken to conceal the identity of individuals so that their privacy is not compromised.

First are the huge data available in medical records sections of hospitals. Almost any hospital these days maintains these records, particularly for inpatients. Over a period of time, they become enormous and can provide important leads on what kinds of patients are being admitted, what the findings were, how they were treated, and with what results. These records will also have investigation results as well as interview findings. Thus, you can evaluate whether or not the records are internally consistent. If the hospital is not careful, many inconsistencies may be detected, and some records may be incomplete.

Second are the data from examination of people who seek special services, such as insurance, a visa, a job in the armed forces, employment in a factory, etc. Some of these may require periodic examination. Over a period of time, these also can become enormous.

Third are the findings of examination surveys. These are not many, since it is not easy to go out in the community and examine people. The most well known of these are the National Health and Nutrition Examination Surveys periodically carried out in the United States on nationally representative samples [1]. This uses specially equipped mobile vans for examination. The data are automated right from inception and available online for follow-up action.

Fourth are the data generated by you and us through our own research efforts on targeted subjects. Many journals are now moving to a system that archives data on a website for selective access so that the communicated results can be verified. This is being done particularly for clinical trial data.

Fifth are the data available in clinics in private practice. Many clinicians are immaculate in recording and maintaining the medical data of patients, and use these to build up a longitudinal history. This helps them to look at any episode of illness in a holistic manner. But, yes, some clinicians are not that particular and waste the information they collect.

Because of the confidence one can attach to the examination data, and their ready availability to those who have access, these could be important source of information on the health status of the people, albeit for the selected group for which these databases are built up. Whereas a large number of publications appear for research data (fourth type), various useful conclusions are drawn from examination surveys (third type in our list). Singh et al. [2] analyzed data from a large number of health examination surveys across the world to conclude that total cholesterol rose more steeply with age from 30 to 54 years in high-income countries and fasting plasma glucose in Oceania, the Middle East, and the United States. The systolic

blood pressure association with age had no specific income or geographical pattern, although this also increased with age. Phillips et al. [3] analyzed examination data (second type in our list) of Vietnam War veterans and concluded that increased follicular stimulating hormone and luteinizing hormone levels are associated with higher all-cause mortality, though their effect was not independent of one another. Palmer and Stephens [4] compiled data of more than 11 million patients from more than 500 hospitals (first type of data in our list) in the United States and concluded that total costs of opioid intravenous patient-controlled analgesia generally ranged from $647 to $694. These examples illustrate that examination data of all types can be extremely useful for meaningful conclusions.

## exchangeability

Two equally sized random samples from the same population are exchangeable because theoretically, both should lead to the same conclusion. In other words, any one of them can be used without altering the quality of the result. This arises from the property of random sampling. Estimates of the mean, standard deviation, proportion, etc. may differ in value from sample to sample but qualitatively are as good from one random sample as from another random sample, provided that both are of the same size and that they are from the same parent population. Exchangeability also means that the sample values can be rearranged without affecting the result. Whether the sample values are 2, 9, 3, 7, 8, and 5 or in another order 9, 8, 2, 5, 3, and 7, it does not matter. You can see that the values of mean, SD, etc. do not alter when the sequence is altered. Another application of exchangeability is illustrated in calculation of the **correlation coefficient**. The correlation coefficient between $x$ and $y$ is not affected if $x$ is replaced by $y$ and $y$ is replaced by $x$. They can be exchanged for calculation of the correlation coefficient. Exchangeability is not actually exercised; the samples are not physically exchanged—it is just the property of the sample, and we use this property to develop our procedures.

The concept of exchangeability was introduced by Haag in 1924 [1]. This concept helps in several ways, but the most obvious is the **distribution** of the difference of two exchangeable variables. When $x$ and $y$ are exchangeable, $z = x - y$ has the same distribution as the difference $-z = y - x$. This really means that the distribution of $z$ is **symmetric** about 0. This property is used in constructing, for example, a **Wilcoxon signed rank test**. Nonparametric **permutation tests** also use the exchangeable property. Procedures that combine results from several samples such as **meta-analysis** tacitly assume that the samples are exchangeable; otherwise, how can you combine them. Forecasting or prediction of values, such as by **regression**, is also based on the concept of exchangeability since the next values are considered to behave in the same manner as the existing ones we have.

Another useful application of exchangeability is in **multilevel modeling** and **generalized estimating equations**. These methods consider clustered data, such as activity at six sites in the brain (measured by electrodes). They will be correlated. In this situation, you may want to assume that the correlation between values at site 1 and values at site 2 is the same as between site 1 and site 4, or between site 5 and site 6. If so, these correlations are exchangeable and lead to relatively easily interpretable estimates of the parameters of the model. Note that this setup is different from longitudinal data on the same set of subjects, which are clustered and correlated, but it will not be realistic to assume that the correlation between values at time 1 and time 2 is the same as between time 1 and time 4. If so, these correlations are not exchangeable.

## expectation of life and the life table, *see also* life expectancy

The average number of years expected to be lived by individuals in a population is called expectation of life. This can be calculated as expectancy at birth or at any other age. The expectation of life at birth (ELB) can be crudely interpreted as the average age at death. The method used for calculating expectation of life requires building up a life table that summarizes the age at death of a group of people.

### *The Life Table*

The ideal method for computing the expectation of life is by observing age at death of a large cohort (called a **radix**) of live births as long as any individual of the cohort is alive. This may take more than 100 years and thus is impractical unless records for over 100 years are complete. Such a *cohort life table* provides summaries of those born in a particular year, and another cohort will be required for another year. This is also called a *generation life table*.

As a shortcut, a *current life table* is constructed. It assumes that the individuals at different ages are exposed to the *current* risks of mortality. Thus, the current **age-specific death rates** (ASDRs) are used on a presumed radix of, say, 100,000 persons. The average of life so obtained is the number of years a newborn is expected to live *at the current levels of mortality*. This may be characterized as cross-sectional and provides a snapshot of the current mortality experience. This is more useful, as it tells about the existing situation and can be computed immediately, obviating the need to wait for

100 years. The calculations are done as follows. The method is also used in some other applications, as described later in this section.

For constructing a life table, it is desirable to do the computation for each year of age, say at age 46 years, 47 years, etc., but the mortality rates are generally available for age groups, such as 45–49 years. When such groups are used in constructing a life table, it is called an *abridged life table*. When each single year of age is used, it is called a *complete life table*.

Table E.4 is an example of an abridged life table for urban females in a developing country for the block years 2011–2015. An example of a developing country provides an opportunity to discuss some features of a life table that do not appear in a life table constructed for developed countries. An explanation of the notations in this table is as follows:

$n_t$ = length of the age interval beginning with age $t$
$q_t$ = probability of death in the age interval $(t, t + n_t)$ when the person is alive at age $t$

The latter is the deaths occurring during the interval as a proportion of the population at the *start* of the interval $t$. Generally, the population is available for the midpoint of the interval rather than at the start. Thus, $q_t$ is estimated from the ASDR, which is based on the population at midyear. This estimate is

$$q_t = \frac{n_t m_t}{1 + (1 - a_t) n_t m_t},$$

where
$m_t$ is the ASDR for the age interval $(t, t + n_t)$, and
$a_t$ is the average length of life lived per year in that interval by those who die in the interval.

When $a_t = ½$, $q_t = \frac{n_t m_t}{1 + \frac{1}{2} n_t m_t}$. The average $a_t = ½$ in this equation works well when the risk of death is uniform throughout the interval. This is generally true for age intervals 5–10, 10–15, …, 65–70 years but not for the lower and higher age intervals. For example, it is seen that infant deaths are highly concentrated in the neonatal period and not uniformly distributed over the 0–1 interval. In low-mortality areas (developed countries), those who survive the neonatal period tend to live almost as long as anybody else. In this case, for $t = 0$, the convention is to use $a_0 = 0.1$. For high-mortality areas (developing countries), $a_0 = 0.3$ is used. Such a higher value of $a_0$ for developing countries seems paradoxical, but infant deaths in developing countries tend to be relatively more evenly distributed, as the deaths also continue to occur in the postneonatal period. This is rare in developed countries. In age interval 1–5 years, deaths are slightly more in 1–2 years than in 4–5 years. Thus, for $t = 1$, $a_1 = 0.475$ can be used for all areas, although 0.4 is advocated for developed countries. Additional adjustment is needed for the last age interval because its length is not known. Other notations are as follows:

$l_t$ = expected number of persons surviving the age $t$.

The radix is 100,000, which obviously survives age $t = 0$. The survivors at exact age $(t + n_t)$ are

$$l_{t+n_t} = \text{survivors at } t - \text{dying in the interval } (t, t + n_t) = l_t - q_t * l_t.$$

For instance, in Table E.4, expected survivors at age 35 years

$$l_{35} = 89248 - 0.01089 \times 89248 = 88276.$$

$L_t$ = Expected number of person-years lived in the interval $(t, t + n_t)$
$= (n_t/2)(l_t + l_{t+n_t})$

for all age intervals except the first two and the last. The last is denoted by $w$. For these three age intervals, $L_t$ is given in Table E.5. These are the adjustments made in appreciation of the fact that the deaths are not evenly distributed in these three intervals. Thus, these deaths cannot be averaged at the midpoint. Appropriate modifications can

**TABLE E.4**
**Abridged Life Table for Urban Females in a Developing Country for the Block Years 2011–2015**

| Age Interval (Years) | Probability of Death in the Interval | Expected Surviving Age $t$ | Person-Years Lived in the Interval | Person-Years Lived beyond $t$ | Expectation of Life at Age $t$ |
|---|---|---|---|---|---|
| $(t, t + n_t)$ | $q_t$ | $l_t$ | $L_t$ | $T_t$ | $e_t$ |
| 0–1 | 0.04989 | 100000 | 96508 | 6214374 | 62.14 |

| 55–60 | 0.05783 | 81157 | 394052 | 1309808 | 16.14 |
| 60–65 | 0.14623 | 76464 | 354367 | 915756 | 11.98 |
| 65–70 | 0.15759 | 65283 | 300695 | 561389 | 8.60 |
| 70+ | 1.00000 | 54995 | 260694 | 260694 | 4.74 |

**TABLE E.5**
**Estimation of $L_0$, $L_1$, and $L_w$ for Developing and Developed Countries**

| Age Interval (Year) | Developing Country | Developed Country |
|---|---|---|
| 0–1 | $L_0 = 0.3\ l_0 + 0.7\ l_1$ for $a_0 = 0.3$ | $0.1\ l_0 + 0.9\ l_1$ for $a_0 = 0.1$ |
| 1–4 | $L_1 = 1.9\ l_1 + 2.1\ l_5$ for $a_1 = 0.475$ | $1.6\ l_1 + 2.4\ l_5$ for $a_1 = 0.4$ |
| Last | $L_w = l_w * \log_{10} l_w$ | $L_w = l_w / M_w$ |

be made for a specific country according to its pattern of mortality. You may find different adjustments in the literature.

In Table E.4, $L_w = 54995 \times \log(54995) = 260694$.

Now,

$$\begin{aligned} T_t &= \text{number of person-years lived beyond age } t \\ &= L_t + L_{t+n_t} + \cdots + L_w \\ &= L_t + T_{t+n_t} \end{aligned}$$

and $T_w = L_w$. This means that the totaling is done from the bottom upward. Thus, the last two columns are calculated after the calculations for the previous columns are complete. Finally,

$$e_t = \text{expectation of life at age } t$$

$$= \frac{\text{number of person-years lived beyond age } t}{\text{number of persons surviving age } t} = T_t / l_t.$$

Table E.5 is peculiar in the following ways: (i) For most of the intervals, as already stated, it is reasonable to assume that the deaths are uniformly distributed, and an average of half-length is lived by the persons dying in the interval. This, however, is not true for the intervals 0–1 year, 1–4 years, and 70+ years. Such a consideration leads to different values of $L_0$, $L_1$, and $L_w$, as stated in Table E.5 for developing and developed countries. (ii) In this example, the expectation of life at 1 year ($e_1 = 64.39$ years) is more than the ELB ($e_0 = 62.14$ years). Thus, a child of 1 year is expected to live for 64.39 more years, whereas at birth, the expectation is only 62.14 years. This discrepancy is due to the high infant mortality rate (IMR). This is true for many developing countries. (iii) This life table is for the block of a 5-year period, namely, 2011–2015. The annual estimates of ASDRs in many developing countries show considerable fluctuation because these are based on sample studies. The average of a 5-year period is fairly stable and is better in reflecting the trend at the midpoint of the block, which is the year 2013 in this case.

The following comments contain useful information regarding life tables:

- All life tables assume that there are no sudden deaths owing to calamities such as famine, earthquakes, and cyclones, or at most, they are minimal and do not affect the general pattern of mortality.
- Males and females in general have differential mortality patterns, and therefore, separate life tables are drawn for the two sexes. A similar distinction may also be needed between other groupings such as rural–urban, low income–high income, and laborer–executive classes.
- Age-specific mortality may change from year to year. The rates in the year 2012 are not necessarily the same as in the year 1995. Thus, a life table is prepared every year or at least once in 5 years, when the changes become noticeable.
- The ELB is severely affected by infant mortality. This is of particular concern to the developing nations, where IMR is high. For this reason, expectation of life at 1 year (EL1) is sometimes preferred as an indicator of longevity.

The expectation of life is a very popular measure of health on one hand and of socioeconomic development on the other. It is considered a very comprehensive indicator because many aspects of development seem to reflect on the longevity of people. In 2013, it ranged from a low of 46 years in Sierra Leone to a high of 84 years in Japan. It has gone up in China from nearly 40 years in 1950 to nearly 75 years in 2013. Earlier evidence suggests that the maximum ELB attainable is 85 years [1], but it is already considered to have the potential to reach 86 years [2]. Note that this is an *average* attainable by a population. Individuals have been known to live for as long as 125 years.

### *Application of Life Table Method to Other Setups*

As remarked on earlier, the life table is a fairly general method and is used in a wide variety of situations. The method can be used for any **arrival–departure process**, of which the birth–death process is a particular case. The outcome of interest can be remission or recurrence or any such event. Note that one can be flexible with regard to the arrival time, which can vary from subject to subject. In Table E.4, the population was fixed and subject to departures only. But the structure could be that subjects join the group at different chronological points in time, remain in the group for varying periods, and leave at different points in time. Tietze [3] proposed a life table–like method for acceptors of temporary methods of birth control. For example, oral contraceptive users start taking the pill at different points in time, continue taking it for different periods (say from 1 to 36 months), and then stop for a variety of reasons (accidental pregnancy, appearance of side effects, planned pregnancy, etc.). The life table method can be used to assess the expected duration of continuation of intake in this situation. Pharoah and Hollingworth [4] used the life table survival to work out the cost-effectiveness of statins in lowering serum cholesterol concentration in people at varying risk of fatal cardiovascular disease in the United Kingdom. The other important application of the life table method is in studying the pattern of survival of patients with different treatment regimens or with different risk factors. For this, see **survival analysis**.

For other forms of expectation of life such as healthy life expectancy and health-adjusted life expectancy, see the topic **life expectancy (types of)** in this volume.

E

## experimental designs, *see also* experimental studies

An experimental design is the specification of the process under which an experiment is carried out from the beginning to the end. This is the pattern, scheme, or plan to collect evidence. *Experiment* is the term used for a study where human interventions are intentionally introduced to assess their effect. Thus, the experimental design would involve steps such as the type of subjects, what intervention would be introduced, how, when, who, etc., and then how its effect would be evaluated. The former would include the selection of subjects, the size of the sample, and the method of assigning the interventions to the subjects; and the latter would include defining the primary and secondary outcomes and their method of measurement, collection of data, and their processing. You can see that experimental designs have heavy statistical content. All these are specified in advance so that no bias creeps in. Credibility of research findings depends on the ability of the design to provide infallible evidence. It should have all the features listed under the topic **designs of medical studies**, and much more, as described here.

In an expanded form, some include the entire **protocol** under the design. In our opinion, aspects such as setting objectives and review of literature are part of the protocol but not of the design. In addition, there is a limitation too, particularly in the context of health and medicine. Broadly speaking, experiments include clinical and field trials, but it is customary in health and medicine to restrict the term to laboratory experiments that are done on animals or tissues and specimens. We also limit to this restricted usage in the following paragraphs, although many of these steps are directly applicable to clinical and field trials as well.

An experiment must be designed such that it can answer the question of interest clearly and efficiently. It includes features such as what factors to investigate, what levels of various factors are important, how many groups of units are needed, how to allocate groups to various interventions including control, etc. Validity of experimental results is directly affected by the structure of the design and its correct implementation. For this reason, attention to experimental design is extremely important. It is an important component of the study protocol also.

A design is easy to construct and a constructed design is easy to understand when a few terms used in this context are clear. First, a *factor* is an **independent** characteristic whose levels are set by the experiments. In an experiment on mice, mice can be divided by strain (Sprague–Dawley, Wistar, Donru, etc.) to see the effect in different strains, or by their weight into light, moderate, and heavy to study the effect in different weight categories. The factor is strain in the first case and weight category in the second case.

Levels of the factor connote the strata into which a factor is divided. When there are three weight categories of mice as in the preceding paragraph, weight has three levels. The weight levels light, moderate, and heavy have gradient, but that is not necessary. Strains of mice do not have any such gradient, but they are still called levels. If four strains are considered for the experiment, it has four levels. The design will greatly depend on how many levels of various factors need to be studied to adequately answer the research question.

An essential factor in an experiment is the intervention. It has a minimum of two levels—intervention present and intervention absent (control). If there are three dose levels such as 0, 5, and 10 mg/kg of body weight of mice, the intervention has three levels.

The last term in the context of experiment is the **response**. Response is the outcome over which the experimenter has no control. It can be qualitative, such as positive change, no change, and negative change, or can be quantitative, such as time taken in recovery or the magnitude of decrease in the level of pain. Nuances of **qualitative** and **quantitative** characteristics are discussed in a separate, topic but note here that the statistical analysis of data heavily depends on the nature of the response variable.

Haphazard collection of data without a design can be expensive and time-consuming, requiring many runs, and yet not provide the focused conclusions you are looking for. **Confounding** may occur, and that can make it difficult to distinguish the effect of various factors. Thus, design is important. A well-designed experiment can (i) easily spot where the differences exist, (ii) provide more reliable and focused answers to your questions, (iii) reduce cost by avoiding wastage, and (iv) provide insight regarding the patterns that otherwise would be difficult to discern.

### *Choice of Experimental Unit*

An experiment necessarily requires exposing units to an intervention whose effect is unknown. If the effect is known, there is no need to do that experiment. Any investigation originates from uncertainty—the environment in an experiment is doubly uncertain because of the intervention. A suitable design certainly helps in controlling some of these uncertainties, but the choice of experimental units, the method of selection, and the size of the experiment are also important.

As mentioned earlier, an experiment can be carried out on biological material, on animals, and later on human beings. Commonsense ethics dictates that the preference is the lowest biological entities and then progressively to higher ones when the lower entities fail to meet the requirement. Thus, the first efforts must be directed to identify a suitable material such as tissue, cell, blood sample, serum, or body fluid for experiment. For example, for the effect of temperature on erythrocyte sedimentation rate (ESR), the experimental unit for exposure to various temperatures would obviously be blood sample. Material already may be available in a laboratory, and this is collected for the investigation required for the patient but is preserved as a record. In that case, no fresh consent is required. The investigation would be unlinked anonymous, and the person concerned does not come into the picture. See the following example for such an experiment.

The twin organisms *Acinetobacter calcoaceticus–Acinetobacter baumannii* can be isolated and identified from clinical samples such as tracheal tips, wound swabs, urine, and blood. The biofilm forming ability of the complexes can be studied under different conditions, such as different media strengths, room temperatures, and pH values of the medium. Biofilm forming ability is measured by optical density value. This property may be related with the antimicrobial susceptibility pattern and the site of isolation of strains. Thus, the results of such an experiment can help devise coatings or other mechanisms that inhibit the biofilm forming ability of these bacteria in humans.

In some situations, however, caution may be needed in conducting experiments on biological material. A great debate is going on regarding research on stem cells, particularly when they are obtained from human embryos, even though such embryos pile up in some hospitals.

If biological specimens are not able to serve the purpose, the search shifts to a suitable animal model. Sometimes, stage 1 of the experiment is done on biological specimens and stage 2 on an animal model. For live animals, preference is given to small animals such as mice, guinea pigs, and rabbits. Ethics for them is slightly relaxed compared to bigger animals such as monkeys and dogs. The choice is primarily influenced by the suitability of the animal for the disease under consideration and the possibility of the implication of results for humans. Mice are a favorite because they are small, prolific, vertebrate, and mammals, and get diseases such as diabetes and cancer. They may mimic human conditions well. Whatever species and strains are used, they must be sensitive so that the effect, if any can, show up. No group should be in a different room or a different shelf, because the environment may be different.

Before embarking upon animal experimentation, consult the local ethics, which is generally quite well documented. The issues regarding administering harmful substances to animals, their torture, and sometimes sacrifice are more concerned with ethics than statistics. See books such as that by Wolfensohn and Lloyd [1] for animal experimentation ethics and care.

### *Types of Experimental Designs*

The design of experiments is a vast subject, and full books have been written on this topic (see, e.g., Refs. [2,3]). Thus, our description in this volume is necessarily short. We have also divided this into specific topics for different types of designs. See the following topics for details:

**balanced and unbalanced designs**
**completely randomized designs**
**crossover designs**
**randomized block designs**
**one-way designs**
**two-way designs**
**factorial and partially factorial designs**
**repeated measures designs**

Other aspects of the experimental design are selection of subjects and sample size. Laboratory experiments are generally conducted on homogeneous material, and the selection generally is not difficult. The only consideration is whether this material will allow you to proceed with human trials or with trials that improve health care. Because of homogeneous material and controlled conditions in a laboratory, there is no need for a big sample size for medical experiments. Many experiments are done on just about five rats in each group. For further details, see **sample size for medical experiments**. Also see the topic **experimentation (statistical principles of)**, where randomization, replication, and controls are discussed. They apply to clinical trials also.

### *Choosing a Design of Experiment*

The question of interest should be precisely defined so that a design can be devised that can adequately answer that question. An elaborately conceived design will fail if it answers a wrong question. Thus, always devote some time in brooding over the problem and converting it to an investigable question. This can be a big help in devising a right design. A precise question can help to decide what specific factors to investigate, and what and which levels of these factors should be included. Narrow them down to as small a list as you can manage without sacrificing the utility of the experiment. If there is any doubt regarding a particular factor even after consulting the literature and experts, it is better to include it in the experiment and check yourself whether it is helpful in explaining the response. Alternatively, compare the cost of ignoring a factor with the cost of inclusion, and do what looks more efficient.

**TABLE E.6**
**Design Appropriate for Various Experimental Conditions**

| Outcome of Interest | Conditions | Design |
|---|---|---|
| Effect of a stimulus or doses of stimuli in homogenous group of units | No interest in stratified analysis | One way |
| Effect of two or more treatments in the same group of subjects | No carryover effect and no natural periods of remission | Crossover |
| Average outcome for combination of levels of two or more factors, including interaction | All combinations of factor levels are relevant and feasible; interest is in stratified analysis if the units are heterogeneous | Factorial—it can be two way or multiway depending on the number of factors |
| Average outcome for each level of each factor but interactions not of much interest | Some combinations of levels of one or more factors not relevant or not feasible | Partially factorial |
| Trend over time | – | Repeated measures |

Although the appropriate conditions for each design are mentioned at the time of discussing that design, the summary in Table E.6 may be helpful to get an overall view.

## experimental studies, *see also* experimental designs

The essential ingredients of an experiment are a purported manipulable cause and an anticipated effect. The relationship is speculative—if already confirmed, there is no need for an experiment. An experiment is a procedure to verify or falsify a causal relationship by introducing the purported cause and observing the effect. This definition requires that a cause be hypothesized and its possible outcomes visualized in advance. Observations are geared to measure this anticipated outcome. Experiments tend to provide results that transcend time and space, and in many cases beyond the population under study. Observational studies lack such generalization.

Broadly speaking, the occurrence or nonoccurrence of different maternal complications in anemic and nonanemic women is an experiment, albeit performed by nature; so is the occurrence of goiter of various grades in areas with iodine deficiency in water. When a rare or unique opportunity is available to observe or to study the effects of specific events as a result of naturally occurring changes,

it is called a **natural experiment**. For example, the tsunami of 2005 provided a rare opportunity to study the health consequences of such a disaster. John Snow's classical discovery that cholera is a waterborne disease was the outcome of a natural experiment. Snow identified two mixed populations, alike in many important respects but different in the sources of water supply to their households. The large difference in the occurrence of cholera among these two populations gave a clear indication that cholera is a waterborne disease. This was demonstrated in 1854, long before the advent of the bacteriological era. Such natural experiments generally come under the domain of **observational studies**.

This section concerns experiments with *human intervention* for changing the course of events. They are therefore also called **intervention studies**. By exercising control on the extraneous factors that can affect the outcome, experiments are the most direct method to study cause–effect relationships. Experimental evidence is generally more compelling than that available from observational studies. Science is achieved by experiments.

A medical experiment can be carried out in a laboratory, clinic, or community. The subjects for experiment in a clinic or community are human beings, and such an experiment is generally termed a **trial**. A laboratory experiment, on the other hand, may involve inanimate entities, such as physical forces or chemicals: in the context of medicine, laboratory experiments are generally conducted on biological material or animals. Laboratory experiments often provide important clues to the potential of the intervention for formulation into a therapeutic agent. When successful, they pave the way for human studies. Thus, such experiments have a special place in medical studies. Even if you do not plan to conduct an experiment yourself, the details mentioned herein will help you to better understand and interpret the results of experiments conducted by others.

## *Basic Features of Medical Experiments*

Sometimes, passive observation is not enough. You may have tried twisting the tail of your dog to see how he/she reacts. There is always a curiosity to explore the consequences of our actions. The first basic feature of any experiment is manipulation—the stimulus. The natural course of events is sought to be changed by human intervention. Although an experiment can be carried out for an intervention whose mechanism of action is still unknown, cause–effect inference is complete only when a biological explanation is available.

The term *medical experiment* is generally restricted to laboratory experiments performed on animals and other biological specimens. In the context of drug development, an experiment in the laboratory is performed in the first phase to develop a molecule that has desirable biochemical properties—and thus has propensity to be beneficial in promotion of health, prevention of sickness, or treatment of disease—and second to establish that these properties are indeed present. This exercise requires enormous inputs of theoretical knowledge about various compositions. Once such a compound is obtained, its properties are investigated, the compound is modified as needed, and the drug development starts. A formulation is prepared that could ultimately take the shape of a drug. This formulation is first tried on animals that could somewhat simulate human conditions. Trying a new drug on human subjects without establishing its efficacy and safety in laboratory and animal setups is considered unethical, and is almost never allowed.

The second basic feature of scientific experimentation is the meticulous control over the experimental conditions, which helps to draw inference on cause–effect relationships. This is done by following established **experimentation (statistical principles of)** over the units of experiment and the process. The unit of medical experiments is the biologic specimen or animal that receives or does not receive the intervention, and is observed for the anticipated changes.

The third basic feature of an experiment is that it is replicable. Since the experimental conditions are standard and the intervention well defined, it is not difficult for others to repeat the experiment and verify the results if they so want and have resources.

Although these features and other aspects are discussed in this section in the context of experiments on biological samples and animals, they are, by and large, applicable to **clinical trials** as well.

## *Advantages and Limitations of Experiments*

Despite being the most direct method of investigating cause–effect type of relationships, experiments do have some limitations. But first, the advantages.

As already stated, the basic advantage of an experiment is its ability to provide clear evidence of the effect of an intervention when properly designed and performed in standard laboratory conditions. An antecedent–outcome relationship can be obtained if present, although the underlying mechanism may not be clear—in this case, it will not be explained as cause–effect. Thus, a mere opportunity of an experiment generates awareness about complications involved in a medical relationship. An experiment is a good portal to test existing knowledge of the possible **confounders**, and it also opens up the possibility of considering unknown confounders that are in an **epistemic** domain. Thus, an experiment can broaden the possibilities of new explanations and new ways to solve a problem, howsoever limited.

Experiments on biological samples and sometimes on animals can also be done for harmful procedures and substances. Such an opportunity does not exist for human trials. Nobody would deliberately expose people to a pesticide to find how it affects health. This can be done with animals within the perimeter of ethics. Experiments that require sacrifice are also done for small-sized animals. See the following example.

To determine whether continuous or cyclic hormone replacement therapy (HRT) is better, Sun et al. [1] conducted an experiment on 142 Sprague–Dawley rats that were randomly divided into seven groups. Besides normal estrous and ovariectomized controls, the other five groups received treatments imitating clinical regimens with different combinations. The rats were sacrificed, and mitotic index and proliferating cell nuclear antigen (PCNA) were the outcome measures. Note the relevance of animal experimentation in this setup. The results suggest that the continuous regimen was better than the cyclic regimen in postmenopausal HRT.

The most serious limitation of an experiment is that it is carried out in near-ideal conditions that do not exist in the practical world. Thus, the results sometimes are not reproduced when applied in actual conditions. An experiment is necessarily context specific, and generalization is difficult; and even a fully internally valid experimental result may have low **external validity**. Experiments on biological material and animals rarely provide results that can be used on humans, although they do provide evidence one way or another to proceed to human experimentation. Thus, they indeed provide a valid base for clinical trials. A trial on nimodipine enrolled more than 7000 stroke patients, but the review of animal studies did not identify its protective role. Had animal studies properly been reviewed, this waste could have been avoided [2].

As stated earlier, experiments are sometimes done without understanding the biological processes involved in the anticipated relationship between antecedents and the outcome. In that case, the results may remain uninterpretable till such time that the basis of the relationship emerges.

## experimentation (statistical principles of)

The purpose of statistical principles of experimentation is to provide adequate control of the experimental conditions so that the effect of uncertainties is minimized and a valid conclusion can be drawn. These include control group, randomization, and replication. **Blinding** and **matching** are more relevant for human trials, and these are discussed under those topics. Nonstatistical principles include ethics. For ethics in animal experiments, see Monamy [1]. For humans, see the topic **ethics of clinical trials and medical research**, but the following also applies to human trials.

### *Control Group*

An important source of bias in all medical studies is the **Hawthorne effect**. In the context of experiments, this says that the experimental units tend to behave differently when they know that they are being observed. The same occurs when an inert procedure is used that otherwise should not produce any change. To account for this psychological effect, an experiment is almost invariably carried out by including a control group that does not receive the active ingredient of intervention but receives null stimulus or an inert substance such as saline injection or a placebo. All other procedures and maneuvers remain the same. In some experiments, the control group could receive the existing or prevalent intervention while the test group receives the new intervention. For example, in an experiment on a new drug that could relieve pain, the control could receive the existing drug after pain is induced in both groups of mice by some mechanism.

When a separate group of units receives the control regimen, this is called a parallel control group. Some experiments are done without a parallel control group. Measuring tail-flick latency in mice to heat exposure before and after an analgesic does not have a parallel control. Such an experiment is called a before–after study, where each unit serves as its own control. This is also called an uncontrolled trial, but there is a control in this setup as well, though not a separate group.

Control is required in an experiment so that the *net effect* of the intervention can be evaluated. Although the need for a control is not debated, what actually is required for control is a subject of debate. Units in the control group should be equivalent to the experimental units at baseline. Since medical experiments are on biologic material or on animals, this is not as much a restrictive requirement. For an experiment on the shape of red blood cells at various ionic strengths, various groups of cells including the control would be equivalent so long as they belong to the same genetic stock. It is because of such baseline equivalence and standardized conditions in the laboratory that experiments are able to provide compelling evidence of the presence or absence of a cause–effect type of relationship.

### *Randomization*

Randomization is a standard scientific procedure and now almost universally adopted in medical experiments. This envisages random allocation of units to different stimuli, one of which could be null—the control. Even though the units in all groups should be homogenous to begin with, randomization is advocated for providing a chance to the residual or unforeseen heterogeneity to equally divide among various groups. *The test group should be no different than the control group except for the intervention itself.* Then, any difference from control in the outcome can be legitimately attributed fairly to the intervention. The effect of chance, arising from including a limited number of units in the experiment, would be small when such equality is assured. Randomization also tends to remove the possible bias of the investigator in allocating units to different stimuli. In addition, randomization is a necessary ingredient for validity of the statistical methods needed to analyze the data.

Randomization apparently looks easy but actually can be difficult to implement. For example, assigning the even-numbered subjects in sequence to the test group and the odd to the control group has the potential to cause bias because it can be easily tempered. Assigning one group of mice to the test and the other to the control can also be biased because the first group may be of a specific type and the second group of another type. If an experiment is to be conducted on 30 mice with 15 each in the test and the control group, genuine randomization is best achieved by computer-generated random numbers. This applies to human trials also. The website http://www.randomization.com does this very efficiently and tells you which numbers will be in group 1 and which in group 2. If there are more than two groups, random allocation can be done accordingly by using the simple procedure provided at this site.

Randomization tends to work well in the long run but may fail for a particular experiment. The standard practice is to compare the baseline of the two groups after allocation to confirm that they are indeed equivalent with respect to the known factors. In the case of experiments on mice, they can be compared for age, sex, weight, or any other characteristics that might affect the outcome. Statistically, this equivalence can be confidently inferred only when each group has a reasonably large number of units. Also, beware that such equivalence is for averages or proportions in the two groups, and not for one-to-one matching. Average equivalence is enough for most experiments that aim to compare the average outcome in one versus the other group or groups.

### *Replication*

Replicability is a basic feature of any experiment, and it is through replication that considerable confidence is added when the same results are repeatedly obtained under similar conditions. Replication by another worker in a different setting helps to confirm that the results were not dependent on local conditions that were unsuspectingly assisting or hindering the outcome. Such replication also provides evidence for the robustness of the results. Consensus among the researchers and evidence from the experiments make a concoction that could hardly be denied in science.

Sometimes, the investigator himself/herself wants to replicate the experiment to be on firm footing. This is particularly desirable when the response varies widely from subject to subject. The variability across subjects remains unaltered, whereas replication reduces variability in experimental results. If the results between replicates are similar, their reliability naturally increases.

Replication fulfills an important statistical requirement. They help in quantifying the **random error** in the experimental results. Replication is also an effective instrument in reducing the effect of this error. Random errors occur due to imprecision of the process—in methods, measurements, etc., such as in staining, magnification, rotation, counting, and timing; in the environment, such as room temperature, humidity, or minor variation in chemicals and reagents; or due to the varying care adopted by different observers.

Replications help to estimate the effect of random errors on the outcome.

## experiment-wise and comparison-wise error rate

Experiment-wise error rate is the combined probability of **Type I error** when several statistical **tests of significance** are done using the same set of data. On the contrary, the probability of Type I error committed by single test of significance is the comparison-wise error rate. The term *comparison* here is for a test of significance, and the term *experiment* is for a study. In most practical situations, several tests of significance are done in one study, and each test commits its own Type I error—thus, experiment-wise error rate becomes important.

Type I error is erroneously rejecting a null hypothesis when it is true. This is like punishing an innocent person, which can happen because of strong circumstantial evidence. You can see that this is a serious error compared with **Type II error**, which is accepting a false null (not being able to punish the guilty because of a lack of evidence). Type I error occurs because the sample happens to be such as to allow us to reject the null hypothesis. Because of its seriousness, we set the limit of the chance of Type I error to a low level, called **level of significance**, and denoted by $\alpha$. This is generally kept at 5%. When a test of significance is done on a set of data, the actual probability of Type I error is called ***P*-value**. The null is rejected when the *P*-value is less than $\alpha$. When two or more tests are done on the same data, each will have its own *P*-value. The combined *P*-value can become enormous when several tests are done on the same data. This means that the probability of Type I error can become too high. This brings in the concept of experiment-wise error rate. When several tests are done, it is advisable that the experiment-wise error rate is fixed at, say, a 5% level, which is the maximum for the combination of the tests, and the individual tests are done with a much more restricted level of significance to keep the combined error rate within the limit.

As an illustration, if the level of significance for one test is $\alpha$, the combined level of significance for $K$ tests inflates to $[1 - (1 - \alpha)^K]$. This is the experiment-wise error rate for $K$ tests. If $\alpha = 0.05$ and you have done $K = 6$ tests on the same data, the combined level of significance is $[1 - (0.95)^6] = 0.26$. This is the threshold of the probability of Type I error you are allowing in the study results. This high chance of error is not acceptable by any standard. If you want to keep this chance limited to not more than 0.05 for $K = 6$ tests, then $[1 - (1 - \alpha)^6] = 0.05$ gives $\alpha = 0.0085$. Thus, the level of significance of each test should be 0.0085. In a way, this highlights the need to keep the number of statistical tests to minimum. This also is the principle behind **multiple comparisons** in analysis of variance (ANOVA) when each group is compared with each of the others.

## expert systems

Expert systems in medicine are computer aids for diagnosis, treatment, and prognostic assessments of patients. They take signs and symptoms and other patient details as inputs and provide guidance on what possibly could be the ailment with what probability, what investigations to order, how to use these results to modify the diagnosis, what possible treatments can be advised, and what other advice can be given to the patients. They tend to take away the element of forgetting something and help in supplementing the information base. Thus, expert systems partly address **epistemic uncertainties**.

Epistemic uncertainties arise not only because of universal ignorance about some biological processes but also substantially from the failure to judiciously apply the available knowledge. The knowledge base in medicine is enormous, and it is rapidly increasing, making it increasingly difficult for a physician to remember and recall everything about a disease at the time of facing a patient. Errors while prescribing drugs are also not uncommon. Computers have tremendous capacity to store information in a systematic manner and to retrieve it selectively as needed at an instant's notice. They can be programmed to take signs and symptoms as inputs and provide prompts on likely diagnoses along with the probability of each. Also, laboratory, radiological, and other investigations can be suggested that might help in focusing on or excluding a specific diagnosis. Computer alerts on alternative strategies for treatment, as also on the prognostic indicators, can be obtained after a plausible diagnosis is identified. For this, a database is prepared containing various possibilities, and rules are devised to selectively retrieve the information after proper matching (for details, see Giarratano and Riley [1]). All this is put together in a software package and is called an expert system. The success of an expert system largely depends on (i) acquiring wide and valid information; (ii) articulated pooling of this information into a knowledge base; (iii) devising correct rules for diagnosis, treatment, and prognosis; and (iv) adequate programming that uses the knowledge base and rules effectively for practical management. If these are not fulfilled, an expert system may give a false sense of security.

An expert system can have an interface with the introduction of newly emerging diagnostic and treatment strategies so that they are automatically incorporated when approved. It can also warn against the possibility of a drug reaction, allergy, or overdose. The function of this system is no more than a reminder on the basis of the inputs, and the decision always remains with the physician. He/she may or may not agree with the investigation, diagnosis, and treatment suggestions of the expert system.

An appropriately prepared expert system can be of considerable help in reducing errors in medical decisions. The advantage of such an expert system is that it is capable of processing a large amount of information without error as per the program or the knowledge given to it by a group of experts after considerable discussion. An individual clinician may not know as much. As always, there are *if*s and *but*s. Medical care is much more than just diagnosis and treatment. Timely detection and timely intervention, adequate care of the patient, proper advice on prognostic implications, etc., are important ingredients, which may not be properly accounted for by an expert system. A patient's own preferences and perceptions also matter. Deficiency in one can cause a chain reaction and upset the whole process. Simultaneous consideration of all such factors is computationally difficult. Thus, errors can occur with an expert system also.

Expert systems are easy to talk about but are extremely difficult to develop. No expert system can be better than the expertise given to it. This implies that the system should be based on the knowledge of real experts. They are rare, and each expert is a specialist of one's own subdiscipline. To put various experts together to develop a comprehensive computer-based system has turned out to be almost an unachievable ideal. For this reason, efforts remain limited to specific diseases. Some are briefly described in the examples given as follows.

Irrespective of the expertise of the system, it is seldom able to think as critically as a human mind can. It restricts itself to the structured inputs and can incorporate only explicit knowledge. Tacit knowledge rooted in context, experience, social values, etc. resides in the human mind but is hard to deliver to an expert system. An expert system can never be helpful in a situation that has not been thought of at the time of its preparation. Such situations

can always arise because of highly individualistic interactions of various biological and environmental factors. An expert clinician can perceive alternative scenarios for a particular condition and can immediately react to an unforeseen observation, but an expert system cannot. Thus, sufficient caution should be exercised while using any expert system. They must be considered only as an aid and not as a guide. The decision at each step has to be entirely that of the attending clinician; he/she may or may not agree with the suggestion of the expert system. An expert system cannot replace a clinician but can act as a supplementary, perhaps a very useful supplementary, when prepared with a sound knowledge base and correct rules. As of now, the nature of the help of an expert system is the same as that of laboratory and radiological investigations.

For the reasons just explained, not many good expert systems are available. Most of those in the market are of dubious quality and should be used with due care. The purpose of introducing expert systems here is to explain that they can really help in minimizing uncertainties, both in clinical and research setups, when properly developed and judiciously used. But that is a big *if*!

Here are the briefs of some expert systems.

- Differential diagnosis of disorders and diseases manifested by tall stature [2]: For this the diagnostic criteria were developed by a panel of seven experts. In addition, manuals and textbooks, databases, and online resources were also consulted. Linguistic terms were also studied. An interface was made up by a set of slides. The major sources of information were the London Dysmorphology Database and Orphanet. The expert system produces the five most probable diagnostic possibilities and ranks them in order of likelihood depending on the inputs provided to it. These inputs are based on the information provided by the patient and the initial assessments by the clinician.
- Automated visual fields: Feldon et al. [3] used visual fields from eyes with 189 nonarteritic anterior ischemic optic neuropathy to develop a computerized classification system using nonischemic optic neuropathy decompression. The expert panel had six neuro-ophthalmologists, who described definitions for visual field pattern defects using 19 visual fields and several levels of severity representing a range of pattern defect types. The expert panel subsequently used 120 visual fields to revise the definitions. These were converted to a rule-based computerized classification system. The system was subsequently used to categorize visual field defects for an additional 95 nonarteritic anterior ischemic optic neuropathies. Agreement with the experts was not really high, and further modification was done.

The two expert systems cited are not for complex conditions and are focused on specific conditions. Yet, they illustrate the kinds of problems encountered in developing an expert system.

Among others that you may want to review are (i) a decision support system to improve clinicians' interpretation of an abnormal liver function test [4], (ii) a three-stage expert system based on support rector machines for thyroid disease diagnosis [5], and (iii) a medical expert system for the diagnosis of ectopic pregnancy [6].

## explanatory and predictive models

An explanatory model [see **models (statistical)**] is the one that describes an outcome in terms of antecedents—leading to clues on how the outcome may have occurred. In contrast to this is a predictive model, which also applies to antecedent–outcome relationships, but in in this model, the choice of the predictors is not important—the only objective is to be able to predict the outcome. In the case of an explanatory model, the choice of antecedents is important as they reflect the **etiological factors** and not just any associative or correlative factors. Etiological factors can also be called determinants. These are not required for predictive models.

You may notice a considerable overlap in usage of these terms in medical literature. A good explanatory model is always a good predictive model, but a good predictive model is not necessarily a good explanatory model. This is because the antecedents used for prediction may not be etiological factors. Blood pressure level in nonhypertensive subjects can be predicted by age, sex, and socioeconomic status, but also, almost equally well, by fat intake, exercise, and genetic history. Predictive models are not unique—two models with different antecedents can be equally good for prediction. This is not likely to happen with an explanatory model since the antecedents would be those that determine the outcome.

Chi et al. [1] used a model to find that decayed, missing, and filled surfaces (dmfs), not having a dental home, low caregiver education, and living in a nonfluoridated community are the factors for development delays in low-income preschoolers in the United States. If it is an explanatory model, these factors are believed to be the determinants and not just associated factors. On the other hand, Wopken et al. [2] developed a prediction model of tube feeding dependence after curative radiation in head and neck cancer. The most important predictors were weight loss prior to treatment, advanced T-stage, positive N-stage, bilateral neck irradiation, accelerated radiotherapy, and chemoradiation. Some or all of these factors may be determinants, but since this is not investigated, it is prudent to call it a predictive model.

It is difficult to hypothesize factors as determinants and not just correlates. For blood pressure, income could be a good correlate, but it is difficult to say that it determines, even partially, the blood pressure level. For a factor to qualify as a determinant, you may have to go a step ahead of association and establish a **cause–effect relationship**. Thus, the criteria for this kind of relationship should be largely fulfilled. When this is done, the model with these antecedents could be called an explanatory model. Apparently, this kind of exercise was not undertaken by Chi et al., quoted in the preceding paragraph.

Thus, it looks unfair to call it an explanatory model. This illustrates our assertion that there is confusion in the literature about the terms predictive model and explanatory model.

Automatic selection of variables such as by stepwise methods may not be a good strategy for explanatory models because then the effect is adjusted only for those regressors that remain in the model after such statistical selection. However, these methods are generally adequate for predictive models.

## explanatory variables, *see* variables

## exploratory data analysis, *see also* exploratory studies

As the term implies, exploratory analysis is just to explore the data and not to come to any conclusion. The term was first used by John Tukey of Tukey test fame. Finding out the characteristics of a data set is exploratory analysis. This includes calculating the mean and standard deviation (SD), finding out the shape of the frequency **distribution**, locating the **outliers** or wrongly entered values, making two-way or complex tables to explore any relationship, making some graphs for visual exploration, etc. All this comes under the rubrics of **descriptive analysis**. This is an open-ended exercise as anything that comes to mind can be explored. This not only helps to understand the data but also can help in cleaning and filtering the data, thus prepare them for the analysis. Exploratory data analysis sets the tone for the real statistical analysis with methods such as regression, analysis of variance (ANOVA), discriminant analysis, and tests of significance. In some situations, though, exploratory analysis would include so-called advanced analysis with some tentative outcome or tentative method to see if that gives any result worth pursuing.

Most biostatistical methods are valid under certain conditions. For example, ANOVA is valid under **Gaussian conditions**, which means that either the distribution of the outcome variable must be Gaussian or the sample size must be large, and the values must be independent of each other. This requires that the data be first *explored* to confirm that these conditions are fulfilled. **Logistic regression** analysis requires that at least 10 values are available for each cross-section of the independent variable categories. Exploratory data analysis will tell if this really is so in your data. If not, you may want to reduce the number of independent variables or the number of categories. Otherwise, exploratory analysis can also indicate which variables could be appropriate for inclusion among the independents in a regression if that is not already committed in the **protocol**.

There seems to be some confusion in the medical literature between exploratory study and exploratory analysis. For example, Liang and Wu [1] used multinomial logistic regression, probit regression, and structural equation model methods to analyze data on health-related quality of life yet call it exploratory analysis. What they possibly mean is exploratory study as an exploratory analysis rarely can be so intensive. See the topic **exploratory studies** for details.

## exploratory studies

Exploratory studies are those preliminary studies that are done to explore whether or not a particular topic is worth studying with a full-scale study. Such studies, by their very nature, are generally carried out on a relatively small sample, may not have a perfectly valid **design**, and may also have restricted coverage in terms of variables. Concepts such as statistical **power** and the statistical **significance** of the differences and relationships do not strictly apply to exploratory studies. An exploratory study can examine multiple end points to be able to choose a few for the final study and can also be geared to provide information on what type of subjects should be included, what exact intervention (if any) can be studied, and what type of measurements and by whom would be appropriate. In summary, this kind of study provides a basis for planning and carrying out the final study on a much firmer footing. In some situations, a large-scale study on a new concept is also called exploratory when the objective is to find the proof of concept so that this concept can be pursued further by other similar studies by different workers at different locations.

Many studies in medical journals are termed exploratory because of their own limitations. Muratori et al. [1] called their study exploratory when they studied outcome in 70 children with autism who received usual treatment probably because the sample size was small. Wan et al. [2] also called their study exploratory while studying oral mucosal colonization of human gastric *Helicobacter pylori* in 60 mice since the objective was to explore whether buccal mucosa in mice could serve as a workable animal model for further research on this topic. Some researchers use the term *exploratory* for their study as an abundant caution lest their results be challenged. This is just to express a lack of confidence in the results either because the study was not properly done or because the idea put forth is too radical to be accepted right away. Thus, the term can have varied usage.

## exponential curve/function, *see also* exponential distribution

Exponent is the mathematical term for the power of a number. For example, in $3^6$, 6 is the exponent. As you can see, the function of an exponent is to multiply. Thus, the series 2, 4, 8, 16 is exponential since each term is twice its previous term, whereas the series 2, 4, 6, 8 is **linear** since each term is two more than the previous. If the exponent is more than 1, the numbers rapidly rise—$20^2 = 400$ and $30^2 = 900$. If the exponent is less than 1, they gradually fall. For example, $64^{0.5} = 8$, and $81^{0.5} = 9$. The difference between 64 and 81 is large, but the difference between 8 and 9 is small because the exponent is less than 1.

In health and medicine, we will be mostly concerned with outcomes that have exponents greater than 1. Bacterial growth in the absence of any intervention is exponential. It only means that the number of bacteria multiplies and does not increase additively. The curve depicting this phenomenon is called an exponential curve, and the equation describing this is called an exponential function or exponential model. An exponential curve will have a slow rise in the beginning and steep rise later (Figure E.7). Thus, it shows accelerated growth. Scott et al. [1] reported that the volume of fetal cerebellum increased approximately sevenfold from 20 to 31 gestational weeks, and the exponential curve is a better fit than a line. This may not be as steep as shown in Figure E.7, but for example, intrauterine pressure follows nearly the same steep rise with gestational age [2] as shown in in this figure. Consider Ebola virus cases in the world, which have exponentially increased from 9 in March 2014 to 14,500 in November 2014. These are the reported cases, and the unreported ones may be much higher. The plot of the number of cases with time will be similar to Figure E.7.

Simply stated, the exponential function has the following form.

$$\text{Exponential function: } y = ae^{bx},$$

where $e$ stands for the Naperian base and $x > 0$. This base is the usual mathematical constant used in exponential functions since it helps to use natural logarithms. In terms of logarithm, this function is $\ln(y) = \ln(a) + bx$. The equation now becomes additive and not multiplicative. Logarithmic transformation converts exponential function into a linear equation. The shape and location of the exponential curve, for example, whether it will rise steeply or slowly, will depend on the values of $a$ and $b$. If the rise in the value is rapid and steep, the value of $b$ will be large. The value of $b$ is positive for exponential growth and negative for exponential decay, where decay means declining trend. These parameters may or may not have biological meaning depending on the application. For example, for the area of opacity of cataract eye lenses (in terms of pixels) at time $t$ (days), $O_t$ can be expressed as [3]

$$O_t = O_m(1 - e^{-k(1-t)}),$$

where $O_m$ is the opaque area at maturity. The constant $k$ can now be interpreted as the opacification rate. This equation has been used to study the effect of particular eye drops on opacification rate. Tumor growth in cancer is frequently studied using exponential growth models. For one such study for tumors in lung cancer, see Li et al. [4].

## exponential distribution, *see also* exponential curve/function

A quantitative variable $x$ is said to follow an exponential distribution when its chances of occurrence show a sharp rise or sharp fall with the increasing value of $x$. For example, the probability of death after the age of 70 years steeply rises as age increases. This probability never comes down. Thus, the age at death after 70 years follows nearly an exponential distribution. One of the possible shapes of the distribution is the same as that of an **exponential curve**—the difference being that the vertical axis in the case of **distribution** is the **probability density**, which measures the proportion of subjects, whereas it can be any variable in the case of an exponential curve. The area under any statistical distribution is 1, so is with exponential distribution. As a medical professional, you may never need the following, but just for information, note that

$$\text{exponential distribution: } f(x) = \lambda e^{-\lambda(x-\alpha)},\ \lambda > 0, \text{ and } x \geq \alpha.$$

In this equation, the minimum value of $x$ is denoted by $\alpha$. In our example on age at death, $\alpha = 70$ years. The value of $\lambda$ determines the steepness of the rise in probability of the event (death in our example) with $x$ (age in our example). When $\alpha = 0$, the mean of this distribution is $1/\lambda$, and the standard deviation is also $1/\lambda$. Thus, this essentially is a single-parameter distribution, namely, the average number of events per unit interval. In the case of age at death for persons alive at age 70 years, the distribution takes a slightly different shape (Figure E.8a). A special feature of an exponential distribution is that the probability density at subsequent values of $x$ multiplies with a constant no matter what the preceding value is.

Exponential distribution is frequently used for the length of intervals between two consecutive random events, such as admission and discharge from a hospital, two episodes of diarrhea or two episodes of angina, and two births. Many survival durations also follow an exponential distribution. The probability of surviving for long, particularly after a terminal disease such as cancer, steeply declines as the duration increases and the shape reverses (Figure E.8b). Both are exponential. One is an exponential rise, and the other is an exponential fall. Leroy et al. [1] explored exponential distribution, among others, for time to onset of adverse drug reactions from treatment exposure. Closas et al. [2] observed that the incidence of influenza in nonepidemic periods follows an exponential distribution.

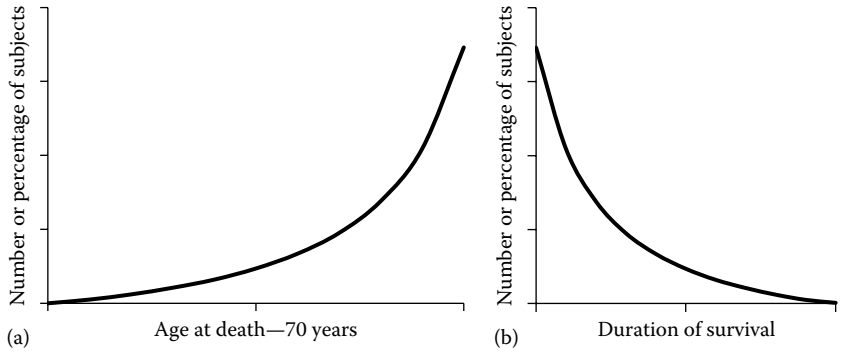

**FIGURE E.8** (a) Exponential distribution of age at death for the persons alive at age 70 years; (b) exponential distribution of survival duration after a terminal disease.

When a variable follows an exponential distribution, you cannot use **Gaussian distribution**–based methods such as Student *t* and analysis of variance. Log transformation of data may help in such cases.

## extrapolation, *see also* interpolation

Extrapolation is the scientific estimation of a value outside the range of the actually observed values. In the context of statistics, a model such as a **regression equation** is constructed on the basis of the observed values, and this model is used to extrapolate unobserved values. It is presumed that the unobserved values outside the range of observed values will follow the same pattern as the observed values, although this can be a big *if* in some situations. In the case of time series, extrapolation refers to the prediction of the future values on the basis of the trend of the past values. Extrapolation requires the following precautions.

- The model must be good to begin with in the sense that it describes the dependent variable with reasonable **validity** and **reliability**.
- Extrapolation can be done for values slightly outside the range of observed values because values grossly outside may not follow the same pattern—this would not be known, since these values have not been studied.
- Keep in mind that it is just an estimated value and is subject to errors and uncertainties.

Wodarz et al. [1] have discussed how extrapolating the risk of low-dose radiation from a model on high doses can be wrong because the cellular response can be very different at low doses. Thus, there are hazards in extrapolation, and it cannot be indiscriminately done. Nagao [2] studied the relationship between Kawasaki disease and decrease in **total fertility rate** (TFR) in a **time series** from 1979 to 2011 in Japan and concluded by extrapolation that this disease emerged in the 1960s because TFR dramatically decreased in the 1940s through the 1950s. That sounds too far back but may still be true if the trend was the same at that time also.

Extrapolation is kind of the reverse of **interpolation**, where unobserved values within the range of observed values are estimated.

**FIGURE E.9** (a) Actual points; (b) eyeball fit; (c) second-degree polynomial fit.

## eyeball fit

The term *eyeball fit* is generally used for a graphical trend where the equation is not obtained but the **scatter plot** is used to guess the pattern of the trend using our own sensory expertise. If this expertise is sufficiently good, the eyeball fit may not be much different from the trend obtained through statistical equations. In some situations, particularly when graphical representation serves the purpose, the eyeball fit may be even better than the equation-based trend. In many situations, eyeball fit provides an insight into what equation we should be looking for. This is quick and does not require any computation. However, this is not science and is not easily acceptable.

Consider the data points in Figure E.9. The eyeball fit in Figure E.9b has a jug-handle shape with a flat top, whereas the second-degree polynomial curve in Figure E.9c does not have a jug-handle bend, and the peak is relatively sharp. Statistically, there is nothing wrong with the polynomial fit as the square of the **multiple correlation coefficient** $R^2 = 0.928$ obtained for this curve is extremely good and gives confidence in the curve. The number of points in this example is too small for any firm conclusion, but the bend in the jug handle and the flat top may be real and better for explaining the biological phenomenon under study. If knowledge and gut feeling so dictate, an equation that incorporates these two features can be obtained. If such an equation seems difficult, the eyeball fit can still be used to graphically explain how the bend and the flatter peak could be real. This is the advantage of the eyeball fit. This can be explored particularly in cases where the right equation is difficult to conceive and obtain.

## factor analysis, *see also* factor scores

Factor analysis is a statistical method to identify unobservable underlying factors that possibly lie behind the observed values of several correlated **continuous variables**. The term *factor analysis* was coined by Charles Spearman in 1904, and the method is also generally ascribed to him [1]. How do you assess the health of a child? You will see his/her height, weight, skinfold, eyes, nails, etc. Health is not directly observable but is measured through a host of such indirect variables. Conversely, you may have a variety of variables, and you want to know what factors are underlying those variables to cause those values. There are situations where the observed variables can be considered to be made up of a small number of unobservable, sometimes abstract, factors. These factors can also be considered as **constructs** that are latent in the data. A latent construct can be measured indirectly by determining its influence on responses on measured variables. The purpose of factor analysis is to unravel these factors.

Health in its comprehensive form (physical, social, mental, and spiritual) can be measured in adults by a host of variables, such as the kind and severity of medical complaints if any, obesity, lung functions, smoking, sexual behavior, marital relations, job satisfaction, unmet aspirations, income, and education. It is not apparent how much of, say, job satisfaction is ascribable to physical health; how much to each of the other components (social, mental, and spiritual) of health; and how much is the remainder that cannot be assigned to any of these components. For a variable such as obesity, the physical component may be dominant, and for a variable such as education, the social component may be dominant. The technique of exploratory factor analysis may sometimes be used to identify such underlying factors.

### *Exploratory Factor Analysis*

The theory of exploratory factor analysis presumes that the variables being studied share some unknown number of common factors that give rise to **correlations** between them. Nothing is considered known about the nature of the relationships. The strength of the explanatory factor analysis method is that it identifies relatively few underlying factors. The variables actually measured are considered as manifestations of these factors, so the observed variables are now better understood as **surface attributes**. On the other hand, the underlying factors are the **internal attributes**. The primary objective of factor analysis is to determine the number and nature of the underlying internal attributes, and the pattern of their influence on the surface attributes. In a successful factor analysis, a few factors would adequately represent relationships among a relatively large number of variables. These factors can then be used subsequently for other inferential purposes.

Factor analysis is easy to understand through the **principal components** approach. In this approach, the first linear component is discovered that is able to account for maximum variation among observed variables. The second linear component is obtained from the remaining variation, and so on. The first principal component may be able to take care of 62% of total variation, the second 23%, and the third only 8%.

Consider two variables—height and weight—whose essence is captured by body mass index (BMI) for many applications. This combined variable provides most of the information contained in two different but correlated variables. BMI is not a linear combination of height and weight, but there are situations where most of the information contained in two or more variables can be captured by one linear combination of them. Similarly, when really successful in capturing the essence of several variables, principal components can reduce the number of variables, called *data reduction*—or more appropriately, *dimensionality reduction*.

### *Statistical Procedure for Factor Analysis*

The statistical procedure of factor analysis is to obtain each observed variable as a combination of a few unobservable factors, i.e.,

observed value of a variable = linear combination of factors + error.

If the observed variables are $x_1, x_2, \ldots, x_K$, the factor analysis seeks the following:

$$\left.\begin{aligned} x_1 &= a_{11}F_1 + a_{12}F_2 + \cdots + a_{1M}F_M + U_1, \\ x_2 &= a_{21}F_1 + a_{22}F_2 + \cdots + a_{2M}F_M + U_2, \\ &\vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \\ &\vdots \quad \vdots \quad \vdots \quad \vdots \quad \vdots \\ x_K &= a_{K1}F_1 + a_{K2}F_2 + \cdots + a_{KM}F_M + U_K, \end{aligned}\right\}$$

where $F_1, F_2, \ldots, F_M$ are the $M$ unobservable factors common to $x_k$s, and $U_k$s ($k = 1, 2, \ldots, K$) are called *unique factors*. A schematic representation is in Figure F.1, where the number of $x$ variables is six

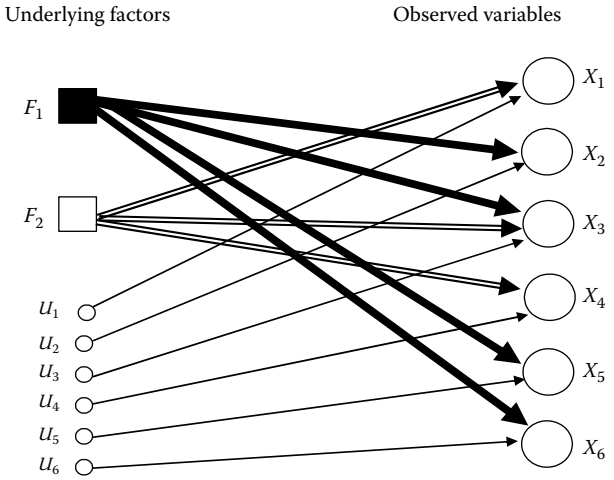

**FIGURE F.1** Schematic representation of factors.

but the number of factors is two. Unique factors represent the part that remains unexplained by the factors.

The coefficients $a_{km}$ ($k$ = 1, 2, …, $K$; $m$ = 1, 2, …, $M$; $M \ll K$) are estimated by the factor analysis procedure. These coefficients are called **factor loadings** and measure the importance of the factor $F_m$ in the variable $x_k$ on a scale of 0 to 1. When a loading is small, say less than 0.20, the corresponding factor is dropped from the previous equation. Thus, different variables may contain different sets of factors. Some factors would overlap and would be present in two or more variables. In Figure F.1, factor $F_1$ is common to $x_2$, $x_3$, $x_5$, and $x_6$, and $F_2$ is common to $x_1$, $x_3$, and $x_4$. Each $x$ has its own specific $U$. See Streiner and Norman [2] for more details.

The aforementioned set of equations mentioned differs from the usual **multiple regression** equations because the $F_m$s are not single independent variables. Instead, they are labels for combinations of variables that characterize these constructs. They are obtained in such a manner that they are uncorrelated with one another. The statistical method of principal components is generally used for this purpose. For details, see Kline [3]. Statistical software easily provides an output but might ask you to specify different aspects of the methodology. You should not undertake this exercise yourself unless the intricacies are clear. Do not hesitate to obtain the help of a biostatistician when needed. However, the following basic steps may clarify the steps required for this exercise.

Step 1. Obtain the correlation matrix of all $x$ variables you have observed. This is just a square arrangement of the correlation of these variables with one another.

Step 2. Check that correlations are sufficiently high among subsets of variables. You can use the **Bartlett test** of sphericity to test the null hypothesis that the correlation matrix is an identity. Identity means that the diagonal elements are 1 (correlation of $x_k$ with $x_k$ is always 1) and the off-diagonal elements are 0 (correlation of $x_k$ with any other $x$ is 0 for all $k$). You can expect good results from factor analysis when the Bartlett test is statistically significant.

Step 3. Check that the variables indeed share some common factors that are probably giving rise to these correlations. This can be checked as follows for linear correlations: **Multiple correlation** of each $x_k$ with other $x$'s should be high. The **partial correlations**, which are correlations between two variables after the effect of others is adjusted, should be low.

Two tests to find whether the data set you are examining is suitable for factor analysis are the **Kaiser–Meyer–Olkin** (KMO) [4] measure and the Bartlett test of sphericity. We have already mentioned the Bartlett test. The KMO measure is based on partial correlation and interpreted as follows: <0.5, unacceptable; 0.51–0.60, poor; 0.61–0.70, mediocre; 0.71–0.80, middling; 0.81–0.90, good; 0.91–1.00, excellent.

Step 4. Once convinced from steps 1–3 that an appropriate setup to try factor analysis exists, enter the correlation matrix into factor analysis software. The output will give you factor loadings and a host of other information that can help to identify the factors.

## Features of a Successful Factor Analysis

There are some steps in factor analysis that are not considered fully scientific. Despite this, the technique is popular with social scientists and is now making inroads into medical sciences as well. Beware that the technique sometimes fails to identify meaningful factors. Its success is assessed on the basis of the following considerations.

One of the steps in factor analysis is breaking down the total variation among variables into variations accounted for by different factors. The analysis is considered successful when only a few factors are able to account for a large part of the total variation, say more than 70%. A criterion for successful factor analysis is to be able to find some factors with very high loadings (close to ±1) while the others have very low loadings (close to 0). Also, the factors should largely be distinct or at least nonoverlapping. To achieve this, the technique of rotation of axes is sometimes adopted. Besides the popular **varimax rotation**, other rotations are quartimax and equamax. The rotation sometimes helps to extract factors with selectively high loadings and thus to obtain interpretable factors.

Perhaps the most important decision in factor analysis is the choice of the number of factors to be extracted. The statistical procedure theoretically is such that as many factors can be extracted as the number of variables. But only a few factors would be important. This importance is generally assessed by the *eigenvalues* for the factors. Eigenvalues depend on the correlation structure among the variables. Factors with eigenvalues greater than 1.0 can be considered important because they explain more variance than is explained by a single variable. When common factors are indeed present, only a few factors are likely to have this property. If the number of factors so identified is more than you think it should be, the threshold of the eigenvalue can be raised from 1.0 to 1.5 or any other suitable number. The other alternative is a **scree plot** of eigenvalues. The points where this plot levels off can be regarded as indicative of the number of factors.

Thanakwang et al. [5] carried out factor analysis of a 36-item scale for active ageing in Thai adults. The KMO value was 0.933, and Bartlett's test of sphericity was also highly significant. Both indicated the appropriateness of the data for further factor analysis. Seven factors with eigenvalues greater than 1 were identified. These accounted for 68.53% of the total variance.

## Confirmatory Factor Analysis

The method described in the preceding paragraphs is mostly for exploratory purposes. This method does not assume any preconceived structure of the factors. If the objective is to assess whether a set of variables conforms to a *known* structure of the factors, then confirmatory factor analysis is needed. This requires that the model is fit to the data and its adequacy is evaluated. Confirmatory factor analysis requires a much bigger sample size and is much more difficult than exploratory factor analysis. This can be done as a part of **structural equation modeling** [6].

For more details of both types of factor analysis, see O'Rourke and Hatcher [7].

## factorial and partially factorial designs

A design of an experiment that includes combinations of the levels of two or more factors under experiment that can be assigned to any unit of the study is called a factorial design. The outcome under study must be quantitative, and the two factors must be amenable to simultaneous administration. When all possible combinations of the levels of various factors are included in an experiment, it is called *fully* factorial. The *fully factorial design* answers the following question: what *combination* of levels of various factors is the most effective? Statistically, a factorial design has two or more categorical independent variable and a single quantitative dependent variable.

Figure F.2a represents a full-factorial design of 3 factors, each at 3 levels. There are a total of $3^3 = 27$ combinations, such as (0, 0, 0), (0, 0, 1), (0, 0, 2), etc., where 0, 1, and 2 are the *levels of the factors*. Note that no combination is left out. If each combination is to be given to 10 subjects each, this design will require 270 subjects. In the case of an unbalanced design, the number of subjects in different groups can vary (Figure F.2b). This figure shows 3 × 2 factorial designs where one factor has 3 levels and the other has 2 levels. The factor levels are considered nominal in a factorial design so that the distance between them is the same, a feature that could be absent if any of them is quantitative with or without categories.

A factorial design is useful in the study of potential **interactions**. This design is easy to implement when prior knowledge is available regarding the levels of various factors that should be simultaneously considered. The 3 × 2 experiment described in Table F.1 is a factorial experiment. In this experiment, factor 1 is the type of hormone replacement therapy (HRT), which has three levels, and factor 2 is the estrous status of the mice, which has two levels. All six possible combinations are included so that the design is fully factorial. This assumes that the estrous status of the mouse can be determined by the experimenter—HRT in any case can be randomly assigned.

Note for Table F.1 that mice are allocated to each level of each factor so that there are six groups. In this example, each group has the same number of mice ($n = 10$), but that is not a requirement. It is just that equal numbers make the analysis and interpretation a lot easier. When the numbers of subjects in different groups are unequal, the design becomes **unbalanced**.

**TABLE F.1**
**A Two-Way Factorial Design (3 × 2) with 10 Mice in Each Group (Number of Mice in Each Group Shown after Random Allocation)**

| | Factor 2 | |
|---|---|---|
| **Factor 1** | **Normal Estrous** | **Ovariectomized** |
| Continuous HRT | 3, 7, 8, 14, 18, 30, 31, 37, 48, 52 | 1, 5, 10, 11, 15, 20, 27, 42, 43, 49 |
| Cyclic HRT | 4, 9, 13, 21, 32, 39, 44, 47, 50, 57 | 6, 17, 26, 33, 34, 40, 51, 56, 58, 59 |
| No HRT (control) | 12, 22, 23, 25, 36, 41, 45, 53, 55, 60 | 2, 16, 19, 24, 28, 29, 35, 38, 46, 54 |

An experiment with $K$ factors, each with $C$ levels, is called a $C^K$ factorial experiment. A simpler format is $K$ factors at two levels each—a $2^K$ factorial experiment. See the following example for a $3^2$ experiment.

In the case of potentially therapeutic or anesthetic agents, it is common to try to evaluate combinations of various dosages of two or more formulations. In an experiment on anesthetic drug A (e.g., xylocaine), dosages under experiment could be 0 (none), 1, and 2 mg, and for drug B (e.g., bupivacaine), dosages could be 0, 0.5, and 1 mg for adult rabbits. The possible combinations of factor levels in this experiment are given in Table F.2.

All combinations are included in a fully factorial experiment, relevant or not. This can be implemented only when each level of one factor can be administered with each level of the other factors. In the case of drugs, for example, it is possible that a high dose of one drug cannot be given with a high dose of the other drug. In this case, a fully factorial experiment cannot be done. See the following.

**TABLE F.2**
**Combinations in a $3^2$ Factorial Experiment**

| | Group | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | **1** | **2** | **3** | **4** | **5** | **6** | **7** | **8** | **9** |
| Dosage of drug A (mg) | 0 | 0 | 0 | 1 | 1 | 1 | 2 | 2 | 2 |
| Dosage of drug B (mg) | 0 | 0.5 | 1 | 0 | 0.5 | 1 | 0 | 0.5 | 1 |

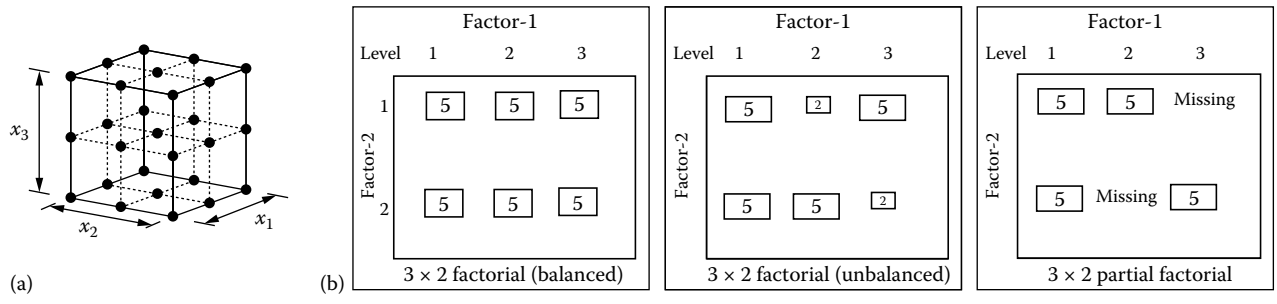

**FIGURE F.2** (a) Pictorial representation of full-factorial design of 3 factors each at 3 levels (a 3 × 3 × 3 design). (b) Factorial (balanced and unbalanced) and partially factorial designs.

### Partially Factorial Designs

A factorial design is called incomplete when one or more combinations of the levels of factors are missing. In the experiment described in Table F.1, one might be tempted to study control mice (no HRT) only for normal estrous and not for ovariectomized mice: if so, the experiment is no longer fully factorial. If there is prior information that 2 mg of drug A in combination with 1 mg of drug B in our example in Table F.2 is harmful, this combination will be unethical and omitted. Such designs are called *partially factorial*. This is also called a *quasi-factorial design*, sometimes *fractional factorial design*. This also is used in setups where the total number of combinations becomes too large to handle. Suppose you have 4 levels of factor 1, 3 levels of factor 2, and 5 levels of factor 3. This makes a total of $4 \times 3 \times 5 = 60$ combinations. This may be too expensive to carry out. Then only the most relevant combinations can be included. The right panel of Figure F.2b shows a partially factorial design where some combinations are missing. The following example illustrates an application of the partially factorial design.

Carbamazepine and lamotrigine are anticonvulsant drugs, which may have a role in treatment of epilepsy and bipolar disorders. For experiments on mice, they require a vehicle such as methylcellulose. The effect of these drugs is often studied on various parameters in mice. One among these is oxidative stress, measured by malondialdehyde (MDA), glutamine synthase (GS), etc. For an example of such an experiment, see Pavone and Cardile [1].

An experiment on carbamazepine (factor A), lamotrigine (factor B), plus the vehicle (factor C) has these three factors. With *given* and *not given* as two levels of each of these factors, a full-factorial experiment requires $2 \times 2 \times 2 (= 2^3) = 8$ groups. Although the vehicle alone can be given, A and B cannot be administered without the vehicle. Thus, the combinations available are O (placebo), C, AC, and BC. In this experiment, only four groups were feasible or relevant against the required eight for a full-factorial experiment. Thus, this would be a partially factorial experiment.

The statistical analysis of a full-factorial experiment is relatively easy, and interpretation is even easier than that of a partially factorial experiment. Thus, biostatisticians tend to advise a full-factorial design and avoid the partial setup. However, in conditions where one or more particular combinations of levels of factors are undesirable or irrelevant, as in the example in the preceding paragraph, a partially factorial experiment can be designed and executed. Statistical analysis of this design will be tough but can still be done with the help of modern software. The main casualty in such designs is the interaction of two or more factors because that rarely can be evaluated in a partially factorial design. Nonetheless, partially factorial designs can still be devised if the study of a particular interaction is important. For further details, see Mee [2].

### Analysis of Factorial Designs

Analysis of data from fully factorial designs is done by two-way, three-way, or higher-way analysis of variance (ANOVA), depending on the number of factors. The analysis has two distinct steps. One is the estimation of the main effects and interactions, and the other is testing their statistical significance. Estimation of **main effects and interaction effects** are described separately under that topic. For statistical significance of the factor effects, ANOVA is done on the same pattern, as explained for **two-way ANOVA**. This can be extended to three or more factors. The ANOVA described therein is for fixed effects, as **random effects** are discussed separately. Also, note that the method of analysis is the same whether the factor-level combinations could be randomly assigned to all the participants or the randomization is restricted to certain groups, as in a **randomized block design**.

Analysis of a partial factorial design is tough, as indicated earlier. The missing combinations generate empty cells. For example, if you have 5 levels of factor 1 and 3 levels of factor 2, you should have all the 15 combinations in your design for a fully factorial experiment. If you have just 9 of these 15 combinations, the other 6 are considered empty cells. Any hypothesis that involves any of the missing combinations cannot be tested. When empty cells are present, the usual Type III sum of squares that we generally use in ANOVA is not applicable; instead, Type IV sum of squares is used. These types are described under the topic **sum of squares (types of)**.

The method of analysis just mentioned is valid when the levels of the factors are nominal with no order. When these are ordered or quantitative, such as dose of 0, 1, and 5 mg, and the objective is to examine graded response in such ordinal categories, it is better to use a regression approach, as in a **general linear model**. Statistical software packages generally require that the command for such analyses be written with extreme care and the output be properly interpreted. Thus, this kind of analysis should be undertaken only by statistical experts.

## factor loadings, *see* factor analysis

## factors (classificatory and experimental)

A factor in biostatistics is that characteristic of subjects that is under consideration for its implication on the research outcome. Obesity, drug doses received (or assigned), education, severity of disease, and type of diet are examples of factors. The term is used for **discrete variables** rather than for **continuous variables**. The convention is to call continuous variables **covariates** or **concomitant variables** in place of factors. Thus, blood pressure (BP) level can be a covariate but generally will not be considered as a factor unless it is categorized as hypertension (yes/no) or as systolic level into categories such as <110 mmHg, 110–129 mmHg, 130–139 mmHg, etc. Thus, a factor can be quantitative but not continuous. The categories of the factor, be it dose, disease severity, BP, or any other, are called *levels of the factors*. If BP is categorized into six categories, the factor BP has six levels. For BP, these categories have order, but that is not necessary. Blood group has four categories without any order, but they still would be called levels.

In analytical studies, the term *factor* is used for **antecedents** rather than for **outcomes**. Outcomes can also be construed as responses in many situations. Researchers commonly aim to find out how outcome or response is affected by the level of various factors. However, the term *factors* is also used in **descriptive studies** where there is no interest in any specific outcome, such as to find out what segment of the population is using different types of tobacco products (in this setup, the factor is tobacco, and different types of tobacco products are the levels) or what the signs–symptoms profile of cases of tuberculosis of the bone is.

For a research setup, factors can be divided in two broad statistical categories. One is classificatory, over which we do not have any control, and the other is experimental, over which we have some control. This distinction is important for interpretation of the results, though possibly not so much for statistical calculations. As an example, consider obesity as a factor. This is something that

cannot be assigned to a person in any study, as this is preexisting. When the subjects are divided by obesity (thin, normal, overweight, and obese), this factor is classificatory, as you just have to observe which category the subject belongs to. Contrast this with a setup of a clinical trial with three doses of a drug, and you can assign a subject to any of the doses you want, generally by a random method. This is what is regularly done in the random allocation of subjects to the doses of the drug. Dose in this setup is an experimental factor. The researcher has the option to allocate the level of an experimental factor to any consenting subject in the study, but this option is not available for the level of a classificatory factor.

What is the implication? The **effect** of the level of an experimental factor is interpreted to apply to the entire population of subjects from which the subjects are chosen, while the effect of the level of a classificatory factor is interpreted to apply to only that part of the population that has that level. If there is a total population of 800 subjects, and a trial on a sample of 90 subjects is conducted, of which 30 were allocated to receive a dose of 5 mg, the estimate of the effect of this dose based on these 30 would be applicable to all 800 subjects. On the other hand, if only 150 of these 800 are overweight, and 20 of these 90 subjects in the trial are overweight, the estimate of the effect of overweight on the outcome based on 20 overweight subjects will be applicable to the 150 overweight subjects in the population, and not to all 800. See how the interpretation differs depending on whether a factor is classificatory or experimental. Of course, we are assuming in our explanation that the selection and allocation is **random**, so the subjects are representative of the concerned population.

## factor scores, *see also* factor analysis

**Factor analysis** is the statistical method used to identify a small number of underlying factors in a set of a large number of correlated continuous variables. This method tries to express each variable in terms of the small number of identified factors. It is also possible in this analysis to perform a reverse process whereby factors are expressed in terms of the variables. This reverse process gives the following type of equation for each the $M$ factors underlying $K$ variables ($M \ll K$):

$$F_m = b_{m1}x_1 + b_{m2}x_2 + \ldots + b_{mK}x_K;\ m = 1, 2, \ldots, M.$$

The coefficients $b_{mk}$ ($m = 1, 2, \ldots, M$; $k = 1, 2, \ldots, K$) are called *factor score coefficients*. When the observed values of ($x_1$, $x_2$, …, $x_K$) for a subject are substituted in the aforementioned equation, the quantity obtained is called the factor score for the $m$th factor for that subject. This measures the importance of the factor for that individual. If the factor score for the third factor ($F_3$) is high for the sixth subject and relatively low for the tenth subject, it can be concluded that $F_3$ is influencing the sixth subject more than the tenth subject. Such factor scores for each factor can be obtained for each subject by using appropriate software. These scores can be used for a variety of purposes. Chandra Sekhar et al. [1] used these scores to develop an index of need for health resources in different states of India, and Jabłoński and Kozakiewicz [2] used them to develop a rule to predict death of acute mediatinitis patients.

## fallacies (statistical), *see also* misuse of statistical tools

Fallacies are anomalies that considerably reduce the credibility of a report. Statistical fallacies are common in medical literature. This section enumerates some such fallacies, hoping to create awareness of situations when these can occur.

Statistics show that more people die in hospitals than at home. Also, there is a strong association between dying and being in bed. The absurdity of such associations is apparent. No one would advocate avoiding hospitals or beds to prolong life. These might seem to be extreme examples, but the same sort of errors of logic sometimes passes unrecognized in the medical literature [1].

Presented in Figure F.3 is one statistical fallacy regarding the use of line diagrams. It is commonplace to see the lines with ±1 standard deviation (SD) as error bars for each point on the $x$-axis with vertical lines on one or both sides of the line. This can be fallacious because the actual variation is much more, something like ±3SD. Sometimes, ±1 standard error (SE) is shown, which is even more fallacious because that applies to the mean and not to the values.

### *Fallacies in Analysis*

Biological processes are complex, and most biostatistical analyses fail to match the reality of the biological systems. For example, **models** are acknowledged as necessarily simplified versions of the intricate biological processes. Thus, fallacies are bound to arise. Many times, they present a false aura of precision due to their underlying mathematical formulation. Because of imposed simplicity, even statistically adequate models may fail to live up to the expectations in practice. In general, there is no 100% correct model: it is just that some models are better than others. Here are some more examples.

There is no doubt that hardly any relationship in medicine is linear. Yet, a **linear relationship** is the most commonly studied form of relationship in health and medicine. This simplification seems to work fairly well in some situations but can destroy an otherwise very clear relationship in others, for example, the rise and fall of lung function with increase in age from 0 to 70 years. This is aptly represented by a parabolic curve, but the relationship vanishes if only linearity is considered. Another example is the relationship between glomerular filtration rate and creatinine level, illustrated in an example by Indrayan [3]. The linear relationship in this case is medically unsatisfactory despite a high $R^2 = 0.81$. These examples

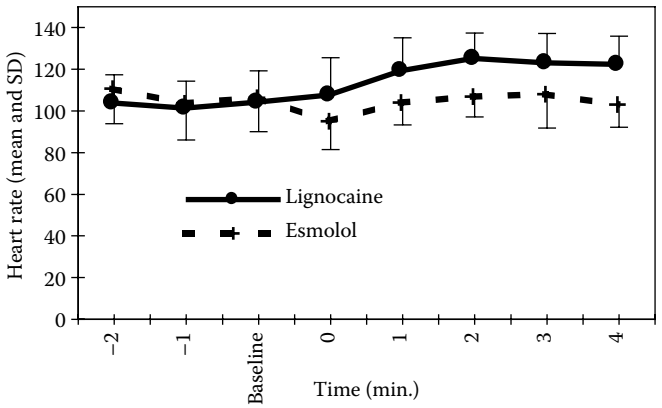

**FIGURE F.3** Heart rate in women with pregnancy-induced hypertension undergoing cesarean section—esmolol and lignocaine groups. (From Wilson A, Siskind V. *Int J Epidemiol* 1995;24:678. http://www.ncbi.nlm.nih.gov/pubmed/8550263. With permission.)

show that there is a definite need to curb the tendency to linearize a clear nonlinear relationship.

Investigators tend to look for one equation—either linear, curvilinear, or whatever—for the entire range of a measurement. Left ventricular ejection fraction (LVEF) ranges from 10% to 90%—less than 50% is considered a coronary risk, and more than 60% does not provide any benefit. If coronary risk is plotted against LVEF, it will be flat after 60%. One model over the entire range of 10% to 90% would not capture this phenomenon. For measurements that show one pattern for $x \leq a$ and another $x > a$, a **spline regression** is needed. Without this, the results could be fallacious. Realize, however, that a spline can be used only if you know, or at least suspect, that the patterns could be different over different ranges of $x$. If this is not known, the fallacy can continue for a long time.

A **Gaussian** form of distribution of various quantitative measurements is so ingrained in the minds of some workers that they take it for granted of medical measurements. For large $n$, the **central limit theorem** can be invoked for inference on means, but nonparametric methods should be used when $n$ is small and the distribution is far from Gaussian. At the same time, note also that most parametric methods, such as $t$ and $F$, are quite **robust** to mild deviation from the Gaussian pattern. Their use in such cases does limited harm so long as the distribution has a single mode. Special attention is required if the distribution looks **bimodal**.

For many statistical procedures, the assumptions of **independence** of observations and of **homoscedasticity** are more important than that of a Gaussian pattern. Independence is threatened when the measurements are serial or longitudinal. Homoscedasticity or uniformity of variance is lost when, for example, SD varies with the mean. And this is not so uncommon. Systolic levels are higher in postmenopausal females, and so are their variances. Persons with higher body mass index (BMI) also tend to exhibit greater variability in BMI than those with lower BMI. Thus, care is needed in using methods that require uniformity of variance.

### Further Problems with Biostatistical Analysis

- **Categorizing** a **continuous variable** causes loss of information and can result in bias, loss of **statistical power**, and increase in **Type I error**. Different categorizations can lead to different conclusions. In some cases, a clever investigator can choose categories after seeing the data to connive to reach a preconceived result. On the other hand, in a situation such as finding a trend with regression, a continuous scale tends to disregard faraway values as outliers, if they are few, even when these contain important information.
- Mean and SD are inappropriate for variables with highly skewed distributions. For such variables, the median and interquartile range are more appropriate. The interquartile range comprises the middle half of the subjects. The difference (median – $Q_1$) when compared with ($Q_3$ – median), where $Q_1$ and $Q_3$ are the first and third **quartiles**, gives an idea of the extent of skewness. Interquartile range also rules out the "absurd"-looking statement, such as mean lipoprotein(a) [lp(a)] level is 8 ± 20, since this cannot be negative. The distribution of lp(a) is highly positively skewed, and the SD is very high. Most values are around 5 mg/dL—thus, the mean could indeed be 8 and SD could be 20 mg/dL, but mentioning this as 8 ± 20 gives an erroneous impression.
- A real anomaly arises when too many 0s occur in a data set (such as runs by batters in baseball games). In medicine, this happens when, for example, you are studying smoking among adolescents. If the duration is recorded as 0 for nonsmokers and the actual duration on a continuous scale for smokers, neither the mean nor the median will work well because of the large number of 0s. If duration is categorized as 0 or more than 0, or in three or four categories, the analysis can be appropriately done by using proportions.
- Gaussian distribution of values is required for many statistical methods, but it can be difficult to check in some cases. Small samples would not be able to provide evidence against Gaussianity because of a lack of power. The tests such as **Kolmogorov–Smirnov**, **Anderson–Darling** (A-D) and **Shapiro–Wilk** work well with large samples and not with small samples, although the A-D test can work for relatively small samples. For really small samples, check whether some extraneous evidence (from experience or literature) is available that the distribution is a Gaussian. The other option is to examine the plot, and if this suggests a non-Gaussian pattern, it might be safe to use **nonparametric** methods for small samples.
- On the other hand, some researchers are nonparametric enthusiasts and use these methods even when the sample size is large. This could result in loss of power. So far, fortunately, the number of such enthusiasts is not high.
- In paired comparisons, change such as from preintervention to postintervention is a natural outcome of interest. Since baseline (*pre-*) values can affect the amount of change, many times, percent change is calculated. This works well provided that (i) negative and positive changes are not canceling on averaging and (ii) percent change is independent of the baseline. These limitations tend to be overlooked, causing fallacies.

### Arbitrary Variable Selection

More than 100 signs–symptoms of hypothyroidism can be identified. These include puffy face, cold intolerance, thin hair, and brittle fingernails. This probably is true for many medical conditions. Two kinds of fallacy can arise in such cases. One is due to a priori (before modeling) selection of variables. If all the variables cannot be studied because of a limitation of sample size or otherwise, there must be sufficient reason for including some and excluding others. In many situations, such reasons do not adequately exist, and subjective preference plays a role, which obviously affects the results. If all known variables are entered into the model, the sample size must be enormously large. Sometimes, one variable at a time is considered, and the statistically significant ones are included in a multivariable setup. This ignores interdependence—thus, the choice is statistically difficult, and the choice of variables remains questionable. Keep this limitation in mind while making an inference, or else fallacies will occur.

Quite often, the factors affecting the outcome are not fully known (see **epistemic uncertainty**). Obviously, only known or, at best, suspected factors can be studied. Large unexplained variation is one indicator of the inadequacy of a model that can be due to exclusion of relevant variables. Unknown factors can be important even when they account for only a small part of the unexplained variation. This can happen when an unknown factor is closely linked to one or more of the known factors.

### Other Statistical Fallacies

There are a large number of several other fallacies that can be listed. Fallacies occurring due to **data dredging**, improper use of the

**person-years** metric, misinterpretation of **intention-to-treat analysis** and **equivalence studies**, misinterpretation of **number needed to treat**, etc. are discussed under the respective topics. Discretion in the use of proportion in place of the mean in some cases or vice versa in interpreting cross-sectional as prospective outcomes (or interpreting prevalence as incidence), and lack of comprehensive adjustments for **confounders** can also cause fallacies.

It is hoped that the examples given in this section give the reader a flavor of statistical fallacies: where and how they can arise, and how destructive they can be. Many more examples could be given: see the work of Indrayan [3] for a comprehensive review. Remember that the scientific community is not free of greed, and their fraud is difficult to detect.

3. Indrayan A. *Medical Biostatistics*, Third Edition. Chapman & Hall/CRC Press, 2012.

## false negative and false positive

The terms *false negative* and *false positive* in biostatistics are used in two separate contexts. The first is for medical tests, which include not just laboratory and radiological investigations but also narratives, such as signs–symptoms used in diagnosis and monitoring, and indices, such as pain score for clinical assessment. The second is for statistical tests of **significance**, which also can provide false-negative and false-positive results.

The result of a medical test is called false negative when the test is negative, whereas the disease is actually present. It is called false positive when the test is positive when there is actually no disease. False negativity and false positivity are evaluated after using the test on a series of homogeneous patients whose actual disease status is known. These values are used to assess the extent of the validity of the test and to identify the situations where the test can be used—a test with low false negativity can be useful for screening, and a test with low false positivity can be useful for confirming a diagnosis.

Denote the presence of disease by D+ and absence by D–, test positivity by T+ and test negativity by T–. Also, let true positives be abbreviated as TP, false positives as FP, true negatives as TN, and false negatives as FN.

Table F.3 contains the results of electrocardiograms (ECGs) performed on a total of 700 subjects with complaints of prolonged acute chest pain. Of these, 520 cases were earlier confirmed for the presence of myocardial infarction (MI) and 180 for its absence. The test under review in this case is ECG. In 104 cases, the ECGs were normal among the 520 who have had MI. Thus, the false-negative rate of ECGs in this example is 104/520 = 0.20, or 20%. This is high by any standard. Similarly, false positives are those that have shown ECG aberrations but had no MI. This rate in this example is 9/180 = 0.05, or 5%. Thus, you get a feeling of how good this test is at correctly detecting the presence or absence of disease in those whose disease status is already known. False-negative and false-positive terms for medical tests have intimate implications in the concepts of **sensitivity and specificity**, and **predictivities**. See these topics for more details.

**TABLE F.3**
**MI and ECG in Cases of Acute Chest Pain**

| | MI | | |
|---|---|---|---|
| **ECG** | **Present** | **Absent** | **Total** |
| Positive | 416 (TP) | 9 (FP) | **425** |
| Negative | 104 (FN) | 171 (TN) | **275** |
| **Total** | **520** | **180** | **700** |

The second usage of false-negative and false-positive terms is for the results of statistical tests and is more complex. In order to understand this, see the topic **tests of hypothesis (philosophy of)**. A statistical test requires that a null hypothesis be set and a test criterion appropriate for the kind of data and the design of study be calculated assuming that the null is true. The value of this criterion is used to find the ***P*-value**, which is the probability of rejecting the null when, in fact, it is true (also called the probability of **Type I error**). If you consider rejecting a null as a positive result, this error means a false-positive result, and is like punishing an innocent in a court of law and also like declaring a person without disease as sick. This can have severe implications for science too. Correspondingly, a false-negative result of a statistical test is when an effect is present but we conclude that there is no effect. This is **Type II error** and not as serious. The complement of the probability of Type II error is called the statistical **power**. See these topics for more details.

## familial aggregation

Familial aggregation is said to be present when similarity in members within a family is more than expected by chance. You may have heard that some diseases run in families—meaning thereby that if one is suffering, other members of the family also have a tendency to suffer. Diabetes and hypertension are examples of such diseases. This could be because of shared environment (diet, stress, infections, etc.) or because of genetic influence, or both. For example, 20–25% of all cases of colorectal cancer in Australia are observed to occur in families, but the contribution of genetics and shared environment is not yet known [1]. Such aggregation can happen with any characteristic or trait. For example, the dietary constituents of members of a family are more likely to be similar than across families. Tobacco and alcohol use have strong aggregation within families.

Statistically, familial aggregation is established by comparing within-families variation with between-families variation. For this, you need to obtain data on members of a large number of families. For a quantitative variable such as blood pressure, *within* variance and *between* variance can be easily obtained by the method **analysis of variance (ANOVA)**. Average levels in the members of the families of the affected persons versus the average in the family members of those not affected can give some idea of the familial aggregation. The extent of familial aggregation of a quantitative measurement can be measured by computing the **intraclass correlation coefficient**. For qualitative characteristics, such as whether an adult is hypertensive or not, proportions within families can be compared with proportion between families. In a **case–control study** setup, family members of the subjects with disease and family members of the subjects without disease are investigated for the relative presence of the condition. The difference between these two proportions can be considered a measure of aggregation. The procedure is not so straightforward in a cohort study setup. Hudson et al. [2] have provided the details of the method generally used for cohort studies also, although their paper is on aggregation of two disorders.

Segregation of the genetic effect from the environment effect in familial aggregation can be difficult. Many times, first-degree and second-degree relatives are studied to delineate the genetic effect. This could be sex linked too. The environmental effect can be studied in genetically dissimilar people living together for long, such as those who are married.

Familial aggregation has both medical and statistical implications. When an unsuspected familial aggregation is discovered for any health condition, this sends an alert to the researchers, first to confirm this with other such studies and second to examine possible causes of this. In most situations, some ascribable cause would be found, but in some cases, this could be obscure—perhaps beyond our present knowledge. The biostatistical implication is that because of aggregation, the values seen within a family are not independent—thus, the usual methods of analysis are not applicable. Statistically, a family is a **cluster** whose values are more akin to one another than values seen outside the cluster. This clustering may have to be factored into the analysis by using methods such as **hierarchical analysis** and **generalized estimating equations (GEEs)**.

A good biostatistical study that explores familial aggregation of cerebral palsy in a cohort setup in Norway is that by Tollånes et al. [3]. This study uses twins, first-degree relatives, second-degree relatives, and third-degree relatives as comparator groups.

## fertility indicators

The fertility indicators measure the level of fertility in a community. The term *fertility* can be used for individuals, but the term *indicators* is used for groups. Fertility is the actual performance in terms of live births and excludes stillbirths and abortions. Do not confuse fertility with the capability to reproduce, for which the right term is *fecundity*. A couple may be fully fecund but not fertile if they decide not to reproduce.

Having laid down the basics, we are now in a position to explain various indicators of fertility. There are many, but the one that is simplest and most commonly used is the crude birth rate (CBR). This is the number of live births in a population in 1 year per 1000 population counted at midyear. This can be written as

$$\text{crude birth rate: CBR} = \frac{\text{number of births in a year}}{\text{midyear population}} \times 1000.$$

CBR generally varies between 5 and 30, i.e., generally between 5 and 30 births take place per 1000 population in 1 year. It generally varies inversely with the stage of development of the population. Birth rate can be standardized using the standard age structure of women of childbearing age (generally 15–49 years) along the lines we have explained for **standardized death rate**. But this is rarely done.

Since the real focus for fertility is women of the reproductive age group, the denominator can be replaced by this segment of the population. This will give the number of live births per year per 1000 women of age 15–49 years, called the **general fertility rate**. In terms of formula, this is

$$\text{general fertility rate: GFR} = \frac{\text{number of live births in one year in a population}}{\text{total number of women of age 15–49 years in that population}} \times 1000.$$

The denominator includes women who rarely contribute to the fertility, such as unmarried women. Thus, this indicator can be further restricted to married women in areas where only married women reproduce. Both the numerator and the denominator will be counted for married women only. The name of the indicator then would be general *marital fertility rate*.

The two indicators just mentioned are overall indicators and can be made more specific. Since fertility in women varies greatly with age (remember that we are talking of actual live births and not the capability), **age-specific fertility** for age groups 15–19, 20–24, 25–29 years, etc., of women may be of some interest. This is obtained when the number of births to the women of a specific age is divided by the number of women of that age. Thus, for example,

$$\text{age-specific fertility rate for age group 30–34 years: ASFR} = \frac{\text{number of live births in 1 year to women af age 30–34 years}}{\text{total number of women of age 30–34 years in that population}} \times 1000.$$

According to the World Population Prospects of the United Nations for 2012 [1], the average age-specific fertility rate for age 15–19 years in the world was 89.8 births in the block years 1950–1955, which declined to just 48.9 births in the block years 2005–2010. Much of this is due to an overall decline in fertility, but some is also due to a shift in the fertility to higher age groups. Compared to 48.9 in the age group 15–19 in the block years 2005–2010, the rate was 151.7 in the age group 20–24 years. It was 157.2 in Malawi and 50.6 in India during this period. Thus, there is a huge difference across age groups as well as across countries.

Sometimes, the interest is in comparing the age trend of fertility in two or more populations. For example, Figure F.4 shows that fertility is highest in age group 20–24 years in India and in age group 30–34 years in Ireland. Actual values are shown in Table F.4.

There are some other fertility indicators that are not so simple. First is the **total fertility rate**. This is the average number of births

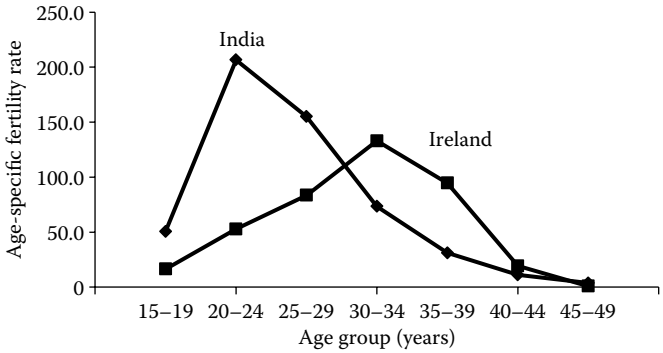

**FIGURE F.4** Age-specific fertility rates in India and Ireland, 2005–2010. (From UN. *World Population Prospects: The 2012 Revision*. http://esa.un.org/wpp/excel-data/fertility.htm.)

**TABLE F.4**
**Age-Specific Fertility Rates (per 1000 Women) in India and Ireland, 2005–2010**

| | Age Group (Years) | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | **15–19** | **20–24** | **25–29** | **30–34** | **35–39** | **40–44** | **45–49** | **Sum** | **TFR = 5*Sum/1000** |
| India | 50.6 | 206.6 | 155.0 | 73.4 | 31.2 | 11.2 | 3.8 | 531.66 | 2.6583 |

to a woman during the entire reproductive phase. In place of follow-up for 34 years from age 15 years to age 49 years, the current age-specific fertility rates are used for calculating this rate. This makes it somewhat hypothetical but helps in getting the current status. The calculations are done as follows.

Total fertility rate (TFR)

= 5*Σ(ASFR for the 5-year age groups per woman).

Summation is over the age groups. In case the ASFR for each year of age, 15–16, 16–17, etc., is available, there is no need for the multiplier 5 in the formula. The calculations for India and Ireland are illustrated in Table F.4. Since TFR is per woman, we have to divide by 1000 in the last column (the ASFRs in Table F.4 are per 1000 women). Since TFR is independent of the age structure of women, it is comparable across populations. Thus, it would be legitimate to say that fertility in India was about one-half birth more than in Ireland during 2005–2010.

**Gross reproduction rate** (GRR) is the average number of daughters that would be born to a woman during her lifetime if she passes through her childbearing years conforming to the age-specific fertility rates of a given year. This is the same as TFR but is now restricted to female births. If these are one-half of the total births (as they nearly are in almost any population), the GRR would be nearly one-half of the TFR. Thus, GRR is nearly 1.33 for India in the block years 2005–2010 and 1.00 in Ireland.

Both TFR and GRR assume that all women remain alive all through the reproductive phase. However, some may die early and reproduce less. When an allowance for this is made in GRR, what we get is called the **net reproduction rate** (**NRR**). This rate is more practical and is used to determine whether a population has reached the replacement level or not. A rate nearly equal to 1.00 for a long time indicates that the population has reached to the stationary level. NRR > 1.00 means that the population is increasing, and NRR < 1.00 means that the population is decreasing. Many growing populations in developing countries aim at NRR = 1.00.

In case you are interested to see a report on fertility levels in a developing country, see Ref. [2] for India.

## field trials, *see* clinical trials

## Fieller theorem

The Fieller theorem, first reported by Edgar Fieller in 1954 [1], provides a **confidence interval** (CI) for the ratio of two correlated variables that jointly follow a **bivariate Gaussian distribution**. The Fieller theorem can be used for finding the CI of the ratio of two means and two proportions. It yields approximate intervals when the distributional assumptions relating to the two variables are not strictly satisfied. The CI requires that the covariance of the two variables under consideration is also available or can be estimated.

The Fieller theorem says that if $u_1$ and $u_2$ are (possibly correlated) means of two samples with population means $\mu_1$ and $\mu_2$, respectively, variances (in this case, the square of the standard errors, since $u_1$ and $u_2$ are sample means) $v_{11}\sigma^2$ and $v_{22}\sigma^2$, and covariance $v_{12}\sigma^2$, then a $100(1-\alpha)\%$ CI for the ratio $\theta = \mu_1/\mu_2$ is given by

$$\frac{1}{(1-g)}\left[\left(\frac{u_1}{u_2} - g\frac{v_{12}}{v_{22}}\right) \pm \frac{z_{1-\alpha/2}\sigma}{u_2}\sqrt{v_{11} - 2\frac{u_1}{u_2}v_{12} + \frac{u_1^2}{u_2^2}v_{22} - g\left(v_{11} - \frac{v_{12}^2}{v_{22}}\right)}\right],$$

where $g = \dfrac{z_{1-\alpha/2}^2 v_{22}\sigma^2}{u_2^2}$. The minus sign within the equation will the give lower limit of the CI, and the plus sign will give the upper limit. This complex-looking equation, in fact, is the solution for θ in the quadratic equation

$$\frac{(u_1 - \theta u_2)^2}{(v_{11} - 2\theta v_{12} + \theta^2 v_{22})\sigma^2} = z_{1-\alpha/2}^2. \tag{F.1}$$

This exploits the premise that $\theta = \mu_1/\mu_2$ implies $\mu_1 - \mu_2\theta = 0$. This is a linear combination whose estimate is $u = u_1 - u_2\theta$. Being a linear combination of Gaussian variables, $u$ will follow a Gaussian distribution with mean 0 and variance as in the denominator of Equation F.1. If you take the square root of Equation F.1, you will get the familiar result that $z = u/\mathrm{SE}(u)$ has a Gaussian distribution with mean = 0 and variance = 1.

As a medical professional, you may never have to use this complex equation. But there are some practical situations where CI for ratio of means is required. Most prominent of these is the relative potency of a drug in bioassays. This CI can be adapted to the proportions such as for the relative efficacy of one regimen compared with another, where both efficacies are in terms of percentage.

If you happen to come across a problem where the CI of a ratio of means or proportions is needed, try to get hold of a statistical package where this can be obtained. There are not many at this time, and that is the reason why we have given the formula despite it being so complex. However, keep the following in mind when applying this result:

- Variances and the covariance of $u_1$ and $u_2$ would be rarely known, and as usual, they would need to be replaced by their sample estimates. This would immediately turn a Gaussian distribution to a **Student *t*-distribution**. Thus, $z$ in the CI will be replaced by the table value of t at the

desired **confidence level**. The degrees of freedom for this would be $(n_1 + n_2 - 2)$.

- If you look at the CI formula, you will find that $(1 - g)$ is in the denominator. For CI to be sensible, $(1 - g)$ should be neither negative nor too small. This stipulates that $g < 1$ and not close to 1. The value of $g$ will be too large if $u_2$ in the denominator of $g$ is too small. There are alternative ways to find the CI in these situations, as discussed by Franz [2].

Beyene and Moineddin [3] have also presented some alternative ways to find the CI of a ratio. Another method to find the CI of a ratio estimator is bootstrap, as discussed by Campbell and Torgerson [4].

## file-drawer effect

The file-drawer effect refers to the practice of researchers choosing not to publish their completed studies because of a negative outcome, i.e., studies that do not support the thrust of their research. Negative outcome here refers to the finding of no statistical **significance**, not to the finding that something affects us negatively. Negative outcome may also refer to finding something that is contrary to one's earlier research or to what one expects from conventional wisdom. A similar problem arises when journal editors are reluctant to publish currently unpublishable or unpopular findings. This, along with the file-drawer effect, is called **publication bias**. This bias runs behind the curtain, and one rarely knows how many studies have been lost.

The practice of reporting and publishing only positive research skews the understanding of the topic at hand toward positive findings. For example, **systematic reviews** and **meta-analyses** seek to summarize available publications on a topic. These will give a biased result if the file-drawer effect is in operation. There is no easy way to assess if it is there and how much. Thus, there is no way to adjust the result, and we many times find that the result obtained by the best of reviews is not able to yield the desired outcome in practice. Note that systematic reviews are considered the gold standard for reaching a **valid** and **reliable** conclusion, but few realize that these also can be flawed due to the file-drawer effect in particular and publication bias in general.

Because of the file-drawer effect, researchers might spend time unnecessarily researching something that in fact has already been researched (but not reported). The advent of a clinical trials registry that requires each **clinical trial** to be registered at the time of initiation may address this problem regarding trials because the researchers are bound to report their findings. But other forms of research remain unattended to.

## finite population correction

Finite population correction is the factor used in adjusting the estimates of the **standard error (SE)** of sample summaries (such as mean and proportion) when the sample size is large relative to the size of population and the **sampling is without replacement**. The usual estimates of the SE of parameters such as mean and proportion are valid when the chance of each unit being selected is the same. This happens in random sampling with or without replacement from an infinite population or in random sampling with replacement from a finite population. Statistically, a population is considered finite when sample size is relatively large, say, exceeding 5% of the population size. In this situation,

$$\text{finite population correction: FPC} = \sqrt{\left(\frac{N-n}{N-1}\right)},$$

where $n$ is the sample size and $N$ is the population size. This accounts for the added precision (reduced SE) gained by sampling close to a larger percentage of the population. The smaller the $n$, the higher the correction. When the FPC is used,

$$\text{SE}(\bar{x}) = \sqrt{\left(\frac{N-n}{N-1}\right)}\frac{\sigma}{\sqrt{n}} \quad \text{and} \quad \text{SE}(p) = \sqrt{\left(\frac{N-n}{N-1}\right)}\frac{\sqrt{p(1-p)}}{\sqrt{n}}.$$

The correction is negligible, for example, if you have a sample of 200 from a population of 10,000. Also note that a sample of size 200 out of 10,000 has nearly the same SE as a sample of 200 from 50,000. That is, the **sampling fraction** $(n/N)$ after a certain limit does not matter in the reliability of the estimate (the smaller the SE, the higher the reliability or precision). This may sound strange to those not familiar with sampling. Many would not believe that a sampling fraction of 200/10,000 = 0.02 (or, 2%) and a sampling fraction of 200/50,000 = 0.004 (or 0.4%—one-fifth of the previous) have practically no effect on the reliability of the estimate so long as the population is large. This is a remarkable result in sampling theory. It busts the erroneous belief that a sample mean based on a very small fraction of the population cannot be as precise as one with larger sampling fraction.

The correction we have stated is for **simple random sampling**. Similar corrections are available for other sampling methods such as **stratified** and **two-stage sampling**. For this, see the classical book by Cochran [1].

There are examples in the medical literature of the use of FPC. Godinho et al. [2] sampled 345 out of 803 policemen in Montes Claros, Brazil, to study periodontal disease. They used FPC because of a large sample relative to the population. Kolahi et al. [3] used FPC for **clustering sampling** for calculating the confidence interval (CI) for the incidence of diarrhea in children in Iran when they selected a sample of 2016 children out of an estimated 22,000.

## Fisher–Behrens problem, *see* Welch test

## Fisher exact test

The Fisher exact test [1] is used to test the statistical significance of the association between two qualitative characteristics when the

sample size is small. The usual test for association is **chi-square**, but it fails to oblige when $n$ is small since an exact method is needed in this case. For a **2 × 2 table**, the null hypothesis can be tested by the Fisher exact test (also known as the **Fisher–Irwin test**). Here, the **null hypothesis** is a statement of "no effect" or "no difference," and the alternative hypothesis is that there is an association. As usual, the test of significance is designed to assess the strength of the evidence against the null hypothesis.

Ronald Fisher

Consider the notations given in Table F.5 for an antecedent–outcome setup. The notations are the same for any 2 × 2 table. $O$ is the notation for the observed frequency and $\pi$ for the probability, subscripts identify the cell, and the dot in the subscript is for the total. If the margins $[O_1\cdot(\pi_1\cdot), O_2\cdot(\pi_2\cdot), O\cdot_1(\pi\cdot_1), O\cdot_2(\pi\cdot_2)]$ are considered fixed, then the probability by **multinomial distribution** is

$$P = \sum \frac{O_1\cdot!O_2\cdot!O\cdot_1!O\cdot_2!}{n!O_{11}!O_{12}!O_{21}!O_{22}!},$$

where the sum is over all the configurations in a 2 × 2 table that are observed to be as or more extreme in favor of $H_1$, without altering the marginal totals. This is the exact ***P*-value** in this case. This can be easily calculated manually for small $n$ (say $n < 10$) but can become difficult for larger $n$. Most statistical software packages would give this exact $P$-value for small $n$ using the aforementioned equation. Reject $H_0$ if $P < 0.05$, where the **level of significance** is set at 5%; otherwise, be content with the assertion made in $H_0$. The calculations are illustrated in a simple example given later in this section.

The probability in the aforementioned equation gives the *one-tailed* $P$-value. This is typical for the Fisher exact test. If a *two-*tailed value is needed, proceed as follows: (i) Double the one-tailed $P$-value if any (row or column) marginal totals are equal. Equal totals imply symmetry, and this allows such doubling. (ii) Calculate a separate $P$-value from the aforementioned equation for each tail if the marginal totals are not equal.

As already mentioned, the Fisher exact test assumes fixed marginal totals. This restriction is valid for a situation where, for example, you have six persons with disease and six without disease, and the test is built in a manner such that it is constrained to give six positive and six negative results. You can see that this is an unnatural restriction and would rarely hold in practical situations. This restriction makes the test overly conservative (i.e., fails to reject $H_0$ where it should). To overcome this problem, another test called the **Barnard test** is advocated, which does not require fixed margins. This test is computationally difficult and is not popular yet. For comparison between the Fisher exact and Bernard tests, see Mehta and Senchaudhuri [2].

**TABLE F.5**
**General Structure of a 2 × 2 Contingency Table**

| Variable 2 (Outcome) | Variable 1 (Antecedent) Present | Absent | Total |
|---|---|---|---|
| Present | $O_{11}$ ($\pi_{11}$) | $O_{12}$ ($\pi_{12}$) | $\boldsymbol{O_1.(\pi_1.)}$ |
| Absent | $O_{21}$ ($\pi_{21}$) | $O_{22}$ ($\pi_{22}$) | $\boldsymbol{O_2.(\pi_2.)}$ |
| **Total** | $\boldsymbol{O._1}$ **($\boldsymbol{\pi._1}$)** | $\boldsymbol{O._2}$ **($\boldsymbol{\pi._2}$)** | $\boldsymbol{n}$ |

**TABLE F.6**
**Example of Fisher Exact Test**

| | Antecedent | | | | | |
|---|---|---|---|---|---|---|
| **Outcome** | **+** | **–** | **Total** | | | |
| + | 1 | 7 | **8** | 0 | 8 | 8 |
| – | 5 | 2 | **7** | 6 | 1 | 7 |
| **Total** | **6** | **9** | **15** | **6** | **9** | **15** |

For illustration of the calculation of the Fisher exact test, consider the data in Table F.6. In the left panel are the observed frequencies. In the right panel are the frequencies that would be more adverse to the null hypothesis of no association. No other extreme configuration is possible because marginal totals have to remain the same, and one cell frequency is already 0 in the second configuration.

From the previous equation,

$$P = \frac{8!7!6!9!}{15!1!7!5!2!} + \frac{8!7!6!9!}{15!0!8!6!1!}$$
$$= 0.0336 + 0.0014$$
$$= 0.035.$$

This is less than 0.05. Since it is a **one-tailed probability**, the conclusion too would be one-sided. In this case, there are seven subjects with positive outcome when the antecedent is absent and five subjects with negative outcome when the antecedent is present. Of a total of 15 subjects, these 12 favor the antecedent as an inhibitor to the outcome against the other 3 who do not. A small $P$-value shows that this is statistically significant. Thus, the conclusion is that the presence of the antecedent inhibits the outcome in a statistically significant manner at a 5% level of significance. For such one-sided conclusions, one-sided $\alpha$ is used.

The Fisher exact test can be extended to larger tables. Mehta and Patel [3] have described a network algorithm for performing the Fisher exact test in ($R \times C$) contingency tables. This extension was first proposed by Freeman and Halton [4].

## Fisher–Irwin test, *see* Fisher exact test

## Fisher *z*-transformation, *see* comparison of two or more correlation coefficients

## fixed and random effects, *see also* mixed effects models

The terms *fixed* and *random effects* are used for the levels of **factors** that are analyzed by **analysis of variance (ANOVA)**. For example, in a trial, different doses of a drug such as 0 (placebo), 5, 10, and 20 mg are the four levels of the factor "drug." The interest in this case is restricted to these particular doses, and no inference is drawn for any other dose such as, say, 12 mg. Thus, these levels are fixed. If the outcome is the fever clearance time in malaria patients, you can exactly estimate the effect of these specific doses on this outcome. Now suppose this trial is done in 5 out of, say, 200 centers in a country. In this case, the interest is not limited to these selected five centers but is extended to find if there is any intercenter difference in the outcome in these 200 centers. Let these 5 centers be a random sample of all the centers so that a generalized conclusion about the effect of centers can be made. The 5 centers in the study could be any of those 200. In this case, the effect of centers on the outcome will be modeled as a random effect. In the case of fixed effects, no inference can be drawn about any other level except the ones under study, while for random effects, the inference would be valid for the entire population from which the factor levels are randomly drawn. If drug levels have fixed effects and centers have random effects, the model will be called a **mixed effects model** when both are studied together.

In our example of a trial at five different centers, the interest would not be in estimating the mean effect of the specific centers on the outcome but would be in the variance across such centers. This will delineate how different outcomes in different centers are. The larger the variance, the greater the effect of centers. Thus, the method of conducting the ***F*-test** is different when random effects are present. This is sometimes referred to as **variance components analysis** because of the emphasis on variances rather than the means. For details, see Searle et al. [1].

When a drug is given to, say, a sample of 10 subjects, and **repeated measures** are taken at fixed points of time for each subject to see the time effect as in **bioequivalence studies**, such data can be analyzed by two-way ANOVA considering time points as factor 1 and subjects as factor 2 and $n = 1$ (1 observation for each time and subject). The assumption in this case is that the interest is only in comparison of means at different points in time and not the time trend of the response. Time trend would mean extrapolating the effect of time to the time points not actually studied. This analysis also requires that after the time effect is extricated, the **residuals** are independent and have same variance. But this procedure violates one basic premise. The conventional ANOVA considers levels of the factors fixed and of specific interest to the problem. Subjects are almost invariably a random sample from a defined population. When such subjects are considered factor levels, as just suggested for repeated measures, these give rise to what we have called a random effect. For details of the analysis of repeated measures, see Raghavarao and Padgett [2]. We have also provided some details under the topic **repeated measures ANOVA** in this volume.

## flowchart

A flowchart is a text-based diagram that provides a sequence of steps on how to proceed with a problem or to approach a problem for reaching a defined goal. It contains text in boxes of various shapes that identify the step/s. Arrows provide the direction and lead to the next steps. Thus, a flowchart maps the process and provides an algorithm. This helps to achieve clarity that otherwise may be difficult in a description with words.

An example of a flowchart is in Figure F.5. This is on a pathologist's report in a case of testicular cancer. Note that there are different shapes of the boxes: each has its specific meaning. For example, an oval shape is for the beginning and end, rectangles are for the process at the designated step, a diamond is where your decision is required, and a rhombus (not in this figure) is for entering data. An arrow coming from one shape and ending at another shape signifies flow. Diamonds for a decision typically contain a yes/no question or true/false test. This shape is unique in that it has two arrows coming out of it, one corresponding to "yes" or "true" and the other corresponding to "no" or "false." The arrows anywhere can have labels. For more details on the shapes used in the flowchart, see the illustration by Grout [2].

Flowcharts can be used for describing the algorithm for managing patients, as done by Bruyere et al. [3] for cases of knee osteoarthritis. Such charts can also be used to describe some crucial aspects of the design of a study, such as the **CONSORT** flowchart for clinical trials.

## focus group discussion

A focus group discussion (FGD) is a tool to gather data on soft aspects of social concerns that can rarely be studied by surveys. Soft aspects include opinions, beliefs, feelings, attitudes, etc. These concerns can quickly change in an interactive setting in a group since people's response on soft issues is many times guided by the views of the others. Surveys tend to collect data on immediate feelings as they do not provide an opportunity to go deeper or to be affected by the opinions of others. FGDs are an ingenious way to get to the bottom of feelings of people, which some researchers feel may show up better in a group discussion. It is a tool for now expanding **qualitative research** as opposed to the regular quantitative research. There is a growing realization that feelings of people are important contributors to the success or failure of programs, rather than just physical facilities. For example, Crankshaw et al. [1] used FGD to elicit the health care provider perspective on delivering safer conception services for HIV-affected couples in South Africa.

For an FGD, a small group of, say, 6–10 of the people concerned with the issue under investigation is gathered at a convenient location and asked to discuss a specific topic or posed a specific question

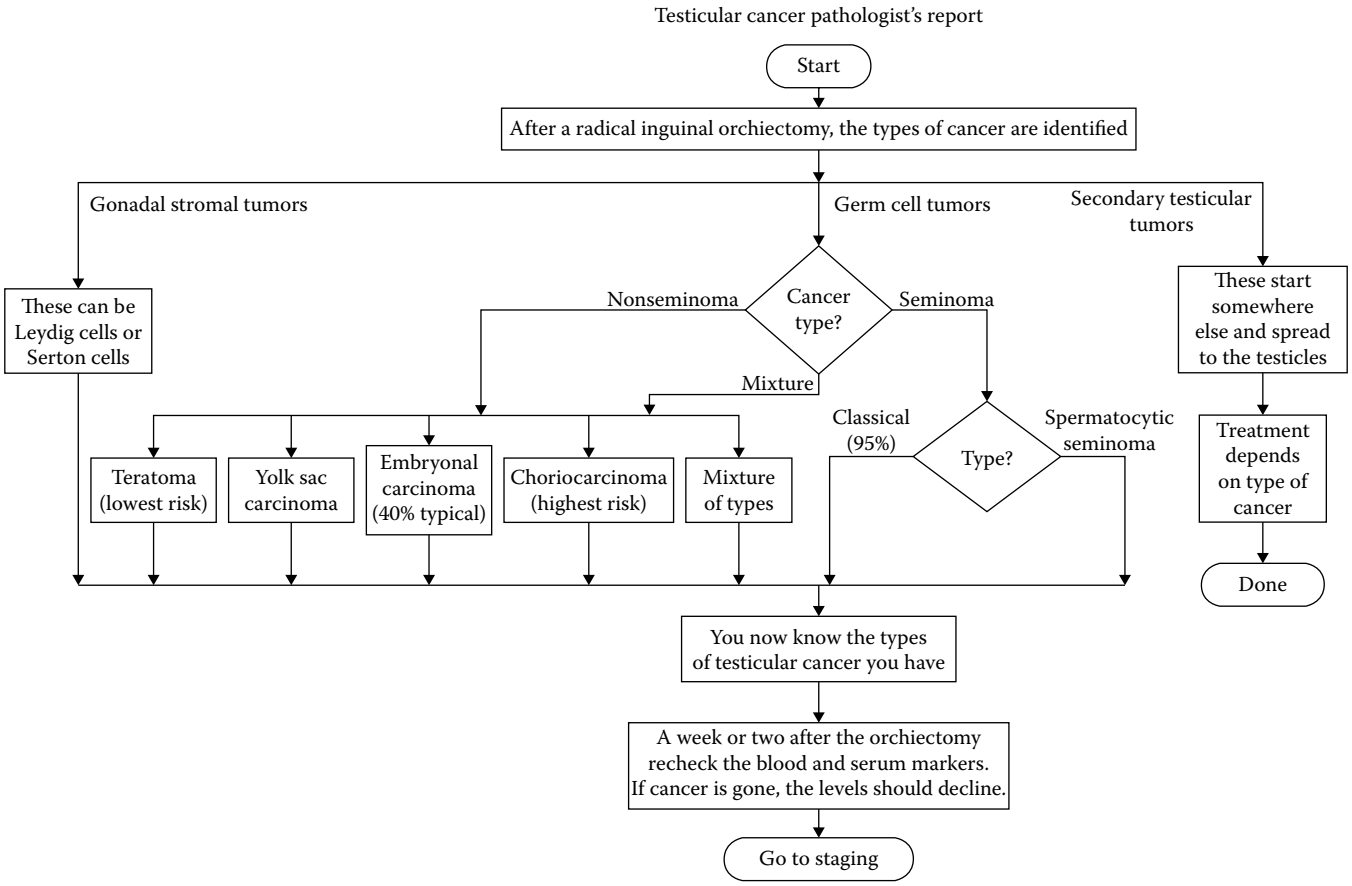

**FIGURE F.5** Flowchart of pathologist's report in case of testicular cancer. (From RFFlow5. Medical flow charts. http://www.rff.com/medical-flowcharts.htm. With permission.)

(or a set of questions). The group is subjectively chosen so that it can have diverse opinions and possibly have full knowledge of the problem or program being discussed. Generally, they are strangers to one another. They can even be the opinion makers of society.

The questions are carefully chosen and properly worded so that everybody clearly understands them with the same meaning. The agenda is carefully drawn keeping in view the objectives of the whole exercise. The members of the group are encouraged to express themselves openly and fearlessly for a range of views to emerge. The discussion is guided by a neutral moderator to ensure that the discussion does not go off track. The moderator is also assigned the task of keeping the discussion lively and ensuring that everybody participates. At the end, an expert prepares a report that summarizes salient features and the consensus arrived at from the discussion. This report is on themes and not on quantitative outcomes of the discussion. In case diverse opinions remain, sometimes, another group of people is consulted. The summary of the discussion can help in understanding the apprehensions and anxieties of the people on one hand, and appreciation and other positive feedback on the other, regarding the problem or the program under discussion. This understanding can help in implementing the process more smoothly or changing it.

FGD results carefully consider inconsistencies and variations that are bound to exist among members of such a group. Diverse opinions are welcome, although the discussion has to be kept on track. The discussion may provide an insight into varying beliefs and experiences, and how they affect attitudes and behaviors. For more details of FGD, see Hennink and Leavy [2].

Because of the substantial role of subjective opinions in this methodology, many researchers suspect the findings of such qualitative research. Indeed, another FGD may lead to another finding, but the regular qualitative research also has potential for this aberration. Our advice is to restrict FGDs to only those areas where regular surveys fail to provide a comprehensive picture, or use them to supplement the findings instead of considering FGD an independent tool.

## follow-up studies, *see* prospective studies

## forecasting

Forecasting is the scientific estimation of unobserved values, particularly future values. Weather forecasting and forecasting of company stocks are regular occurrences, but forecasting is frequently used in the medical and health setup as well. Prognosis of a patient is an exercise in forecasting. For example, the existence of extranodal spread in various types of breast cancer has predictive value in forecasting the number of metastatic lymph nodes and the disease

prognosis [1]. Forecasting a critical patient's extent of recovery in the next 24 hours dictates what steps are required to be taken to save the patient. In the public health domain, forecasting the trend of, say, infant mortality rate (IMR) may be helpful for insights on what planning is needed and what resources must be allocated to reach a particular target in the specified time frame. All these examples illustrate attempts to study previous experience in similar circumstances and try to extrapolate on the basis of what circumstances are likely to develop in the future. Statistically, these circumstances are the **independent variables** of the model, and the outcome under forecast is the **dependent variable**.

Statistical tools generally used for forecasting are **time series models** and **regression**-based **predictive models**. However, all statistical methods, as of now, including the two just named, consider the average behavior of a *group* of patients and hope that an individual patient will revolve around this average. This strategy can and does misfire in some situations but still works well in the long run in the sense that the results are likely to be close to those predicted in many similar cases. Admittedly, the strategy may desperately fail for a particular individual. Perhaps clinical acumen of the attending physician or surgeon is more important for individual forecasting than biostatistical modeling.

With time series models, the independent variable is time. Most time series throw up dependent values at sequential points in time even when the effect of time is removed. This happens because of the presence of other factors that move with time but are not exclusive to the time. For example, in the case of IMR, the rate in the year 2020 will depend not just on the trend in previous years but also on what other social (e.g., educational or nutritional) and health infrastructure changes are anticipated for the future that are not in the past pattern. Thus, the ordinary regression methods do not apply, and special techniques such as **moving average** and **autocorrelation** are used for time series modeling. These methods take care of other factors as well that may be changing with time. Predictive regression models can have a large number of independent variables (or, call them predictors in this case) but mostly require that the residuals are independent and not autocorrelated. This works well when time is not a factor, such as in prediction of glomerular filtration rate when creatinine level is controlled.

No matter what statistical model is used, the forecast presumes that the conditions prevailing earlier continue and the effect of those not earlier prevailing can be conjectured. That is, the relationship derived from the available data is adequate to predict the unavailable values. For example, Axelsen et al. [2] found that influenza forecasts are driven by temperature, humidity, antigenic drift, and immunity loss. All these values must be available. Another requirement is that the model must be based on a large number of observations that include varying values of the predictors. Both of these are strong requirements and should be thoroughly examined for their validity before forecasting. For this reason, statistical models are able to correctly forecast values when the conditions, such as the status of a subject, are expected to change marginally and not substantially. For a time forecast, perhaps the next few years can be predicted with precision provided you already have a sufficiently long time series.

## frailty models

Statistically, frailty is the unobserved individual heterogeneity in survival models. The usual **survival analysis** is valid when the hazard of the outcome is homogenous across the subjects after taking all the covariates into consideration. However, in many cases, it is not possible to measure all the covariates—sometimes due to the cost involved and sometimes because the importance of some covariates is in doubt—and considerable heterogeneity remains. In addition, our knowledge is always limited (see **epistemic uncertainties**), and some covariates are just not known. In any case, all individuals differ in their vulnerability. Ignoring heterogeneity produces an overestimate of the life expectancy and underestimates rates of individual aging. Assessment of the achievements made by way of health improvement or interventions gets affected. Frailty models contain a random effect component for studying such "hidden" heterogeneity. This is considered to have a multiplicative effect on the baseline **hazard function**. Thus, frailty models are kind of an extension of the **proportional hazards model**—popularly known as the Cox model. They go deeper into the mechanism of cause–effect than the conventional models and may have wider applications. The term *frailty* was first suggested by Vaupel et al. [1] in the context of mortality studies. For further details of frailty models, see Weinke [2]. For technical details and extensions, see Hougaard [3].

According to Vaupel et al. [1], the concept of frailty assumes that all persons have different frailty at birth but it stays same all through life. This can be modified to have variation with age. It surely varies from person to person. Frailty is assumed to have a statistical distribution (generally a gamma distribution) with a mean and a standard deviation different for different age groups. Subjects with frailty more than the mean at any age are those who experience increased hazard. This can happen with mine workers for the age at which they work in mines, or for drivers who are on the road for much of their working life.

Because of the random component, frailty models can give different results than obtained by regular analysis. Zarulli et al. [4] found that the estimate of the effect of education level on mortality after the age of 50 years in Turin is higher by frailty model than by the regular approach. Yewhalaw et al. [5] used frailty models for studying time to malaria in Ethiopia.

## Framingham Heart Study

In 1948, a long-term study into chronic circulatory disease was started in Framingham, Massachusetts, in the United States with the objective of identifying possible **risk factors** and to characterize the natural history of the disease. This has popularly come to be known as the Framingham Heart Study. It is a **longitudinal study** with regular follow-up and is now studying the offspring of those first studied. In fact, the study is on its third generation. For example, see Coviello et al. [1].

The cohort initially recruited for this study is a random sample of 5209 persons of age 30–62 years. Both men and women were recruited. This forms nearly two-thirds of the population of the city of Framingham at that time. Thus, this is an example of an unusually large proportion of the population being sampled. The participants regularly undergo an examination and laboratory investigations almost every 2 years. As of 2014, 31 examinations had been done. The cohort has been expanded to include other people from Framingham and by recruiting the second and third generations. Further details of the study are available at their website [2].

This study is credited with coining the term *risk factor* [3]. Among the biostatistical contributions of this study was the development of new **multivariate** statistical methods to analyze the incidence of multifactorial diseases that help us to estimate the effect of different risk factors. It is also credited with developing a simple coronary prediction model on the basis of measurements such as blood pressure and cholesterol level [3].

## *F*-ratio, *see* *F*-test

## frequencies, *see also* frequency curve/distribution/polygon

Frequency in statistics is the count of occurrence of an event or a value among the subjects of a study or the number of subjects that display a particular **attribute**. You can see that no frequency can be negative. Calculating frequencies requires no advanced statistical knowledge, just basic numerical skills: perhaps the ability to calculate percentages. Frequency tables represent the most initial method for analyzing **categorical data**. Categories can be **nominal**, **ordinal**, or **metric**—that does not matter—but generally, the number of categories does not exceed 12 in such a table. Whereas nominal and ordinal categories are almost always small in number and discrete, metric data can be **discrete** or **continuous**. Examples of *metric* data that are discrete and naturally fall into categories are parity, number of angina episodes, and number of organs affected in an injury. For continuous data, frequency is obtained for values in various specified class intervals. **Class interval**, also called bin, refers to the division of the range of values into smaller parts. For example, for systolic level of blood pressure (BP), the class intervals (in mmHg) can be 100–109, 110–119, etc. Frequencies can be used to review how values in the sample are distributed over different categories. This is used to postulate a statistical **distribution** of the values, which in turn determines the specifics of the statistical method to be used for analysis of the data.

Whereas frequencies reduce to simple counts for discrete variables, they can be time consuming and prone to error for continuous variables when computed manually. Use the help of a computer as much as possible. Most statistical packages have the facility to do this. If you have a small data set and want to do it manually, proceed as follows.

Step 1: Ready the data to be plugged into the frequency table.
Step 2: Decide how many categories would be appropriate and what the class intervals should be. They do not have to be equal, but equal intervals help in proper interpretation regarding percentages in different intervals.
Step 3: Prepare a table format with the first column containing class intervals in ascending order and the second column for tally marks representing the counts. The third column will contain the frequencies as finally obtained. See Table F.7 for systolic BP levels in 33 subjects. The fourth column can have cumulative frequency or percentages as needed.
Step 4: Tally the data into class intervals. Each data value falls exactly into one class interval. Count the tallies and record the result. This is illustrated in Table F.7. Note how the fifth mark is crossed. This makes manual counting easy.

The last column, containing cumulative frequencies, is explained next.

### *Cumulative Frequencies*

Sometimes, the interest is not in the frequencies in different intervals but in the number or percentage of subjects that have not reached a particular threshold. Cumulative frequency at threshold $x$ is the count of subjects with value $\leq x$. In Table F.7, cumulative frequency till level 119 mmHg is 3 and till level 129 mmHg is 14. This means that 14 persons have a systolic level less than or equal to 129 mmHg. This is obtained by sequentially adding the frequencies in the class

**TABLE F.7**
**Manual Construction of a Frequency Table**

| Class Intervals Systolic BP (mmHg) | Tally Marks | Frequencies (*f*) | Cumulative Frequencies |
|---|---|---|---|
| 100–109 | // | 2 | 2 |
| 110–119 | / | 1 | 3 |
| 120–129 | ## ## / | 11 | 14 |
| 130–139 | //// | 4 | 18 |
| 140–159 | ## / | 6 | 24 |
| 160–179 | ## | 5 | 29 |
| 180+ | //// | 4 | 33 |
| **Total** | | **33** | |

intervals. If you want to know what percentage of people have a normal level of systolic BP (i.e., less than 140 mmHg), the answer from Table F.7 is 18 out of 33, or 55%.

Cumulative frequencies are commonly used for durations such as what percentage of people survived for at least 2 years after a particular surgery or what percentage stayed in a hospital for at least 10 days. Statistical use of cumulative frequencies is in the calculation of various **quantiles** (percentiles, deciles, quintiles, quartiles, and tertiles). A graphical method of obtaining quantiles requires that we draw an **ogive**, which is a graphical depiction of the cumulative frequencies.

## frequency curve/distribution/polygon

A frequency curve and a frequency polygon are graphical representations of **frequencies** in different class intervals of a **continuous variable**. These terms are not used for discrete variables. The curve is a smoothened polygon for a sample of subjects and tends to indicate the shape of the statistical **distribution** of the data. We explain these with the help of an example.

Consider the data in Table F.8 on total cholesterol level in a sample of 82 subjects attending a hypertension clinic. The **class intervals** are chosen in accordance with their clinical implications. To start with, note the **histogram** of these data in Figure F.6a. The frequency histogram (Figure F.6a) transforms to a frequency polygon (Figure F.6b) and then to a frequency curve (Figure F.6c). These are drawn in consideration of unequal class intervals, as explained under the topic **histogram**.

### *Frequency Polygon*

A polygon is a shape enclosed by straight lines. A frequency polygon is drawn to depict frequencies of a continuous variable, as in cases where a histogram can be drawn. That is, the continuous variable is plotted on the *x*-axis and the frequencies on the *y*-axis. For a polygon, plot the points corresponding to the frequency (or percentage) on the midpoint of the class intervals, and join them with straight lines. This procedure is the same as joining the midpoints of the tops of the bars in a histogram. For the data in Table F.8, the polygon is shown in Figure F.6b. Note how zero frequency in the interval 320–339 mg/dL is shown. The frequency before the first interval and that after the last interval re each 0, and so lines are also drawn to join zero points. This completes the polygon as an enclosed shape. This is commonly used to study the shape of the distribution. The polygon is closer to the theoretical curve than the histogram, as explained next.

**TABLE F.8**
**Distribution of Subjects Attending a Hypertension Clinic by Total Serum Cholesterol Level**

| Cholesterol Level (mg/dL) | Number of Subjects (*f*) | Percent (%) |
|---|---|---|
| <199 | 3 | 3.7 |
| 200–239 | 13 | 15.9 |
| 240–259 | 16 | 19.5 |
| 260–279 | 17 | 20.7 |
| 280–299 | 24 | 29.3 |
| 300–319 | 6 | 7.3 |
| 320–339 | 0 | 0 |
| 340–399 | 3 | 3.7 |
| **Total** | **82** | **100.0** |

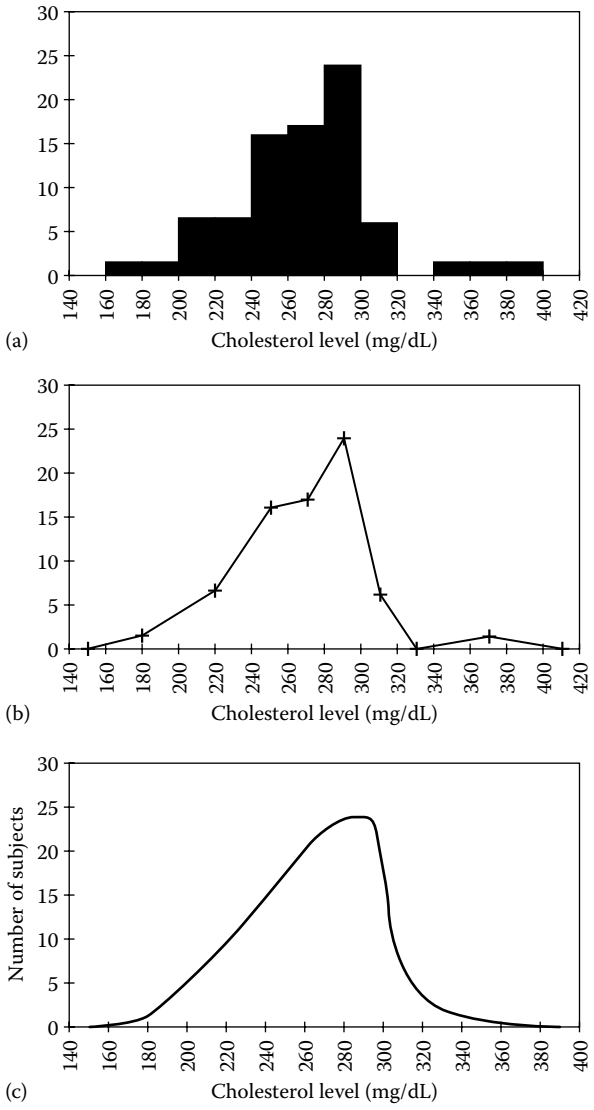

**FIGURE F.6** Different forms or representation of frequencies: (a) Histogram for cholesterol data in Table F.8; (b) frequency polygon for cholesterol data in Table F8; (c) frequency curve for the cholesterol data in Table F.8.

### *Frequency Curve*

Imagine the shape of a frequency polygon when the number of subjects is extremely large and the width of intervals is extremely small. If the data are for 3000 cases and the cholesterol intervals are only 5 mg/dL, the polygon will tend to take the shape of a curve. This can be considered a smooth version of the polygon. Theoretically, a curve would be obtained when the subjects are infinite and the intervals are infinitely small. This is called a frequency curve. A fairly good approximation of this "infinite" curve can be obtained by drawing a smooth curve closest to the polygon. A few points may be far off from the curve so drawn. The curve for the data in Table F.8 is shown in Figure F.6c. Note that a frequency of 0 in the interval 320–339 mg/dL is ignored to achieve a smooth and regular shape of the frequency curve. When an extremely large number of measurements are available, the frequency in the interval 320–339 mg/dL will not be 0.

Quite often, a frequency curve takes a regular shape and is best obtained by means of a mathematical equation. Such an equation seems to work well as a good approximation to the data arising in

practice. This is called a frequency distribution or just a statistical distribution. **Gaussian distribution** is the most common example of a frequency distribution.

Basic information provided by the histogram, polygon, or curve is the nature of the **distribution** of the subjects over various values of the variable, i.e., whether they are evenly distributed or are concentrated around some value, and whether the values are widely scattered or are compact. Thus, these figures are more of an exercise in data exploration than an analysis of data. The method of **statistical analysis** of the data depends on the shape of the distribution.

## frequentist approach, *see* Bayesian inference

## Friedman test

Developed by Milton Friedman in the years 1937–1940 [1–3], the Friedman test is a **nonparametric test** for **repeated measures** in a **one-way design** for quantitative outcome for the null that the responses in repeated measures have the same distribution. This test is primarily for correlated values such as at different points in time but can be used in a two-way setup when values at different levels of the same factor could be correlated [4]. The Friedman test will test for either factor 1 or for factor 2 considering that the other factor is nuisance and is just a replicate with no intrinsic importance. Thus, the Friedman test is an alternative for an ***F*-test** for a **two-way design** with one observation per cell for the situations where the observed values do not follow any **Gaussian** pattern. The *F*-test is not applicable to non-Gaussian data, particularly when the sample size is small. However, an *F*-test can be used to test for interactions, whereas the Friedman test cannot do this.

We explain the Friedman test with the help of an example of a two-way design with one observation per cell. Suppose one is studying the cholesterol level in different types of hypertension, and suppose the interest is in simultaneously considering obesity as well. Both are not to be considered together, but only one at a time. Let the data be as in Table F.9. As in possibly all nonparametric tests, we need to **rank** the values from the minimum to the maximum. These ranks are given in the parentheses in the table.

**TABLE F.9**
**Total Cholesterol Level (mg/dL) in Persons with Different Levels of Obesity and Types of Hypertension**

| | Obesity (Factor 2) | | |
|---|---|---|---|
| **Hypertension Group (Factor 1)** | **Thin** | **Normal** | **Obese** |
| No hypertension | 248 | 233 | 263 |
| | (2) | (1) | (3) |
| Isolated diastolic hypertension | 247 | 249 | 258 |
| | (1) | (2) | (3) |
| Isolated systolic hypertension | 261 | 275 | 267 |
| | (1) | (3) | (2) |
| Clear hypertension | 225 | 290 | 285 |
| | (1) | (3) | (2) |
| **Total of ranks ($R_{\cdot k}$)** | **(5)** | **(9)** | **(10)** |

*Note:* Ranks are in parentheses.

This is a two-way layout. Factor 1 is hypertension status, and factor 2 is obesity. The former has $J = 4$ levels and the latter has $K = 3$ levels. A separate test for the effect of hypertension status and obesity on cholesterol level can be carried out by the Friedman test. The underlying distribution can be non-Gaussian. The procedure for testing for differences between levels of factor 1 in a two-way layout can be stated as follows:

Step 1. For each $k$th level of factor 2, rank $J$ observations belonging to $J$ levels of factor 1 in order of magnitude from 1 to $J$. Denote the rank of the observation for the $j$th level of factor 1 and $k$th level of factor 2 by $R_{jk}$ ($j = 1, 2, \ldots, J$; $k = 1, 2, \ldots, K$).

Step 2. Calculate $R_{j\cdot} = \Sigma_k R_{jk}$. This is the sum of the ranks received by $K$ subjects, one each in $K$ levels of factor 2. If $H_0$ of no difference between levels of factor 1 is true, $R_{j\cdot}$ would be nearly same for all $j$ ($j = 1, 2, \ldots, J$). This leads to the criterion $S$ due to the Friedman, as specified in the next step.

Step 3. Calculate

$$\text{Friedman test for factor 1: } S_1 = \frac{12}{JK(J+1)}\Sigma_j R_{j\cdot}^2 - 3K(J+1).$$

Step 4. If $S_1$ is large, the probability of the sample values coming from a distribution as specified by $H_0$ is small. Reject $H_0$ if the ***P*-value** is less than the predetermined **significance level**. Computer packages may give the *P*-value right away. Otherwise, use Friedman tables, for example, as given by Lindley and Scott [4]. This provides critical values of $S_1$ for small values of $J$ and $K$ for $\alpha = 0.05$. If $K$ or $J$ is large, $S_1$ has an approximate **chi-square distribution** with $(J - 1)$ degrees of freedom (df's). In that case, use the chi-square distributions to obtain the *P*-value.

The preceding procedure is for testing differences in the levels of factor 1 ignoring factor 2. For testing differences in the levels of the other factor, $J$ and $K$ switch their position.

$$\text{Friedman test for factor 2: } S_2 = \frac{12}{JK(K+1)}\Sigma_k R_{k}^2 - 3J(K+1).$$

Again, for large $J$ or $K$, $S_2$ has an approximate chi-square distribution with $(K - 1)$ df's.

Consider the data in Table F.9 on total plasma cholesterol level (in mg/dL) in 12 subjects belonging to different hypertension groups. In parentheses are ranks within each hypertension category. In this example, $J = 4$ and $K = 3$. For levels of obesity (factor 2),

$$S_2 = \frac{12}{4\times 3(3+1)}(5^2 + 9^2 + 10^2) - 3\times 4(3+1)$$
$$= 3.5.$$

For this value of $S_2$, when $J = 4$ and $K = 3$, $P = 0.273$ from a statistical package. This is more than 0.05. Thus, the evidence is not enough to conclude that obesity affects cholesterol level in these subjects. You may wish to calculate $S_1$ for hypertension groups. This is $S_1 = 3.40$ and corresponds to $P = 0.446$. Thus, there is no sufficient evidence for a difference in cholesterol levels in different hypertension groups either.

The following comment for the Friedman test may be useful. The chi-square approximation is used for fairly small sample sizes. This is quite an approximation. Such an approximation becomes

necessary mostly because the exact distribution of these criteria, particularly for the Friedman test, is very difficult to obtain. In case you have software that gives you exact probabilities, there is no need to use chi-square approximation.

For $K = 2$, the Friedman test is reduced to a two-sided **sign test**. For more details, see Conover [5].

## *F*-test

An *F*-test is used to compare variance in one group of subjects with variance in another group of subjects when both groups are independent of one another. The values also should be independent of one another in each group. If they are serial values where a value depends on its previous value, independence is lost, and this test will not be applicable. Independence is also lost when values belong to some kind of affinity group or a cluster, such as family members or those sharing some other environment. The **null hypothesis** under test is that the variances in their respective populations are the same, i.e., $H_0: \sigma_1^2 = \sigma_2^2$.

Equality of variances is an important requirement of many statistical procedures, such as the **Student *t*-test** for two groups. The *F*-test helps to find whether that requirement is violated in the two groups you are studying. For this test, the ratio of the two variances is used as the test criterion, and because of this, it is also called the **variance ratio test** or ***F*-ratio test**. Under the null, this ratio would be equal to 1, and any large deviation from 1 is evidence that the variances are unequal. Since two variances are involved, it has a pair of **degrees of freedom** (df's), one for the numerator and the other for the denominator. The method is applicable to a variety of situations as described next, such as analysis of variance (ANOVA) for comparing means in three or more groups and regression where, also, the test actually is of equality of variances.

The *F*-test is valid only when the underlying distribution of values in each group follows a **Gaussian distribution**, at least nearly so. For other underlying distributions, the **Levene test** can be used for equality of variances under the conditions stated under those topics. Conventionally, though, **transformations** are advised so that the transformed data follow a Gaussian distribution. Generally, logarithm, square root, or inverse transformation does the trick.

Statistically, *F* is the ratio of two independent **chi-square** variables, each divided by its df's. Chi-square with $v$ df's itself is defined as the sum of squares of $v$ independent **standard Gaussian variables**. When the underlying distribution is Gaussian, it can be shown that the sample variance is the sum of squares of $(n - 1)$ independent standard Gaussian variables divided by $(n - 1)$. Thus, the ratio of sample variances in two independent groups is the ratio of two independent chi-squares, hence equal to *F*. The shape of the distribution of *F* is generally highly skewed just as is the shape of chi-square.

### F-*Test for Equality of Two Variances*

The most elementary application of the *F*-test is as just stated—comparison of variances in two independent groups. The criterion for this test is $F = s_1^2/s_2^2$, which is the ratio of the two sample variances. This follows an *F*-distribution provided that the variances are equal. The df's for this test are $(n_1 - 1, n_2 - 1)$, where $n_1$ and $n_2$ are the respective sample sizes. It is customary to consider the group with larger sample variance as group 1 so that the ratio is not less than 1. But this is not necessary. One can use the relationship that $1/F$ also has *F*-distribution with reversed $(n_2 - 1, n_1 - 1)$ df's. While working with statistical software packages, you will not need to do so as the software will take care of this and give you the correct ***P*-value**. Reject the null when the *P*-value is less than the predetermined **level of significance** $\alpha$. Let us reiterate that this test is valid only when the distribution of values in both groups is Gaussian.

### F-*Test for Equality of Means in Three or More Groups (ANOVA)*

The most common application of the *F*-test is in **analysis of variance**, where the objective is to find whether the means of three or more groups are equal or not. (For two groups, the **Student *t*-test** is used, although *F* can be used for two groups also.) Since there are three or more groups, the *F*-test cannot be used for testing equality of variances, although that is an important requirement of the *F*-test. Instead, the Levene test or **Bartlett test** is used for testing equality of variances in this setup. The *F*-test is used in this case to test whether or not the between-groups variance is the same as the within-groups variance in this setup. Note that between-groups variance is calculated as the variance between the group means. Substantially higher between-groups variance compared with within-groups variance is an indication that means across groups are substantially different from what are expected from natural variation between the values. These variances for the sample values are obtained by the concerned **sum of squares** divided by the respective df's. For a brief on this, see the terms **one-way ANOVA** and **two-way ANOVA** in this volume. For example, in the case of one-way ANOVA,

$$F = \frac{n\Sigma_k \left(\bar{y}_k - \bar{\bar{y}}\right)^2 /(K-1)}{\Sigma_k \Sigma_i \left(y_{ik} - \bar{y}_k\right)^2 /[K(n-1)]},$$

where $K$ is the number of groups and $n$ ($i = 1, 2, \ldots, n$) is the size of sample in each group; $\bar{y}_k$ ($k = 1, 2, \ldots, K$) is the mean of the $k$th group; and $\bar{\bar{y}}$ is the overall mean. You can see that the numerator is the between-groups variance in the sample and the denominator is the within-groups variance in the sample. Thus, basically, this is the same as the ratio of two sample variances. This can be extended to two-way and higher-way ANOVA and for testing the statistical significance of the **interactions** also. Another extension is for **repeated measures ANOVA**. As explained under the respective terms in this volume, all these tests use the ratio of two **mean sums of squares**, which are the estimates of the corresponding variances. The null of equality of means is rejected when the value of *F* exceeds a threshold at specified level of significance and the corresponding df's. Equivalently, the value of *F* also gives the *P*-value. This also can be used for decision one way or the other.

### F-*Test in Regression*

The next common application of the *F*-test is in checking the statistical significance in **regression**. For this, the regression variance is estimated by the regression sum of squares divided by its df's. This

can be obtained for any particular regressor or a subset of regressor variables in the regression. This is compared with the **mean square due to error (MSE)**, which is based on the residuals that remain unaccounted for by the regression. This is the sample estimate of the error variance. Again, under the null hypothesis of no effect of regressors on the dependent, these two estimates of variance should be equal and should give $F = 1$ under the condition of homoscedasticity. For the regression to be statistically significant, the $P$-value corresponding to the value of $F$ should be less than the prespecified level of significance $\alpha$. This can also be checked for any particular predictor or any subset of predictors.

## funnel plot

A funnel plot is the **scatter plot** of the estimates of the **effect size** under consideration from different sources against the size of the sample. The premise is that as the sample size increases, the variation in the values of the effect will decline. This happens because the variation of the effect is measured in terms of its **standard error (SE)** and SE has $n$ in the denominator, which decreases as $n$ increases. An example of a typical funnel plot is shown in Figure F.7 for odds ratios (ORs). Because this is a ratio, the plot on the $x$-axis is on a log scale.

A funnel plot is frequently used in **meta-analysis** where the effects reported in many studies are combined to obtain a more reliable estimate. Results based on small sample sizes or with high SE in different studies will obviously spread across a broad range of values. If you plot **odds ratios** in three studies each with a small sample size, they are likely to be further apart from one another compared with ORs in three other studies each with a large sample size. If you are reviewing a large number of studies—some of small size and some of large size—and plot OR on a horizontal axis and sample size on a vertical axis, the plot generally will be as shown in Figure F.7. This is called a funnel plot because of its resemblance with an inverted funnel.

In place of OR, you can have any other effect size such as **relative risk** (RR) and difference in means or proportions. On the vertical axis, you can have the inverse of the SE instead of sample size. An asymmetric shape of the funnel plot raises suspicion over the results

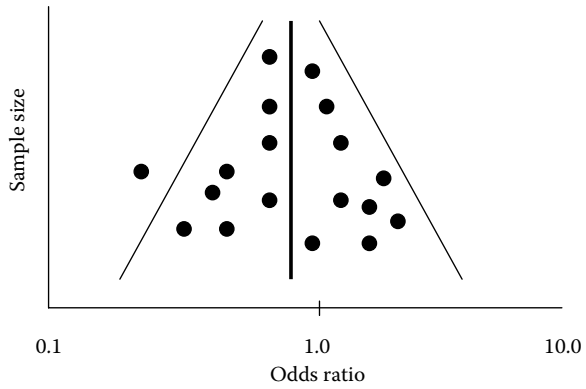

**FIGURE F.7** A typical funnel plot.

of meta-analysis since the selected studies may suffer from publication bias, favoring either higher or lower effect sizes. It also suggests the possibility of a systematic bias in smaller studies. Check whether most smaller studies tend to consistently give a larger (or smaller) effect size compared to larger studies. If so, the bias is evident, and the results of meta-analysis would be invalid. When biased studies are not included in meta-analysis, heterogeneity among results of various studies does not cause much of a problem. Your final confidence interval would depict this heterogeneity. However, funnel plot asymmetry can arise due to a host of other reasons as well, as discussed by Sterne et al. [2]. Besides publication bias, these include location bias, poor methods, inadequate analysis, and perhaps fraud. Asymmetry can also arise just due to chance in the studies included in meta-analysis.

## gain from a medical test

The objective of a medical test is to help a clinician to come to a more **valid** decision regarding the presence or absence of disease. Gain from a medical test is the addition it makes to the chance of correct prediction. This is the difference between the pretest and posttest probabilities of the disease.

As explained under the term **predictivities**, these can be understood as the posttest probabilities. They measure the likelihood of the disease or of no disease after the test result becomes known. The pretest probability is the **prevalence** in the group from which the patient has come. Assuming that the patient is a random arrival from the group on which the test is done, the chance that he/she has the disease is the same as the prevalence rate of the disease in that group. A test is useful only if it substantially alters the posttest probability of disease or its absence compared with the pretest probability. This difference is the gain attained by the test. This is easily appreciated as gain when the terms *pretest* and *posttest probabilities* are used instead of *prevalence* and *predictivity*. The gain intimately depends on the prevalence of the disease, or its pretest probability. In any case, this depends on the sensitivity and specificity of the test. The following example illustrates the gain from a medical test.

Consider α-fetoprotein determination as a test for hepatoma in patients with cirrhosis. If this test has a sensitivity of 96% and specificity 88%, what is the gain from the test at different levels of prevalence?

Posttest probabilities for positive and negative outcomes have been obtained in Table G.1 with the following formulas as explained under the term **predictivities**:

$$\text{Positive predictivity: } P(+) = \frac{S(+) * p}{S(+) * p + [1 - S(-)] * (1 - p)}$$

$$\text{Negative predictivity } P(-) = \frac{S(-) * (1 - p)}{S(-) * (1 - p) + [1 - S(+)] * p},$$

where $p$ is the prevalence rate per unit, and $S(+)$ and $S(-)$ are the **sensitivity and specificity**, respectively.

In this example, where the sensitivity is 96% and specificity is 88%, the gain in $P(+)$ is maximum when the prevalence is between 20% and 40%. That is, when a person before the test is estimated to have nearly a 1-in-3 chance of the disease, the test result would be most useful in enhancing confidence in arriving at a decision about the presence of the disease. This substantially enhanced confidence may not be enough, even less than 80%, but that is the best achievable with the help of this test for that pretest likelihood.

The gain from a test has an important clinical implication. If you already believe before the test that the person has an extremely high chance of being positive or an extremely high chance of being negative, then generally, the application of the test could make only a marginal difference in your belief. In our example, though, when the pretest likelihood of the absence of the disease is as low as 10%, a negative test firms up the belief to 71% that the disease is absent. That is a very substantial gain.

These gains would vary from one set of sensitivity—specificity values to another set. You may want to confirm that for $S(+) = 80\%$ and $S(-) = 74\%$, the gains are maximum when the pretest chances are nearly 50–50.

For an example of the real application of the gain, see Wojcinski et al. [1]. They reported that sonoelastography increased the probability of detecting malignancy in BI-RADS-US 3 lesions of the breast from 4.5% pretest to 13.2% posttest. They concluded that sonoelastography yields additional diagnostic information in the evaluation of BI-RADS-US 3 lesions. They have also mentioned sensitivity, specificity, and predictivities of this test.

**TABLE G.1**
**Gain by the Test at Different Levels of Prevalence for Sensitivity 96% and Specificity 88%**

| Probability of Presence of Disease (%) | | | Probability of Absence of Disease (%) | | |
|---|---|---|---|---|---|
| **Pretest (Prevalence)** | **Posttest *P*(+)** | **Gain by the Test** | **Pretest (100 − Prevalence)** | **Posttest *P*(−)** | **Gain by the Test** |
| 10 | 47 | 37 | 90 | 99 | 9 |
| 20 | 67 | 47 | 80 | 99 | 19 |
| 30 | 77 | 47 | 70 | 98 | 28 |
| 40 | 84 | 44 | 60 | 97 | 37 |
| 50 | 89 | 39 | 50 | 96 | 46 |
| 60 | 92 | 32 | 40 | 94 | 54 |
| 70 | 95 | 25 | 30 | 90 | 60 |
| 80 | 97 | 17 | 20 | 85 | 65 |
| 90 | 99 | 9 | 10 | 71 | 61 |

## gamma distribution

For those not aware, a statistical **distribution** is the pattern of values over their range—what values are common and what values are rare, etc. Most well known is the **Gaussian distribution**, with a peak in the middle and symmetric decline on either side. Gamma distribution typically is **skewed** to the right and is used for those variables that cannot have negative values. For example, blood sugar level in a population is likely to have a right-skewed distribution since many people will have values more than the **mode** and few people will have less (Figure G.1). Thus, blood sugar level in a population can be modeled to follow a gamma distribution. The name comes from the mathematical gamma functions used as the divisor in this distribution (referred to in the mathematical literature as the Euler integral of the first kind—the second kind being beta) to normalize it so that the area under the curve is 1, as is needed for any statistical distribution.

Just as a Gaussian distribution has two **parameters**, namely, the mean μ and standard deviation (SD) σ, the gamma distribution also has two parameters, generally denoted by α and β. These parameters do not have simple interpretation such as mean and SD. As a medical professional, you may never have to use its mathematical form, but for the information of those interested, the density function of the gamma distribution that defines the pattern of values is given by

$$\text{Gamma distribution: } f(x) = \frac{\beta^{\alpha}}{\Gamma(\alpha)} x^{\alpha-1} e^{-\beta x};\ x > 0;\ \alpha \text{ and } \beta > 0,$$

where Γ(α) is, what is called a *gamma function*. In its simple form, when α is an integer, Γ(α) = (α − 1)!. This is read as (α − 1) factorial and, for a positive integer α, defined as α × (α − 1) × (α − 2) × … × 2 × 1. For example, 5! = 5 × 4 × 3 × 2 × 1 = 120. The values of α and β determine the shape of the distribution. For example, in Figure G.1, α = 2 and β = 0.5. The mean of this distribution is α/β, and the variance is $\alpha/\beta^2$. This gives β = (mean)/(variance) and α = $(\text{mean})^2$/(variance). In case you have data such as blood sugar level of 80 persons, you can find the sample mean and sample variance, and use these values to estimate α and β.

The application of the gamma distribution in health is common for modeling the cost of care, even when calculated per day. Generally, this cost is around a specific value *x*, but in some cases, it is relatively high, and in some others, steeply high—giving rise to the right-skewed pattern of a gamma distribution. For example, Parthan et al. [1] used gamma distribution for modeling the cost of care of nonmetastatic breast cancer patients. The pattern of gamma distribution is also seen for most durations, such as duration of hospitalization or duration of disease. This could be around 3–4 days for most patients but could be 10 or more days in some patients and even 20 days in isolated cases. In neurosciences, interspike interval also follows a gamma distribution. Thus, gamma distribution has some notable applications in health and medicine.

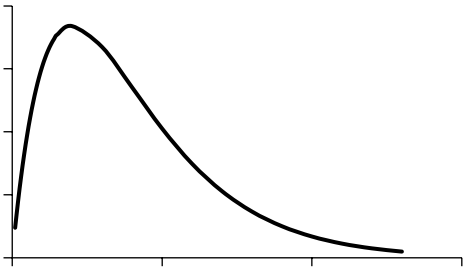

**FIGURE G.1** Gamma distribution with α = 2 and β = 0.5.

For those interested, note that **exponential distribution** is a special case of gamma distribution when α = 1. The popular **chi-square distribution** is also a special case of the gamma distribution where α = ν/2 and β = ½, ν being the degrees of freedom.

## Gantt chart

A Gantt chart is a visual depiction of the proposed timeline for carrying out various stages of a project (Figure G.2) and generally is a part of the research **protocol**. Bars one below the other are made for sequential activities, and the length of the bars is proportional to the time proposed to be taken. Figure G.2 shows for the project that identifying a research problem is envisaged to take a period of 30 days, and 15 days down the line, the process of collecting the existing information is expected to start. This activity is planned to take 60 days. And so on. Two or more activities can go together, and this is shown by overlapping bars. The collection of data will take 240 days, and scrutiny of the data will start after the data collection and will go on for 90 days.

A Gantt chart is useful to provide a full view of the stages of the project and the timeline. We have illustrated its simple use in the context of research. For another more complex usage of Gantt chart, see Sakaguchi [1].

## garbage-in garbage-out (GIGO) syndrome

A processing system requires inputs and delivers output. Garbage-in garbage-out syndrome says that when inputs are bad, the outputs cannot be good. This is often abbreviated as GIGO and is mostly used for computer systems. Most computers are programmed to process any input by a specified algorithm and produce some output, mostly without worrying about the applicability or the appropriateness of the process. Statistically, a **regression** model, for example, can be obtained irrespective of the values of dependent and independent variables. If these values or the variables are irrelevant or nonsensical, the model will still be obtained, but that could be equally useless. Thus, no regression model can be taken at face value. This is true for any statistical model. One can calculate mean, median, percentage, etc. for any set of data. Most statistical software packages still have not been given the intelligence to judge the appropriateness of the method. If the values were obtained by a wrong method or without care, the output values will also lead to wrong conclusions. Poor data can only lead to inapplicable results—sometimes even nonsensical.

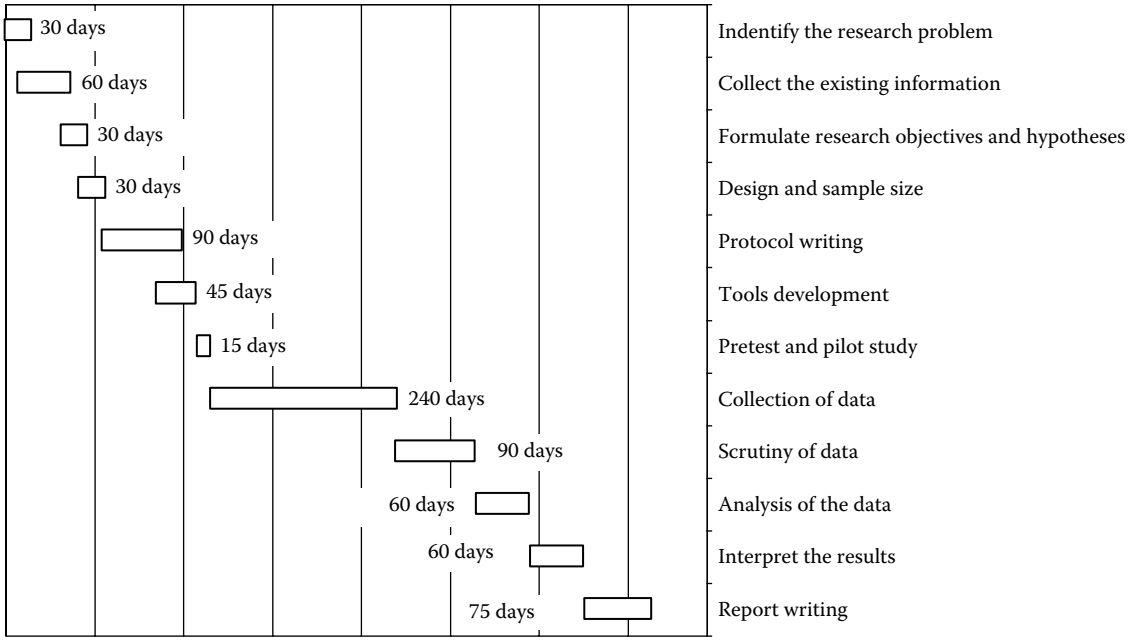

**FIGURE G.2** A Gantt chart showing the time to be taken for completing various stages of a project.

If medical research is not meticulously planned, the results cannot be expected to provide sufficiently valid conclusions. You will get some conclusions, but those conclusions will not apply to the situation you target. Thus, it is necessary that high-quality data are obtained on a well-defined topic and that they are adequately processed to get valid conclusions. Many research studies fail to reach to this expectation. Anthonisen [1] illustrates this without inhibition for research for noncredible results on obstructive sleep apnea.

## Gaussian conditions

Gaussian conditions are those statistical requirements under which many **Gaussian distribution**–based biostatistical methods are applicable to non-Gaussian data. For example, strictly speaking, the **Student *t*-test** is applicable only when the data follow a Gaussian distribution. However, the test is robust and can be used with sufficient confidence even when the distribution is mildly different from Gaussian provided that Gaussian conditions are fulfilled. This is true for analysis of variance (ANOVA), ***F*-test**, and related tests such as the **Tukey test** and **Dunnett test**. **Binomial distribution** for proportions also approaches Gaussian distribution under Gaussian conditions. Primarily, the condition requires that the sample size ($n$) is large and the sample summary under consideration is of the type *mean*. No fast rule is available, but the following are generally accepted as Gaussian conditions:

For means of continuous data: $n \geq 30$
For proportions: $np \geq 8$ and $n(1 - p) \geq 8$, where $p$ is the proportion in the sample

The latter could mean that $n$ should be at least 26,667 when $p = 0.0003$. The smaller the $p$, the larger the requirement of $n$.

Note that these conditions work for (i) a slight departure from a Gaussian pattern and not for violent departures, and (ii) mean-type summaries and not, say, median or percentiles. These conditions arise from what is called the central limit theorem (CLT), which says that mean-type sample summaries that are based on a linear combination of values tend to become Gaussian as the sample size increases. As explained for the term **central limit theorem**, proportion and correlation coefficient, too, are mean-type summary measures and amenable to this manipulation, as are the differences between means, proportions, correlations, etc.—even the odds ratio and relative risk after taking logarithm, as they become linear combinations with this transformation.

When Gaussian conditions exist, there is no need to worry too much about the form of the distribution of the data unless you have extraneous information that the data would be extremely different from Gaussian. This gives considerable freedom to use various statistical tests and is one of the important reasons for statisticians advocating a large sample size.

## Gaussian deviate, *see also* Gaussian distribution

A Gaussian deviate is the difference of a Gaussian variable from its mean, measured in standard deviation (SD) units. If a variable $x$ has a Gaussian distribution with mean $\mu$ and SD $\sigma$, the Gaussian deviate is $z = (x - \mu)/\sigma$. More fully, this is called a *standardized Gaussian deviate*, and sometimes **Z-score**. This will have what is called a **standard normal distribution** or a standard Gaussian distribution. If pulse rate in a population of healthy adults has a mean of 70 per minute and the SD is 4, the Gaussian deviate for a person with pulse rate = 63 per minute is $(63 - 70)/4 = -1.75$, and for a person with pulse rate = 81 is $(81 - 70)/4 = 2.75$. The first person's pulse rate is 1.75*SD away from the mean on the lower side, and that of the second person, 2.75*SD away on the upper side.

Where do we need a Gaussian deviate? This deviate converts a variable with a Gaussian distribution to its standard in the sense that the deviate $z$ has mean = 0 and SD = 1. The primary advantage of such a conversion is achieving comparability. If the first person in our example has a respiration rate of 16 per minute and the population mean is $\mu = 17$ and SD $\sigma = 2.5$, the Gaussian deviate is $(16 - 17)/2.5 =$

−0.4. Now you can see that the pulse rate of this person is 1.75*SD below the mean, whereas respiration rate is only 0.4*SD below the mean. The pulse rate is far below its average compared to the respiration rate. This kind of information may have significance in clinical evaluation of the person. Such a comparison cannot be made without resorting to the deviates—in this case, a Gaussian deviate if the distribution of pulse rate and respiration rate is Gaussian. In addition, well-known properties of the Gaussian distribution can be used to say that the pulse rate is on the border of being unlikely in a healthy person since it is almost 2*SD away from mean, whereas respiration rate is just about the average seen in healthy adults.

As an extension, consider the distribution of sample mean $\bar{x}$. Because of the **central limit theorem (CLT)**, this follows a near-Gaussian distribution for large $n$ with mean $\mu$ and standard error (SE) (the SD of a sample summary is called SE) $\sigma/\sqrt{n}$ irrespective of the distribution of $x$. Thus, the Gaussian deviate is $z = \frac{\bar{x}-\mu}{\sigma/\sqrt{n}}$. Similarly, for sample proportion $p, z = \frac{p-\pi}{\sqrt{\pi(1-\pi)/n}}$. These kinds of deviates are the basis for the Gaussian ***z*-test**, as described under this topic.

## Gaussian distribution

If you are not already familiar with **frequency curves** and **distributions (statistical)**, you may want to review those topics. That will help you to understand this section better.

A continuous variable $x$ is said to have a Gaussian distribution when it has the highest chance of being around the value of its mean and the chance tapers off in a specific fashion symmetrically on either side to become extremely unlikely to have values far away from the mean. The shape is typically that of a bell, and the curve is called a *bell-shaped curve*. Mathematically, a Gaussian distribution with mean $\mu$ and SD $\sigma$:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\frac{(x-\mu)^2}{\sigma^2}}; \quad -\infty < x, \mu < +\infty; \ \sigma > 0.$$

This looks like a complex form, but it conveys what is already stated in nonprecise terms regarding the highest chance around the mean and its tapering off on either side. The equation specifies the peak and how the chances decline on either side. The shape of the distribution is symmetrical around the mean. The value of the mean defines its location, and the value of the SD defines its scatter (Figure G.3). Nothing else is required to specify a Gaussian distribution.

This kind of curve arises with random errors that concentrate around 0 but occasionally can be far away too. For this reason, this is called the normal curve of error. As a side note, many would be surprised that something as chaotic as random errors follow a nice predictable pattern. This distribution originated with de Moivre in 1733 [1] and was popularized by Karl Gauss when he showed that this distribution holds for random errors.

Karl Gauss

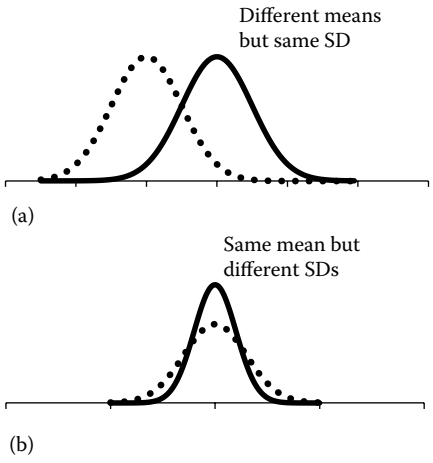

**FIGURE G.3** Gaussian distributions with (a) different means but same SD and (b) same mean but different SDs.

The Gaussian distribution is the most commonly occurring statistical distribution and has been extensively studied. This is commonly called **normal distribution**, but we prefer to call it Gaussian because of other connotations of "normal" in health and medicine. Many medical parameters follow this pattern in healthy subjects. For example, when unhealthy people are excluded, pulse rate, body temperature, kidney functions, liver functions, etc. mostly follow a Gaussian pattern. However, in sick subjects, the values may be **skewed**, sometimes highly skewed. For contrasting with other shapes of statistical distributions, see the topic **distributions**.

### *Properties of a Gaussian Distribution*

A Gaussian distribution has the following properties:

Property 1: The shape is symmetric like a bell.
Property 2: The mean, median, and mode coincide.
Property 3: The limits from (mean − 2SD) to (mean + 2SD) cover the measurements of nearly 95% of subjects. These are referred to as ±2SD limits or sometimes as 2-sigma limits (Figure G.4).

Another often-cited property of a Gaussian distribution is that the limits from (mean − 3SD) to (mean + 3SD) cover almost all subjects (99.7% to be exact). These 3-sigma limits are rarely used in health and medicine except in **quality control**, such as in a laboratory.

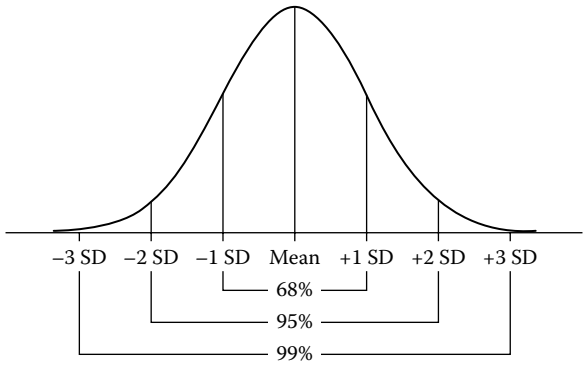

**FIGURE G.4** Mean ± 1, 2, and 3 SD limits in a Gaussian distribution.

Properties 1 to 3 hold true for the population as a whole but can also be used for samples as an approximation. The approximation works well when the sample is representative and the size is large. Sometimes, these properties are used inversely. When these properties hold for a set of data, the distribution is considered Gaussian. This inverse property also works well in most practical situations.

For illustration, consider the serum iron data in Table G.2 for a random sample of 165 healthy subjects. This has mean = 1.207 mg/L, median = 1.199 mg/L, and mode = 1.196 mg/L. These three are nearly equal. The smooth shape of the distribution is shown in Figure G.5. For these data, SD = 0.227 mg/L. Thus, the ±2SD limits are

$$(1.207 - 2 \times 0.227) \text{ to } (1.207 + 2 \times 0.227),$$

or 0.75 to 1.66.

Nearly 94% of healthy subjects mentioned in Table G.2 have serum iron levels within these limits, whereas ±2SD should have 95%. This difference of nearly 1% is due to **sampling fluctuation** and is likely to vanish as the sample size increases.

The utility of ±2SD limits in the practice of medicine is severalfold. Foremost is in determining the **normal range** for healthy subjects so that the value seen in a new subject can be assessed to be within the limits, borderline, or grossly outside. For this, the normal range must be based on the mean and SD of values in healthy subjects. Values far away from these limits are suspected to arise from health aberrations and investigated for factors causing such "abnormal" values. The second utility is in finding the **confidence interval** for the value of a parameter such as population mean μ and probability of an occurrence π. For this, the Gaussian distribution of the sample summary statistics, such as sample mean and sample proportion, is used provided that **Gaussian conditions** hold. Third is in the testing of a hypothesis for finding the chances of a sample coming from a population where the null hypothesis is true. Because of such wide and varied uses, many consider Gaussian distribution as the backbone that holds up most statistical methods.

When you know that a variable has a Gaussian distribution, you can easily find the probability that its value is within a specified range or more than or less than a particular value. For example, if the serum iron level has a Gaussian distribution, you can easily find the chance that it is more than 1.32 mg/L or that it is between 0.75 and 1.12 mg/L for any random person. How to do this is explained under the topic **Gaussian probability (how to obtain)** in this volume. Gaussian distribution can also be **bivariate Gaussian** or **multivariate Gaussian distribution**, as explained under those respective topics.

1. Frequency curve. http://www-groups.dcs.st-and.ac.uk/~history/Curves/Frequency.html, last accessed 23 July 2015

**TABLE G.2**
**Serum Iron Level in 165 Healthy Subjects**

| Serum Iron (mg/L) | Number | Percent |
|---|---|---|
| 0.50–0.69 | 2 | 1.2 |
| 0.70–0.89 | 12 | 7.3 |
| 0.90–1.09 | 33 | 20.0 |
| 1.10–1.29 | 68 | 41.2 |

## Gaussian probability (how to obtain)

Gaussian probability is the chance that the value of a variable with **Gaussian distribution** lies in certain specified range. Statistical packages give this probability easily once you specify its mean and standard deviation (SD), but the meaning and application of this probability is best understood when obtained with the help of what is called a *Gaussian table*. This table is built for the standard **Gaussian** (normal) **distribution**. When a variable has mean μ, the difference (variable − μ) has a mean of 0. The SD, however, remains σ as before. This difference is called a deviate. When a deviate is divided by its SD σ, it is called a relative deviate or a **standardized deviate**. For a Gaussian distribution, this is called a **Gaussian deviate**. For a variable $x$, the standardized deviate is $(x - \mu)/\sigma$ whether the distribution is Gaussian or not. The mean of this deviate is 0, and SD is 1. The standardized deviate for any variable is denoted by $z$.

The standardized Gaussian deviate can be used to find a probability of any type related to a Gaussian distribution with any mean and any SD. For this, convert the variable to its standard form with the help of the just-mentioned equation and then use a Gaussian table. This table generally gives the probability to the right of a given value of $z$, that is, $P(z \geq a)$. This probability is the same as the corresponding area under the curve. See the shaded area in Figure G.6a.

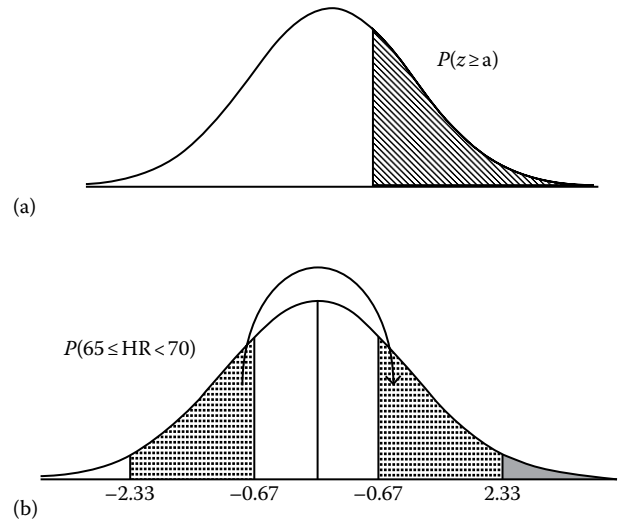

**FIGURE G.6** (a) The shaded area is the probability generally given in Gaussian tables. (b) Use of the symmetric property of the Gaussian distribution.

Figure G.6b illustrates how to use the symmetric property of the Gaussian distribution to get other kinds of probabilities.

The value of $z$ such that the probability to its right is $a$ is denoted by $z_a$, i.e., $P(z \geq z_a) = a$. Statistical software can give this probability, but we illustrate with the help of Gaussian tables available in statistical books that give this probability. For example, from a Gaussian table, $z_{0{\cdot}025} = 1.96$. This notation is different from the one used in other topics but is more convenient here. Its complement, $P(z \leq z_a)$, is called the cumulative probability till $z_a$ and is denoted by $\Phi(z_a)$. For example, $\Phi(1.96) = 0.975$. The following example illustrates the calculation and one use of these probabilities.

You know that heart rate (HR) varies from individual to individual even in healthy subjects. Suppose this follows a Gaussian pattern in a population with mean HR = 72 per minute and SD = 3 per minute. (i) What is the probability that a randomly chosen subject from this population has an HR of 74 or higher? (ii) What percentage of people in this population will have HR between 65 and 70 (both inclusive) per minute?

Since mean = 72 and SD = 3, the standardized Gaussian deviate is

$$z = \frac{\text{HR} - 72}{3}.$$

For HR = 74, $z = (74 - 72)/3 = 0.67$. Thus, $P(\text{HR} \geq 74) = P(z \geq 0.67)$. From the Gaussian table, this probability is 0.2514. In other words, nearly 25% of these healthy subjects are expected to have an HR of 74 or higher.

For (ii), proceed as follows:

$$P(65 \leq \text{HR} \leq 70) = P(\text{HR} \leq 70) - P(\text{HR} < 65)$$

$$= P\left(\frac{\text{HR} - 72}{3} \leq \frac{70 - 72}{3}\right) - P\left(\frac{\text{HR} - 72}{3} < \frac{65 - 72}{3}\right)$$

$$= P(z \leq -0.67) - P(z < -2.33)$$

$$= P(z \geq 0.67) - P(z < 2.33) \text{ because of the symmetric property of the Gaussian distribution (Figure G.6b)}$$

$$= 0.2514 - 0.0099 \text{ from Gaussian distribution}$$

$$= 0.24.$$

Thus, nearly 24% of these subjects are expected to have HR between 65 and 70. However, this answer is far too approximate, as explained next.

### Continuity Correction

The Gaussian distribution is meant for continuous variables. For a really continuous variable, $P(z > 2.33) = P(z \geq 2.33)$, that is, it does not matter whether or not the equality sign is used. This is what was done in the preceding calculation. Consider the following.

Realize that a variable such as HR is measured as **discrete** but can be considered **continuous** because of the large number of its possible values. However, in doing so, it is assumed that the rate 70 is a manifestation of values between 69.5 and 70.5. Strictly speaking, when HR is measured, it is not necessarily exactly 70 per minute. While counting beats, it is possible that there are 70 in 59.7 s and 0.3 s remains. In other words, if these are counted for 10 min, the number may reach 704. Thus, a rate of 70.4 per minute is not impossible. In that sense, it is not wrong to say that the rate 70 really means that it is between 69.5 and 70.5. This is called correction for continuity.

When this is acknowledged, HR between 65 and 70 (both inclusive) is actually HR between 64.5 and 70.5. Thus, the exact probability that HR is between 65 and 70 is

$$P(64.5 \leq \text{HR} < 70.5) = P(\text{HR} < 70.5) - P(\text{HR} < 64.5)$$

$$= P\left(\frac{\text{HR} - 72}{3} < \frac{70.5 - 72}{3}\right) - P\left(\frac{\text{HR} - 72}{3} < \frac{64.5 - 72}{3}\right)$$

$$= P(z < -0.50) - P(z < -2.50); \text{ see the equation for } z$$

$$= P(z > 0.50) - P(z > 2.50) \text{ because of the symmetry}$$

$$= 0.3085 - 0.0062 \text{ from Gaussian distribution}$$

$$= 0.30.$$

Now, with the correction for continuity, nearly 30% of subjects in this healthy population are expected to have an HR between 65 and 70. This answer is more accurate than the 24% reached earlier without the continuity correction. Note how this correction can affect the probability. The probability of HR ≥ 74 calculated earlier will also change accordingly.

Gaussian probability can be computed for any variable that follows a Gaussian distribution. The most common for sample summaries are the sample mean and sample proportion. We illustrate these with the help of an example each.

### Probabilities Relating to the Mean and the Proportion

The same sort of calculations can be done to find various probabilities for sample mean $\bar{x}$ and sample proportion $p$ provided that they follow an approximate Gaussian distribution as per the **Gaussian conditions**. The following examples may fix the ideas.

Suppose a sample of size $n = 16$ is randomly chosen from the same healthy population as in the previous HR example. What is the probability that the mean HR of these 16 subjects is 74 per minute or higher? Since the distribution of HR is given as Gaussian, the sample mean also will be Gaussian despite $n$ not being large. For the sample mean, the mean is the same $\mu$, but the SD of mean, now called **standard error (SE)**, is $\sigma/\sqrt{n}$. Thus,

$$P(\bar{x} \geq 74) = P\left(\frac{\bar{x} - \mu}{\sigma/\sqrt{n}} \geq \frac{74 - 72}{3/\sqrt{16}}\right)$$

$$= P(z \geq 2.67), \text{ as per the explanation just given for sample mean}$$

$$= 0.0038 \text{ from Gaussian table.}$$

This probability is less than 1%, whereas the probability of individual HR ≥ 74 is nearly 0.25 (see the previous part of this example). This happens because the SE of $\bar{x}$ is $3/\sqrt{16} = 0.75$, which is substantially less than SD = 3. The lower SE indicates that the values of

$\bar{x}$ will be very compact around its mean of 72, and very few $\bar{x}$s will ever exceed 74 per minute if the sample size is $n = 16$.

Realize that the mean, not only of HR but of any variable, in any case can be a fraction. In this example, the mean 74 is actually 74.0. Thus, there is no need for any continuity correction when calculating probabilities for the mean.

Now take an example of qualitative data where the interest is in proportion instead of mean. Consider an undernourished segment of a population in which it is known that 25% of births are preterm (<36 weeks). Thus, $\pi = 0.25$. In a sample of $n = 60$ births in a random month in this population, what is the chance that the number of preterm births would be less than 10?

Since $n\pi = 15$ in this case, which is more than 8, the Gaussian condition is fulfilled, and Gaussian approximation can be safely used. The probability required is

$$P(\text{preterm births} < 10) = P(p < 10/60),$$

where $p$ is the proportion of preterm births in the sample. Since the mean of $p$ is $\pi$ and $\text{SE}(p) = \sqrt{\pi(1-\pi)/n}$, this probability can be obtained as follows:

$$P(\text{preterm births} < 10) = P\left(\frac{p-\pi}{\text{SE}(p)} = \frac{\frac{10}{60} - 0.25}{\sqrt{0.25(1-0.25)/60}}\right)$$

$$= P(z < -1.49), \text{ as per the application for sample proportion}$$

$$= P(z > 1.49) \text{ because of the symmetry of } z$$

$$= 0.0681 \text{ from Gaussian table.}$$

Thus, there is a less than 7% chance that the number of preterm births in this population on a random day would be less than 10 out of 60.

## Gaussianity (how to check)

Many statistical methods are probably overly dependent on **Gaussian distribution**, although this is not a strict requirement for **sampling distributions**, because of the **central limit theorem**. Many times, you would want to know whether the pattern of your data is Gaussian or not—for example, to decide whether the median would be a more appropriate **central value** or the mean would be more appropriate. For sampling distribution also, knowledge about the pattern of the original values is helpful. For example, there is a tendency for small sample $\bar{x}$ to follow the same kind of distribution as the individual $x$'s. The distribution of duration of labor in childbirth is known to be **skewed** to the right. That is, a long duration (relative to the mode) is more common than a short duration. The distribution of mean duration in a small sample of, say, eight women is also likely to follow the same pattern, although in attenuated form. In such cases, if the pattern is not known, it is worthwhile to investigate whether or not it is Gaussian.

Some gross methods for assessing Gaussianity are (i) studying shape of a **histogram** or **stem-and-leaf plot** and checking if it follows the symmetric pattern expected for a Gaussian distribution; (ii) approximating equality among the values of mean, median, and mode; (iii) a **quartile plot** or **box-and-whiskers** plot; and (iv) a **proportion-by-probability (P-P) plot** and **quantile-by-quantile (Q-Q) plot**. All these are presented in this volume under the respective topics. The other alternative is to calculate **standardized deviate** for each observed value, order them from minimum to maximum, and plot them against the corresponding Gaussian probability on a probability paper. This is called **normal probability plot**. If the distribution of observed values is Gaussian, the plot will be nearly a straight line. Another method is to check if mean ±1SD covers nearly two-thirds and mean ±2SD nearly 95% of the values. The range should be nearly 6SD.

More exact methods are based on calculations that check statistical significance from the postulated pattern, such as Gaussian. An overview of these is as follows.

### *Overview of Significance Tests for Assessing Gaussianity*

Although the following tests are discussed in the context of assessing Gaussianity, the methods are general and can be used to assess whether the observed values fall into any specified pattern. Ironically, all these methods require large $n$, in which case the sampling distribution of $\bar{x}$ and of $p$ tends to be Gaussian anyway. The methods would still be useful if the interest is in assessing the distribution of original values rather than of a sample mean. A useful method is the **goodness-of-fit test** based on chi-square. This is based on the proportion of values in various class intervals and is presented under that topic. Other methods are as follows.

Among several statistical tests for Gaussianity, the three most popular are the Shapiro–Wilk test, Anderson–Darling test, and Kolmogorov–Smirnov test. All these are mathematically complex. Statistical software packages generally have a routine for these tests that you can easily apply. However, it is important that you understand the implications.

The **Shapiro–Wilk test** focuses on a lack of symmetry particularly around the mean. This test is not very sensitive to differences toward the tails of the distribution. On the contrary, the **Anderson–Darling test** emphasizes the lack of a Gaussian pattern in the tails of the distribution. This test performs poorly if there are many ties in the data. That is, for this test, the values must be truly continuous. The **Kolmogorov–Smirnov test** works well for relatively larger $n$, and when the mean and SD of the postulated distribution are known a priori and do not have to be estimated from the data. This also tends to be more sensitive near the center of the distribution than at the tails. Details of these tests are mentioned under the respective topics.

The critical value beyond which the hypothesis is rejected in the Anderson–Darling test is different when a Gaussian pattern is being tested compared to when another distribution such as lognormal is being tested. The Shapiro–Wilk critical value also depends on the distribution under test. But the Kolmogorov–Smirnov test is distribution-free, as the critical values do not depend on whether Gaussianity is being tested or some other form. Only the procedure for calculation differs.

It may sound strange to some, but all these statistical tests cannot confirm Gaussianity, although they confirm, with reasonable confidence, the lack of it when not Gaussian. Gaussianity is presumed when its lack is not detected. This is a serious limitation for small sample size since no statistical test is sufficiently powerful to detect deviation if the sample size is small. For reasonable assurance of Gaussianity, an **equivalence test** possibly can be devised, although not directly available in books.

## Gaussian test, *see* *z*-test

## generalized estimating equations (GEEs)

The method of generalized estimating equations (GEEs) is used to estimate the parameters of a model where several correlated response (**dependent**) **variables** are investigated for their relationship with several explanatory (**independent**) **variables**. Thus, this is

an extension of the **generalized linear models** to the setup where the responses are correlated. The correlation can be because the same subjects are measured at several points in time (as in **longitudinal data**), each subject is measured at several sites (such as a particular brain function at several locations in the brain), subjects share a common environment (such as those living together in a family), or any other such setup. In short, such data can be called clustered in the sense that they are more similar within the cluster than outside the cluster. The GEE method provides a framework for analyzing such correlated data and could be useful for cluster randomized trials. The method is comprehensive since the data can be of almost any type—continuous (**Gaussian** or non-Gaussian) or discrete (proportions or counts), rate or ratio. It can be adapted to estimate **fixed effects**, **random effects**, and mixed effects. The difference between general linear models, generalized linear models, and GEEs is shown in Table G.3.

Consider the cholesterol level of 200 members of 70 randomly selected families. Note first that the number of persons in different families would be different and second that $n$ actually is 70 and not 200. You cannot calculate the **standard error (SE)** of the estimates with $n = 200$ as family is a cluster in this example. Because of common heritance and similar diet, the cholesterol values of members of the same family will be correlated. While the families are statistically **independent**, the individuals within the families are not, and thus, the methods of generalized linear models are not applicable. You can also have information on the sex of each person, his/her age, blood group, body mass index, physical exercise, etc., which could be the regressors in this setup. These could be **discrete** or **continuous** or a combination—that does not matter. The objective is to find the extent and form of the relationship between the regressors and the response variable. The response variable is the cholesterol level of the members of the families in this example. When the response variable is continuous, as in this example so far, you would hope that clustered values jointly follow a multivariate Gaussian pattern so that the usual multivariate method of **general linear models** can be used to estimate the **regression coefficients** and to test a **hypothesis** on them for their statistical **significance**. Besides the Gaussian pattern, this will also require an estimate of the **correlations** between the members of the same family and that these correlations are similar across families. The estimates of correlations will come from the sample values in this setup. Unequal clusters and the requirement of multivariate Gaussianity along with the estimate of the correlations and their homogeneity can be a challenge. In the generalized linear model setup, in place of actual cholesterol level, if you only have the information that it is within normal limits or is high, the dependent variable will be **dichotomous**. This will require that a **logistic** kind of relationship be studied. However, because of correlation among the family members, the usual logistic regression is not applicable. If there is no correlation, both these setups (and many others) can indeed be woven into a unifying method of generalized linear models. When correlations are present, these various setups can be studied by the GEE method.

The same setup arises when a characteristic is measured repeatedly over a period of time in a **longitudinal study**. For example, you may want to measure the pain score before and at 1, 2, 5, and 10 min after administering an anesthesia in a patient being prepared for a surgery. Some patients can be measured only one or two times and some others three or four times depending on how they respond to the anesthesia. The number of observations available on each subject may or may not be the same. But these pain scores of the same patients at different points in time will be correlated. The regressors in this setup could be hemoglobin (Hb) level as a marker of nutrition, blood pressure, body mass index, etc. The GEE method is the most commonly used method for analyzing such longitudinal data. Multiple observations on each patient at different points in time form a cluster in this example.

Since the mathematical details are too complex for most medical professionals, we try to explain the GEE method heuristically so that you have at least the elementary knowledge about this method. The strength of the method stems from (i) using only the mean (and to some extent variance) of the values but not any particular **distribution**—this makes it a semiparametric method, (ii) not requiring any joint or multivariate distribution of the clustered values, and (iii) not worrying much about the specific correlation structure. In fact, the correlation structure is considered kind of a nuisance, and it has been shown that the estimates obtained by the GEE method are statistically *consistent* in the sense that as $n$ increases, it tends to become the actual value in the population with certainty, mostly even when the correlation structure is misspecified. This method is able to produce reasonably valid SEs of the estimates of the regression coefficients—thus, believable **confidence intervals** can be obtained when the sample is truly representative. Unlike the usual methods of generalized linear models, the GEE method does not explicitly model between-cluster or within-cluster variation but directly models the mean response. Note that within-cluster variation is a kind of correlation that we have stated as a nuisance under this method.

The GEE method can be implemented by using an appropriate statistical package. But specifying it correctly for commands in the software is difficult. Also, deciphering the output provided by the software can be a challenge. Thus, this method should not be used by nonexperts.

The method requires that a working correlation structure for responses within clusters be specified, although the actual values of the correlations are not required. If you consider this appropriate, you have the option to consider that there is no correlation. This would mean that the values within clusters are independent and reduces the GEE method to the usual generalized linear modeling. The other option is that the correlation between the first and second values within a cluster is the same as between the first and third values, between the second and the fourth values, etc. This is called **exchangeable** or compound symmetry of the correlations. The third option is that the longitudinal values are **autocorrelated** with lag 1—that is, if the correlation between the first and second values is $\rho$, the correlation between the first and third values is $\rho^2$, etc. The fourth option is to consider that different values within

**TABLE G.3**
**Difference between General Linear Models, Generalized Linear Models, and Generalized Estimating Equations**

| Type of Response Variable | Condition on Responses | Method |
|---|---|---|
| Continuous, nearly Gaussian pattern | Uncorrelated | General linear models |
| Continuous (Gaussian or non-Gaussian) or discrete (proportions or counts, rates or ratios) | Uncorrelated | Generalized linear models |
| Continuous (Gaussian or non-Gaussian) or discrete (proportions or counts, rates or ratios) | Correlated | Generalized estimating equations |

*Note:* In all of these, the regressors can be of almost any type—continuous or discrete—and may define fixed or random effects.

the cluster have different correlations, called unstructured. One of these structures is required to solve what are called GEEs. These equations are obtained by maximizing the likelihood without using the Gaussian distribution, called quasi-likelihood. The choice of the correlation structure is not terribly important under the GEE method, but correct specification does help in getting more reliable estimates of the SEs.

Tang et al. [1] used the GEE method to identify the determinants of quality of life during the dying process of terminally ill cancer patients who were longitudinally followed till death, and concluded that optimal quality of life during the dying process may be achieved by interventions designed to adequately manage physical and psychological symptoms, enhance social support, lighten perceived sense of burden to others, and facilitate experiences of posttraumatic growth. Van Rijn et al. [2] studied the effects of single or multiple concordant human papillomavirus (HPV) infections at various anatomical sites (anal canal, penile shaft, and oral cavity) on type-specific HPV seropositivity by using logit link in GEEs. For details of such links, see **link functions**.

The GEE method was developed by Liang and Zeger [3] in 1986. For further details, see Hanley et al. [4]. For technical details, see Agresti [5].

## generalized linear models, *see also* general linear models

The generalized linear model (GLM) is an extension of the general linear model to the setup where the response variable may have a **distribution** far from **Gaussian**. The response can be **continuous** (with Gaussian or non-Gaussian distribution) or **discrete** (proportion or count or rate). Other conditions remain the same as in general linear models. In case you are not familiar with general linear models, we recommend that you familiarize yourself with the general linear models before trying to grasp the essentials of the GLMs. A brief description of these models is in under the topic **general linear models**.

As in the case of general linear models, there is no restriction on the **independent** or regressor variables in the GLMs. These variables could be continuous or discrete, and may pertain to **fixed or random effects** (or may be mixed). When they are mixed, the model would be called a *generalized linear mixed model*. But these regressors must affect the response through linear coefficients, although the variables themselves could be square or log or any such function. If the effect is not linear, the GLM will study only its linear part. Equation-wise, the GLM is

$$y_i = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_K x_K + \varepsilon_i,$$

where $y_i$ is the response of the $i$th person or unit; the regression coefficients β's are linear (i.e., no $\beta^2$, $e^\beta$, etc.) but $x_2$ could be $x_1^2$, etc.; and $\varepsilon_i$ may *not* follow a Gaussian distribution in GLM. For the general linear model, these errors are required to follow a Gaussian pattern, or nearly so if $n$ is large. In the case of GLM, these errors may follow any of the wide spectrum of distributions of what is known as the *exponential family*. This family includes **binomial**, **Poisson**, **exponential**, **Weibull**, **beta**, **gamma**, etc. Notice that these distributions can be highly **skewed** and can belong to **discrete variables**.

You may be aware that the general linear model is a combination of **regression**, **analysis of variance**, and **analysis of covariance**, but the response variable must be continuous in all these setups. **Gaussian distribution** is required in general linear models for building up confidence intervals and for tests of hypotheses on the model parameters, although point estimates can be obtained with the **least squares method** even when the distribution is not Gaussian. These restrictions are dispensed with in GLM by using what is called a link function, which converts the response to a form that has a relatively easily analyzable distribution. For example, proportions that follow a binomial distribution are converted to **logits**—this transforms the probability between 0 and 1 to values that can be positive, negative, or 0. Similarly, counts (e.g., number of patients coming to a clinic) that follow a Poisson distribution are transformed to logarithms to yield to nearly a Gaussian pattern. Logit and log are the respective link functions in these situations. There are other link functions for other setups, as presented under the topic **link functions**. No transformation is required if the response variable is already Gaussian. This is called *identity link*. However, in the GLM, just as in general linear models, various values of the response variable must not be correlated; that is, they must belong to separate persons or units that do not affect each other and do not, for example, belong to the same family, whose members are likely to provide similar values at least to some extent. When the values are correlated, use **generalized estimating equations (GEEs)**.

Estimates of the regression coefficients β's are obtained such that the likelihood of the sample coming from the distribution postulated by the link is maximum. These are popularly called **maximum likelihood estimates (MLEs)**. For Gaussian distributions, these MLEs are well known and can be easily derived, but many other distributions admissible under GLM require an iterative weighted least squares procedure. *Iteration* in effect means that a start is made with some plausible estimates such as the mean, the model is checked whether it fits well with the observed data, and the estimates are revised according to the discrepancies found. This can go on for several iterations till such time that the updated estimates by two successive iterations are nearly the same. (This is called *convergence*—there may be situations where the estimates do not converge, in which case we say that we are not able to obtain the plausible estimates.) Statistical packages are well trained to do these iterations for you, and you would not get wrong estimates if a standard package is used. These packages will give you the estimates of the β's and their standard errors (SEs) and will also test the statistical significance of each regression coefficient. You can then decide which of the regressors are worth retaining and which ones can be discarded.

As in the case of general linear models, **standardization** by subtracting the mean and dividing by the standard deviation (SD) is recommended for explanatory continuous variables so that each gets similar importance. If standardization is not done, the variable with

large values, such as cholesterol level compared with hemoglobin level, sways the estimates and the statistical tests. In statistical terms, the cholesterol level will get disproportionately large weight in calculations relative to the hemoglobin level in the absence of standardization.

The goodness of fit of the model and the statistical significance of the contribution of each variable or a set of explanatory variables is tested by **deviance**.

The GLM method is originally from Nelder and Wedderburn [1]. Further details of the method are available in Dobson and Barnett [2].

## general linear models, *see also* generalized linear models

General linear model is the name given to the method that unifies ordinary **regression**, **analysis of variance**, and **analysis of covariance**. In all these setups, the response variable, also called the **dependent**, should be continuous and is expected to follow a nearly **Gaussian distribution**. The values must be independent and not correlated. This condition in effect means that the observations must belong to separate units or different persons and not belong to one family, one person at different points in time, or different body sites, or any other affinity group whose members have a tendency to be similar to one another.

To fix ideas, denote the response of the *i*th person by $y_i$ and his/her regressors by $x_{1i}$, $x_{2i}$, …, $x_{Ki}$. If you are trying to explain a particular kidney function by the person's weight, age, sex, water intake per day, fiber content in the diet, etc., this notation is like saying that third person ($i = 3$) in our study has kidney function $y_3 = 54$ mg/dL and her weight $x_{13} = 62$ kg, age $x_{23} = 45$ years, sex $x_{33} = 0$ (where 0 is the notation for females and 1 for males), water intake per day $x_{43} = 3.4$ L, and fiber content $x_{53} = 340$ g. Note that $i = 3$ in all these $x$'s. Under these notations, a general linear model is given by

$$y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \ldots + \beta_K x_{Ki} + \varepsilon_i,$$

where $y_i$ is the response or dependent and $\varepsilon_i$ is the error that has Gaussian distribution with a mean of 0 and any standard deviation (SD) $\sigma$. This is written as $\varepsilon_i \sim N(0, \sigma)$, where $N$ stands for normal distribution, which we like to call Gaussian, since the term *normal* has a different meaning in health and medicine. Note that the SD is the same for each $i$—the condition popularly known as homogeneity of variances or **homoscedasticity**.

The $x$'s are the regressors or the **independent** variables, and the $\beta$is are the **regression coefficients**. These coefficients are the **parameters** of the model. The expression $\beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \ldots + \beta_K x_{Ki}$ is the mean of all the persons in the target population whose regressor values are $x_{1i}$, $x_{2i}$, …, $x_{Ki}$. This can be denoted by $\mu_i$. This and the previous explanation regarding $\varepsilon_i$ imply that $y_i \sim N(\mu_i, \sigma)$. In our example, $\mu_i$ is the population mean of those persons whose weight is 62 kg, age is 54 years, etc. If there are 16 persons in the population with exactly same values of all $x$'s, they will most likely have different kidney function, and $\beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \ldots + \beta_K x_{Ki}$ is the notation of their mean. Thus, general linear models are for means and not for individual values—a fact that many forget while interpreting a model. You can see that the mean response will change if any $x$ value changes, for example, if age is different or weight is different. Now it should be clear that $\varepsilon_i$ is the deviation of the response of the *i*th person in the population from its mean of similar people; thus, $\varepsilon_i$ has zero mean. This is what is being called error. If the model is a good fit (which really means that the estimates of $\beta$'s are such that the residuals are minimal, the SD will be small. A large SD will indicate that the model is not a good fit. This SD is estimated by the square root of **mean square error (MSE)**, which is the sum of the squares of the residuals divided by its **degrees of freedom**. Residuals are explained later on in this section.

The model is linear so long as the coefficients are linear. That is, there is no $\beta^2$, $e^\beta$, or log$\beta$ type of coefficient. This means that when any $x_k$ increases by one, the response $y$ is supposed to increase by its coefficient $\beta_k$. The regression coefficient $\beta_k$ is generally interpreted as the *net contribution* or net effect of the variable $x_k$ ($k = 1, 2, \ldots, K$), but the term *net* is too strong. For this to be really net contribution, the model must include all possible variables that can affect the response. This is a tall order first because it is not generally feasible to include *all* the variables and second because only those variables that are known or suspected can be included. Many are unknown, and this **epistemic uncertainty** is many times forgotten. An example given later in this section will clarify one aspect of the interpretation of the regression coefficient. Also see the topic **linear regression**. In case the relationship is not linear, a general linear model will limit itself to whatever is the linear part and ignore the rest. In this case, the model will not be a good fit to the data.

However, there is no restriction on the $x$'s. The type of $x$'s is the feature that distinguishes among ordinary regression, analysis of variance, and analysis of covariance. In ordinary regression, all $x$'s have to be quantitative; in analysis of variance, all $x$'s have to be discrete—mostly defining the groups through **indicator variables**; and in analysis of covariance, these are mixed. It is easy to unify all these into one theoretical framework because basically all $x$'s are considered fixed in this setup and the value of $y$ is estimated for *given* values of the $x$'s. The requirement of Gaussian distribution, independence, and homoscedasticity is handy in pursuing what is called the **maximum likelihood estimates (MLEs)**. This method finds those estimates of the parameters that make the observed values most likely. These estimates are denoted by $b$'s. Any standard statistical software will easily obtain these estimates for you when the model is properly specified. Proper specification means that you correctly tell the computer program which variable is to be treated as continuous, which as **categorical**, etc. When these estimates are used, the model can be written as

$$y_i = b_0 + b_1 x_{1i} + b_2 x_{2i} + \ldots + b_K x_{Ki} + e_i,$$

and the estimated value of $y$ for the *i*th person is $\hat{y}_i = b_0 + b_1 x_{1i} + b_2 x_{2i} + \ldots + b_K x_{Ki}$. Note that the error term is now denoted by $e_i$ and called **residual** in the context of the sample. This is the difference between the *mean* response in the sample for the persons with values $x_{1i}$, $x_{2i}$, …, $x_{Ki}$ of the regressor variables and the actual observed response for the *i*th person. If there is only one person with these values of the $x$'s, $e_i$ is the difference between the observed $y_i$ and the estimated $\hat{y}_i$.

Under a Gaussian distribution of the response variable, the estimates $b$'s of the regression coefficients $\beta$'s also have Gaussian distribution. This allows us to easily find the **confidence intervals (CIs)** for estimates of $\beta$is and to **test hypotheses** on them by using the property, for example, that the estimate $\pm\, t_{\nu 0.025}$*(estimated SE) is the 95% CI and (estimate − its mean)/(its estimated SE) has **Student *t*** distribution with $\nu$ degrees of freedom (df's). This SE is estimated by the MSE as just explained.

A simple example of a general linear model is the work of Ainslie et al. [1]. They examined how blood flow velocity in the middle cerebral artery (MCAv) in healthy humans is affected by physical activity, body mass index (BMI), blood pressure

(BP), and age. Physical activity was assessed as active or inactive. Thus, this is categorical. The response variable is MCAv, which is quantitative, and it must have nearly the same variance for different ages, different physical activity, etc. for general linear models to be applicable. The authors found that BMI and BP did not have a statistically significant contribution, while age and physical activity were important for MCAv. They have reported a separate model for active and inactive persons, but these combine into the following:

$$\text{MCAv (in cm/s)} = 87.8 - 0.73*\text{age (in years)} + 9.2*\text{activity} - 0.03*\text{activity}*\text{age},$$

where activity = 1 for physically active persons and activity = 0 for inactive persons. When these values of activity are substituted, the models become

$$\text{MCAv (in cm/s)} = 87.8 - 0.73*\text{age (in years) for inactive persons}$$

$$\text{MCAv (in cm/s)} = 87.8 - 0.73*\text{age (in years)} + 9.2\times 1 - 0.03\times 1\times \text{age} = 97.0 - 0.76*\text{age (in years) for active persons.}$$

This model means that MCAv was reduced on average by 0.73 cm/s for each year increase in age in inactive persons but by 0.76 cm/s in active persons, although the baseline for active persons was high (97.0 versus 87.8). Gaussian distribution is not a requirement for getting these equations, because the estimates of the regression coefficients can be obtained by the **least squares method**. But Gaussian distribution is needed to work out the CI. The authors also reported the CI for these regression coefficients. Those who are aware will realize that this model is the same as the analysis of covariance where age is the covariate. Analysis of covariance is the most generalized of the general linear models since it has both continuous and discrete regressors.

The statistical significance of a general linear model is assessed by an ***F*-test**, which is obtained as the mean **sum of squares** due to the model and the mean sum of squares due to error (MSE). The statistical significance of each regression coefficient can also be tested. Appropriate statistical software will do it for you, but the model must be properly specified. Many modifications of the model can be done to test other kinds of **null hypotheses**. For a complete description of the general linear models, their strengths, and their weaknesses, see Vik [2].

When the distribution of the response variable is far from Gaussian, we need to fall back on the **generalized linear models (GLMs)**, and if the responses are correlated, we get help from the **generalized estimating equations (GEEs)**.

## gender inequality index

The gender inequality index (GII) measures the inequality between male and female achievements in three dimensions, namely, health, empowerment, and labor participation. This index was originally proposed by Seth [1] and is now promoted by the United Nations Development Program (UNDP) as a part of the **human development index (HDI)** since gender inequality has been found to be a potential source of adverse human development. This index varies from 0 for areas where men and women fare equally well to 1 where either gender fares as poorly as possible relative to the other [2].

Gender inequality has lately assumed importance around the world, and efforts are made to quantify this inequality so that the trend can be studied and comparison across communities can be made. This certainly has great social implications, but it may affect physical health as well through, for example, smoking, suicides, domestic violence, and life expectancy. It is also strongly related to birth weight, infant mortality, fertility, etc. Varkey et al. [3] have discussed health issues related to gender empowerment in detail, which is a part of GII. In fact, gender empowerment was the earlier index used by UNDP but has now been replaced by GII. **Gender empowerment** was assessed by the proportion of seats held by women in national parliaments, percentage of women in economic decision-making positions, and female share of income. Beside gender empowerment in a modified form, GII includes female disadvantages due to maternal mortality, adolescent fertility, and lack of education.

For calculation of GII, the HDI uses the following indices: (i) **maternal mortality rate (MMR)**; (ii) adolescent fertility rate (AFR), which is the number of births per 1000 girls of age 15–19 per year; (iii) share of parliamentary seats held by each sex (PR) measured in fraction; (iv) attainment at secondary and higher education (SE) levels measured in fraction for females and males separately; and (v) labor market participation rate (LFPR), which is the fraction of working-age women and men in employment. The index uses the **geometric mean** (GM) instead of the usual arithmetic mean of these indices because of their highly skewed distribution. GM is the *n*th root of multiplication of *n* values. If the value of any of these indices is 0, which is not impossible, it is assumed to be 0.1 so that the GM does not become 0.

The first step in the calculation of GII is to obtain

$$G_F = \sqrt[3]{\left(\frac{10}{MMR}\times\frac{1}{AFR}\right)^{1/2}\times(PR_F\times SE_F)^{1/2}\times LFPR_F} \text{ for females.}$$

This basically is the GM of three GMs. The first part is the GM of the two adverse health components, namely, the MMR (whose minimum is assumed to be 10) and the AFR; the second is the GM of the two empowerment components, namely, the parliament seats and the educational attainment; and the third component is labor participation as a stand-alone factor. In the case of males, the adverse health component is 1 since there is no risk of maternal mortality or adolescent fertility. Thus,

$$G_M = \sqrt[3]{1\times(PR_M\times SE_M)^{1/2}\times LFPR_M} \text{ for males.}$$

In the second step, the preceding two indices are aggregated by the **harmonic mean**, which captures the inequality between men and women and adjusts for association between the dimensions. The harmonic mean is the reciprocal of the mean of reciprocals:

$$\text{HARM}(G_F, G_M) = 1/\left(\frac{1/G_F + 1/G_M}{2}\right).$$

This creates an index with equal weight to the two genders, called the equally distributed gender index. This will be used after the third step.

The third step is to aggregate the original indices for males and females with equal weight given to each gender. This is done again by the GM of the "averages" of the three dimensions as follows:

$$G_{F,M} = \sqrt[3]{\overline{Health} \times \overline{Empowerment} \times \overline{LFPR}},$$

where $\overline{Health} = \dfrac{\left(\sqrt{\dfrac{10}{MMR} \times \dfrac{1}{AFR}} + 1\right)}{2}$,

$$\overline{Empowerment} = \frac{\left(\sqrt{PR_F \times SE_F} + \sqrt{PR_M \times SE_M}\right)}{2}, \text{ and}$$

$$\overline{LFPR} = \frac{(LFPR_F + LFPR_M)}{2}.$$

Finally,

$$\text{GII} = 1 - \frac{HARM(G_F, G_M)}{G_{F,M}}.$$

This is the difference between the standard, which is 1, and the equally distributed gender index adjusted for $G_{F,M}$.

For an illustration of the calculations, see the technical notes of the *Human Development Report*, 2013 [2].

## geriatric health (epidemiological indicators of)

Geriatric health is gaining increasing importance as the older population is rapidly rising in most countries. Some epidemiological measures of geriatric health are given here—they can be used for individual assessment. Several others are listed in Ref. [1]. Many more are coming up, and you should keep an eye on the new developments.

### *Activities of Daily Living*

In the case of old age or handicaps, the degree of disability can be measured in terms of an activities of daily living (ADL) index. Scores are assigned to the level of independence assessed on several activities of daily living such as walking, bathing, use of toilet, and dressing. The score could range from 0 for complete dependence to, say, 4 for complete independence on each item. The sum of these scores is called the ADL index (see, e.g., Katz and Akpom [2]). A disadvantage of such an index is that it is insensitive to change when the level improves on some items and deteriorates on the others. Another index is derived from 14 questions ranging from difficulty in self-care (e.g., eating or dressing) to higher-level activities (e.g., carrying weights or doing housework), used by the WHO Eleven Countries Study [3], which can be adapted to suit local conditions. No index, including those just mentioned, is widely acceptable.

### *Mental Health of the Elderly*

Physical limitations emerging from degeneration in old age are recognized, but mental agility also deserves attention. Among many instruments available for measuring the mental health of the elderly, one in common use is the mental health component of quality-of-life questionnaires, such as the short form with 36 items (SF-36) [4]. This is no different from the tool used for the general population of adults. SF-36, however, is restricted to functional status, including for mental health.

Insomnia and anxiety are common in old age. For these, the Pittsburgh Sleep Quality Index [5] and *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-V) [6], respectively, can be used. Both are for the general population and not specific to the elderly. The Beck Depression Inventory is used for assessing the severity of depression symptoms. This is an old instrument but continues to be commonly used, particularly for people of old age.

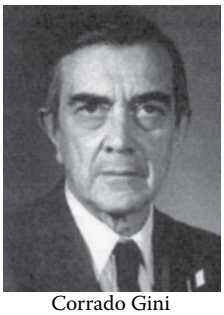
## Gini coefficient, *see also* health inequality, Palma measure of inequality

The Gini coefficient is just about the most popular measure of inequality among various values of a variable. This is used to measure health inequality in a community. For $n$ values, this is given by

$$\text{Gini coefficient: } G = \frac{\Sigma_i \Sigma_j \left| x_i - x_j \right|}{2n^2 \bar{x}}; \; i, j = 1, 2, \ldots, n.$$

The Gini coefficient is applicable to positive values only. If negative values are present and the mean is close to 0, the Gini coefficient may blow up to an unacceptable level. Note also that the Gini coefficient is similar to the **coefficient of variation**. Very different

statistical **distributions** of the variable can give the same value of the Gini coefficient. The value of this coefficient lies between 0 and 1. A value less than 0.2 can be considered tolerable, between 0.2 and 0.4 middling type, and more than 0.4 high inequality. Gini coefficient equal to 1 for an area would mean that just one person in that area is in complete health and all the others have zero health on whatever scale you use, and the Gini coefficient equal to 0 means that all people have exactly similar health—they all could be in poor health or all could be in good health. This coefficient was originally devised by Corrado Gini in 1912 for measuring income disparity [1].



Corrado Gini

Health inequality among different segments of the population has received attention as it doesn't just concern moral issues regarding fairness but also affects the rate of improvement in population health. Inequalities definitely work to the disadvantage of the deprived sections but affect all, as disparities hamper the generation of human capital and inhibit sustainable improvement. While inequalities are inherent in the social fabric, health inequality caused by factors amenable to human intervention is considered unjust. The Gini coefficient remains a favorite index for measuring this inequality, although as described later in this section, there are deficiencies in this coefficient as an index of inequality.

In the case of health, the level in the top and bottom income **quintiles** is a customary measure of health inequality. This is the health of people in the top 20% income bracket and the bottom 20% income bracket. This assumes that the people with the top income will be in the best health and those with the bottom income in the poorest health. The ratio of maximum to minimum can be used, but this ratio disregards the dispersion. The following example illustrates the calculation of the Gini coefficient in the context of **infant mortality rate** (IMR).

In Table G.4 are IMRs in the 20% of the population with the lowest income (lowest quintile), the next 20%, etc., and the highest 20% (top quintile) in a developing country. For these data,

**TABLE G.4**
**Infant Mortality Rates in Income Quintiles in a Developing County**

| Quintile | Infant Mortality Rate |
|---|---|
| Lowest quintile | 73 |
| Second quintile | 68 |
| Third quintile | 51 |
| Fourth quintile | 32 |
| Top quintile | 16 |
| Average ($\bar{x}$) | 48 |

$$\text{Gini coefficient} = \left[|73-68|+|73-51|+\ldots+|73-16|+|68-73| + \ldots+|16-32|\right]/(2\times 5^2\times 48) = 0.25.$$

The low value of 0.25 in this example despite a ratio of more than 1:4 between IMR in the minimum and maximum quintiles shows that the Gini coefficient is not too sensitive to the inequalities. Now you know why an apparently low value such as 0.4 is considered high. You may notice that for other statistical measures between 0 and 1, such as correlation, 0.4 is not considered high.

The problem with the Gini coefficient as a measure of inequality lies in it being nonspecific. We cannot say where the inequality exists. It is oversensitive to the changes in the middle values and insensitive to the changes at the top and bottom [2]. Also, it has no physical interpretation. Another measure, called the **Palma measure of inequality**, has been suggested to remedy these problems. Details are provided under that topic, but briefly, it compares the highest 10% of values with the lowest 40%—these percentages seem to be popping up everywhere in the sense that the remaining **deciles** 5–9 capture just about half the population in almost every setting.

## gold standard

Gold standard is an oft-repeated term in biostatistics parlance but remains quite nonspecific. Ideally, this refers to something that is infallible, that you can rely on completely, that has 100% **sensitivity** and 100% **specificity**. A gold standard is required for comparing the performance of newly developed regimens or tests. Concepts such as sensitivity, specificity, and predictivities exist only when a gold standard exists. However, due to the omnipresence of uncertainties in health and medicine, there is no gold standard—no treatment is 100% effective; no test is perfect. Thus, *whatever is best available is considered the gold standard*. This, of course, varies from place to place, from time to time, from context to context.

Kratiras et al. [1] have discussed the need to redefine the gold standard for the treatment of advanced prostate cancer in the context of continuous and intermittent androgen deprivation therapy. Rapaso-Amaral et al. [2] has questioned considering bone transplant as the gold standard for the repair of alveolar bone defects. These are just a couple of illustrative examples to emphasize that the gold standard continuously evolves as new knowledge become available. In assessing the new against the gold standard, we tend to forget that the gold standard itself can be in error and, thus, our assessment can

be imperfect. Indices such as positive and negative **predictivities** need to be reevaluated as the gold standard is redefined.

There are other uses of the term *gold standard* in medicine. For example, the forehead flap is the gold standard for nose reconstruction [3], and the randomized placebo-controlled clinical trial [4] is considered a gold standard methodology for assessing the performance of a regimen. The former is the gold standard so long as skin at another site is not found more suitable, and for the latter, see the topic **bias pyramid**, where we mention that randomized controlled trials also do not completely rule out bias.

## Goodman–Kruskal gamma, *see* association between ordinal categories (degree of)

## goodness of fit

The term *goodness of fit* is used for a model agreeing with the observed values, or in some cases, to describe whether the observed values follow a specified pattern. You might be aware that the observed values of a variable have a random component yet tend to follow a pattern. Various statistical methods are used to identify this pattern, called a **model**, and then a test of goodness of fit is used to check if the model has really been able to capture the essential features of the data. Mostly, but not always, the **chi-square test** is used for this purpose. There are situations where other tests are used, and these also are listed later in this section.

The most common use of the goodness-of-fit test is in assessing the pattern of categorical data. For example, these categories could be none, mild, moderate, and serious forms of anemia; calendar month of occurrence of sudden infant death syndrome (SIDS) in a year; or cirrhosis, hepatitis, and malignant forms of liver disease. The first two are on an **ordinal scale**, and the last is on a **nominal scale**. The first has 4 categories, the second 12, and the last 3 categories. The interest may be in (i) whether sudden death syndrome occurs twice as often in winter as in summer months; (ii) whether the patterns of none, mild, moderate, and serious hypertension in cases of myocardial infarction (MI) are 10%, 20%, 40%, and 30%, respectively; and (iii) whether the proportions of full, partial, and no recovery within 2 years after surgery in cases of breast cancer are 40%, 50%, and 10%, respectively. Such a problem is known as the problem of goodness of fit because the interest is in finding whether or not the pattern observed in the sample fits the specified pattern well. The procedure is best explained with the help of an example.

**TABLE G.5**
**Blood Group Pattern in a Hypothetical Sample of AIDS Cases**

| Blood Group | O | A | B | AB | Total |
|---|---|---|---|---|---|
| Number of AIDS patients | 57 | 36 | 51 | 6 | **150** |

The blood group of a random sample of 150 patients with acquired immunodeficiency syndrome (AIDS) is investigated to examine the possibility of a preponderance of a particular blood group in AIDS cases. If there were no preponderance, the profile would be the same as in the general population. Suppose this is 6:5:8:1 for blood groups O, A, B, and AB, respectively. The sample observations are shown in Table G.5. If the cases are in the same ratio as in the general population, the number of cases with blood group O should have been $6 \times 150/20 = 45$. The observed number is 57. In view of this difference, does this pattern in AIDS cases really conform to that in the general population? How does one draw a conclusion such that the chance of **Type I error** does not exceed 0.05? A solution is provided under the term **chi-square–overall**. This is valid under certain conditions, particularly, that the sample size is large and almost no cell frequency is less than 5. For small frequencies, a **multinomial test** can be used.

### *Chi-Square Test of Goodness of Fit of a Gaussian Distribution*

A common problem in goodness of fit is to find whether the pattern of quantitative data is different from what is expected under the Gaussian distribution. If the pattern is not different from **Gaussian**, the usual methods of **Student *t***, **analysis of variance (ANOVA)**, etc. can be safely used. If the pattern is very different, you may have to use **transformation** or use **nonparametric methods**. The procedure to test a Gaussian pattern is as follows. This can be used when (i) the data are in grouped form with at least 5 **class intervals** and possibly not more than 12 intervals (fewer intervals make it extremely difficult to assess a Gaussian pattern, and more than 12 intervals tend to negate the advantage of convenient display of grouped data), and (ii) the sample size is large so that number of subjects in any interval is not less than 5 (chi-square is not valid when any cell frequency is less than 5). Otherwise also, the statistical **power** to detect a difference from a Gaussian pattern is low when the sample size is small.

The procedure basically is to calculate the mean and standard deviation of your values. Use these to calculate the **Gaussian probability** in each class interval. Convert this probability to frequency by multiplying by the sample size $n$. These will be the **expected frequencies** in the intervals. Compare the observed frequencies with expected frequencies and calculate chi-square. Use the calculated value of chi-square to find the ***P*-value**. Reject the null of Gaussian pattern when the value of $P$ is less than the prespecified **level of significance** and conclude that the pattern is different from Gaussian. All this is easily done by statistical software.

### *Other Kinds of Goodness of Fit*

There are several other methods to check whether your model is a good fit with the data or not. These depend on the kind of problem

you are investigating. For example, goodness of fit of a linear regression model is assessed by square of the **multiple correlation coefficient** ($R^2$) and tested by an ***F*-test**. This is described under the topic **linear regression**. The goodness of a **logistic model** can be assessed by the classification accuracy and tested by the **Hosmer–Lemeshow test**. The **receiver operating characteristic (ROC) curve** method can also be used for logistic model. For some models, such as **Cox regression**, chi-square-based **deviance** gives a pretty good idea of the goodness of fit. See **log-linear models** for assessing their goodness of fit based on the standardized deviate $z = (O - E)/\sqrt{E}$, where $O$ and $E$ are the observed and expected frequencies, respectively.

## graphs and diagrams, *see also* charts (statistical), maps (statistical)

Tools such as graphs, diagrams, charts, and maps are commonly used for visual display of data. They are generally referred to as *figure* in the literature, although this term also includes non-data-based pictures, such as of a bone or of a lesion. Our description here is restricted to statistical graphs and diagrams.

**Visual display** is considered a powerful medium for communication and for understanding the basic features of a set of data. Salient features are often easily brought forth by an appropriately drawn figure. Also, the impression received from such a figure seems to be more vivid and lasts longer than the impression from numeric data. The main function of a figure is to provide perception and cognition of the basic features of the data, and sometimes, it provides a much deeper understanding of the data. Busy professionals cannot devote time to read the numerical values in a table and make a picture in their mind. Also, numerical tables can be assiduous and can cause fatigue. Some people need a ready-made picture that gives the message regarding the trends and differences. However, for this, an appropriate diagram must be chosen and correctly drawn. If the display requires long time to understand, consider it not sufficiently effective. A large number of methods are available, and the choice is not always easy. All these methods are listed later in this section and described under their respective topics.

Generally speaking, a graph is a figure drawn to a scale. The scale could be on a horizontal axis or on a vertical axis or both. Graphs are used to display the relationship of variables or to display the pattern of their **distribution**. Perhaps the first recorded graph was made by Playfair, published in 1786, which depicted balance of trade between North America and the England during the years 1700–1780 [1].

The term *graph* is disappearing from the medical literature, and the term *diagram* is preferred instead. The **bar diagram**, **line diagram**, and **area diagram** are essentially graphs but are colloquially called diagrams. So are the **frequency curve**, **polygon**, **histogram**, **scatter diagram**, and **radar graph**. Among others are the **pie diagram** and **donut diagram**. Factually, a diagram is a figure depicting data not necessarily to a scale. The schematic depiction of three methods of **observational studies** under that topic is an example of this kind of diagram. There are many others in this book. Graphs and diagrams together are sometimes called **charts**, but we like to use the term chart for text-based figures, as explained under this term. **Bubble charts** are an ingenious way of depicting three- or four-dimensional data.

Some diagrams are more complex than others. Among the complex ones are the **box-and-whiskers plot**, **biplot**, **bihistogram**, **nomogram**, and **Lexis diagram**. This list is restricted to those that are discussed in this volume. There are many others that are either rarely used or far too specialized, and thus not included in this book.

Electrocardiograms (ECGs), electroencephalograms (EEGs), and chymographs are examples of data-based figures commonly used in the practice of medicine. They are examples of far-too-specialized topics to be discussed in this book on biostatistics. But there are other not-so-specialized diagrams such as **growth charts**, **dendrograms**, and **partograms** that are typically used in health and medicine. They are discussed under these respective topics.

A good source for learning about various graphs and diagrams is the celebrated book by Tufte [2]. The topic has evolved enormously lately. Integrated explanations through pictures have given rise to **infographics**. These provide much more information than graphs. Now, we also have interactive graphics where a graph or diagram pops up when selected among the given choices.

### *Choice and Cautions in Visual Display of Data*

It may be helpful to get a clear picture of the situations in which one diagram is more appropriate than others. This is shown in Table G.6 for graphs and diagrams commonly used. As already stated, all these graphs and diagrams are separately explained in this volume under the respective topics.

When the range of values on the $y$-axis is extremely large, examine whether or not a **logarithmic scale** (usually called log scale)

**TABLE G.6**
**The Appropriate Type of Diagram for Various Situations**

| | Scale on Horizontal Axis | | | |
|---|---|---|---|---|
| **Vertical Axis (Must Represent a Quantity)** | **Metric and Continuous—No Categories** | **Metric Categories or Discrete** | **Ordinal** | **Nominal** |
| Frequency or percentage | ×[a] | Histogram[b] | Bar | Bar |
| | | Pie[c] in these three cases when contribution of each category relative to the others is to be shown | | |
| Mean, rate, or ratio | ×[a] | Bar | Bar | Bar |
| | | Line in these two cases for trend | | |
| Values of a variable | Scatter | Scatter | Scatter | Scatter |

[a] Frequency, percentage, mean, rate, or ratio is not possible on $y$-axis when $x$ variable is continuous and has no categories.

[c] Pie diagram has no horizontal or vertical axis.

would be more appropriate. This scale converts 10 into 1, 100 into 2, 1000 into 3, 10,000 into 4, etc. One such representation appears under the topic **scatter diagram (Figure S.2a)**, where the total bilirubin on the *x*-axis is plotted on a log scale. If the ordinary scale, called linear, were used, the points for low levels of bilirubin would become indistinguishably close. Another log scale is on the *y*-axis of a figure under the topic **line diagram (Figure L.6d)**. One advantage of a log scale is that it can represent change relative to the previous value. Cautious interpretation is needed in this case.

Note the following points regarding various graphs and diagrams:

1. A diagram should not be too complex. A large number of relationships can be shown in one diagram, but it is advisable to restrict one diagram to not more than two relationships or not more than three variables. Although a diagram is considered good if it instantly conveys the substance, in science, diagrams may require some effort on the part of the reader to be able to interpret them properly.
2. In terms of choice of scale, a diagram can be made to show a steeper or flatter relationship by choosing the scale accordingly. Figure G.7a and b shows the same relationship between age and average forced vital capacity (FVC), but FVC is plotted on different scales in the two panels, giving a different impression.
3. The scale of calibration should be clearly indicated. Choose a scale that is suitable and does not exaggerate or understate the values. For comparing two or more groups, use the same scale for both groups.
4. In case secondary data are used to draw a figure, provide the source.
5. Figures displaying all the data points, such as a scatter diagram, are preferable because they allow readers to draw their own conclusions. However, many times, it is not feasible to show the entire set of data. Only summary statistics such as percentages, rates, or averages are shown.
6. All graphs and diagrams must be self-explanatory, containing informative (what, where, when) yet concise titles, legends to identify various components of a diagram, labels for axes, unit of measurement, etc.
7. Use diagrams mostly for exploring the data rather than to draw conclusions. Because the sample size *n* is important for conclusions and small or large *n* does not affect many diagrams, conclusions based on a diagram alone can be very fallacious.
8. As much as possible, directly label the categories, lines, etc., so that reader does not have to refer to legend or text for this purpose. If the audience for a figure is the general population, as in a newspaper, consider inserting text boxes to explain the salient features.
9. Never ever try to depict the obvious. For example, a graph of a proportion *p* on one axis and $(1 - p)$ on the other axis (probability of disease versus probability of its absence) is bound to give a perfect line. Such a graph does not tell us anything except the ignorance of the person who drew this type of graph. The two axes must be meaningful in all graphs and able to communicate something to the viewer.

A graph or a diagram is necessarily an approximate depiction. The values 103.2 and 103.4 can be shown to be distinct in a table but would look the same in a graph. Thus, graphs are good for visual display of a pattern or trend but not for depicting exact values.

## gross domestic product (GDP)

Gross domestic product (GDP) is a combined measure of the total income of people living in an area. The term actually applies to an established area, such as a country or a province, but is generally used per capita when divided by the population. Grossly speaking, GDP is the monetary value of the total output (goods produced and services provided) of the area during a 1-year period. This obviously severely depends on the population. GDP per capita is an indicator of productivity but is considered the most valid indicator of the standard of living of the people of an area since people spend most of what they produce. Many health parameters have been seen to be affected by GDP per capita. Availability and utilization of health care facilities are directly related, and parameters such as body mass index (BMI) [1], homicides [2], and infectious diseases such as tuberculosis [3] are indirectly related.

GDP per capita serves as the base for calculating some health-related indicators. The most common of these is the expenditure on health. This can be separately calculated for private expenditure by

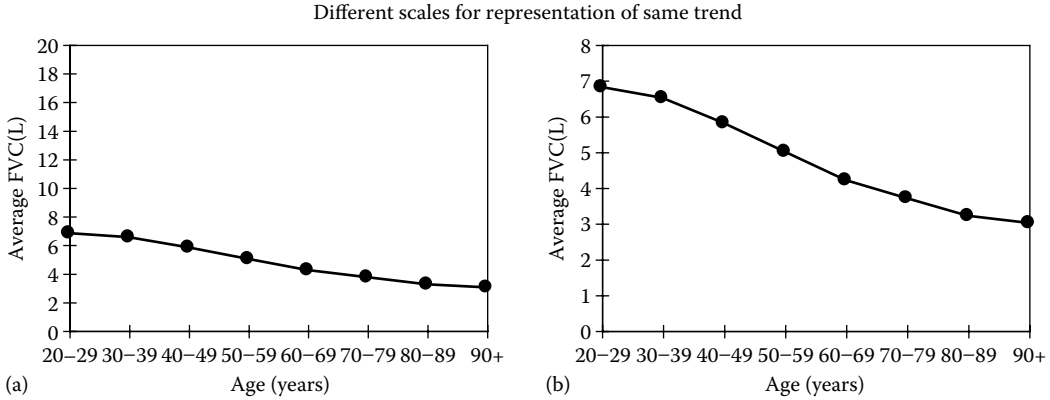

**FIGURE G.7** Effect of choice of scale on the slope or a line: (a) relation of average forced vital capacity with age; (b) the same trend with a different scale on the *y*-axis.

individuals and public expenditure by the government. According to the World Bank estimates for the years 2009–2013, the total (private + public) expenditure on health (excluding water and sanitation) in Brunei Darussalam was only 2.3% of the GDP, whereas it was 10.8% in Belgium [4].

## gross enrollment ratio, *see* education indicators

## gross reproduction rate, *see* fertility indicators

## group average method of clustering, *see* centroid method clustering

## grouped data, *see also* class intervals

When the values of the **quantitative variable** under study are tabulated for the number of subjects in specified class intervals, this is called grouped data. The numbers of subjects in the class intervals are called frequencies. Table G.7 has grouped data on the cholesterol level of 200 subjects coming to a hypertension clinic.

Exact measurements on the **metric scale** are indeed statistically preferable to grouped measurements. The irony is that sometimes, circumstances force the grouping of metric data into categories even after exact data are obtained. The weight of a woman may be recorded to the nearest kilogram but may have to be categorized into 5 kg intervals such as (40–44), (45–49), etc. Data reported in this manner are called grouped data. The process is commonly referred to as categorizing a quantitative variable, and the groups are called **class intervals**. The reasons for doing this may be one or more of the following:

- Consider a data set containing systolic blood pressure (BP) levels of 1200 persons. The only effective way to present these in a report is by using groups such as (100–109), (110–119), (120–129), etc., and stating the number of subjects in each such group. This saves space and at the same time makes the data more intelligible. Storage of grouped data may take only about half a page or 1 kB of space, whereas storage of 1200 individual values may take four pages or 8 kB of space. Such grouping also makes the data more sensible, while 1200 ungrouped values may be difficult to comprehend. This certainly is done for the research papers published in journals, although now, some journals in health and medicine back it up with a website where all the original data are stored for anybody to see.

  Groups such as (0–4) and (5–9) for years of age assume that age is noted in terms of *completed* years or age at last birthday. The interval (5–9) actually means 5 to less than 10 years and can also be written as "(5–10) years." It is customary in such statistical grouping that the upper end of the interval is considered to belong to the next interval. Mathematically, these intervals are written as [0–5), [5–10), etc., but this kind of exact notation is seldom used in practice. Wherever the intervals are continuous, the convention of (0–4), (5–9), etc., is generally followed in health and medicine.
- It is well known that the end digit is predominantly 0 or 5 in many data values. This happens either because of approximation done by subjects themselves at the time of inquiry, such as stating one's age as 45 years instead of the more exact 44, or because of the observer's bias, such as in recording a systolic 130 mmHg instead of the exact 132 mmHg. Intervals (105–114), (115–124), (125–134), etc., or (108–112), (113–117), (118–122), etc., would dilute the effect of such digit preference. In another setting, suppose waist and hip sizes are measured without sufficient care and could be in error of up to 5 mm. Grouping of waist–hip ratio in intervals (0.7–0.8), (0.8–0.9), (0.9–1.0), etc. would minimize the effect of such errors, and the purpose of assessing central obesity could still be adequately achieved despite errors, provided they are minor.

The preceding two reasons are valid for grouping at the stage of reporting or analysis, but sometimes, even the recording is done in a grouped form. This is done for the following reasons:

- Eliciting a woman's age or anybody's income is sometimes considered immodest. Some people prefer to keep such information confidential. Stating them in a grouped form may be more acceptable. The exact value remains confidential, yet data are available in a usable form.
- Many clinicians are accustomed to think in terms of anemia present or absent and its degree as mild, moderate, or severe in place of exact hemoglobin (Hb) or hematocrit values. Thus, they sometimes prefer grouped values. Two or more measurements can also be simultaneously considered in this kind of grouping. Categorization of growth of

**TABLE G.7**
**Cholesterol Level in 200 Subjects Coming to a Hypertension Clinic**

| Cholesterol Level Class Interval (mg/dL) | Number of Persons (Frequency) |
|---|---|
| <150 | 5 |
| 150–199 | 76 |
| 200–239 | 39 |
| 240–259 | 35 |
| 260–279 | 24 |
| 280–299 | 12 |
| 300+ | 9 |
| **Total** | **200** |

a child into excessive, normal, retarded, or dismal depends not only on height and weight but also on the age of reaching different milestones of development. Such multifactorial grouping is sometimes more relevant for the practice of medicine.

- In an experiment on a lethal dose of a drug in mice, it is much easier to observe each morning and record the number of dead mice than to keep a continuous watch and note the exact time of death. In this case, the survival time would be available in 24 h categories. Serum glucose level is measured in units of 5 mg/dL because the analyzer in some cases is so calibrated. Thus, 5 mg/dL categories are inadvertently formed. Greater accuracy may be redundant in this case. If better accuracy is needed, cost and efforts may substantially increase.
- For a continuous variable, grouped data are essential to make a histogram or frequency polygon. The shape of these figures gives a good idea of the statistical distribution the values follow. For example, you can guess from these shapes whether the distribution is Gaussian or not.

Whenever data are available in an exact form, statistical analysis should be done using the exact data. Grouping means that the actual values are lost and various calculations are done assuming that all the values in an interval are equal to the midpoint of the interval. To see how this is done, see, for example, the topic **mean**. Midpoint-based calculation obviously is an approximation. Thus, grouping renders analysis less efficient in the sense that some important features of the data may fail to emerge. Statistical inference becomes less efficient because of the assumption that the values in grouped data are flat within each interval. This is against the factual position. Also, discontinuity is imposed by categorization across interval boundaries. An interval 160–169 of systolic BP disregards that 168 mmHg is more than 162 mmHg and the difference is more than that between 168 and 170, which now belong to separate categories. Cut points of intervals are mostly arbitrary, and different cut points can give different results.

In some cases, though, a larger sample size can compensate for this loss. A larger sample size helps to capture a better spectrum of values even when data are grouped. In fact, in cases in which grouped data can be rapidly obtained at substantial savings, more reliable results can be obtained by investigating a larger sample within the same cost. In such a situation, grouped data on metric measurements can be rightly advocated. However, it is important that the number of groups and width of intervals are appropriately chosen so that the essential features of the data are not compromised and the relevance is not lost. It is generally considered desirable that the number of class intervals be between 6 and 12, and class intervals of equal width are preferred. For some measurements, though, unequal categories with medical implications can be made, as for cholesterol level in Table G.7. End intervals may be open, as in our example, but these should be closed as much as possible so that there is no uncertainty about the maximum and minimum values. For family size, each number by itself could be a category, but this would not be called grouped data.

Despite our advice for using the exact values in place of grouped data for statistical treatment, there are examples where exact values lead to kind of a wrong conclusion and grouped data give the right conclusion. One such example is the relation between BMI and, say, disease frequency. Disease is high at both ends (very low and very high BMI), and a regression on exact data will yield a nice U-shaped curve with minimum disease frequency at 23 or 24 kg/m$^2$ and higher at BMI values on either side. However, when BMI is divided into class intervals, the bottom is found to be rather flat, implying that the disease frequency at BMI of 26 or 27 kg/m$^2$ is not higher than at 23 or 24 kg/m$^2$. For details of this example, see Welch et al. [1].

You will need the aforementioned basic concepts to understand medical literature, when trying to analyze data from your own clinic, and when trying to do research.

## group sequential design

In some studies, particularly in **clinical trials**, it may be worthwhile to plan to conduct them in stages by adding a group of subjects after reviewing the results from the subjects already entered. If the results at any stage provide convincing evidence either of the desired efficacy of the regimen or of futility, there is no need to add subjects. This essentially means that the data are analyzed in stages so that the trial can be stopped or continued depending on the results obtained. This can be planned to be done at as many stages as considered necessary. In the extreme case, one can think of analyzing the data sequentially after each pair of observations (one subject for the test group and one for the control group) and decide to continue or stop. In this case, the term *group* is dropped—it is just a **sequential design**. This is difficult and not considered logistically practical for clinical trials. Instead, the data are analyzed at equispaced stages, such as four stages, each after completing one-fourth of the trial. The null hypothesis is either rejected or not rejected at each stage. No further addition is made in case the hypothesis is rejected or continuing the trial is found to be futile. This is called a group sequential design and is accepted by most regulatory agencies as a valid design.

Group sequential designs are initially planned to have a large number of subjects so that they have adequate statistical **power** to detect relatively small gain, although the actual target may not be to detect such a small gain. Commitment of a large sample up front may be scary to some researchers, but that is a feature of group sequential designs. If interim analysis at any stage provides clear evidence of the desired efficacy, the trial is stopped prematurely, and a decision is made with reduced sample size. If evidence emerges that there is hardly any chance of achieving the desired minimum efficacy and it is futile to continue, then also, the trial is stopped. Otherwise, the trial continues. This interim assessment is done in such a manner that the level of significance is not compromised. For this, methods such as **O'Brien–Fleming** and **Lan–deMets** are used. Your statistical software may have the facility to do these tests not just for means but also for efficacy in terms of proportions and for durations that require log-rank tests.

The total number of stages and stopping criteria are specified in advance in the **design** itself. Minimum clinically relevant gain or efficacy must also be specified a priori. **Stopping rules** are devised in such a manner that the **level of significance** and power are least affected. In this approach, the sample size or the design is not modified once committed to in the protocol. This modification is done in an **adaptive design**, although in this also, the protocol contains what types of modifications are planned and when. For a comparison of group sequential designs with adaptive designs, see Kelly et al. [1]. Pocock [2] has discussed group sequential design in detail.

## growth charts, *see also* growth indicators of children

Growth charts are figures that show specific **percentiles** of parameters of children at various stages of growth. Among the dimensions of physical growth of children are weight, height, body mass index, and head circumference. Each can be assessed against age, or they can be assessed against each other. The requirement of different growth charts for different body measurements arise as different parts (brain, arms, trunk, etc.) grow at varying rates at different times from birth to adulthood. For the purpose of illustration of the type of diagram they are, see Figure G.8a and b, which are weight-for-age charts for girls, developed by the United States National Center for Health Statistics (NCHS) [1] and the World Health Organization (WHO) [2].

The charts show various percentile curves based on the measurements seen in a large number of *healthy* children. Thus, this technically is a line diagram but is called a chart. The 50th percentile is like the median, which can be used as a reference, and the 3rd and 97th percentile curves define the lower and upper limits for healthy growth. The space between these two percentile curves is considered the *road to health*. Sometimes, ***Z*-scores** are used instead of percentiles.

A growth chart is used for longitudinal monitoring rather than for one-time cross-sectional assessment. The *trend* should follow the same pattern as the reference curve. A flattening or declining trend relative to the reference is an indication of decline in nutritional status, and a steeper upward trend not crossing the upper limit indicates improvement. For further details of how these charts are used for assessing various aspects of growth, see the topic **growth indicators of children**.

Preparing growth charts is an intricate process. This is primarily because (i) the growth measurements such as height and weight in children generally do not follow a **Gaussian** pattern—thus, calculation of various percentiles is difficult, and (ii) it is difficult to identify a smooth pattern that does not miss out on natural periods of steep and shallow growth, even no or negative growth. Most old charts used the **LMS method**, which takes care of the **skewness** of data, but now, the **BCPE method** is generally used, which takes care of deviation in **kurtosis** also. Both these methods are described in this volume, and the details for medical professionals have been succinctly provided by Indrayan [3].

## growth indicators of children, *see also* *Z*-score, *T*-score, velocity of growth

The physical growth of a child is assessed by anthropometric measurements such as weight, height, chest circumference, and head circumference. For this, norms are constructed that help to decide whether a child is on the road to health or not. The norms are generally obtained in the form of percentiles for age intervals of 6 months after 2 years, i.e., age 2 years, $2\frac{1}{2}$ years, 3 years, $3\frac{1}{2}$ years,

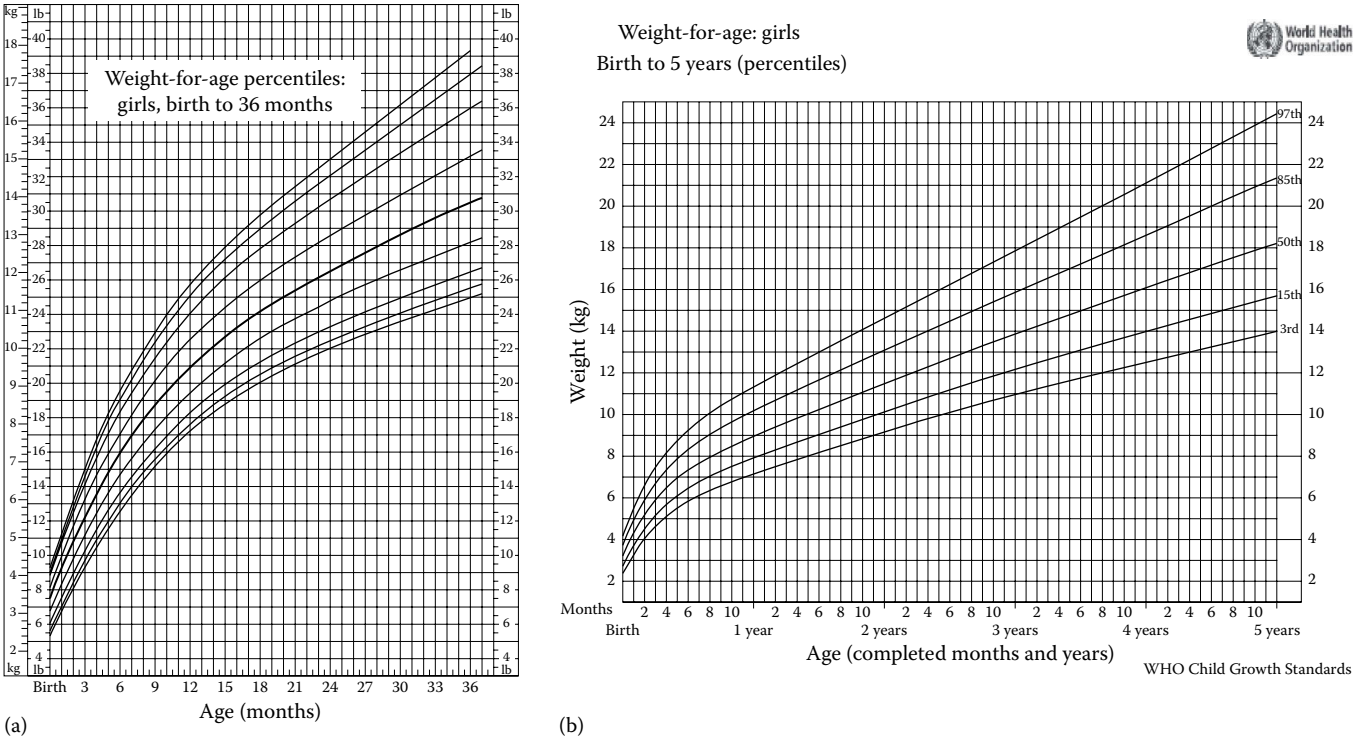

**FIGURE G.8** Weight-for-age charts (girls): (a) NCHS, birth to 36 months; (b) WHO, birth to 5 years.

etc. Smaller age intervals are desirable for age-specific norms for younger children and infants. These norms are plotted and connected by a smooth curve to get **growth charts**. In addition, mathematical models for growth in stature of children are also obtained as discussed by Ledford and Cole [1].

Each of the anthropometric measurements of a child can be independently assessed by either the **percentile** point achieved by the child relative to the healthy children of that age and gender in the same population, or by his/her ***Z*-score**, ***T*-score**, or percent of median. Sometimes, **velocity of growth**, is assessed as discussed in that topic.

Weight for age is the most commonly used indicator of growth of children but provides more effective assessment when the trend over age for the same child is studied. This trend is compared with the trend seen in healthy subjects in that population. The assessment is population specific. The difficulty with weight for age, however, is that it fails to distinguish a thin but tall child from a well-proportioned child.

The weight for height index obviates the need to know age particularly if it is between 1 and 10 years, and can be safely used for children when age is in doubt. This index measures the balance between weight and height (length in the case of children less than 2 years). A weight less than the 3rd percentile point for a particular height indicates wasting (i.e., thinness) associated with failure to gain weight or loss of weight [2]. This is considered an indicator of acute undernourishment. Weight for height fails to detect abnormalities when both height and weight are affected.

Another index for assessing growth is height for age. Low height for age is an indicator of stunting (i.e., shortness) when weight for height is normal. This is frequently associated with chronic undernourishment resulting mostly from poor nutrition or repeated illness, or many times, a combination of these two.

### *Percentiles, Percent of Median, Z-Scores, and* T-*Scores*

In the case of percentiles, the median (50th percentile) is regarded as a reference value, and 3rd and 97th percentiles as thresholds to indicate abnormally low or abnormally high values. Interpretation of the health of children with measurements outside the 3rd and 97th percentiles can be difficult. No matter how healthy the children are who measured to construct the chart, 3% of them will have weight less than the 3rd percentile curve. Thus, even some fully healthy children may show a weight in the low category. This is an acknowledged limitation of a growth chart, but the chart is still useful. Note that low weight in such children is in a relative sense only—relative to the other 97% healthy children. Thus, a low weight does not necessarily indicate poor health in an absolute sense.

The other index used to assess growth is percent of median. If the median weight of healthy children of height 1.10 m is 21.0 kg, and the weight of a child of this height coming to a clinic is 18.5 kg, this is 18.5/21 × 100 = 88% percent of median. A measurement above 80% of the median is regarded as normal, between 71% and 80% as indicating undernutrition of grade I, between 61% and 70% as grade II, and 60% or less as grade III. Each population can evolve its own classification. The parents are advised of suitable corrective steps depending on the grade of undernutrition found in a child. Now, consider the following example.

The interpretation of anthropometric measurements sometimes becomes easier when the **Z-score** is computed. This is the difference of the value from the mean in standard deviation (SD) units. A *Z*-score below –2 is considered low and below –3 exceedingly low. These *Z*-scores can be obtained for almost all anthropometric measurements. This score works well for measurements that follow an approximate **Gaussian distribution**.

Healthy children from well-to-do families were surveyed for their height, weight, age, and gender. The distribution of 450 girls by weight, taken within a week of their seventh birthday, is as follows:

| Weight (kg) | 14–16 | 16–18 | 18–20 | 20–22 | 22–24 | 24–26 | 26–28 |
|---|---|---|---|---|---|---|---|
| No. of girls | 4 | 36 | 85 | 182 | 96 | 40 | 7 |

These give mean = 21.1 kg, median = 21.0 kg, and SD = 2.3 kg. A girl who is nearly 7 years old comes to a clinic from the same area. Her weight is 18.3 kg. Can she be considered underweight?

$$\text{Z-score for the girl} = \frac{18.3 - 21.1}{2.3} = -1.22.$$

$$\text{Weight as percent of median} = \frac{18.3}{21.1} \times 100 = 87.$$

A negative *Z*-score and weight less than 100% of the median both indicate that the girl's weight is less than the average. However, because the *Z*-score is not less than –2 and the percent of the median is not less than 80, the weight can be regarded as within the normal variation, and the girl is not classified as underweight. Thus, there is no cause for alarm. What is important in this case is the longitudinal follow-up to monitor that the pattern remains on normal trajectory.

As explained under the term ***T*-score**, the only difference between a *Z*-score and a *T*-score is that the mean in *Z*-score is replaced by the most desirable or optimum value for that age. Thus, the *T*-score assesses the growth against the optimum.

## growth velocity, *see* velocity of growth in children

## Grubbs test

This test is used to detect outliers in a data set assuming that the distribution of values is Gaussian. **Outliers** are unusual values that do not fit into the general pattern of other values. These affect the values of the mean and standard deviation (SD)—and thus disturb the inference. Data managers are generally careful and ensure that no outliers are present unless there are valid reasons for them to be so. The Grubbs test helps to do this statistically and check that a particularly high value or particularly low value can be regarded as inconsistent with the other values. This test was proposed by Frank Grubbs in 1950 [1].

For any potentially outlier *i*th value, this test is obtained by computing

$$G = \frac{|y_i - \bar{y}|}{s},$$

where $\bar{y}$ is the sample mean and $s$ is the SD. Both are calculated after excluding the potential outliers. Thus, this is just the difference of the potential outlier from the mean of the regular values in SD units. In the first step, $y_i$ is either the maximum or the minimum value. In subsequent stages, you can have the second highest

and second lowest value if these are suspected to be outliers. In any case, the test has to be **one-tailed** since you already know that it is an abnormally high or abnormally low value. Grubbs has provided tables of critical values of $G$ that can be used to decide that the chance ($P$-value) of a value being an outlier is less than the significance level, such as 0.05. Your software may have a provision for this test that will give the $P$-value. If $P < 0.05$, the value can be regarded as an outlier and excluded from analysis so that the results do not become contaminated. This can be done for many values if many are suspected to be outliers. In that case, though, it is advisable to use the **Bonferroni procedure** for apportioning the significance level since the same data set will be used again and again.

There are a couple of important considerations in determining a value as an outlier or not based on the Grubbs test. First, any outlier so determined should be thoroughly examined for whether this was not a data entry error, recording error, or reporting error. If any error is detected, the correct value should be found and replace the incorrect one. Second, the Grubbs test is based on Gaussian distribution. If the data do not follow this distribution, you may erroneously label a value as an outlier. Third, and the most important, is that the mean and, consequently, the SD themselves can be affected by outlier values, particularly when $n$ is not sufficiently large—thus our advice to calculate these after excluding the potential outliers, although this judgment has to be as objective as possible. This can be done only when the potential outliers are just one or two values. If you suspect many outlying values, examine whether the entire data set is contaminated.

There are some other methods for identifying outliers. A **box-and-whiskers plot** has this provision. A simple **histogram** can also show if one or two values are outliers on either side. A **normal probability plot** would also indicate if any value is an outlier or not.

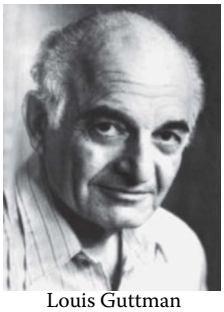
## Guttman scale

A binary (yes/no) set of questions or items are said to be on a Guttman scale, developed by Louis Guttman in 1944 [1], when they follow a hierarchy so that a "yes" to any item implies that the answer is yes to the subsequent (or preceding) items. The characteristic you want to measure is arranged in a continuum from minimum to maximum (or vice versa). For example, visual acuity is assessed in stages, and if a person with a cataractous eye can read font size 24 from a distance of 14 in., this implies that he/she can read font size 48. Thus, a threshold can also be obtained, and one response can predict all other responses in lower hierarchies. Gothwal et al. [2] has done such a study on subjects with a cataract using the Guttman scale. This scale is mostly used to develop short questionnaires that can still discriminate, such as for assessing disease severity and the level of satisfaction with hospital services.



Louis Guttman

Contrast the Guttman scale with, say, a **Likert scale**, where the scores for different items are added. In a Likert scale, generally, all items are supposed to have same difficulty. In Guttman, no addition is needed as the nature of the items is itself cumulative and of increasing difficulty. If a person scores 6, it means that he/she agrees with the first 6 statements.

The scale cited in the preceding example on visual acuity is fully scalable in the sense that there will be hardly any case who is able to read font size 16 but not font size 24. In many practical situations, this hierarchy is not so good. Efforts are sometimes made to frame items from the least to the most difficult in the hope that more able persons will be able to correctly answer more difficult items. However, in this case, a correct answer to item 3 does not necessarily imply a correct answer to items 2 and 1. Such "errors" make the scale really probabilistic.

Sometimes, the study is in reverse mode, where an attempt is made to decide on a Guttman scale of questions from the answers. Such recovery of a good Guttman scale from noisy data is challenging. In this setup, the potential items are placed in a kind of random order and analyzed for difficulty on the basis of the number of correct scores. Then they are placed in hierarchy. This can be understood as the rank ordering of the items. In this case, errors, as mentioned in the previous paragraph, are used to calculate

Coefficient of reproducibility:

$$C_R = 1 - \frac{\text{number of actual errors}}{\text{maximum number of possible errors}}.$$

For this, $K$ hierarchical items on $n$ persons are arranged into $K \times n$ configuration—one column for each person containing Y for correct response and N for wrong response. The number of possible errors is the same as $K \times n$. The items are generally accepted to be on a Guttman scale if $C_R > 0.90$. This means that the errors are less than 10%. Items with large errors can be omitted to improve this coefficient. The *coefficient of reproducibility* does not work if many items are too easy or too difficult for everybody.

Another important criterion is the *coefficient of scalability*. This is the proportion of items that can be correctly identified by the score, i.e., the items that exactly fall into the nice hierarchical pattern. This also is between 0 and 1, the larger the better, but a coefficient exceeding 0.60 is considered acceptable. This means that at least 60% of items must fall into the exact hierarchical pattern. The following example illustrates the procedure.

Consider a scale with $K = 7$ items on motor functions 1 week after stroke in $n = 10$ patients. These are arranged in order of number of Y's in Table G.8. Those who have complete paralysis will have hemiplegia, hemiparesis, etc. They are placed in hierarchy according to the number of Y's. But the hierarchy between hemiparesis and lower extremity, and between balancing and self-care is not apparent as the number of Y's is the same.

The procedure just mentioned can be easily implemented when the number of items is small. When it is large, a **scalogram analysis** is done to select those items that fall best into the Guttman hierarchy of difficulty. A subjective element may creep into the final selection, and it may not be possible to devise a perfectly cumulative scale. An illustration of this is in Table G.9 based on the data in Table G.8. The patient with the most number of Y's is in row 1, and the patient with the least number of Y's is in the last row. This rearrangement makes it easier to spot the errors in the sense that the items do not follow the hierarchy. If they follow the hierarchy stipulated in the Guttman scale, the Y's should form nearly a triangle. An error is an interior N and exterior Y in the scalogram.

**TABLE G.8**
**Motor Functions in 10 Patients 1 Week after Stroke**

| | Motor Function | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Patient No. | Complete Paralysis | Hemiplegia | Lower Extremity | Hemiparesis | Upper Extremity | Difficulty in Self-Care | Difficulty in Balancing | No. of Y's |
| 1 | N | N | Y | N | N | Y | Y | **3** |
| 2 | N | N | Y | Y | Y | Y | Y | **5** |
| 3 | Y | Y | Y | Y | Y | Y | Y | **7** |
| 4 | N | N | Y | Y | Y | Y | Y | **5** |
| 5 | N | N | N | N | Y | Y | N | **2** |
| 6 | N | Y | Y | Y | Y | Y | Y | **6** |
| 7 | N | N | N | Y | Y | Y | Y | **4** |
| 8 | N | N | N | N | N | Y | N | **1** |
| 9 | N | N | N | N | N | N | Y | **1** |
| 10 | N | N | N | N | N | N | Y | **1** |
| **No. of Y's** | **1** | **2** | **5** | **5** | **6** | **8** | **8** | **35** |

**TABLE G.9**
**Table G.8 Reordered for Number of Y's—Scalogram**

| | Motor Function | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Patient No. | Complete Paralysis | Hemiplegia | Lower Extremity | Hemiparesis | Upper Extremity | Difficulty in Self-Care | Difficulty in Balancing | No. of Y's |
| 3 | Y | Y | Y | Y | Y | Y | Y | **7** |
| 6 | N | Y | Y | Y | Y | Y | Y | **6** |
| 2 | N | N | Y | Y | Y | Y | Y | **5** |
| 4 | N | N | Y | Y | Y | Y | Y | **5** |
| 7 | N | N | [N] | Y | Y | Y | Y | **4** |
| 1 | N | N | [Y] | N | [N] | Y | Y | **3** |
| 5 | N | N | N | N | Y | Y | [N] | **2** |
| 8 | N | N | N | N | N | Y | [N] | **1** |
| 9 | N | N | N | N | N | N | Y | **1** |
| 10 | N | N | N | N | N | N | Y | **1** |
| **No. of Y's** | **1** | **2** | **5** | **5** | **6** | **8** | **8** | **35** |

In Table G.9, there is a complete hierarchy for "complete paralysis" and "hemiplegia" since if the response for these is Y, the response to all the lower ones is also Y. This is not so for "lower extremity"—patient nos. 2 and 4 follow the hierarchy, whereas patient no. 1 has Y for this but N for "hemiparesis" and "upper extremity," which are lower down the order. This is where subjectivity creeps in. One researcher may want to put "lower extremity" lower than "hemiplegia" amongst motor functions after stroke. The responses that do not follow the hierarchy are in the box in Table G.9. The number of actual errors is 5, and the maximum number of possible errors is 70. Thus, $C_R = 1 - 5/70 = 0.93$. If we remove difficulty in balancing, $C_R = 1 - 3/60 = 0.95$. Since 5 of the total 7 items are in perfect hierarchy, the coefficient of scalability = 5/7 = 0.71. Both of these measures reveal that the questions in this example are in good agreement with the Guttman scale. This really means that if the response is "yes" to "complete paralysis," there is no need to assess other motor functions. If the answer to this is "no," then you go down to the next assessment.

These are easily illustrated for this small table, but if the number of items and number of subjects are large, as would be the case in most practical situations, you may have to use the help of a software that does this.

For further details of Guttman scale, see Garson [3].

## half-life of medications

When a drug is ingested, it may reach its peak concentration in the system gradually but then starts to decay quickly, or may reach the peak quickly and starts decaying slowly. Half-life is the time taken to go from the peak concentration to half that concentration. Figure H.1 shows the half-life for a drug that reaches its peak gradually but decays quickly. Half-life is utilized to measure the duration that a drug remains in the system and may form the basis for prescribing the periodicity (once a day, twice a day, etc.) of intake. For example, Schulze-Bonhage and Hintz [1] suggested that the antiepileptic drug perampanel can be prescribed once daily because of its long half-life.

If the half-life of a drug is 3 h, it reduces to one-half of its peak concentration in 3 h. It does not mean it will vanish in the next 3 h. After 6 h, the drug concentration will be one-half of what it was after 3 h, i.e., one-fourth of the peak concentration; and after 9 h, it will be one-eighth of its peak concentration. It takes more than four half-lives to reduce the concentration to less than 5% of its peak concentration. After this, the concentration will not vanish but tends to stabilize. A rule of thumb says that it takes about four times the half-life of the drug for the concentration of that drug in the system to reach a steady state irrespective of the half-life. So if you administer a drug with a half-life of 12 h, the steady state will be achieved after 48 h. Drugs with a short half-life reach a steady state relatively quickly compared with those with a long half-life. An example of the statistical use of half-life is in the field of **crossover trials**. For a usual crossover experiment to be successful, there must be no **carryover effect**. The time required for the carryover effect to vanish is called the **washout period**. This should generally be at least four times the half-life of the substance to be confident that there is only a negligible amount of the substance in the system.

The half-life is obtained by fitting a **regression** of concentration on time and locating the time point where concentration is one-half of the peak. In most pharmacologic applications, concentration decline is fast in the beginning and increasingly slow later on, which suggests that a log scale is appropriate. Hence, a linear regression of log(concentration) versus time is generally used. If the slope of this line is $b$,

$$\text{Half-life: } T_{1/2} = \frac{\ln(0.5)}{b}.$$

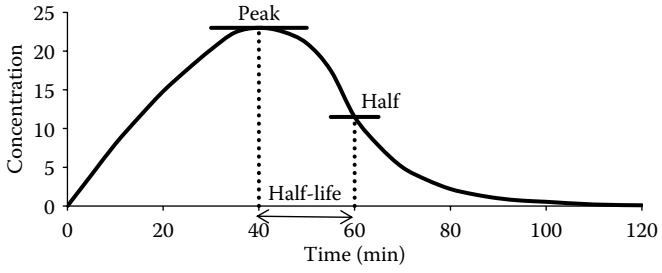

**FIGURE H.1** Half-life of a rapidly vanishing drug after reaching its peak concentration.

Since the concentration is declining over time, $b$ in this case would be negative. The value for ln(0.5) is −0.693 (note that it is also negative). Thus, $T_{1/2}$ would be positive, with a value dependent on $b$. The basic equation is $C_T/C_0 = (1/2)^r$, where $C_T$ is the concentration at time $T$, $r = T/T_{1/2}$ (that is, $r$ is the number of half-lives and $T$ is measured in terms of half-life units), and $C_0$ is the peak concentration. If the half-life of a drug is $T_{1/2}$ = 30 min, the concentration at $T$ = 90 min would be $(1/2)^3$ = one-eighth of what it was at peak concentration since $r$ = 90/30 = 3. The time to reach 10% of concentration in this example is given by $0.10 = (1/2)^r$, which yields $r$ = 3.32, and $T = 3.32 \times 30 = 100$ min.

Feng et al. [2] observed the half-life of Arg-Gly-Asp (RGD)-modified aclacinomycin A (ACM) liposomes to be 1.2 times of that of ACM liposomes and concluded that RGD-modified ACM liposomes have a better antitumor effect than the unmodified ones in lung adenocarcinoma. This illustrates one of the many uses of half-life.

## haphazard sampling

Amongst the many sampling techniques, nonrandom methods of sampling can be used for convenience: these fall under the term **purposive samples**. Examples are given here. Going one step further, a combination of two or more methods of purposive sampling can be used, and this is termed *haphazard sampling*. The main types of purposive sampling are as follows.

Subjects who are easily available or who can easily submit to the study form a **convenience sample**. The sampling of volunteers is the most prominent example. Volunteers have a definite place in medical studies, particularly in phase I of a clinical trial, but they may be class apart from the target population for the regimen under trial. Another convenience sample is that from a captive population, such as medical students. They can be easily persuaded by the faculty to be subjects of their study for effects with no potential harm. For example, they may be persuaded to undergo lung function testing before and after an exercise under trial, or can be asked to fill in an anonymous questionnaire on sexual behavior. Medical students may be physically and mentally healthier than other youths, and those agreeing to participate may be of a specific type—either too bright or too dull. Thus, the results cannot be generalized to the population of interest. A third type of convenience sample in medicine is that of referred cases. These are easily available and may also be easily persuaded to participate. Referred cases, however, are almost invariably complicated cases and do not represent the general class of patients. Ironically, they may not even represent complicated cases: sometimes, referral is done of noncomplicated cases for a particular investigation or examination that another center specializes in.

Other purposive sampling techniques include telephone sampling, snowball sampling, Delphi sampling, and quota sampling.

From the description of these nonrandom methods, you can see that they have extremely limited utility. Besides difficulty in identifying the population that these samples represent, nonrandom samples cannot be used for statistical inference, such as tests of significance and confidence intervals, because these statistical methods require some random element. At the same time, however, nonrandomly selected subjects can sometimes provide useful leads for further studies that can be based on random samples. Nevertheless, large-sized samples, even when nonrandom, may still represent the cross-section of the corresponding population and so can be adequate for statistically valid inferences.

For example, consider a relatively rare and not easily identifiable population such as gay men for sexually transmitted diseases. To survey such a population can be expensive and technically difficult [1], and the data available cannot be counted on as being reliable. Yet, researchers often abandon **probability sampling** methods, relying instead on convenience samples such as patrons of gay bars for this segment of the population because that at least helps in identifying the subjects.

The sampling becomes haphazard when some subjects are included as volunteers, some from those easily available, some from those who are referred cases, etc. The use of such haphazard sampling seriously undermines the credibility of the results. Some researchers may use this method of sampling without acknowledging that they are doing so, or without acknowledging its limitations.

## hard data and soft data

For statistical analysis, the data are mostly entered in terms of numerics into a computer suite of software. These are hard data. They lend validity to what you are doing or plan to do. Some features of the health spectrum are soft in the sense that they can only be understood in the mind but are difficult to put on paper. This applies particularly to psychological variables such as depression, frustration, opinions, and feelings. These form the soft data. Even if put on paper, soft data may defy coding, particularly if this is to be done before the collection of data. A precoded proforma is considered desirable these days because it makes computer entry so easy, but it should be ensured in this process that the medical sensibility of the information is not lost. The entries are created in a structured manner that many soft data defy; consequently, useful soft data many times remain unexploited.

Dixon-Woods [1] reviews the history of safety measurements through to the modern day and explores how different methods of measurement can yield varying results. Her key message is that not everything we need to consider can be measured as hard data; soft intelligence is also needed. "If you're not measuring, you're not managing. If you're measuring stupidly, you're not managing. If you're only measuring, you're not managing." Despite such intricacies of soft data, they still have a place in medicine in situations where perception matters more than reality.

Despite lacking statistical rigor, soft data serve the purpose of providing the context. They help in adding the emphasis, explaining the importance, and communicating the urgency. Soft data may include verbal communications, awards and honors, appreciation and brickbats, endorsements and repudiations, etc. In the context of health care, these could be concerns of the patients, media reports about the success of a new treatment modality or its failure, success stories, etc. A good report would not ignore soft data to leverage a point emerging from the hard data. Media reports generally start with soft data and then reach the hard data, if any at all. Scientific reports are primarily based on hard data but still use soft data for emphasizing the importance of the findings. Sometimes, soft information provides "meat" to the discussion part of a medical research paper.

It is often helpful to statistically relate soft data with hard data. For example, you can find out how improvement in severity score after a treatment translates into satisfaction or increases self-confidence in dealing with illness. This kind of exercise can provide a complete picture, say, before and after a treatment. A step further would be to examine different domains of severity score to find out which particular aspect contributes more to satisfaction than others. The difficulty would be in measuring the level of satisfaction, although something like a **Likert scale** can be used. Those domains that provide a high level of satisfaction can be exploited to advance the clinical objectives.

## harmonic mean, *see* mean (arithmetic, geometric and harmonic)

## harmonic regression

This kind of regression is used to model periodic oscillations in a time series. Periodic oscillations can occur, for example, due to seasonality of some diseases such as dengue occurring in some areas where mosquitoes breed in stagnant water after the rainy season each year, due to circadian rhythm in some of our body functions, due to menstrual cycle, etc. Generally, the trigonometric functions sine and cosine are used for modeling these oscillations. This is a called *sinusoidal curve*. This can incorporate frequency (peak once a year as in the case of dengue, once a week such as sickness absences on Fridays or Mondays, etc.) as well as amplitude, which depends on whether the peak is sharp or shallow and how high it goes from the secular trend. The model can be modified to include asymmetric oscillations such as rapid rise but gradual fall, and the analysis can be done as in the case of regression. An extension of this is **spectral analysis**, which considers the whole process simultaneously. This analysis includes periodicity as well as secular trend (Figure H.1). Ordinary time series analysis requires a priori fixing of periodicity, while spectral analysis discovers the periodicity and decomposes the series into its systematic components that otherwise may appear random.

Pocock [1] describes the harmonic analysis of a 5-year series of weekly records of sickness absence in a factory. There were $n = 260$ weekly observations ($5 \times 52 = 260$). Plotting "spells commencing per week" against "week no." (Figure H.2) gives an irregular plot on a smooth curve. The former shows a seasonal trend, and the latter is a single sinusoidal curve that can be seen to have a period of 1 year. A comparison of the two demonstrates that the seasonal trend is also nearly sinusoidal. There are, however, clear departures from the simple curve, particularly at annual holiday periods.

Bridges et al. [2] used harmonic regression methods to study seasonality of suicides in the United States—as they were above average all spring and below average all winter. Scavone et al. [3] observed that medications administered into the epidural or intrathecal space for labor analgesia may demonstrate variable effects dependent on the time of day, and this may affect clinical research

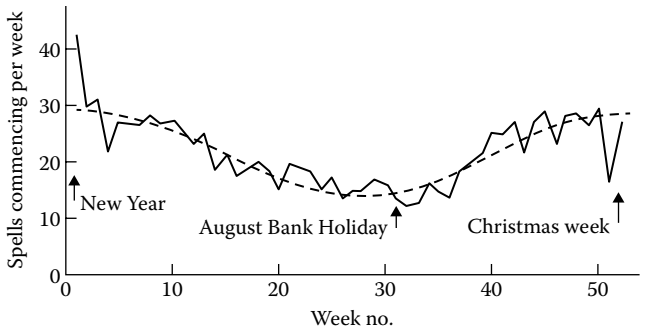

**FIGURE H.2** The estimated seasonal trend in weekly spells of sickness absence, 1960–1964. (From Pocock SJ. *Appl Stat* 1974; 23:103–20. http://www.jstor.org/discover/10.2307/2346992?uid=3738256&uid=2134&uid=2474376657&uid=2&uid=70&uid=3&uid=247437664&uid=60&sid=21104481367491, with permission.)

trials investigating the pharmacology of specific drugs. Their analysis demonstrated a 24 h harmonic cycle for cervical dilation at first analgesia request with maximum values occurring near 17:00 hours and minimum values near 05:00 hours, but the amplitude of the difference was very small. They called it *rhythm analysis*.

As mentioned earlier, the method of harmonic regression involves trigonometric sin and cos terms, and the method of fitting is mathematically complex, which we wish to avoid. Appropriate software may help, but our description may have given you a good idea of what harmonic regression is and where this could be applied.

## harmonization of data

Harmonization of data refers to the process of standardizing the inputs and outputs in research studies, especially if the goal is to combine the data into a single, integrated data set [1]. The concept of harmonization appears more commonly in comparative research since the objective of the process of harmonization is achieving comparability, particularly when the data are coming from heterogeneous sources. It can be applied at any stage of the study, e.g., questionnaire design, sampling, method of eliciting, data editing, but generally, antecedents in an **analytical study** are separately harmonized from outcomes. Separate harmonization helps in ensuring better comparability and is checked before the data are subjected to statistical analysis. This is also a prerequisite for exchange of information and automation, and helps in delivering improved health care as the evidence base becomes more reliable.

On a practical plane, data harmonization refers to the steps taken to ensure that the data from different sources have the same categorizations (e.g., each center uses the same age categories), same definitions (such as hypertension defined uniformly by all involved as blood pressure > 140/90), same method of measurement (each center using the same kind of instrument), same method of interview (e.g., in home or in clinic), same form for recording (this is generally done), same assessment (e.g., for classifying cases into mild/moderate/serious), etc. The procedure to identify outliers, wrong entries, missing values, etc. is also standardized across various sources. If any inconsistencies remain, **adjustments** as needed are made to make the data comparable before analysis is undertaken.

Harmonization has special application to laboratory results, which have a significant role in diagnosis and monitoring of patients. Such harmonization is required not just across laboratories but also across tests in the same laboratory. Different tests in the same laboratory must not give disparate findings just because one is done in standardized conditions and the other in not-so-standardized conditions, or one follows far a more accurate method than others. Also, if the aliquots of the same sample are analyzed by different laboratories, they must reach the same result. Wherever needed, recalibration is done, and for other situations where this cannot be done, limitations are explicitly stated. Reference material is made available for scrutiny by those who suspect the results. For further details, see AAAC [2].

Abner et al. [3] have discussed harmonization of longitudinal studies on aging, cognition, and dementia in the United States. See Magalhaes et al. [4] for efforts to develop a common methodology that could enhance the opportunity of data harmonization in the etiology of multiple sclerosis across several countries.

## Hawthorne effect

In the 1920s, researchers at the Western Electric Company's Hawthorne plant in Chicago observed that workers changed their behavior and responses when they knew that they are being observed. This psychological phenomenon is termed the Hawthorne effect. The effect, however, diminishes over time: it is a short-term effect. In the long term, performance reverts to previous levels.

Many years later (in 1939), Roethlisberger [1] documented the results of the Hawthorne studies. At that time, it was generally thought that financial rewards would be the main driver of performance. The Hawthorne effect negated that as it was observed that greater productivity resulted when management made workers feel valued and aware that their concerns were taken seriously. Although the conclusions of the Hawthorne studies have been called into question, the theory persists—probably because most people understand that they usually do perform better when observed than they do otherwise. For example, Stringly et al. [2] found hand hygiene event rates to be three times higher in hallways within eyesight of the auditor compared with when no auditor was visible.

In medical care, patients may show improvement just because they perceive that they are being looked after well. In clinical trials,

the placebo group can show enhanced efficacy because the subjects know that they are in a trial and are being observed. This is in addition to the placebo effect that comes from the false impression that they are being treated. Thus, the Hawthorne effect can cause a considerable unsuspecting bias.

A good review of the Hawthorne effect is provided by McCambridge et al. [3], who called it research participation effect. After a review of several studies, they observed that it does exist in most studies, although not much can be said about their mechanism or magnitude, and concluded that further research is required to understand this effect. Verstappen et al. [4] proposed a block design that allows for control of the Hawthorne effect in randomized controlled trials of test ordering.

## hazard functions

Hazard function describes the **hazard rate** per unit of time at different points in time. The concept of hazard function is easily understood in the context of the general population, where the hazard of death is high at the beginning of life (neonatal period), is very low for age 5–59 years, and steeply increases thereafter. Thus, it has nearly a **bathtub** shape (Figure H.3a). The rate is higher at both ends of life in developing countries than in developed countries. In other setups, it can remain constant throughout the time period under observation or may continuously rise (Figure H.3b). An increasing hazard indicates weakening, whereas a declining hazard indicates hardening (i.e., as time passes, it becomes more and more difficult to experience the event). Several other forms can be visualized.

Perhaps, it is easier to understand *cumulative* hazard function in place of the hazard function itself. It sequentially adds the hazard from one time to the next time and describes the probability $P(T < t)$, where $T$ is the variable failure time and $t$ is the actual value of the time. Thus, cumulative hazard function is the probability that a failure has occurred before time $t$. This is like the probability that a person dies before the age of 70 years. The death can occur at age 50, 60, or 69 years—all are included. You may realize that the cumulative hazard function is the complement of the survival function and is thus also called *failure function*. This depends on the **distribution** of the failure time.

The hazard of death is not uniform throughout the life of the general population. Though rare, if it is indeed uniform for some conditions, such as for a disease that strikes the young and the old at the same rate and causes death at the same rate, the hazard function $P(T < t)$ takes the form

$$\text{exponential hazard: } F(t) = 1 - e^{-\lambda t}.$$

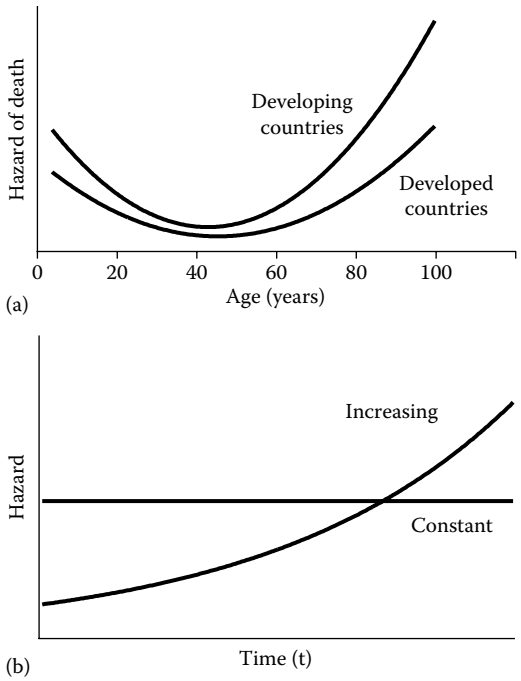

**FIGURE H.3** (a) Hazard of death at different age in general population; (b) constant and increasing hazards.

The function given in this equation is called an **exponential function**. Since hazard is not uniform in most situations, the exponential form of cumulative hazard does not provide an adequate representation. Nonuniform hazard can be understood further by the example of an automobile whose failure rate in the beginning after coming out of the showroom is low and high in, say, the seventh year of running. In this case, the hazards rapidly increase as time passes. In the case of heart transplantation, the initial few days and weeks are critical. After this period, the hazard declines, at least for some time. One such cumulative hazard function that models varying hazards over time is the **Weibull distribution**. The third commonly used cumulative hazard function is **lognormal**. This is appropriate when the duration of survival has a hugely **skewed** distribution to the right—long and very long durations are also present, though mostly, they are not very long. The life span of cells may have this pattern. Data from the Surveillance, Epidemiology, and End Results (SEER) study revealed in a 27-year follow-up that the survival times of cancer patients who died of their disease can be considered to follow a lognormal distribution [1].

All models described in the preceding paragraph are called parametric since they depend on the **parameters** that define the shape of the distribution. Many workers feel that parametric models impose difficult-to-justify restrictions. Also, there are many options, and prior information is rarely available to make a correct choice. You may have to try more than one model to get an adequate fit. On the other hand, a semiparametric model, particularly **Cox regression**, is more flexible and safer. This has become a standard choice for many applications where dependence of the hazard ratio on a set of covariates is studied.

One rather simple nonparametric estimate of cumulative hazard function is

$$\hat{H}(t) = \sum_{T \le t} \left( \frac{d_t}{n_t} \right),$$

where $d_t$ is the number of failures out of $n_t$ at time $t$. Thus, this is evaluated as the sum of the estimated discrete hazards at all the event times up to $t$.

While analyzing survival data, if the hazard function is of interest, choose the one that meets the eligibility requirement. If you are examining a hazard function used by someone else, view it in light of the preceding discussion.

## hazard rate/ratio, *see also* proportional hazards

Let us first explain the term *hazard*. This is the same as *risk* and is the probability of occurrence of an event, generally an adverse event such as death. However, hazard is invariably linked to time, whereas risk may not be. Hazard of death at age between 70 and 71 years is the probability of death among those who are alive at age 70 years. This is the conditional probability (see the topic **probability**) and is not the same as the (unconditional) probability of death. Probabilities of death at different ages will add up to 1 because the ages are mutually exclusive and exhaustive, while conditional probabilities do not have this feature. Conditional probability of death between 80 and 84 years may be 0.6 and of death between 85 and 89 years may be 0.7. Their sum is more than 1. This cannot happen with unconditional probabilities. Hazard at any time can be lower or higher than the unconditional probability for that time. Hazard is more relevant in some situations and statistically easier to work with in a semiparametric model, as in **proportional hazards**.

Now we come to the hazard rate. In a disaster such as an earthquake, thousands of people may die in a few hours. The intensity of death or force of mortality in persons exposed to such disasters is extremely high. Three days is less than 1% of a year, and if 800 people die, the rate is 800/(3/365) = 97,333 persons per year! Such a force of mortality at a particular instant is called the hazard rate.

Note that the hazard rate also is very different from the **probability** of death. While the probability of death cannot exceed 1—the sum total of the probabilities from all the different causes has to be 1—hazard rate can exceed 1. Probability is for the occurrence of an event at the end of a period, while the hazard rate is always per unit of time for any specified duration. It measures the speed of occurrence—probability does not. The interest sometimes is not in the probability but, indeed, in the rate of failure in a particular time interval. The hazard rate is the "limit" of this rate as this interval approaches 0. Statisticians use the concept of limit to obtain a mathematical form that works at a particular point in time when time is continuously observed. The hazard rate at time $t$ is the rapidity of failure in the next instant. This is obtained by dividing the conditional probability of failure in the next instant by the length of that instant provided the hazard remains constant over that period. Hazard rates are absolute, and this concept can be applied to all health conditions that change from one state to another in the course of time. Because of its intimate dependence on time, hazard rate is commonly used in **survival analysis**, where the outcome is measured in terms of duration.

While a hazard rate evidently depends on time, it may also depend on several other factors. In a clinical setup, the hazard rate of serious side effects may depend on the covariates, such as the characteristics of the person like age, gender, and nutritional status, as well as on the type of regimen, type of domiciliary care, alertness, competence of the attending physician, etc. When two or more groups are available, such as an experimental and a control group, the groups can be compared with respect to the hazard rate at a particular point in time for a given set of covariates. For such a comparison, since many factors are involved, it is sometimes helpful to obtain the hazard rate as a function of various covariates. One such model is a form of regression, known as **Cox regression**. In this type of regression, the term *hazard rate* is generic and is not restricted to death. It can be used for any other event of interest, such as appearance or reappearance of symptoms, or even for a favorable event, such as discharge from hospital, cessation of smoking, or resumption of daily activities.

Turning now to the hazard ratio, this is obtained as the ratio of hazard rates in the presence of a risk factor and the rate in its absence, such as with a particular disease and without that disease. This can vary with time, and this is what makes it different from odds ratio or relative risk, which have no time element. Presence or absence of a risk factor could be in terms of levels also. For example, we can have the hazard ratio of death of patients with mild disease and with serious disease. In a clinical trial setup, hazard rates could be the "hazard" of recovery, say, per week in patients on the test regimen and on the control regimen.

We all know that the hazard rate of death increases after the age of 60 years as we age further. This is so for healthy persons and more so in persons with some terminal disease. The rate rapidly increases in both groups as we age, but the rate is much higher in persons with terminal disease. In none of these groups is the hazard rate constant as we move from age 60 years to age 90 years. Since the hazard rates increase in both groups, the ratio of hazards at different ages may still be constant. If the hazard rate of death in persons of age 70–74 years is 82 per thousand per year in healthy people, the rate may be 133 per thousand in persons with terminal disease of the same age group. The hazard ratio is 1.5 in this age group. In age group 80–84 years, the rates may be 150 per year and 225 per year, respectively. The ratio is still 1.5 in age group 80–84 years as in the age group 70–74 years despite a more rapid increase in the cases with disease. This is what is called **proportional hazards**. See this topic for further details. Sometimes, hazard rate is reported without reference to the time. For example, it is sometimes calculated as the ratio of median survival duration in the two groups. This can mislead just as all other averages could—hazard ratio could be high during early follow-up and low in the late phase of the follow-up period. For an interesting account of the hazards of hazard ratios, see Hernán [1].

A common misinterpretation occurs when a hazard ratio of 2 is understood to mean that the occurrence of events (such as death) is twice as fast in one group as the other. This is not so. A hazard ratio of 2 in age, say, 70–74 years means that the chance of occurrence of an event (e.g., death) is twice as much in one group as in the other.

## health-adjusted life expectancy, *see* life expectancy

## health inequality, *see also* Gini coefficient, Palma measure of inequality

As the name implies, health inequality is the disparity in health of different sections of the society. People with income in the top 10% bracket enjoy disproportionately far superior health than people with the bottom 10% income. This is like the popular perception

that the top 20% of people control 80% of the wealth in almost any free society—called the **champagne glass effect**, as per the details given later in this section. Health also has a similar skewed distribution.

When looking across different segments of the population, health inequality affects the rate of improvement in population health overall. It is true that deprived sections of the population suffer most from health inequalities, but health inequalities affect all sections as disparities hamper the generation of human capital and inhibit sustainable improvement. In addition, all inequalities are unfair and violate social norms.

The most common statistical measure of health inequality is the **Gini coefficient**, as described under this topic along with an illustrative example of how this is calculated. This coefficient is generally between 0.2 and 0.6 and does not capture inequalities as much as it should. Cobham and Sumner [1] make a passionate plea that the Gini coefficient should not be used, although their argument is in the context of income. This more or less applies to health also. An alternative method, called the **Palma measure of inequality**, has been proposed that seems to be more sensitive to inequalities. This measure also is described separately. Asada et al. [2] consider the Gini coefficient as a univariate measure and propose a three-stage approach for measuring health inequality involving cross-disciplinary dialogues.

### *Champagne Glass Effect*

A champagne glass (Figure H.4) is a very effective tool to depict inequality. In this glass, the top 20% of height contains 80% of the champagne. In health also, generally, the top 20% of people use 80% of the health resources either to keep themselves fit and healthy or to enjoy medical care facilities to reduce suffering and to live long. Only 20% resources are left to meet the needs of the remaining 80% of the population. In this depiction, the size of the bowl can be increased if the distribution is even more skewed or can be reduced if it is not so skewed.

## health infrastructure (indicators of)

Availability of hospitals, health centers, dispensaries, and doctors, on one hand, and availability of food, safe drinking water, and sanitation facilities, on the other, together form the health infrastructure. The second component of this infrastructure (food, safe water, etc.) is not important for developed countries because nearly 100% of the population in those countries have these facilities, but it is very important for developing countries.

The following indicators can be used to measure the extent of availability of the health infrastructure:

$$\text{Population served per bed} = \frac{\text{population}}{\text{number of beds}}.$$

This can also be stated as beds per 1000 population and can also be termed density of beds, or **bed–population ratio**. According to the World Bank estimates, the number of beds per 1000 population was 0.8 in Sudan, 3.6 in Sri Lanka, and 6.5 in Belgium in 2012 [1]. These can be divided into intensive care unit (ICU) beds, general care beds, beds for cancer patients, beds for pediatric patients, etc., depending on the focus of the study.

The second health infrastructure indicator is the density of doctors, measured by the number of physicians per 1000 population, also known as **doctor–population ratio**. This can be calculated as

$$\frac{\text{number of physicians}}{\text{per 1000 population}} = \frac{\text{number of physicians}}{\text{population}} \times 1000.$$

The information available with the World Health Organization (WHO) by 2014 shows that nearly 46% of member states have less than 1 physician per 1000 population [2]. The definition can be extended to include doctors of other systems such as homeopathy and Ayurveda. These can also be broken down into doctors of various specialties and superspecialties. The formula remains the same for other personnel such as dentists, nurses, pharmacists, and field workers.

For accessibility, one can think of the percentage of the population with access to an approved health care facility within, say, 5 km. This is in accordance with considering health care accessible in a developing country when it can be reached by the public on foot or by local means of transport in no more than an hour.

A large number of other indicators of health infrastructure can be devised to serve a specific need. For example, you may be interested in medical seats per million population available in educational institutions, laboratories available, ambulance services for emergency cases and their response time, etc. In addition are the following:

$$\text{Per capita availability of food grains per day} = \frac{(\text{total production of food grains}) - (\text{waste}) - (\text{exports}) + (\text{imports}) \text{ in a year}}{\text{population} \times 365}.$$

Water supply is considered safe when it is treated surface water or untreated but uncontaminated water such as from springs, sanitary wells, and protected boreholes. Excreta disposal (sanitation) facilities are considered adequate if they can effectively prevent human, animal, and insect contact with excreta.

The percentage of the population with such access is an important indicator of health infrastructure. According to a WHO/United Nations Children's Fund (UNICEF) report for the year 2014 [3], the world sanitation coverage has increased by 21 percentage points in developing countries since 1990. As of the year 2014, the coverage was 64% in the world, ranging from 36% in the least developed countries to 96% in developed regions. For water coverage, the increase since 1990 in developing countries is 17 percentage points, and it stood at 89% in 2014, ranging from 67% in the least developed countries to 99% in developed regions. Even this basic amenity is not available to a large section of the population in some parts of the world.

Among other indicators that could be considered for infrastructure is expenditure on health. The World Bank computes this in three indicators for each country of the world, namely, health expenditure per capita in US dollars, public health expenditure as percent of total health expenditure, and total health expenditure as percent of gross domestic product (GDP). The country-wise data are available on their associated websites [4].

## health measurement

We describe these separately for individuals and populations.

### *Measures of Individual Health*

Health measurement at the community level is fairly structured and discussed later in this section, but how do you know that you are healthier than your neighbor? This requires that we first understand individual health. One appealing explanation is as follows [1].

The human body has a mechanism to adjust itself to minor variations in the internal as well as external environment. Perspiration in hot weather, shivering in the cold, increased respiration during physical exercise, excretion of redundant nutrients, replacement of lost blood after hemorrhage, and decrease in the diameter of the pupil in bright light are examples of this mechanism. This is a continuous process that goes on all the time in our body and is referred to as homeostasis. Health could be defined as the dynamic balance of body, mind, and soul when homeostasis is going on perfectly well. The greater the capacity to maintain internal equilibrium, the better the health. Perhaps human efficiency is optimal in this condition. Sometimes, infections, injury, nutritional imbalances, stress, etc. become too much for this process to handle, and external help is needed. Medicine can be defined as the intervention that tries to put the system back on track when aberrations occur.

Health being a multidimensional concept, its measurement is intricate and mostly reduces to perceptions. Measurement of physiological and biochemical parameters can give an idea of the level of health of a person, but a person with an amputated leg could be healthier in his/her own right than a person with both legs but not able to walk! This is a normative issue and could be a biostatistical adventure. The measurement of health can be difficult at this stage of our knowledge. Yet, one can think of capacity to work as expected from a healthy person of one's age, both physical and mental, as an acceptable measure of individual health. If you include "a joyful attitude towards life, and a cheerful acceptance of the responsibilities that life puts upon the individual" [2], the measurement becomes even more challenging. Health should also not be equated with well-being [2] as well-being is governed by a host of factors of which health is just one. A definition that can help develop operational indicators of individual health is elusive. Perhaps measures such as **quality of life** or health-related quality of life can be considered as good surrogates. Irrespective of what metric is used, there are issues, such as whether health is to be measured for current status, for the past 1 year, or over a lifetime of experience.

Limiting the discussion to physical health, in Figure H.5, person A has had a healthier life than person B, although both lived the same number of years. Another measure could be the healthy years of life, but that would be more meaningful when considered in old age. This would subtract years spent with any disability, or the degree of disability can be discounted to compute weighted healthy years. This is similar to adjustment by **disability weights** done in computing **disability-adjusted life years (DALYs)** for community health. Note, however, that this kind of metric is mostly restricted to physical health and ignores social and mental health in terms of capacity to do intellectual work or in terms of contributions to the well-being of the family and the society. Another approach could be to divide health into its domains, such as level of mobility, level of self-care, level of

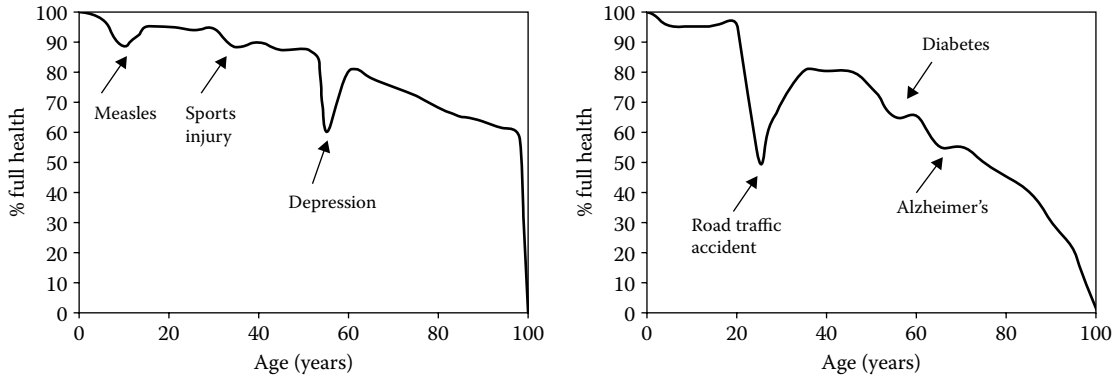

**FIGURE H.5** Lifetime physical health for person A (left panel) and person B (right panel). (From Sigerist HE. *Medicine and Human Welfare*. Yale University Press, 1941, with permission.)

pain, and level of cognition [3], and measure each domain just as we do for quality of life. Also see the topic **positive health**.

### *Measures of Population Health*

Measurement of population health or of a group of people is not so difficult, particularly the physical component. Several measures are available that are well defined and extensively used. Among them are the **incidence** and **prevalence** of various health conditions. These can be calculated for a specific age-sex group or any other group of interest, such as people in a particular occupation or people working in a particular factory. Another is duration of morbidity per year, for which sickness absenteeism could be a surrogate. Third is the severity of disease—a less healthy population will have a higher number of severe cases per 1000 population.

The second common indicator of population health is the **mortality rate**. This is measured in terms of crude death rate, standardized death rate, infant mortality rate, age-specific death rate, etc. Higher age-specific death rate in comparison with another population is a definite sign of poorer health. A good statistical property of death is that this can be ascertained without controversies, unlike morbidity, which has many gray areas.

A comprehensive measure of population health (in fact, a lack of it) is the **disability-adjusted life years (DALYs)** lost. This combines years of life lost due to early deaths and equivalent years lost due to disability from diseases and other adverse health conditions. This computation also requires **disability weights**. Another good measure of population health is the **life expectancy**, particularly the healthy life expectancy. All these indicators are for absence of disease or mortality, and would not be able to compare two populations with, say, the same life expectancy. The difference in health levels may not be substantial in countries with the same life expectancy now but may become important in future when, for example, many countries attain a life expectancy of more than 90 years—a threshold beyond which further improvement would be rare. At that stage, the percentage of the population living healthy at age 90 years could be an effective indicator.

The concept of positive health as conceived by Indrayan [1] for individuals is probably not applicable to communities. Indicators such as average total lung capacity and average hemoglobin level can be considered as possible candidates.

## health programs (evaluation of), *see* evaluation of health programs/systems

## health situation analysis

This is the assessment of the health conditions of a population. Health situation analysis is generally undertaken before devising or launching a health program so that the program can be fine-tuned to meet the specific needs of the population, or for identifying the priority areas of concern.

Health situation analysis would include the quality and type of health services required for a community based on indicators such as the size of the community, its age–gender structure, its socioeconomic profile, and the prevalence of various conditions of health and ill-health in different sections of the community. The health services also depend on culture, traditions, perception, socioeconomic status of the population, existing infrastructure, etc. Expectations and demands are also considered. All these aspects need to be properly assessed to prepare an adequate plan for the provision of health services. The basic aim of this analysis is to provide the baseline information for such a plan. The situation can rapidly change because of either natural growth of the population or interventions, so a time perspective is always kept in view in this analysis.

For launching a health program, generally, the broad problem requiring a plan of action is fairly well known before embarking on the health situation analysis, and only the specifics are to be identified. It seems ideal to talk about both good and bad aspects of health, but in practice, a health plan is drawn up so as to meet the needs as perceived by the population. These needs are obviously related to the adverse aspects of health rather than to the positive aspects. Sometimes a **survey** is required, and sometimes an expert group is set up to identify the specifics of the problem.

The health situation analysis is also expected to provide clues to deal with the problem at hand. The magnitude of the problem in different segments of the population can provide an epidemiological clue based simply on excess occurrence in specific groups. Determinants or risk factors for the health condition under review are also assessed. These could also be available from the literature or from the knowledge and experience of experts in that type of situation.

Assessment of the functionally available **health infrastructure** is also an integral part of the health situation analysis. This includes facilities such as hospitals, beds, and health centers; staff in terms of doctors, nurses, technicians, etc.; supplies such as equipment, drugs, chemicals, and vehicles; and most of all, their timely availability at the functional level so that they can be effectively used.

## health statistics

Used as a plural, *health statistics* are data relating to various aspects of health. These include, but are not limited to, data on births, growth of children, nutrition, morbidity, health behavior, availability and utilization of health services, health costs, and deaths. **Vital statistics** that relate to fertility and mortality are part of health statistics. Some workers include **demographic** data, such as on age-sex structure, growth of population, migration, education, and occupation, in the ambit of health statistics since these factors affect health. Some would include even environmental data, such as on pollution, occupational hazards, and traffic accidents. In its broad sense, **medical biostatistics** relating to incidence and prevalence of diseases, hospital data, causes of death, **case fatality**, etc. can also be considered part of health statistics. All these can be studied for different segments of the population as needed, such as urban/rural, male/female, child/adult, etc.

Health statistics can be best understood by reference to the National Center for Health Statistics (NCHS) under the remit of the Centers for Disease Control and Prevention [1]. Using data open to the public, NCHS generates statistical tables, charts, and graphs illustrating various health statistics for the US population. For example, in 2014, NCHS published a special issue of health statistics from the Federal Interagency Forum on Child and Family Statistics entitled *America's Young Adults* [2]. Among others, this report concludes that there has been a steady downward trend in smoking since 1983 in 18- to 24-year olds regardless of race or gender. Also, from 1990, there has been a

steady trend downward in death rates among 18- to 24-year olds, with the most common cause of death being unintentional injuries.

You can see that the health statistics can be those that are directly collected from persons, households, health facilities, or even published reports. But these can also be derived from those data after necessary calculations or other processing. The data are further analyzed to derive useful health statistics that can be operationally utilized for taking action, or to convey meaningful conclusions. The example cited in the preceding paragraph illustrates this kind of derived statistic. The calculation of **disability-adjusted life years (DALYs)** lost based on morbidity and mortality is a fine example of how routine health statistics can be converted to information with far-reaching implications.

As always, the derived health statistics would be only as good as the original data themselves. All efforts must be made at the primary source level to ensure that the information is correctly obtained based on appropriate instrumentation and proper assessment. The definitions must be fully standardized, and the staff should be fully trained to use uniform methods. The data should be both **valid** and **reliable**. Exercise special caution while combining secondary data with primary data—the two may have followed very different procedures and may differ in unanticipated vital aspects. Some adjustment for known deficiencies in the data can be made at the time of analysis, but these adjustments may be available for highly restricted conditions.

## healthy life expectancy, *see* life expectancy (types of)

## hierarchical clustering, *see also* cluster analysis

Hierarchical clustering is a method of successive grouping of given units into an unknown number of homogeneous groups such that the values of the units within each group are alike but the units between groups are different. Technically, these groups are called clusters, which are sought to be internally homogeneous and externally isolated as much as possible. The method starts with identifying two units that are most similar and putting them into one group. Call this *entity*. Then similarity between this entity and all the other units is examined, and again, the most similar ones are merged into groups. This could mean that either the number of units in the previously formed entity becomes three or another entity of two units is formed. This procedure is repeated, merging one unit at each stage. That is why it is called hierarchical. The full name of this procedure is *hierarchical agglomerative clustering* because of sequential merging. The process can go on till such time that all units merge into one big group, but the purpose is to stop as soon as we find that subsequent merging is destroying the internal homogeneity of the clusters. We explain this in a short while in this section. A **dendrogram** is a graphical display of the merging taking place at each stage, and this can help in deciding when to stop.

A similar procedure can be adopted by beginning with all the units together as one big cluster. Divide this into two clusters such that these are very different from one another. Then divide them into three clusters, and so on. This process is called a *hierarchical divisive algorithm*. There are not many examples of the use of this method. Most clustering applications use an agglomerative algorithm.

Statistically, the problem is of dividing a fixed number of units, $n$, into a small but unknown number of homogeneous clusters, $K$, with respect to $J$ measurements on each unit. Now these clusters will have $n_1, n_2, \ldots, n_K$ units, respectively, such that $n_1 + n_2 + \ldots + n_K = n$. For example, we might divide various hemoglobinopathies into clusters that are internally similar but distinct from others, as measured by, say, anion high-performance liquid chromatography (HPLC). Clusters so formed would include hemoglobin (Hb) A2, Hb variants, HbF, even Hb, and red blood cell (RBC), as measured by mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), etc. The number of clusters is determined by calculating a measure of internal homogeneity at each stage of the clustering process. When the homogeneity is significantly disturbed, the process is stopped.

The process obviously requires a measure of affinity or similarity. For quantitative data, generally, **Euclidean distance** is used, which is a measure of differences instead of similarity. Units with the least distance are considered most similar. This can be obtained not just for univariate values but also for multivariate values. For qualitative binary data, the Jaccard coefficient or any other measure described under the topic **association between dichotomous characteristics (degree of)** can be used. For ordinal data, measures such as Somer $d$ are available (see **association between ordinal characteristics**), and for polytomous data, measures such as the contingency coefficient (see **association between polytomous characteristics**) are available. However, there are not many examples of the use of the clustering method for qualitative data.

The primary problem in hierarchical clustering is measuring the distance between two entities, where one entity has, say, $n_1$ units and the other entity has $n_2$ units. It is for this purpose that one of the methods among **complete linkage**, **simple linkage**, **Ward**, **median**, etc. is used. Generally, the method of complete linkage is preferred as it was found best at not discovering false clusters of random data in a simulation study [1].

The most difficult decision in the hierarchical clustering process is regarding the number of clusters naturally present in the data. The decision is made with the help of criteria such as pseudo-$r$ or the **cubic clustering criterion** [2]. These values should be high compared with the adjacent stages of the clustering process. Another criterion could be the distance between the two units or entities that are being merged in different stages. If this shows a sudden jump, it is indicative of a very dissimilar unit joining the entity. Thus, the stage where the entities are optimal in terms of internal homogeneity and external isolation can be identified. The entities at this stage are the required natural clusters.

See Everitt et al. [3] for further details of the hierarchical clustering process.

## hierarchical designs

Hierarchical design is a synonym for **nested design**, where one factor works within another factor. Consider a study on 600 stroke patients treated in 20 hospitals located in five countries. The recovery of these

patients would depend, among others, on (i) patient characteristics such as disease severity and the nutrition level, (ii) hospital practices such as nursing care and competency of the doctors, and (iii) country characteristics such as work culture and attitudes. The final outcome is the joint effect of these factors. Note that country-level characteristics can be measured only for the five countries participating in the study, and hospital practices can be assessed for 20 participating hospitals, whereas patient data would be available for 600 patients.

The analysis of data from hierarchical designs will consider, for example, within-hospital variation (across patients) as well as between-hospital variation. Within-country variation will be between hospitals as well as between patients. There will also be a between-country variation. Usual analysis does not consider this hierarchy, and **multilevel models** are required to analyze such data. In these models, the **analysis of variance (ANOVA)** is modified to include hierarchical structure. Whereas patients can be considered random samples from each hospital, if hospitals and countries are also random samples representing a bigger population, these also will be modeled as **random effects** in ANOVA. Setting up such an ANOVA with statistical software will require skill, and we would suggest getting the help of a qualified statistician to do such analysis for you. The analysis will have to take this hierarchy into consideration.

The details of analysis for two hierarchical factors are provided by Ellison and Barwick [1]. For another real-life example, see Kong et al. [2]. They have discussed methicillin-resistant *Staphylococcus aureus* (MRSA) transmission by patient proximity in hospitals with a nested structure where beds are positioned within cubicles and cubicles are positioned within wards. Any study on MRSA in this kind of hospital will follow a hierarchical design.

## hierarchical models/regression

Inclusion of **regressors** of different levels in a **regression analysis** gives rise to hierarchical regression. For example, for studying risk factors of coronary diseases, you can have some variables at an individual level, such as cholesterol level and body mass index, and some variables at a family level, such as housing and interpersonal support. In this situation, you cannot run the usual regression because (i) the number of families will be different from the number of individuals and their information will be on different variables, and (ii) the individuals within a family will tend to provide correlated information. This nesting and resulting clustering effect violates the requirement for validity of the usual regression. In our example, cholesterol level and body mass index among members of the same family are likely to be correlated because of a common diet, environment, and lineage. The same situation occurs while studying ambulation time after bariatric surgery done by different surgeons. Each surgeon uses his/her own precautions before, during, and after surgery, which may have a profound effect on the ambulation time besides, of course, the patient characteristics, such as extent of obesity and age. Models that describe hierarchical regression are called hierarchical models. These are also called **multilevel models/regression.** The other name is *nested models.*

The reasons that hierarchical models cannot be analyzed by the regular methods are twofold. First, some information will be available for each individual (level 1), some for subgroups (level 2), and some for groups (level 3). A model is built that incorporates this structure. Second, ordinary **regression** works well when the **regressors** are considered fixed—a condition that is rarely met in a hierarchical structure. Consider the duration of stay of patients in critical care in small, medium, and large hospitals. You might want to know whether or not this duration of stay varies according to the size of hospital, which in turn determines the quality of the facilities, the care available, and the confidence of the patients. If so, the chosen small, medium, and large hospitals are considered random samples of such hospitals in the city or state. In that case, their effect is not fixed but is random (see **fixed and random effects**). In addition, of course, the duration of stay will depend on the condition of the patient at the time of admission, which can be assessed by the **APACHE score**. Let the size of the hospital be defined by the number of beds: small if the number of beds is less than 100, medium if the number of beds is between 100 and 399, and large if the number of beds is 400 or more. The exact number of beds is not under consideration. A sample of $n_1 = 15$ patients from a small hospital, $n_2 = 30$ patients from a medium hospital, and $n_3 = 50$ from a large hospital are chosen from those undergoing critical care. In this example, the hospital effect is fixed, but the effect of the APACHE score is random as the sample of patients is random. The linear regression model in this situation will be of the following type:

$$y_{ij} = a_i + b_i x_{1i} + c_i x_{2ij} + d_i x_{1i} * x_{2ij},$$

where

- $y_{ij}$ = duration of hospital stay of $j$th patient of the $i$th-sized hospital ($j = 1, 2, \ldots, n_i$; $i = 1, 2, 3$)
- $x_{1i}$ = size of the $i$th hospital ($i = 1$ is small, $i = 2$ is medium, $i = 3$ is large), assuming that the size of hospital has a linear effect on the duration of hospital stay
- $x_{2ij}$ = APACHE score of $j$th patient of the $i$th hospital ($j = 1, 2, \ldots, n_i$; $i = 1, 2, 3$)
- $a_i$, $b_i$, $c_i$, and $d_i$ together define the intercepts and slopes for the patients, APACHE score, and the hospitals of different sizes

The basic premise in hierarchical regression in the context of this example is that the duration of hospital stay tends to follow different patterns depending on the size of the hospital, and that both hospital size and the APACHE score should be considered together as the factors affecting the duration of hospital stay. Depending on the data, the regressions may appear as shown in Figure H.6. The lines have different intercepts and different slopes. The usual line obtained after ignoring the hospital size, which assumes that all durations and APACHE scores are from the same target population, is also given. Note how this composite line hides the differences present in the lines for different hospital sizes.

The analysis basically is in terms of fitting two models: first for individuals using the usual regression analysis and second for considering the estimates of this regression as dependent on the second-level factors. See Garson [1] for details.

This example is for two levels (size within hospital and subjects within size) and can be extended for more levels. For example, one extension could be to include doctors as the factor influencing the hospital stay through their knowledge and attitude. The levels can be fixed effects if both levels are fixed (hospitals and wards—neither is a sample, and the conclusions are valid for these only), both can be random, or one can be fixed and the other random.

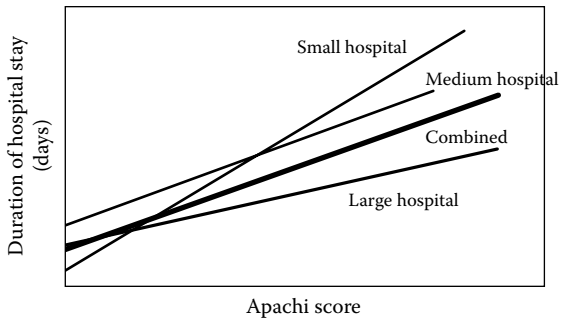

**FIGURE H.6** Hierarchical (multilevel) regressions.

This kind of regression can also be used in the analysis of **longitudinal** data. Suppose that after surgery, each patient is recorded for pulse pressure every 5 min till such time that the patient stabilizes. The first patient becomes stable in 40 min so that he is recorded for $n_1 = 8$ time points, the second in 30 min so that $n_2 = 6$, etc. If the patients are considered to be fixed (i.e., not a random sample), the situation is the same as mentioned previously. If they are a random sample, a slight modification of the model will be required.

## histogram

A histogram is a set of contiguously drawn bars showing a **frequency distribution**. The bars are drawn for each group (or interval) of values such that the area so enclosed is proportional to the frequency in that group. Generally, the variable values are plotted on the horizontal ($x$) axis, and the frequencies are plotted on the vertical ($y$) axis. The vertical axis can represent percentage instead of frequency. This will affect the scale but not the shape of a histogram.

A histogram for the data in Table H.1 is shown in Figure H.7a. Note the following for these data. The first is an open interval because the lower end point is not mentioned. For the purpose of drawing the histogram, this interval is assumed to be of the same width as the next interval, i.e., 160–199. Thus, the first and the second intervals have width of 40 mg/dL each, whereas all others except the last have width of 20 mg/dL. For the area of the bar to represent frequency, the height of the bar for the first two intervals should half of the frequency in these intervals. This suitably adjusts for the double width of these intervals. The interval 320–339 has no subject, and this is represented by a blank space in the histogram. The last interval has width 60, which is three times the width of most of the other intervals. To adjust the area for this width, the height of the bar for this interval is one-third of the frequency in that interval.

**TABLE H.1**
**Distribution of Subjects Attending a Hypertension Clinic by the Total Serum Cholesterol Level**

| Cholesterol Level (mg/dL) | Number of Subjects ($f$) | Percent (%) |
|---|---|---|
| <199 | 3 | 3.7 |
| 200–239 | 13 | 15.9 |
| 240–259 | 16 | 19.5 |
| 260–279 | 17 | 20.7 |
| 280–299 | 24 | 29.3 |
| 300–319 | 6 | 7.3 |
| 320–339 | 0 | 0 |
| 340–399 | 3 | 3.7 |
| **Total** | **82** | **100.0** |

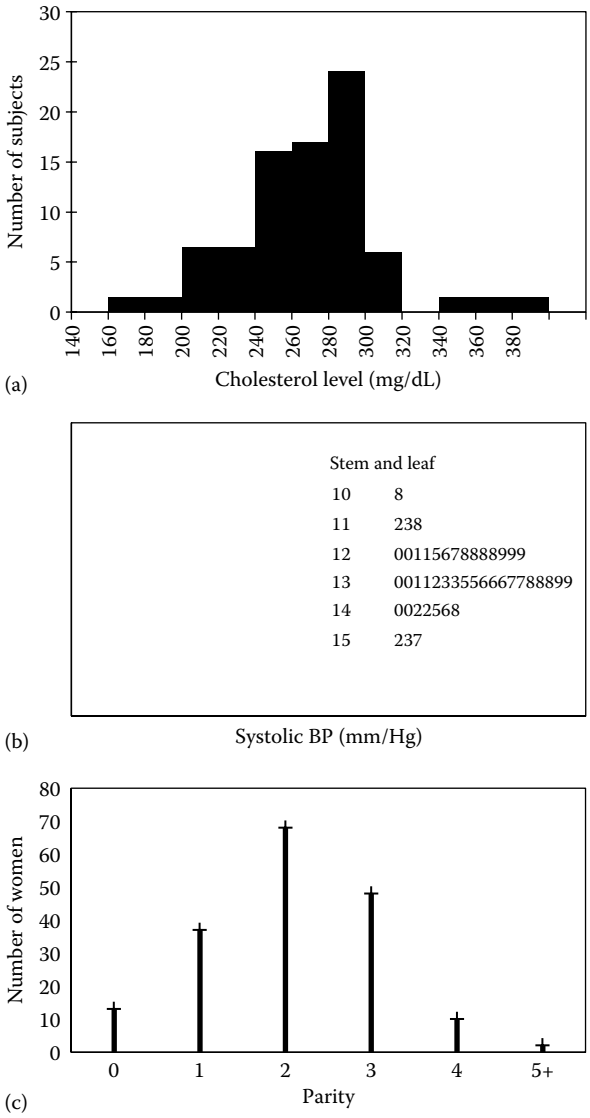

**FIGURE H.7** (a) Histogram for the data in Table H.1; (b) stem-and-leaf plot; (c) line histogram for discrete data.

The following two conditions are prerequisites for a histogram to be a valid representation: (i) Characteristics to be represented on the horizontal axis must be on a metric scale, preferably a continuous variable, such as cholesterol level in Table H.1. The categories must be numeric intervals and must be mutually exclusive and exhaustive. Ordinal and nominal scales are not represented by a histogram, nor are **multiple responses**. (ii) The data to be represented on the vertical axis must be either percentages that add up to 100 or frequencies that add up to total $n$. They cannot be other values such as means, rates, or ratios. These two conditions are fairly severe and restrict the use of histograms to a very specific kind of data.

Figure H.7b and c presents two variants of the histogram. The first is a **stem-and-leaf plot** in Figure H.7b, which seems like a horizontal version of a histogram. Our plot shows systolic blood pressure

of a group of people where the first two digits of the values are considered the stem and the third digit the leaf. Since actual values are depicted, recurrence of the same values becomes more evident in this representation, but intervals that are not multiples of 10 or that are unequal are difficult to display in a stem-and-leaf plot. This kind of plot is attributed to John Tukey [1].

When the variable is really discrete with a small number of values (such as parity), the frequency can be represented by vertical lines in place of bars, as shown in Figure H.7c. This is the second variant of the histogram.

## historical cohort, *see* prospective studies

H

## historical controls, *see* controls

## homogeneity of variances, *see* homoscedasticity

## homoscedasticity

This is the equality of variances of values in different groups. Suppose you measure cholesterol level in different obesity groups: thin, normal, overweight, and obese. If the variances of cholesterol level in these groups are the same, we say that the groups are homoscedastic with respect to cholesterol levels.

If there are $K$ groups in a study, they are homoscedastic if $\sigma_1^2 = \sigma_2^2 = \ldots = \sigma_K^2$. You can see that this is applicable to quantitative data only, and it is a requirement for testing the null hypothesis of equality of means across groups. In most practical situations, this can be depicted as in Figure H.8, where only means differ but the variances are the same.

Popular statistical tests such as **Student *t*** (for two groups) and **ANOVA *F*** (for three or more groups) are valid only when the condition of homoscedasticity is fulfilled. They also require a Gaussian pattern of the sample means and independence of values, but that is not an issue here, and we have not shown a Gaussian pattern in Figure H.8. Homoscedasticity is not as easily met as it seems. In our example, generally, the cholesterol level will be higher with increased obesity, and the variances will also increase. As the values increase, the variability also increases, violating the homoscedasticity. It is always advisable to check that this is not the case before using these statistical tests.

There are many ways that homoscedasticity can be checked. Check this graphically by a **box-and-whiskers plot** for different groups. Varying height of the boxes would indicate different variances. Statistically, the variation must be substantial in sample values for violation of homoscedasticity. Generally, the largest variance should be no more than four times the smallest. The conventional statistical test for checking homoscedasticity is the **Bartlett test**.

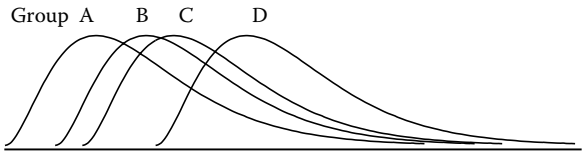

**FIGURE H.8** Distribution in four groups differing only in mean but not variances.

This is heavily dependent on a Gaussian pattern for the distribution of the values. Many software packages now use the **Levene test**. This is based on the median and so is more robust to departure from Gaussianity. **Transformations** of the data, such as logarithm (ln$y$), square ($y^2$), and square root $\left(\sqrt{y}\right)$, are tried in cases where violation occurs. Experience suggests that a transformation can be found that converts a grossly non-Gaussian distribution to an approximately Gaussian pattern and, at the same time, also stabilizes the variance across groups.

If the distribution pattern is already Gaussian and the test reveals that the variances in different groups are significantly different, then the $F$-test should not be used. In fact, there may not be much reason for doing the test for equality of means when the variances are found to be different. It is rare to find that the variance of a variable is different from group to group but the mean is the same. The nature of the variable and measuring techniques should ensure roughly comparable variances. A difference in variances is itself evidence that the populations are different. However, in the rare case in which the interest persists in equality of means despite different variances, try transformation of the data as suggested before. But this should not disturb the Gaussian pattern too much.

## Hosmer–Lemeshow test

This is one of the tests used to check the adequacy of a model (or the lack of it), particularly for logistic regression. The other tests for this purpose are likelihood-based **deviance**, *Nagelkerke* $R^2$, **receiver operating characteristic (ROC) curve**, and bootstrap, in addition to the usual chi-square. Simply stated, the Hosmer–Lemeshow test compares the observed frequencies in arbitrary but rational-looking strata of regressor values ($x$'s) with the expected frequencies in those strata as per the model using a slight modification of the usual chi-square. Because of several regressors in most logistic regressions, these strata are sometimes referred to as profiles. Corresponding to these strata of $x$'s, find the expected frequencies based on the fitted logistic model and compute the following:

$$\text{Hosmer} - \text{Lemeshow test: } \chi^2_{HL} = \sum_{g=1}^{G} \frac{(O_g - E_g)^2}{E_g(1-p_g)} (g = 1,2,\ldots,G),$$

where $O_g$ and $E_g$ are the observed and expected frequencies, respectively, in the $g$th stratum, and $p_g$ is the proportion of subjects in the $g$th stratum. We have stated its simplified version so that its basic features are clear. This chi-square will have 2 degrees of freedom (df's) less than the number of strata. If the $P$-value is less than the prefixed level of significance, such as 0.05, conclude that the model is not consistent with the data. Remember that $P \geq 0.05$ does not mean that the model is good but only that the evidence against it is not sufficient with this amount of data.

The default procedure in many statistical software packages is to divide predicted probabilities from the fitted logistic regression into, say, 10 **decile** groups and compare the observed number of responses in these groups with the predicted number of responses using cells defined by the groups. For 10 groups, this chi-square will have 8 df's. Your software will do all of this for you. The validity condition of chi-square applies, which says that not many expected cell frequencies should be less than 5 and that none should be close to 0. This implies that $n$ should be really large.

Consider a study to explore the predictors of malnutrition in children from a deprived section of society. One hundred malnourished and 100 normal children of age between 1 and 5 years—matched for age within ±6 months and sex—were considered for the study.

**TABLE H.2**
**Contingency table for Hosmer–Lemeshow test**

| | Group = Normal | | Group = Malnutrition | | |
|---|---|---|---|---|---|
| Strata No. | Observed Frequency | Expected Frequency | Observed Frequency | Expected Frequency | Total Observed |
| 1 | 19 | 17.244 | 0 | 1.756 | **19** |
| 2 | 21 | 20.765 | 3 | 3.235 | **24** |
| 3 | 15 | 15.451 | 5 | 4.549 | **20** |
| 4 | 11 | 12.959 | 9 | 7.041 | **20** |
| 5 | 11 | 10.897 | 9 | 9.103 | **20** |
| 6 | 10 | 9.019 | 12 | 12.981 | **22** |
| 7 | 6 | 6.558 | 14 | 13.442 | **20** |
| 8 | 2 | 4.095 | 17 | 14.905 | **19** |
| 9 | 4 | 2.521 | 17 | 18.479 | **21** |
| 10 | 1 | .492 | 14 | 14.508 | **15** |

The potential predictors were decided either from the previous knowledge or significant predictors from univariate analysis. The dependent variable is group (malnutrition = 1, normal = 0), and the predictors are maternal education (illiterate = 1, literate = 0), daily income of parents (low = 1, not low = 0), immunization (no = 1, yes = 0), colostrum (not given = 1, given = 0), breast-feeding till 6 months (no = 1, yes = 0), and mode of feeding (bottle = 1, others = 0). Consider only these six predictors for this exercise.

A statistical software package formed 10 strata of values of the predictors and produced Table H.2 for the observed and expected frequencies in normal and malnourished groups in these strata after running a logistic regression. These start with nearly 20 subjects in each stratum since the total number of subjects is 200. These frequencies give Hosmer–Lemeshow $\chi^2 = 6.001$ with 8 df's and $P = 0.647$. Thus, there is no evidence that the model-expected frequencies differ from the observed frequencies, and the model can be considered to be adequate. Since some frequencies are less than 5, that raises questions about the validity of this test for these data.

The Hosmer–Lemeshow test has been criticized lately for arbitrariness that creeps in while defining the groups and for being insensitive to deviations in individual cases (see, for example, Hosmer et al. [1]). Also, for large samples, this test magnifies the discrepancy between the observed and expected, resulting in an unnecessarily small *P*-value.

For more in-depth exposition, see Hosmer et al. [2] and Allison [3].

## hospital statistics

Because of digitization almost all around the world, hospitals generate a large volume of data on what kind of and how many patients are served, and with what outcomes. These are the hospital statistics and can be used to serve a variety of purposes.

### *Utilization of Hospital Services*

Hospital statistics are conventionally used to find ways and means to maximize utilization of hospital services. Basic information desired from these data is the following:

$$\textit{Bed - occupancy rate}\ (\%): \frac{\text{bed-days of occupancy}}{\text{total bed-days}} \times 100.$$

This can be calculated for any week, any month, or any year. If a hospital has 300 beds, the total bed-days in a year are 300 × 365 = 109,500, and if the occupancy is 66,364 bed-days, the occupancy is 66,364 × 100/109,500 = 60.6%. Bed-days of occupancy is itself evident from the load of inpatients. Some hospitals with fast turnover may have 90% occupancy, whereas others, particularly those at the periphery, may have just about 30%. Some busy pediatric hospitals in developing countries, particularly in the public sector, may have more than 100% occupancy if one bed is occupied by two patients at the same time for some days and hardly any bed is ever vacant. This is a reality in some hospitals in developing countries.

*Average length of stay* per patient (days):

$$\frac{\text{patient-days in hospital}}{\text{total number of admitted patients}}$$

Separation of a patient can be due to discharges or death. This kind of indicator may be extremely useful for the casualty department of a hospital, where patients are supposed to move fast to regular care. Such an indicator should be calculated separately for each department since in some departments, such as those dealing with cancer cases, the length of stay could be substantially longer, and for others (say, hernia surgery), it may be short.

### *Quality of Care*

Quality should be assessed against a prefixed standard, but in the case of hospitals the objective is to achieve 100% excellence. This is generally negatively assessed in terms of errors:

$$\text{Average medication errors per patient-day: } \frac{\textit{medication errors}}{\text{patient-days}}.$$

This can be calculated for any month, any year, etc. Similar indicators can be developed for transfusion infections and surgical site infections, maybe even incidence of bedsores, ventilator-associated pneumonias, and needlestick injuries. Correct assessment on the basis of such indicators depends mostly on honest reporting, and that is suspected in many situations. They require more sincerity on the part of the hospital administration or proper enforcement by regulatory agencies such as accreditation boards.

Most valid indicators of quality of care in hospitals are based on mortality. These indicators can be classified into those related to inpatient procedures, such as esophageal and pancreatic resections, craniotomy, and hip replacement, and those based on inpatient conditions, such as acute myocardial infarctions, acute stroke, and gastrointestinal hemorrhage. These rates are generally calculated per 1000 separations (discharges and deaths) of patients undergoing these procedures or suffering from these conditions. Although these rates would depend on the severity of cases that a hospital gets (some hospitals tend to receive more patients in critical conditions because of their good reputation), they may be used for comparing areas, hospitals, and time, to get an idea of how good a hospital is relative to its previous performance. If the case mix is not substantially

different, these indicators can also be used for assessing how good hospitals are relative to the hospitals in other areas. These indicators, however, do not consider the cost aspect at all.

The Agency for Healthcare and Quality works intensively in this area, and they provide a tool kit [1] for assessing quality of services in hospitals.

### *Research Based on Hospital Statistics*

Two kinds of research can be done on the basis of routinely generated data in hospitals. First is the analytical research that tries to link the outcome with the condition of the patient at admission as mediated by hospital care and patient cooperation. This requires that the records be immaculately maintained and complete for each patient. This kind of research also includes an assessment of how the final diagnosis matches with the initial diagnosis or how it matches with the investigation results. This can be done for each consultant, each department, etc. to build up a profile. Second is developing norms based on the measurements of those patients who do not have any abnormality. Many hospitals run preventive health checkup programs for corporate employees or for insurance companies, and investigate thousands of subjects each year. Many of these people are absolutely healthy. The levels of parameters such as biochemical measurements, heart measurements as revealed by echocardiograms, and bone mineral density can be used to establish local norms in place of depending on the international norms.

## Hotelling $T^2$

This is the **multivariate** analogue of the **Student *t*-test** and can be used to test whether the means of a particular *set* of variables have predefined values or, more generally, whether the means in two groups for a set of variables are the same. The test was first proposed by Harold Hotelling in 1931 [1].

Harold Hotelling

Consider kidney functions (such as creatinine clearance, urea clearance, and diotrast or *p*-aminohippurate clearance) in healthy females of age 50–59 years, where the interest is in finding whether the means seen in vegetarians are the same as in nonvegetarians. The only difference between this setup and that of the Student *t* is that now we want to consider three or four kidney functions together in a multivariate setup in place of considering them one at a time. A multivariate setup allows consideration of the correlations among the variables that a univariate setup ignores.

As in the case of the Student *t*, Hotelling $T^2$ is valid under certain conditions. These are as follows: (i) either the sample size is large or the distribution of the values is nearly Gaussian—in this case, **multivariate Gaussian**; (ii) the **dispersion matrices** of the variables in the two groups are nearly equal (this corresponds to equal variances in the univariate setup)—this condition is especially important if the sample sizes in the two groups are unequal; and (iii) the values across individuals are independent—that is, the values in one person does not affect the values in the other person (for example, the individuals do not belong to the same family). Equality of dispersion matrices is tested by the **Box *M*** test. This test gives correct results only when the underlying distribution is multivariate Gaussian. Alternatively, the multivariate analog of the **Leven test** can be used, which is robust to non-Gaussianity.

Realize that Hotelling $T^2$ is a special case of the multivariate analysis of variance (MANOVA) test. In other words, MANOVA for two groups gives the same result as Hotelling $T^2$, just as ANOVA gives the same result as Student *t* for two groups. The underlying formula of Hotelling $T^2$ requires an understanding of matrices and determinants, which we are avoiding in this book for medical professionals. Most statistical packages have a provision to do MANOVA and, hence, Hotelling $T^2$. If you are interested in its mathematics, see Anderson [2].

## human development index

Human development is considered to be an important aspect of well-being and thus of health. The United Nation's Development Programme (UNDP) each year computes a human development index (HDI) for each country by using a common base so that it can be realistically compared across countries, sometimes even across times. This is calculated by combining three components of development, viz., education, income, and life expectancy. The methodology is periodically reviewed and revised, and the one available in their 2014 report [1] requires the following:

- Per capita income in real terms by converting it to **purchasing power parity** (PPP) dollars. Complex calculations are done for this conversion. This is needed to restore parity in income in different countries with different price levels.
- **Life expectancy** at birth (ELB).
- Mean years of schooling.
- Expected years of schooling. This is the number of years of schooling that a child of school entrance age can expect to receive if prevailing patterns of age-specific enrolment rates were to stay the same throughout the child's life.

Each of these four components is converted to an index relative to the observed minimum and the observed maximum value. These are known as goal posts. For per capita income, the minimum estimated by UNDP is PPP $100, the maximum is PPP $75,000, and the logarithm is taken. ELB is used as a surrogate for health. For this, these goal posts are a minimum of 20 years and a maximum of 85 years. For mean years of schooling and expected years of schooling, these are from 0 to15 years and from 0 to 18 years, respectively. Education index is the average of the indices for mean years of schooling and expected years of schooling. The HDI is the **geometric mean** of the

income index, life expectancy (health) index, and education index. The following example is taken from the Human Development Report 2014, and illustrates the calculations for HDI of Costa Rica for the year 2011.

Indicator values for Costa Rica:

ELB (years), 79.93; mean years of schooling, 8.37; expected years of schooling 13.50; gross national income per capita (PPP 2011 dollars), 13,011.7

Health index = $(79.93 - 20)/(85 - 20) = 0.922$

Mean years of schooling index = $(8.37 - 0)/(15 - 0) = 0.558$

Expected years of schooling index = $13.50/18 = 0.750$

Education index = $(0.558 + 0.750)/2 = 0.654$

Income index = $[\ln(13{,}011.7) - \ln(100)]/[\ln(75{,}000) - \ln(100)] = 0.735$

HDI = $(0.922 \times 0.654 \times 0.735)^{1/3} = 0.763$

Such values are calculated for each country each year, and the countries are ranked from maximum to minimum. In absolute value, an index of 0.5 is sometimes considered the minimum for reasonable development.

Indrayan et al. [2] proposed that the index of components of HDI henceforth be computed on the basis of the percentage of the population that reached a minimum threshold. For income, this threshold could be the minimum required for adequate food, housing, and clothing (say PPP $10,000 per capita per year); for ELB, the percentage of persons of age 60 years and above; and for education, the percentage of adults (18 years and above) with at least high school education. This modification will make the index and its components readily interpretable as it would indicate how well the country has been able to meet the minimum level.

## Huynh–Feldt correction, *see also* repeated measures ANOVA

This is used for correcting both the degrees of freedom (df's) of the *F*-test for univariate **repeated measures ANOVA** in the case where the condition of **sphericity** of the dispersion matrices at different points in time is violated [1]. The sphericity condition is that the differences between all pairs of times have the same variance. Violation of sphericity is detected by the **Mauchly test**. Remember that the ability of all statistical tests to show significance depends on the sample size—thus, nonsignificance can arise due to inadequate sample size. This can happen with the Mauchly test as well. If this test is statistically significant, the Huynh–Feldt correction is applied to the df's of the *F*-test, although the value of *F* remains the same. This correction will reduce the df's by a factor called epsilon, making it difficult to reject the null hypothesis. The greater the departure from sphericity, the lower the epsilon. If the df's for your *F*-test are (5, 25) and epsilon = 0.4, then the corrected df's are (2.0, 10.0). Note that lower value of epsilon means a bigger correction to the df's. Rarely, the Huynh–Feldt correction can exceed the value of 1, but if it does, 1 is used, and no correction to df's is done.

Many statistical packages provide results with the Huynh–Feldt correction and also the corresponding *P*-value for repeated measures ANOVA. This is also known simply as Huynh correction. You may find other types of epsilon also (such as Greenhouse–Geisser) in your software output, but the Huynh–Feldt epsilon is widely accepted.

For a more in-depth exposition of the Huynh–Feldt correction, see Tamhane [2].

## hyperpopulation

This term is used in two senses in biostatistics: first for an imaginary population from which a sample can be assumed to have come and second for the population generated through **simulations** or by **resampling**.

All statistical methods of inference such as **confidence interval** and **test of significance** require a random sample of subjects. Consider a study of homosexual men attending clinics in two cities. Neither group can be considered to be truly random. Yet confidence intervals and ***P*-values** for statistical significance of the difference between the two groups are calculated, such as done by Koblin et al. [1]. These *P*-values are valid only when the cohorts are considered a random sample from what is called a hyperpopulation of homosexuals in the two cities. This hyperpopulation exists in concept but not in reality, and may possibly include the past and, more importantly, cases arising in the immediate future.

Patients coming to a clinic during a particular period can be considered a random sample from the population of patients that are currently coming to that clinic. But this limited definition of population is sometimes forgotten, and generalized conclusions are drawn on the basis of *P*-values. This practice is quite frequent in medical literature and is mostly accepted without question with the underlying assumption that this generalization is for the hyperpopulation.

The second use of the term is either when you do simulations to generate a population of values of the type needed for inference, or when repeated sampling is done with replacement from the available sample. In the first case, with high-speed computers at your disposal, you can generate millions of values that follow, for example, a Gaussian distribution with a specified mean and standard deviation. These values are not real—thus the term *hyperpopulation*. In the second case, if a sample of reasonable size is available, you can generate innumerable samples of any size by replacement. This is called **resampling** and has strategies such as **bootstrap** and **jackknife**. This technique allows generation of a hyperpopulation of samples and has been found to be effective in drawing valid conclusions in cases where the **sampling distributions** are intractable.

## hypothesis (null and alternative), *see* null and alternative hypotheses

## hypothesis (research)

A research hypothesis is a precise expression of the expected results regarding the state of a phenomenon in the target population. Realize that research is about replacing existing "hypotheses" with new ones that are more plausible. In medical research, a hypothesis could purport to explain the etiology of diseases, preventive strategies, screening and diagnostic modalities, distribution of occurrence in different segments of the population, the strategies to treat or mange a disease, methods to prevent recurrence or adverse sequel, etc. Consider which type of hypothesis can be investigated by the proposed research.

Hypotheses are not guesses but reflect the depth of knowledge of the topic of research. They must be stated in a manner that can be tested by collecting evidence. For example, the hypothesis that dietary pattern affects the occurrence of cancer is not testable unless the specifics of diet and the type of cancer are specified. Antecedent and outcome variables, or other relevant variables, should be exactly specified in a hypothesis. Generally, a separate hypothesis for each major expected relationship is generated.

The hypotheses must correspond to the general and specific objectives of the study. Thus, carefully examine each objective, and assess which of these generate a new hypothesis. Whereas objectives define the key variables of interest, hypotheses are a guide to the strategies to analyze the data.

Beware that, just like objectives, hypotheses, too, are governed by the current knowledge. For example, nobody wants to know how music aptitude affects cancer risk, although a future endeavor may reveal an association between the two. Researchers are already examining the hypothesis that infections may trigger some cardiac ailments. The hypothesis that childhood nutrition, perhaps even during pregnancy, can manifest in chronic diseases 40–50 years later surprised many when it was initially proposed, but it is now accepted as not only plausible but also likely and real.

A research hypothesis can be very different from statistical null and alternative hypotheses. Statistical hypotheses are grounded to real values as seen in empirical research, whereas a research hypothesis can be philosophical or abstract.

## hypothesis testing (statistical), *see also* null and alternative hypotheses

Hypothesis testing in statistics is a general term for assessing whether sample data are consistent (or otherwise) with statements made about the **population** of interest at the time of planning the study. Hypothesis testing is an approach used for choosing between two statistical **hypotheses**, namely, **null and alternative**, regarding the population. These are regarding the values of the parameters of a distribution of the variable of interest or regarding the shape of its distribution.

Over the years, statistical testing of hypotheses has become important in the development of ideas emanating from empirical research. It hails from the ideas put forward by Neyman and Pearson [1] and further developed by Lehmann and Romano [2].

Let the competing hypotheses be $H_0$ (null hypothesis) and $H_1$ (alternative hypothesis), and let a summary of the data (or statistic) denoted by $T$ be considered appropriate to test one hypothesis against the other. Chi-square, Student $t$, and ANOVA $F$ are examples of such summaries. The value of $T$ is calculated on the basis of the sample values under the assumption that the null hypothesis is true. The statistical **distribution** of $T$ should also be known, particularly under the null hypothesis, so that we can find how likely or unlikely the value obtained with these calculations is. This would indicate whether or not the sample values are in conformity with the null. To do hypothesis testing, the conventional procedure is to first define a critical region (see **acceptance and rejection regions**) in advance of collecting data and then reject $H_0$ in favor of $H_1$ depending on whether the calculated value of $T$ falls within the critical region or not. The procedure now used is not based on the critical region but just to find the probability that the value of $T$ is as much as obtained or more extreme. This is what is called the ***P*-value**. This is the crucial value in the testing of hypotheses. The lower the $P$-value, the greater the inconsistency of the sample data with the null. A sufficiently low value of $P$ is an indication that we reject the null in favor of the alternative. Although this procedure can be understood as providing graded evidence in terms of exact $P$-value, a cut-off is needed to decide when to reject the null. Generally, a $P$-value less than 0.05 is considered sufficiently small to reject the null. This threshold is called the **level of significance**.

As explained under the topic **tests of hypothesis (philosophy of)**, statistical testing never allows acceptance of a null hypothesis. We either reject or do not reject the null. The following example may help you to understand the steps and the philosophy behind the statistical tests of hypotheses.

Suppose an argument erupts concerning the percentage of births in a community that are premature. Based on everyday experience, a practitioner asserts that 10% of births are premature, neither less nor more. To test this assertion, a random sample of 60 births is systematically observed, and 8 of them are found to be premature. This is 13.3%. Can we conclude that the percentage of premature births in the population is not 10%? Consider the following steps:

1. Assertion of 10% premature births in this case is the null hypothesis. This is what is to be tested (and possibly to be refuted). Thus, $H_0$: $\pi = 0.10$, where $\pi$ is the probability of premature birth in this segment of the population. Since there is no assertion about a particular direction of difference, it could be negative or positive. That is, $H_1$: $\pi \neq 0.10$. Let the level of significance be fixed at $\alpha = 0.05$. That is, the chance of Type I error should be less than 5%.
2. The quantity of consequence in this case naturally is the proportion, $p$, actually observed in the sample. For this sample of 60 births, $p = 8/60 = 0.1333$. Since $n$ is 60 and $np \geq 8$, we can invoke the **central limit theorem** and assume that $p$ will approximately have a Gaussian distribution. The standard Gaussian deviate in this case is

$$z = \frac{p - \pi}{\mathrm{SE}(p)}.$$

   This can be used as a test criterion. When $H_0$: $\pi = 0.10$ is true, then from the usual formula of the standard error (SE) is $\mathrm{SE}(p) = \sqrt{0.10 \times 0.90/60} = 0.0387$. Thus, for this example, under $H_0$, $z = (0.1333 - 0.10)/0.0387 = 0.86$.
3. The $P$-value is the probability of obtaining this value of $z$ or a value more extreme toward $H_1$. Since $H_1$ is two-sided,

$$P\text{-value} = P(Z \leq -0.86) + P(Z \geq 0.86) = 0.1949 + 0.1949 = 0.39$$

   from the Gaussian distribution. This $P$-value is certainly very high in comparison with the conventional threshold

0.05. If $H_0$ is rejected, the chances of its being wrongly rejected are as much as 0.39 (or 39%). This is too high an error. Since $P \geq 0.05$, $H_0$ is plausible, and the assumption $\pi = 0.10$ cannot be rejected. The sample does not provide sufficient evidence against $H_0$.

The difficulty is that if the null is $\pi = 0.11$, that also will not be rejected by this set of data, and the same is true for, say, $\pi = 0.08$. This is true for many other values of $\pi$. If we accept, which value of $\pi$ do we accept? For this reason, statistical tests never provide evidence in favor of the null—just enough evidence against the null or nothing at all. When a null is not rejected, not much of significance is added to the current knowledge except that the null is not implausible.

The values in this example can provide sufficient evidence to reject some other values of $\pi$. For the purpose of illustration, change $H_0$ to $\pi = 0.25$. Under this $H_0$,

$$z = \frac{0.1333 - 0.25}{\sqrt{0.25 \times 0.75/60}} = -2.08.$$

Now $P = P(Z \leq -2.08) + P(Z \geq 2.08) = 0.0188 + 0.0188 = 0.038$. This is less than 0.05. Thus, this $H_0$ is not plausible and is rejected. It is concluded that the percentage of premature births is not 25. The percentage (13.33%) observed in the sample is sufficiently different from 25 in a statistical sense but not sufficiently different from 10. Thus, the $H_0$ that the premature births are 25% can be rejected but not the $H_0$ that they are 10%.

The size of the *P*-value comes from two things: the size of the estimated treatment difference and its estimated intersample variability (which derives partially from the sample size). Thus, the *P*-value partly reflects the size of the study, which has no biological importance, and partly the size of the effect and sampling variability. An extremely low *P*-value can arise even when the effect size is extremely small, perhaps negligible, in situations where the sample size is inordinately large. Thus, many consider the **confidence interval** a much better procedure than the testing of hypothesis for valid inference.

We also need to consider the types of error that can arise using hypothesis testing. **Type I error** occurs if there is no treatment effect or difference but our data happen to wrongly conclude that there is. **Type II error** occurs when the data fail to detect a treatment effect or difference that is actually present. Its complimentary is the **power** of the test that measures the chance of declaring a treatment effect or difference of a given size to be statistically significantly different from the value under the null hypothesis.

# I

## $I^2$ (index of heterogeneity) in meta-analysis, *see also* meta-analysis

$I^2$ is an index of heterogeneity of the **effect sizes** in different studies compiled for **meta-analysis**. Effect size could be the difference in means or in proportions, odds ratio, relative risk, or any other measurement. Meta-analysis is the term used for the method of combining evidence from various studies on the same effect. One of the requisites for studies compiled for this purpose is that they should not have widely different results from one another. Some variation is natural, and that is why we need meta-analysis, but that should be within the range generally perceived as natural across studies in different areas and in different populations with different sample sizes, and possibly with some minor variation in methodology. It is preferred that the studies chosen for meta-analysis have similar methodology, but that might be difficult to ensure.

$I^2$ is the percentage of total variance attributed to the between-study variation. Generally, this kind of contribution is obtained by the method of analysis of variance (ANOVA), but that can be done only when the original individual values are available. In the case of meta-analysis, only the effect size is available for the study groups as a whole, and raw data are rarely available. Thus, we need another measure that takes the form of $I^2$ as follows.

The first step in this is to calculate **Cochran** $Q = \Sigma_k w_k (T_k - \overline{T})^2$, where $T_k$ is the effect size found in the $k$th ($k$ = 1, 2, …, $K$) study and $\overline{T}$ is the weighted average of these effect sizes. This is given by $\overline{T} = \Sigma_k w_k T_k / \Sigma_k w_k$. $w_k$ is the weighting factor of the $k$th effect size: this could be any measure you choose, but the most common choice is the inverse of the variance of the $k$th effect size. The actual variance would almost never be known and is estimated by the square of the estimated standard error (SE) of the effect size that most studies report. Cochran $Q$ follows a **chi-square distribution** with ($K$ − 1) degrees of freedom (df's) provided $T_k$s have approximately **Gaussian** (Normal) **distribution**. $Q$ itself can be used as an index of heterogeneity—the higher the value of $Q$, the higher the heterogeneity. The null hypothesis of equality of effect sizes can be rejected if the chi-square-based ***P*-value** for the value of $Q$ is less than the predetermined **level of significance**, such as 0.05. But the difficulty with $Q$ is that this can become large just because the number of studies is large. Thus, it would unnecessarily reject the null even if there is homogeneity in effect sizes in a large number of studies. More importantly, $Q$ depends on the metric of the effect sizes.

The next step is to make $Q$ independent of $K$ and the metric of effect size as much as possible. For this, Higgins and Thompson in 2002 [1] proposed several measures, but the following has come to be widely accepted as the index of heterogeneity:

$$\text{index of heterogeneity: } I^2 = \left(1 - \frac{K-1}{Q}\right) * 100\%.$$

This requires $Q > (K - 1)$; luckily, this generally is the case. If that is not so, the value of $Q$ is considered equal to 0—it cannot be negative. A value 25% of this index is generally considered low, 50% moderate, and 75% high. If this index is high for the effect sizes in the studies selected for meta-analysis, the studies that are causing this high value are excluded from the analysis if not important. However, just one or two studies with very large $n$ can also inflate the value of $I^2$ because they get a large weight due to their small SE, and these should not be excluded.

For more details, including the confidence interval for $I^2$, see Huedo-Medina et al. [2]. Many statistical software packages that have a capability for meta-analysis have incorporated this index in their output. For a real-life example, see the work of Viguiliouk et al. [3], who found $I^2$ = 37% in 12 studies they included in a meta-analysis studying the effect of tree nuts on glycemic control in diabetes and concluded that the difference between a nuts diet and nonnuts diet was not statistically significant, though the direction was in favor of tree nuts.

## ICD, *see* International Classification of Diseases

## icicle plots

Icicle plots depict the process of **hierarchical clustering** of values, where the most similar ones are clustered together in the first stage, the next most similar in the second stage, and so on, till all units are plotted to form one big cluster. What we have stated is the **agglomerative algorithm**, but we can have a divisive algorithm also, which starts by considering all units together as one big cluster and divided on the basis of some metric of distance. Icicle plots can be used for divisive algorithms also, although practical use is commonly for agglomerative algorithms.

For an example, see Figure I.1a, which is an icicle plot for hierarchical agglomerative clustering of nine subjects with respect to their values of urea, uric acid, and creatinine levels. This resembles a row of icicles hanging from a windowsill. The plot shows, for example, that case nos. 2 and 7 had the most similar values and were merged in the first stage. This merging is shown in the bottom row of the figure. One row up shows the merging of case nos. 4 and 6, and so on. Thus, the entire agglomerative process is shown. In the last stage, all merge together in the top row. The method we followed for this clustering is **average linkage**, but any other method can be used

For contrast, we have also shown the corresponding **dendrogram** in Figure I.1b. This is not as good in showing the process but is

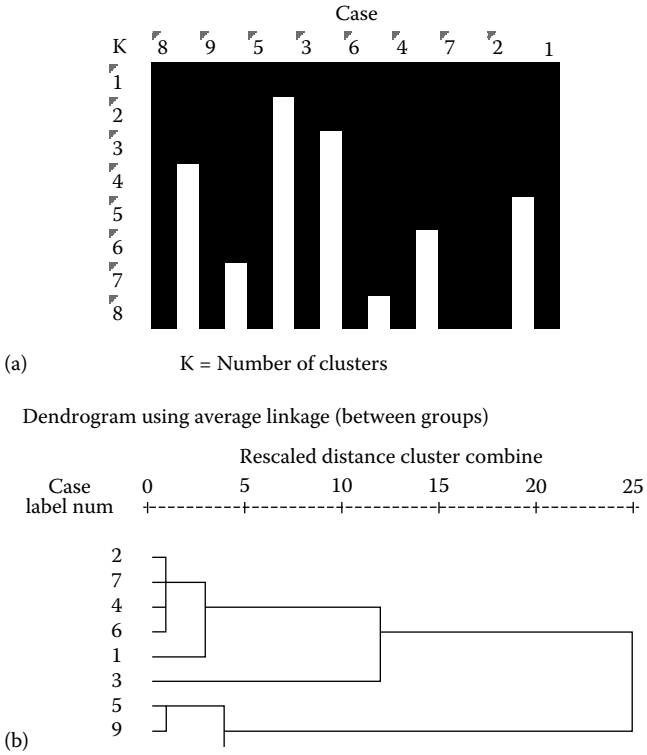

**FIGURE I.1** (a) Icicle plot and (b) dendrogram for hierarchical clustering of nine cases with respect to kidney functions.

good in showing the distances between entities merged at different stages. This can be used to decide the optimal number of clusters. The icicle plot does not have this property. In our example, the distances (depicted by the horizontal length of the lines) are not big for three clusters, but when we reach the two-cluster stage, the distance shoots up, and it becomes huge for one cluster, indicating that three clusters are appropriate for these data.

## imprecise probability, *see* probability

## imputation for missing values, *see also* nonresponse

Imputation is the process by which the missing values in a set of data are sought to be replaced by plausible values. Because of various problems as discussed for **missing data**, these are quite common in medical setups. Excluding them altogether from analysis may yield a biased picture since experience suggests that missing values generally are not random but are special in the sense of being either too high or too low or having any such aberration. Perhaps no imputation is needed when the sample is large and the missing values are less than 5% because in this case, the available 95% of values can lead you to the right conclusion, or at least one as good as with imputations. If there are more missing values, they can be imputed by various statistical methods, as described later in this section, provided the their structure is known or can be modeled.

If a higher attrition is anticipated, the usual practice is to inflate the sample size accordingly so that enough data are available for analysis. Despite enough data available at the end, missing data can still cause bias in the sense that specific types of values are missing and the ones left for analysis fail to reflect the full spectrum of values.

Imputation helps in (i) providing the comfort of working with complete data; (ii) using predetermined statistical methods of analysis that otherwise may require substantial alteration to take care of the **unbalanced** data due to missing values; and (iii) computationally recovering the complete record of each subject—otherwise, the cost of collecting data can be prohibitive in some situations. But it is not without problems since imputed values are artificial and not real—thus, they may lead to concocted results. Because of this, imputation should not be done if, say, more than 10% of values are missing, and the results from the available data should be acknowledged as possibly biased. When imputations are limited, they are not likely to impact the results much.

In an experiment or a trial, missing values are imputed to be the most adverse to the regimen under trial so that a positive conclusion about its efficacy and safety does not breach the conventional 5% probability of Type I error. For example, the cases that could not be evaluated for the outcome are counted among the failures. For this, **intention-to-treat** analysis is advised. However, if 10% of values are missing, this failure rate itself may be too high in some setups, and imputation may become necessary if all missing data cannot be considered as failures.

For data missing apparently at random, the imputation methods are as follows. The first is the **regression** method, which requires that the available values be used to find a regression equation that can predict the missing values. Not only the available values of the variable in question are used, but other variables such as age and sex for which relatively complete data are available are also incorporated in this equation. Baseline markers of disease and other pretreatment and posttreatment measures that can affect missingness could also be useful. One can also think of treatment compliance and tolerability of the regimen as predictors of missingness. A prerequisite for this is that the regression must be statistically adequate with, say, a **coefficient of determination** of more than 90%. When this is not feasible, the second method is to replace the missing value with the average of the available values. This may not work well, as it takes away the chance component and unnecessarily tends to reduce the variance and produce false statistical **significance**. The third is the closest match method, which requires examination of the data of all subjects to find the one that is closest in all other reports and substitute this subject's value for the missing value. Among other methods are (i) replacement of a missing value by generating a random value from the distribution of the variable when known and (ii) adding a random residual to the respective mean values. Both these methods can work only when the missing values are entirely random. Yet another method is to determine classes of similar subjects and replace missing values with a random value from the same class.

Another popular method is to replace the missing value by carrying forward the last value. This is done in **longitudinal studies** on the assumption that no change occurred during the interregnum. This may work well in a **clinical trial** setup, where it is known that a subsequent value will be the same or will have improved because of the regimen, and will not be more adverse. This is in accordance with the principle that missing values should be replaced by pessimistic values. If you are concerned about missing values in clinical trials, consult the article by Powney et al. [1] that has discussed various methods used in a sample of 100 trials.

It is easy to imagine that imputing a missing value with its estimate by any method fails to account for uncertainty about the missing value. Analysis based on such single imputations, as they are called, treats this imputed value as though this is the actual observed value. To account for uncertainty about the actual missing value, sometimes, one missing value is replaced by several plausible values. It is like a random sample of missing values and is called **multiple**

**imputations**. Such multiple-imputed data sets are then analyzed as usual. The process mostly results in relatively more valid inferences. See Carpenter and Kenward [2] for details.

Adjustments done by imputation or otherwise certainly reduce the validity of the data, but that is the best one can do when the missed values cannot be ignored. Remember that imputation is an exercise in salvaging the damage, which helps but does not rectify. The only better course is to do everything possible to obtain complete data.

## inception cohort, *see* cohort studies

## incidence

Incidence is the number of conditions or the number of persons having an onset of a condition in a specified period. A condition is considered to have had its onset when it is first noticed. This could be the time when the person first felt sick or injured, or it could be the time when the person (or the family) was first told of a condition that was previously unknown. Thus, a person who has had diabetes for a long time is considered to have onset at the time when diabetes was first detected. Sometimes, the time of onset depends on whether or not the induction period (from exposure to subclinical) and latent period (from subclinical to clinical) are considered.

The incidence rate is an important indicator of burden of disease in a community. It can be calculated per cent, per thousand, per million, etc., as convenient, of exposed subjects, and it measures the risk of developing morbidity in a randomly chosen subject from that group. Incidence rate may increase without a real rise in new cases when the reporting or case detection improves. A real rise indicates that the existing strategy to control the disease has not succeeded and alternative or improved strategy is needed. Analysis of differences in incidence in various socioeconomic, biological, and geographical groups may provide useful tips to devise a better strategy for control of the disease. Also, note the following:

- Incidence rate is necessarily associated with duration. If the period is 1 year, the rate obtained will also be for that year, and 1-year incidence would be different from 1-month incidence, although not necessarily one-twelfth of the annual incidence. Notice that incidence can be obtained only through a **follow-up study**.
- Incidence rate can also be calculated for spells or episodes instead of the affected persons. This would count a person two or more times if the same person has repeated spells within the reference period, such as for diarrhea and angina. The term *incidence density* is preferred in this case.
- Incidence reflects causal factors and is better interpreted as **risk**. This is used to formulate and test hypotheses on the etiology of the disease.
- *Incidence rate ratio* can also be obtained for two exclusive groups. If the incidence of liver diseases in alcohol users is 5 per 1000 per year and in nonusers 0.5 per 1000 per year, the incidence rate ratio is 10. However, this has a better and more popular name, **relative risk**.

Just like **prevalence**, precise incidence is central to the epidemiology of any disease, but it is very difficult to obtain. Full enumeration is typically too expensive, very labor intensive, and almost impossible to achieve for the monitoring of disease frequency. Thus, an estimate is obtained by studying a sample. A critical component in disease monitoring is the degree of undercount. One way to improve the estimate of the rates is by correcting them for the level of ascertainment. Comparison of different populations, communities, or countries is accurate when the incidence estimates from a surveillance system or some other source are adjusted for the degree of underascertainment.

Prevalence is greatly affected by the duration of disease—the higher the duration, the higher the prevalence, since the cases tend to accumulate. This is not so for incidence, since incidence is absolute and depends on the risk factors, susceptibility, demographic factors such as age and sex, etc., but not on the prevalence or duration of disease. For this reason, many times, incidence is considered a better indicator of morbidity than prevalence. For example, the definition of an epidemic is based on incidence and not prevalence. An increase in incidence raises an alarm for initiating new control measures, whereas prevalence indicates how much medical infrastructure is needed to handle the cases.

A uniform follow-up is not necessary to calculate incidence rate, although it is required in any case. In case some subjects are followed up for, say, 3 years, some for 4 years, some for 2 years, etc., we can use the concept of **person-time** for calculating the incidence. For person-years, this would be given by

$$\text{incidence rate per 100 person-years} = \frac{\text{new cases occuring in the observed period}}{\text{person-years observed}} * 100.$$

However, the incidence must be evenly distributed over different periods for this to be valid. This does not apply for diseases arising from something like smoking, since the initial years of smoking may be more harmful than later years, when the damage is already done. The multiplier in the formula given in this equation is not necessarily 100, and it can be chosen as per convenience. Also, any other time unit such as person-weeks can also be used.

### *Incidence from Prevalence*

A follow-up study is relatively more expensive than a **cross-sectional study**. Thus, it is easier to obtain the prevalence than the incidence. The duration of sickness can also be generally easily guessed from experience. Because prevalence depends on the incidence and duration, the relationship can be exploited to find the incidence based on prevalence and duration. In a steady state, *if there are no intervening factors*,

$$\text{incidence} = \frac{\text{prevalence}}{\text{average duration of sickness}},$$

where incidence and duration are in the same time unit. If the annual incidence is to be calculated, then the duration too should be measured in terms of years. If the average duration of sickness for a particular disease is 15 days, then this is 15/365 = 0.041 years. If the prevalence rate is 1.2 per 1000 and the average duration is 15 days, the incidence rate is 1.2/0.041 = 29 per 1000 per year under a steady state. If the prevalence rate is per 1000 persons, then incidence too is a rate per 1000 persons. Incidence can be calculated for specific groups, by age, gender, occupation, and region, by inserting the prevalence and duration for the chosen group.

The relationship between incidence and prevalence can be visualized as a reservoir where water coming in by way of incidence builds up a level (prevalence) that remains constant if the outflow due to deaths and cures together is the same as the inflow (see Figure P.12 under the topic **prevalence and prevalence rates**). If deaths are reduced by health measures or when a new treatment becomes available that cures faster, the prevalence will decline provided that the incidence remains the same. Interestingly, if the treatment is such that it prevents death but does not cure, as happened with antiretroviral therapy for HIV, the prevalence would increase rather than decrease. The net effect of such a treatment is prolonged disease (increase in duration of disease). If incidence increases and cure rate and deaths together remains the same, the level will rise.

The concept of duration of sickness is generally applicable to all acute conditions but not so much to chronic conditions. Some not-so-severe conditions such as hypertension, varicose veins, and lower vision are rarely fully reversed in a manner that would allow leading a normal life without ongoing treatment. For such conditions, the duration of disease is anybody's guess. If the condition is more concentrated in the elderly, such as cataracts, mortality affects the prevalence. Mortality itself may be higher in the group with disease than in the nondiseased group. Such conditions interfere with the parameters of this equation, and more elaborate calculations may be required to estimate incidence from the prevalence of such conditions.

## inclusion and exclusion criteria

The concept of inclusion and exclusion criteria is generally restricted to **clinical trials** for deciding the eligibility of subjects to be in the trial. Actual participation depends on whether (i) the eligible subject provides consent and (ii) the subject is in the randomly selected sample from the eligible subjects.

Inclusion and exclusion criteria are important components of the study **protocol** since they are part of the case definition that delineates the **target population**. This is decided before the study starts with the purpose that only appropriate subjects participate and that they remain safe. The inclusion and exclusion criteria also help in reaching a focused and reproducible conclusion. The likelihood of exploiting the subjects is minimized, and the possibility of harming them is ruled out upfront. Each of these criteria must be fully justified in the protocol because reviewers can always question them, and they must also meet the requirement of regulatory agencies.

Inclusion criteria are those characteristics that are necessary for subjects to be considered as eligible for inclusion keeping in view the objectives of the study. Besides the disease under consideration, these characteristics could be age of at least 20 years, any sex, positive electrocardiogram, complaint of acute chest pain, etc. These establish the baseline about the type of cases on which the trial would be done and also make the subjects relatively homogeneous. In case healthy controls are needed, these also should be fully specified; for example, specify that merely the absence of that particular disease or absence of any disease would be considered for eligibility of these subjects.

Exclusion criteria are those characteristics the presence of which can affect the correct assessment of the outcome in the subjects. If a person is already under treatment for cardiovascular problems, he/she may become ineligible for inclusion in the study. A person can be excluded also because he/she (i) is too old or too weak to pass through the rigors of a clinical trial, (ii) has a serious form of disease that requires immediate attention, (iii) has a condition for which the test regimen or the control regimen can be harmful, (iv) is not likely to complete the follow-up, or (v) has comorbidity that could contaminate the response. Also, conditions such as obesity, anemia, subclinical diseases, and psychological conditions can compromise the results. These are just examples—in fact, inclusion and exclusion criteria are trial and regimen specific, and cannot be generalized.

Sometimes, research requires that only a very specific type of cases are included so that unadulterated results are obtained that prove a point, just as is mostly done for clinical trials with efficacy as the end point. But then the generalizability suffers. You will want your results to apply to the patients seeking medical help but not to be applicable to such general class of patients. Nevertheless, investigation of such a restricted class of cases fulfills the basic objective of coming to a conclusion about the efficacy and safety of the regimen.

The terms *inclusion criteria* and *exclusion criteria* are also used in the context of selection of studies for **systematic review** and **meta-analysis**. These criteria specify parameters such as minimum sample size, type of subjects included, proper methodology, specific measure of effect, being published in indexed journals, etc. This is done to include only the relevant studies and exclude frivolous ones. These criteria enhance the credibility of results and specify the population for which the ultimate conclusion will apply.

## incomplete tables, *see* contingency tables

## independence (statistical), *see also* dependence and independence (statistical)

An event A is considered to be statistically independent of event B when the chance of occurrence of one is not affected by occurrence or nonoccurrence of the other. The sex of an unborn child is not affected by the sex of another children in the same family. They are independent. My being hypertensive depends, to an extent, on my mother being hypertensive—thus, my hypertension status is not independent of the status of my mother. Liver disorders and injury in an accident of the same person are independent, but diabetes and hypertension are not. In 100 patients of kidney disease enrolled for a trial, the treatment response of one person will not be affected by the response of another person in the trial. They are independent. Persons with some **affinity** or belonging to a **cluster** are not independent, as they can give similar responses. Intraocular pressure (IOP) in the right eye is not independent of the IOP in the left eye. **Repeated measures** of a subject, say on pain score after a surgery, are not independent since pain score at time point 2 depends on what was the score at time point 1.

Strictly speaking, blood pressure of a male of age 34 years living in Nigeria will not be entirely independent of the blood pressure of a male of age 72 years living in Japan, because both are males and sex is one of the determinants of blood pressure. But this kind of far-fetched dependence is ignored in statistics since this is negligible in a probability sense.

Statistically,

necessary and sufficient condition for independence:

$$P(\mathrm{AB}) = P(\mathrm{A})*P(\mathrm{B}),$$

where $P$ stands for probability, $P(\mathrm{AB})$ is the joint probability of the two events occurring together, and $P(\mathrm{A})$ and $P(\mathrm{B})$ are individual probabilities. *Necessary and sufficient condition* means that independence implies this, and if this holds, independence is assured. This is known as the multiplication rule of probability and can be extended to three or more events. In practice, this equation may hold only approximately because of **sampling fluctuations**. Another probabilistic formulation of independence is that $P(\mathrm{A|B}) = P(\mathrm{A})$ and

$P(B|A) = P(B)$, where what comes after the vertical slash is what is already known to have occurred. These two mean that knowledge of occurrence of an event does not alter the probability of occurrence of the other. This is intuitive also—if they are independent, one should not affect the other.

Most statistical methods require that the values be independent. For example, this is a requirement for the **analysis of variance (ANOVA)** and **regression** analysis. When a sample of *n* subjects is randomly selected from a population for a study, these are independent since the values in one subject will not be affected by values in the other subjects. It is because of this independence that the joint probability of the sample values, called **likelihood**, can be obtained by simply by multiplying the individual probabilities. Many statistical procedures have been devised using this likelihood. Repeated measures require a modification of these methods because of dependence, as do serial values such as in a time series.

We have described independence in the context of events and values. *Independent variable* has a different meaning. For this, see **dependent and independent variables**.

## independent and paired samples

Two or more samples are considered independent when the values in one sample are not affected by the values in the other group. In a sample of 40 males and 50 females for studying kidney function, the two groups are independent since the values in males will have no effect on the values in females. On the other hand, if you are studying one group of subjects before a treatment and after the treatment, the values obviously are not independent since *after* values will depend on what the values were before the treatment. These are called paired samples. However, while dealing with quantitative measurement in a paired setup, the difference of *after* values from *before* values in one subject will be independent of the difference in another subject in the sample.

Beside *before* and *after* measurements, there are other examples of paired values in medicine. Blood pressure measurements in the two arms or in one arm and one leg of the same person are paired. Values in twins are a popular example of paired measurements. Measurements in husband and wife, living together, say, for 10 years, would also be paired because of a shared environment. One-to-one matching, as in some case–control studies, also provides paired values.

Independent samples require a different statistical method compared to a paired sample. You may be already aware about the **Student *t*-test**, which is different for independent samples compared to for paired samples. Similarly, the **chi-square test** for independent samples is different from chi-square for paired samples, called the **McNemar test**.

A paired setup can be extended to a multiple setup where three or more measurements are clustered. At the time level, this takes us to the setup of **repeated measurements** or serial measurements on the same group of people. At the family level, measurements of members of the family would be dependent on each other in most situations. When you have four observers, the observer-sensitive measurements, such as assessment of attitude, taken by each observer will have some dependence because of his/her method of assessment. Measurements taken at six sites of the brain will also be dependent. If you are measuring lung functions by forced vital capacity, forced expiratory flow in 1 s, peak expiratory flow rate, and total lung capacity in a sample 80 subjects, these four measurements are not independent of one another, although in this case, the measurements are different. Separate statistical methods, mostly **multivariate methods**, are required for analysis of such data.

## independent variables, *see* dependent and independent variables

## indexes, *see also* indicators

Index is a combination of two or more **indicators** that provides a relatively more comprehensive picture of the status. In health and medicine, indicators measure a specific aspect of health, whereas an index combines them to give better context. An index, when properly constructed, can enhance the utility of indicators and can sometimes generate even new information.

The most popular example in medicine is **body mass index** (BMI), which combines height and weight. Popular among others are the **APACHE score**, used for assessment of the severity condition of critical patients, which is an index but is called a score, and shock index, used for patients of ST-elevation myocardial infarction. Other examples are the ankle-brachial (pressure) index, bispectral index, glycemic index, and craniofacial index. At the community level, we have the **human development index**, **physical quality of life index**, and **disability-adjusted life years**. All these are a combination of two or more measurements.

An index is quantitative and therefore involves calculation that could be a nemesis for some clinicians. Some indexing instruments come ready with software to perform the calculations and directly provide the results. The bispectral index is automatically calculated by software. High-pressure liquid chromatography (HPLC) automatically calculates the peak area of intensity of signals corresponding to concentrates of drug-evoked potentials. Thus, for some indexes, calculations are not much of a problem. Perhaps a greater problem is their **validity** and **reliability**. A large number of indexes are available, and many are being devised every year, but studies that provide evidence of their reliability and validity for different segments of population are rare. The most widely used index for obesity is the BMI, but its utility, too, is sometimes questioned in comparison with the waist–hip ratio (WHR), which is sometimes seen as a better correlate of coronary events. The utility of WHR in cancer and lung disease has not been fully evaluated, while BMI has been extensively investigated. Thus choice of an index can be an issue in situations where two or more indexes are available for assessing the same aspect of health, and you need to be judicious in making the choice.

## indicators, *see also* indexes

An indicator is a tool to measure the quantitative level of a characteristic. This definition works well when the characteristic is graded and has a level. This is not always true as, for example, the site of cancer and the sex of a person are characteristics that cannot be assigned a grade at the individual level. For groups, though, the percentage of patients with cancer of different sites and sex ratio in a group of arthritis cases are quantities. These are indicators at the group level and not at the individual level.

The term *indicator* is generally used when the focus is on a *specific* aspect of a characteristic. Severity of disease in a patient can be assessed by the severity of pain, inability to perform essential functions of life, prognostic implications such as the chance of death within a week, etc. Each of these is an indicator since each is concerned with a particular aspect of severity of disease. An indicator is a **univariate** assessment and perhaps the most direct measurement of particular aspects of characteristics of interest. Indicators provide the exactitude that one would like to have in the assessment, or may want to have in the resource material consulted to update one's knowledge.

Critics may be concerned with the limited utility of indicators because they focus on one particular aspect of health and ignore the other aspects, howsoever related. For example, **case-fatality rate** is an indicator of the chance of death but is oblivious to the pain and suffering it brings to the patient and the family. The weight of a person is an indicator that, by itself, loses importance unless related to height. Glomerular filtration rate (GFR) is better interpreted in the context of creatinine excretion. At the same time, though, the focus of an indicator on a particular aspect is its greatest strength. Case fatality does measure the most important aspect of prognosis that is important for both the patient and the doctor, measuring weight does help when monitored in the same person over a period, and GFR does give an indication about kidney function. They are good standalone indicators, although putting them in the context of other related parameters does help in providing a better interpretation.

### *Choice of Indicators*

Quite often, multiple indicators are available for apparently the same characteristic, and one may have to make a choice. Triglyceride, high-density lipoprotein (HDL), and low-density lipoprotein (LDL) are indicators of different lipids. Many times, these are considered together, but if one has to choose, the selection would depend on the relevance for the condition of the patient and the specific aspect of the lipid of interest. For example, triglyceride level can be a good indicator of lipoprotein, called natural fats, and LDL level can be a good indicator of risk of developing atherosclerosis. Conversely, a researcher may want to find which of the three is a better marker of coronary events, and why the others are not as good.

The nutrition level of a child can be assessed anthropometrically by weight, height, and skinfold thickness. Even though these are assessed in relation to age, they are univariate and thus are indicators in a relaxed sense of the term. The choice among weight, height, and skinfold thickness as anthropometric indicators of nutrition level in children would depend on whether one is looking at short- or long-term nutrition, or at the adiposity. Against this, weight for height, for example, requires two measurements; hence, it is bivariate and technically transgresses to the realm of **indexes**.

Blood hemoglobin (Hb) concentration and hematocrit (Hct) values assist in evaluating plasma dilution, blood viscosity, and oxygen-carrying capacity. Hb concentration, in general, is easily affected dietary supplements, whereas Hct is a long-term measure. A related measure is red blood cell (RBC) count. Each of these is an indicator used in specific contexts, and you should be able to decide which ones would serve your purpose.

At the community level, events such as child mortality can be measured by neonatal mortality, postneonatal mortality, and infant mortality. The neonatal period can be divided into early (<7 days) and late (7 to <28 days) periods. Although all of them could be used together to provide a holistic picture, a professional may want to concentrate on one indicator that best measures the specific aspect of interest. If the focus is on antenatal care, maternal nutrition, and skilled attendance at birth, perhaps early neonatal mortality rate is the best indicator. If the focus is on breastfeeding, infections, and child nutrition, postneonatal mortality may be better. If the interest is in studying the inability to thrive in the face of repeated infections and midterm sequel of low birth weight, mortality between 1 and 4 years may be better. In summary, different indicators may seem similar, but each indicator has a specific application. The focus of application helps to decide which particular indicator to use.

## indicator variables, *see* variables

## indirect standardization, *see* standardized death rates

## Indrayan smoking index, *see also* smoking index

Developed by Abhaya Indrayan, the Indrayan smoking index [1] is just about the most comprehensive measure of the burden of smoking in an individual. Besides the usual duration and number of cigarettes, this index incorporates the effect of age at the start of smoking, intermittent smoking, passive smoking, and time elapsed since cessation in the case of past smokers. This can be adapted to include all forms of smoking—cigarette with and without filter, bidi, pipe, cigar, etc. This index is given by

$$\text{Indrayan smoking index: } S = (3 - a/15)\left(\frac{1}{2}\sqrt{\Sigma p_k n_k x_k} - y\right),$$

where

- $a$ is the age (years) at start of smoking (take $a = 30$ for $a > 30$ assuming that starting after the age of 30 years has the same effect as start at age 30 years),
- $p_k$ is the intensity of smoking for $n_k$ years ($p_k = 1$ for regular cigarettes and bidi, 0.67 for filter cigarettes, 5.0 for cigar, 2.5 for pipe, and 0.15 for passive smoking—these are suggested values and can be changed as desired),
- $x_k$ is the number of cigarettes/cigars/etc. smoked per day for $n_k$ years, and
- $y$ is the number of years elapsed since quitting in the case of past smokers (this must be less than $\Sigma p_k n_k x_k$)—$y = 0$ for current smokers.

Abhaya Indrayan

A value less than 0 of this index is interpreted as 0 since smoking cannot have any beneficial effect. This is a comprehensive index of the present burden of smoking as it incorporates (i) the duration of smoking, (ii) the quantity of smoking, (iii) smoking of filter cigarettes and other forms of smoking that can be factored to cigarette smoking, (iv) progressively higher burden from smoking more pack-years in life (but the cumulative effect tends to flatten), (v) benefit of the time elapsed since quitting, and (vi) deleterious effect of starting smoking early in life. The index has a built-in feature to consider current smokers and ex-smokers and obviates the need to divide ever smokers into such a dichotomy. The index models the entire history of smoking into a single metric. The modification of cigarette-years by this index in some typical conditions is shown in Figure I.2. This index does incorporate a large number of aspects of smoking but fails to capture occasional smoking or the beneficial effect of interruption.

To see how this index works, consider the smoking history of the following three persons:

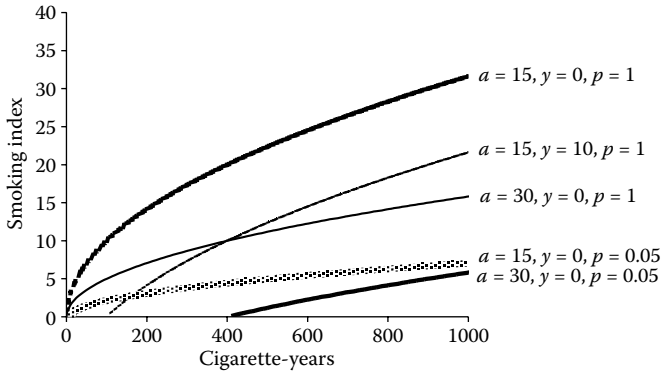

**FIGURE I.2** Indrayan smoking index for some typical values (see text).

Person A: Started smoking at age 12 years. Initially smoked 10 regular cigarettes for $3\frac{1}{2}$ years. Since then has been smoking 20 filter cigarettes a day for the last $17\frac{1}{2}$ years.

Person B: Started smoking at age 21 years. Smoked 12 cigarettes a day for 1 year, 15 cigarettes a day for $2\frac{1}{2}$ years, 20 cigarettes a day for $1\frac{1}{2}$ years, no smoking for 6 months, and 2 cigars a day for 1 year. He has not smoked for the past 4 years.

Person C: Never smoked but spouse smoked. When both were together, an average of 5 cigarettes a day were smoked. This started at age 27 years and went on for 6 years. There has been no exposure to cigarette smoke for the past 3 years.

The smoking index is as follows:

$$\text{Person A:}\quad S=(3-12/15)\left(\frac{1}{2}\sqrt{10\times3.5+0.67\times20\times17.50}\right)$$

$$=2.2\times8.21=18.1.$$

An index of 8.21 increases to 18.1 because of the deleterious effect of starting smoking at an early age of 12 years.

$$\text{Person B:}\quad S=(3-21/15)\left(\frac{1}{2}\sqrt{12\times1+15\times2.5+20\times1.5+2\times1}-4\right)$$

$$=1.64\times(4.73-4)=1.2$$

The present burden of smoking is small because of quitting 4 years ago.

$$\text{Person C:}\quad S=(3-27/15)\left(\frac{1}{2}\sqrt{0.15\times5\times6}-3\right)$$

$$=1.2\times(-1.9)=0\ \text{(negative value is to be taken as 0)}$$

The burden is small because of passive smoking, and that, too, vanished because of no exposure for the past 3 years.

The Indrayan smoking index is a vast improvement over the usual index of pack-years because of incorporation of so many facets. Indrayan et al. [2] have tried to validate this on a data set on smokers, but the index is yet to be adopted on a large scale because of the subjective consideration of the effect of an early start, benefit of quitting, and equivalence of other forms of smoking with cigarette smoking. All these, however, are flexible in this index, and it is a pointer on how a comprehensive index can be devised.

All smoking indexes, including this one, are heavily dependent on age. The higher the age, the greater the chance of a higher index because then the person may have smoked for a longer duration. The burden of smoking naturally accumulates as age advances. Thus, this should be calculated separately for each age group, particularly for comparing one population with the other.

## infant mortality rate, *see* mortality rates

## infection rate

Infection rate is the number of new infections in a specified duration per 1000 persons at risk. The duration could be per week, per month, per year, etc., depending on how quick the spread of infection is. The population can also be 100 to make it percent, per million, or any other number so that the infection rate becomes a convenient number. In terms of formula,

$$\text{infection rate}=\frac{\text{number of new infections in a unit of time}}{\text{population at risk at midpoint of the time}}\times K,$$

where $K$ is the constant of your choice depending upon whether you want it to be per 100, per 1000, per million, etc. This rate measures the risk of infection per unit of time in a given setting.

Surveillance or any such system would be required to keep track of infections. Many countries have this in place for infections such as HIV. For example, according to one report [1], HIV infection rate in the United States dropped from 24.1 per 100,000 people in 2002 to 16.1 in 2011. This gives some indication of how the epidemic is relenting in that country. When broken up into groups, the infection rate actually increased in the gay and bisexual communities during this period.

A common application of infection rate is in the hospital setting, where infections occurring in the patients admitted in a hospital are a serious concern for administrators. Most good hospitals keep an immaculate record of hospital infections. Only those infections that occur after admission are counted; thus, these can be considered hospital acquired and are called *hospital infection rate* or *nosocomial infection rate*. The denominator can be changed to hospital-days (see **person-time**) of stay in the hospital in place of the number of patients admitted. If the rate is per month and a patient gets two infections in a month, that patient would be counted twice under this scheme. When calculated ward-wise or department-wise, this rate can provide vital information on where the problem needs more attention. However, for comparison across wards or across hospitals, the rates may have to be **standardized** for the age of the patients, severity of disease, etc. It can also be calculated for each surgery site, catheter related, endoscope related, etc.

1. BBC News. HIV infection rate in the US falls by a third in a decade. http://www.bbc.com/news/world-us-canada-28389275, last accessed August 8, 2014.

## infectious disease models, *see also* epidemic models

Infectious disease models are biostatistical equations that try to predict the number or proportion of infectives in a population on the basis of susceptibility of the population, **infectivity** of the disease, latency of the disease, and other such features. These models help in better understanding of the exact role of various factors in the trend of **incidence** and **prevalence** of infectious diseases. They are applied to express the dynamics of infectious diseases and thereby devise strategies for their control. They can be used to evaluate the impact of the programs that are designed to reduce infections or increase immunity (such as vaccinations). If the models are really appropriate, they can help identify the optimal control strategies for minimizing infections. Infectious disease models have been most commonly tried for HIV-AIDS, malaria, and tuberculosis [1].

**Models**, by definition, are simplified versions of a complex process. Thus, they can never be 100% correct, and if they yield correct results in a large percentage of cases, they are considered good. The same is true for infectious disease models. A simple model that works reasonably well under certain regularity conditions is the so-called *SIR model*. Under this model, $S$ is the fraction of susceptible individuals in the population, $I$ is the fraction of infected persons, and $R$ is the fraction of resistant individuals. Resistant individuals are those that are almost permanently immune (either because previous infection has provided this kind of immunity or due to immunization). In a closed population, this would mean $S + I + R = 1$ in the long run. If β is the per capita contact rate, the rate of transmission of infection = $\beta * I * S$, provided, and this is a big *if*, that there is homogeneous mixing in the population. This rate is generally high for dense populations and is associated with greater duration of infectiousness and greater infectiousness of the disease. If you wish to consider those who are exposed but not infected yet (latent cases) also, denote them by $E$, and this becomes the *SIER model*. The rate of transmission is also called the infectiousness of the disease. Such a model can be used to predict the impact of changes in any parameter of the system. Eames et al. [2] discussed these models for studying the impact of school closure on the swine flu epidemic in the United Kingdom in 2009.

The model described in the preceding paragraph is deterministic as there is no probability element. When extended to incorporate the chance element or the distribution (such as distribution of contact rate with the provision that some segments of the population have high contact rate and some have low contact rate), the model becomes stochastic. This helps to prevent ascribing variations in the spread of disease to infectiousness when it is explainable by chance alone. For an example, see the work of Brown et al. [3], who proposed a biosurveillance network for detecting emerging zoonotic outbreaks using a stochastic SIER model.

For further details of infectious disease models, see Vynnycky and White [4].

## infectivity, pathogenicity and virulence, *see* disease spectrum

## inference (statistical)

Statistical inference is the scientific induction of results from a sample to the population. This is an extrapolation based on the evidence provided by the sample. This works well under commonsense condition, namely, that the sample is an adequate representative of the population. Representativeness can be almost assured by two statistical tenets: the sample is large enough to reflect the full spectrum of the subjects, and it is randomly drawn. Statistical texts are full of references to these features of the sample, and indeed, these can hardly be overemphasized. They are so much ingrained in the statistical thought process that they are many times taken for granted. *Random* samples allow the use of the probability rules, which are essential for latching onto the mathematical basis for providing rationale and also help in achieving representativeness. Nonrandom samples can also be representative, and they also can be used for inference, perhaps for the right inference, but the inference so arrived at will lack the scientific rationale. On the other hand, a random sample can be nonrepresentative, particularly when small, which can lead to wrong inference but may still escape criticism because of the randomness property. Large samples increase our confidence—thus, reliable inference can be drawn. The best assurance for reliable and valid conclusion inference is a large sample and random selection.

Statistical inference is basically of two types: **estimation** and **testing of hypothesis**. Both generally require specifying the unknown **parameters** that are to be estimated or tested. Exceptions are when the hypothesis of randomness or of a specified form of **distribution** is tested where the focus is not on any specific parameter but is on other features of interest. In routine situations, the parameters targeted for inference are the mean of the population, proportion or probability of occurrence of an event, correlation coefficient and regression among the variables, odds ratio for an event, etc.

Statistical estimation is of two types: the point estimate and the interval estimate. Estimating a parameter by one value is called the point estimate, whereas constructing a range of values outside which the value of the parameter is extremely unlikely is called the interval estimate. The latter is better known as the **confidence interval** (CI) when the range excludes extremely unlikely small values as well as extremely unlikely large values, and called **confidence bound** when only one-sided values are excluded. If you find in a trial that the efficacy of a regimen is 83%, this is the point estimate of the efficacy that you expect in all cases of that type. The CI will say something like "the efficacy is not likely to be less than 77% or more than 89%." If we say that the efficacy is not likely to be more than 93%, this is the upper confidence bound, and if we say that that the efficacy is not likely to be less than 65%, this is the lower confidence bound. The interval estimate heavily depends on the **confidence level** you want to put into the range. Generally, a confidence level of 95% is chosen so that the probability that a random value is outside is 5%. This is the convention generally followed to determine whether an event is extremely unlikely. The procedure for obtaining the CI for a large number of different types of parameters is presented in this book under the respective topics.

Inference regarding the point estimate can be drawn in practically all situations without worrying about the underlying **distribution** of the values. The point estimate almost invariably is the corresponding value in the sample; for example, the point estimate of the population median is the sample median, and for population relative risk (RR), it is the relative risk found in the sample subjects. However, if you want to find the reliability of the point estimate in the sense of how likely it is to hold in repeated samples, you would immediately need to know the distribution of the underlying values. Distribution is also required for finding the CI and the bound. **Nonparametric methods** are available for inference in case a definite distribution cannot be postulated. Another inference method now under considerable discussion is the **bootstrap**, which also is a nonparametric method.

The second type of statistical inference is **testing of hypothesis**. The thrust in this inference is to find whether the data are consistent with the hypothesized value of the parameters. A **null hypothesis** is set up, and the chance of the consistency of the data with this null is evaluated through a test criterion with known distribution. This type of inference also is more efficient when the distribution of the underlying values is known, at least approximately, since that helps to construct a suitable test criterion. Several procedures for testing a hypothesis on specific parameters are discussed in this volume under the respective topics. Nonparametric methods, including bootstrap, are available that do not depend on the underlying distribution, but these have limitations. First, they are not as efficient as the usual parametric methods for known distributions, and second, they are not as developed yet.

All inferences based on tests of hypotheses involve errors, as discussed for Type I error and Type II error. Statistical inferences are never absolute and can be wrong in individual cases, though they have high likelihood of being right in the long run when based on appropriate methods.

## infographics

Infographics contain some textual information in addition to graphs, as in Figure I.3a on deaths attributable to smoking in the United States, and may even contain many graphs with textual information, as in Figure I.3b on maternal mortality. The purpose is to present a complete picture so that the reader does not have to refer to the text. An infographic is supposed to be complete in itself.

Figure I.3b contains a lot of information: the number of countries with fast and slow progress in controlling maternal mortality; the global trend in maternal mortality rate since 1990 and the decline since 2003; the number of women still dying; the percentage of maternal deaths due to HIV in southern sub-Saharan Africa; the rate of decline in maternal mortality in East Asian countries; the major causes of maternal deaths; and the distribution of maternal deaths in the world by cause. Perhaps the cognitive part of the graphics is lost when so much of the information is depicted in one infographic. The other infographic in Figure I.3a is simple and effective in conveying the number of smoking-attributable deaths occurring due to various causes in the United States during 2005–2009.

## informatics (medical), *see also* expert systems

Medical informatics is the science concerned with the processing and engineering of the systems of information related to health and medicine. Thus, it has two distinct parts: first is information processing, and second is devising and maintaining information systems. The latter is mostly the domain of computer science experts, but the former has a lot to do with biostatistics, although these days, this part also is heavily dependent on computers.

The MEDLARS (Medical Literature Analysis and Retrieval System) project of the National Library of Medicine of the United States is just about the most well-known product of medical informatics. This started in 1964 and became available online in 1971 as MEDLINE. This system now has more than 22 million citations from more than 5000 medical journals across the world in different languages and is the most comprehensive database of medical literature. Back citations from the year 1951 have also been added. PubMed is the search portal that includes MEDLINE and online books. Its wide and free availability has made it look like an ordinary database, but consider the enormous efforts that went and are going into collecting, retrieving, collating, and organizing the information from such diverse sources.

Another major component of medical informatics is **expert systems**. These collate the medical information regarding diseases and other health conditions, particularly on diagnosis and treatment. With more than 2000 known disease entities, their stages, severity levels, variations across populations, and varied modes of treatment (including many unknowns), it is an uphill task to systematically organize all the information in one place. Not much success has been achieved yet on this front, not even when a single disease is considered. Expert systems require statistical considerations of probabilities of the presence or absence of disease, sensitivity–specificity/predictivities of medical tests, etc.

Beside the two mentioned in the preceding two paragraphs, the third is **data mining**. With almost every hospital now maintaining electronic records of at least the admitted patients, it is possible to dig through these data sets for signals that can identify the modes of diagnosis and of therapy that have yielded successful results. In the course of time, as public pressure for transparency grows, these databases may be available online. One can then pool several databases and come to more reliable results. This activity can gain substantial momentum when the records of patients in different clinics follow a uniform pattern so that the analysis and inference is straightforward from the pooled database.

The fourth is the ongoing effort to computerize and link the medical activities at the most peripheral levels, such as primary health centers in villages. Their linkage with the specialists at, say, district hospitals can substantially improve outcomes. *Telemedicine* is gradually but surely making headway into the medical systems with this objective.

The fifth is about computer applications to health gadgets that can communicate with care professionals for help. The 911 service in the United States is an example that may have saved millions of lives by instant tracing of the location of the distress calls and providing help within minutes. Another is health applications on mobile phones [1] and perceived-health monitors [2]. Your investigation and examination reports reach your phone or computer, which you can use subsequently for consultation with any doctor. Personalized medicine is also moving forward on the strength of information technology (see, for example, the work by Binefa et al. [3] on colorectal cancer).

For more information on medical informatics, see Ong [4].

## informed consent, *see* ethics of clinical trials and medical research

## instrumental variables, *see* variables

## intention-to-treat analysis

The intention-to-treat (ITT) strategy analyzes all participants in a **clinical trial** according to their original group assignment regardless of what occurred subsequently. This reduces bias due to nonrandom loss or shift of participants that can occur during the course of the trial. The efficacy of a regimen may be overestimated if ITT is not done. ITT analysis is conservative and provides more confidence. ITT is only for aligning groups—the statistical method of analysis, such as Student *t*-test and ANOVA, remains the same as in the usual setup.

ITT analysis is an ingenious strategy to partially circumvent the limitation imposed by a specific kind of distortion in the data and is particularly advocated for **randomized controlled trials**. Consider a typical trial for a new drug for vertigo in which randomized patients are given a tablet and told to take one if and when an attack occurs. Some subjects will have vertigo and take the tablet, and some will not have an attack and will not take the tablet. Should the analysis be based on those who had the attack or on all those who were randomized? There might be other situations where patients randomized to receive the intended treatment shift loyalty in the middle of the study and go for another treatment. Sometimes, the assigned regimen is not given in full, due to side effects, or one or more subjects receive the incorrect regimen in error. Sometimes, there is noncompliance, and some patients do not follow the complete regimen. Deviation from protocol can occur for a variety of other reasons also. These are examples of some situations where ITT analysis can be helpful. Since this can occur in practice as well, this simulates **pragmatic trials** and can be tried as an additional analysis to the regular per-protocol analysis that excludes the missing or distorted data. *Per-protocol analysis* is done on those who have taken a full course of medication, who took no prohibited drugs, and whose outcome is available as per the protocol. If the results do not materially differ in these two analyses, the confidence in the results naturally strengthens. For a complete ITT analysis, the outcome must be known for all patients, including those who shifted to other treatments. There is no consensus on how to handle nonresponse in ITT analysis, but the most acceptable method is to consider all nonresponses as adverse to the treatment. ITT analysis is recommended especially for superiority, **equivalence**, and noninferiority trials.

An appropriate situation for ITT analysis is given in Table I.1, where medical and surgical treatments are the two treatments under comparison for stable angina pectoris [1]. The outcome measure is 2-year mortality. Some patients switched from medical to surgical and some from surgical to medical under compelling circumstances.

A total of 373 patients were allocated to receive medical treatment (groups A and B) as first-line treatment, but 50 of these ended up getting surgery (second-line treatment; group B). Similarly, out of 394 patients allocated for surgery as first-line treatment (groups C and D), 26 got medical treatment (second-line treatment; group D). The ITT analysis would be (A + B) versus (C + D). Two-year mortality in these groups was 7.8% and 5.3%, respectively. On the contrary, if the protocol is to be strictly followed, the comparison would be of group A with group C, and the deviant groups B and D would be ignored. If the patients actually receiving medical (A + D) and surgical (B + C) treatments are compared, the 2-year mortality was 9.5% and 4.1%, respectively.

**TABLE I.1**
**ITT and Other Analyses to Compare Medical and Surgical Treatments for Stable Angina Pectoris**

| | Treatment—Allocated/Actual | | | |
|---|---|---|---|---|
| | Medical/Medical | Medical/Surgical | Surgical/Surgical | Surgical/Medical |
| | A | B | C | D |
| Number of patients | 323 | 50 | 368 | 26 |
| Number of deaths | 27 | 2 | 15 | 6 |
| Mortality | 8.4% | 4.0% | 4.1% | 23.1% |
| ITT analysis (A + B versus C + D) | 29/373 = 7.8% | | 21/394 = 5.3% | |
| As per protocol (A versus C) | 27/323 = 8.4% | – | 15/368 = 4.1% | – |
| As per actual treatment (A + D versus B + C) | 33/349 = 9.5% (A + D) | 17/418 = 4.1% (B + C) | | |

*Source:* Adapted from European Coronary Surgery Study Group. *Lancet* 1979;i:889–93. http://www.thelancet.com/journals/lancet/article/PIIS0140-6736(79)91372-2/abstract.

Note how different approaches can provide different results. ITT analysis provides a pragmatic estimate of the effect or of the difference in actual situations, and not the potential difference in ideal situations. Thus, this analysis mirrors clinical decisions and avoids bias in most situations. However, there are exceptions, such as safety of a regimen. ITT also fails to take care of fallacies, such as a participant tossing the drug or placebo in a toilet or taking four doses one day after missing them on the previous three occasions. The latter might come out from the interview of the subjects; the former may never surface.

Whereas efficacy of a regimen can be evaluated for clinical realities where some patients end up in an unintended group, common sense dictates that safety analysis should be on as "as-treated" basis. It would be unfair to ascribe a serious side effect to placebo where the patient supposed to receive placebo actually received the test drug. For not-so-serious side effects such as headache and nausea, which can occur due to nonpharmacological reasons and can occur in a placebo group, ITT analysis can still be adopted. In the case of efficacy, the major concern is with avoidance of **Type I error**, while for safety, avoidance of **Type II error** matters more—as in equivalence studies.

## interaction, *see also* main effect and interaction effect in ANOVA

Biological interaction is generally understood to occur when two or more factors are simultaneously needed to produce or enhance (or retard) an effect. Statistical interaction in the context of **designs** is a departure from the **additive** model. This means that the simultaneous effect of two factors is different from the sum total of their individual effects. *Interaction* is a term that belongs to a *K*-way ($K \geq 2$) experiment but is not restricted to experiments on biological samples and animal experiments. In fact, it is better explained by examples of human experimentation, better known as clinical trials.

The interaction explained in the next paragraph is not a pharmacological interaction between drugs but is a statistical interaction between the *effects* of a regimen when administered in conjunction with another regimen. It is also different from other usages, such as host–environment interaction.

Some factors work more effectively when other conducive factors are also present. Iron supplementation is more effective in increasing hemoglobin level when folic acid is also given. Their combined presence is much more effective than the sum total of their individual effects. This is a positive interaction and is called **synergism**. Since aspirin can reduce the beneficial effect of angiotensin-converting enzyme (ACE) inhibitors in patients with heart failure, they possibly have a negative interaction. This is called **antagonism**. Most interactions cannot be classified into either of these two categories. Osteoporosis is more severe in older women than older men (Figure I.4a). Thus, age and gender interact for severity of osteoporosis. Perhaps age and gender have no interaction for total lung capacity (TLC) as the decline in TLC with age runs almost parallel in men and women (Figure I.4b). A similar pattern of response for various levels of factors, except for a nearly constant difference, indicates absence of interaction. Then they are called factors with an **additive effect**. If the responses are not parallel, interaction is said to be present. Epidemiologically, interaction is called **effect modification**.

In the sense just described, the term *interaction* is used for the product of two or more **antecedent** factors and not for the relationship between an antecedent and an outcome. The differential effect of various levels of an antecedent on outcome is not called an interaction.

Even when interaction is absent and the factors' effects are additive, analysis of a two-way design gives different results from the analysis of two one-way designs—one for each factor. In any case, at least a two-way design is needed to explore whether interaction is present between two factors. Also note that when interaction is present, the average effect (**main effect**) of the factors gives a wrong picture. The interaction could be such that the factor has negative

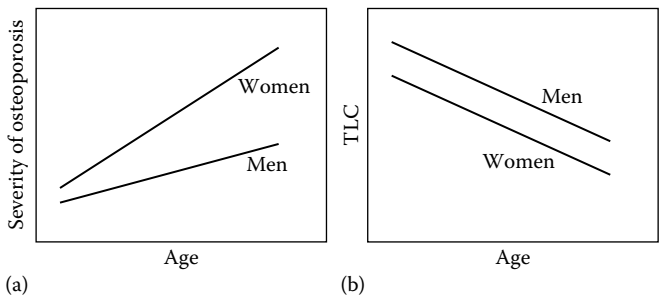

**FIGURE I.4** (a) Age and sex interact to produce differential effect on severity of osteoporosis; (b) age and sex do not interact for effect on TLC.

effect when it is $<a$ and positive effect when it is $\geq a$, which could produce an average close to 0. Thus, main effects have to be carefully interpreted in case interaction is present. The **analysis of variance (ANOVA)** procedure is fully equipped to test for statistical significance of an **interaction effect** through calculation of interaction **sum of squares**. If more than two factors are present, say A, B, and C, you can test for interaction between A and B, between A and C, and between B and C. You can also test for higher-order interaction, in this case, among factors A, B, and C combined. This will be difficult to interpret.

Although methods exist that can evaluate interaction in factors even when only one subject receives each combination of factor levels, generally, it is evaluated when more than one experimental unit is assigned to each factor level combination. More than one subject for each combination of factor levels is essentially the same as **replication**.

We have so far restricted our discussion to interaction between factors in an ANOVA setup, but this can happen in a **regression** setup also. If you have two quantitative regressors such as age and body mass index (BMI), these can interact in the sense that higher BMI in older age can be more harmful than the sum total of these two effects individually. If this is suspected, the product term (e.g., $x_1{*}x_2$) is included as one of the regressors. If the **regression coefficient** of this term is statistically significant, you can conclude that their interaction has a significant effect on the outcome.

## intercept (in a regression), *see* simple linear regression

## interim analysis

As the name suggests, interim analysis is the analysis of data while the data collection process is still going on. This means that the initial part of the data are analyzed with the purpose to look for signals that can indicate either that the objectives are extremely unlikely to be fulfilled or that they are already fulfilled, or that the project is on track and needs no modification, or that some aspects of the study need to be modified.

Interim analysis is not done on an ad hoc basis but is done after careful planning. This must be explicitly stated in the **protocol** with details of when the interim analysis will take place, what the objectives of such analysis are, and what action will be taken on the basis of the interim results. The stage of the project for interim analysis can be specified as after two-thirds of the sample is complete, or after 1 year of enrolment, after 6 months of follow-up, etc. In a phase II trial on hair loss–related quality of life in whole-brain radiotherapy, De Puysseleyr et al. [1] planned interim analysis after 10 patients to assess the futility of continuing. Futility was defined as a mean score of hair loss exceeding 56.7. Nüßlein et al. [2] presented interim analysis after 6 months of a prospective study (it was not a trial) for an otherwise a 2-year study on the effectiveness of abatacept for rheumatoid arthritis. Thus, different stages can be specified as per the requirement.

Interim analysis is commonly done in the case of **clinical trials**. Since these trials are becoming extremely expensive, it would be nice if we can save some effort by analyzing the interim data. Thus, the data are analyzed in two or more stages. The objective of interim analysis in the case of clinical trials is to find if there is sufficient evidence for stopping the trial due to either efficacy or futility. If the interim analysis provides sufficient evidence of the desired efficacy of the regimen at the specified level of significance and good statistical power, the trial is stopped for efficacy. If the interim analysis gives sufficient indication that there is hardly any chance of reaching the desired efficacy, the trial is stopped for futility. As discussed for **stopping rules**, all these are fully specified in the protocol after considerable thinking so that the probability of **Type I error** and of **Type II error** are not adversely affected. If the results of the interim analysis are not going to be revealed to anyone involved with trial conduct and the only effect that the interim analysis may have on the trial is to cause it be curtailed by reason of "futility," then this does not result in an increase in the risk of Type I error. In this case, the investigators know that an interim analysis is going to be run and when. In a reverse argument, if the randomized controlled trial (RCT) is blind and everybody keeps quiet as they should, and the trial continues, the investigators still guess quite rightly that the interim results were positive for continuing. Note that it is rightly guessed even if nobody says anything and everybody is blind. If the investigators thus believe that the drug is working, and even talk about it with the patients, a bias can occur. If the end points are more subjective to assess or psychologically influenced, such as depression, this can introduce a potential bias in the assessor and maybe also in the patient. The bias does not occur if nobody knows that an interim analysis is being run. This builds a case for not including interim analysis in the protocol, so that the investigators are not aware that an interim analysis is being run. You may have to weigh both sides of the argument and reach a conclusion regarding including or not including interim analysis in the protocol.

## internal attributes, *see* factor analysis

## internal consistency, *see also* consistency

Among various meanings of internal consistency, the one most relevant for us is the psychometric property of the multi-item instrument (**questionnaire/schedule**) used in obtaining and recording the responses from the people surveyed. This property says that the items should be framed in a manner such that the responses for different items of the instrument are consistent with one another. Internal consistency is the property of the instrument and not of the responses, but it is through the responses that the internal consistency of an instrument is assessed.

It is important to make a distinction between reliability of an instrument and its internal consistency. **Reliability** in the context of an instrument refers to consistency of the whole instrument, whereas internal consistency refers to the items within a test. As the number of items increases in an instrument, it tends to become increasingly reliable as its repeated application in similar situations tends to give the same result. A lengthy instrument has an averaging effect. As the number of items increases, the ability of the instrument to get a similar *total* response from people with similar feature increases. This happens because any low response reported under one item is likely to even out a higher response

to another item. This is not so with items. The internal consistency of a 12-item instrument could be the same as of an 18-item instrument—this would not be so with reliability. In the literature, you may find internal consistency being considered as part of the reliability.

Consider an instrument containing several questions or items on, say, a scale of 0 to 5. An example is the assessment of ability to perform activities of daily living (ADL) by a geriatric population. Items such as ability to dress, to bathe, to walk around, and to eat can be scored from 0 for complete inability (full dependence) to 5 for complete independence requiring no assistance. It is expected that the ability score on one item would correspond to the score on other items. If there were a difference, it would generally persist across subjects. In fact, all items are different facets of the same entity—the ADL in this case. That the underlying construct is uniform across all items of a test is an important prerequisite for measuring internal consistency. If that is so, the responses will be consistent with one another provided that the items are properly framed and the questions are appropriately asked.

One way to measure internal consistency is to split the test into ostensible halves where feasible. This is generally possible for a questionnaire by randomly dividing questions into two parts. The other method is to put odd-numbered questions in one half and even-numbered questions in the other half. The product–moment **correlation coefficient** between total scores in the two parts across several subjects is a measure of internal consistency. This is called **split-half consistency**. Note that there is no one-to-one correspondence between one item in one half of the test and an item in the other half of the test. Thus, **intraclass correlation**, which otherwise is a measure of consistency, cannot be used in this case. The usual product–moment correlation coefficient between total scores in the two parts is used to assess split-half consistency.

The most acceptable measure of internal consistency of a multi-item instrument is **Cronbach alpha**. This uses the average of correlations between each pair of items and can be obtained only when the items have a quantitative response. If the responses are binary yes/no, the **Kuder–Richardson coefficient** can be used. For details, see Carmines and Zeller [1].

1. Carmines EG, Zeller RA. *Reliability and Validity Assessment*. Sage, 1979.

## International Classification of Diseases (ICD)

The International Classification of Diseases (ICD) is an internationally acceptable system to classify various diseases and other health conditions in a uniform format so that each disease is understood in the same manner all over the world. The full name is International Statistical Classification of Diseases and Related Health Problems. It helps in achieving uniformity not just in classification but also in collection, processing, and reporting of disease data. Each disease is given an alphanumeric code, and its subdiseases, variations, and complications are given distinct subcodes. Thus, for example, migraine without aura has code G43.0, migraine with aura has code G43.1, hemiplegic migraine has code G43.4, and abdominal migraine has code G43.D. There are 12 subcategories of migraine alone. There is code G43.9 for unspecified also, so that nothing is left out. The codes we have mentioned are four alphanumeric characters, but they can have a fifth character to specify that the condition is not intractable (fifth character 0) or intractable (fifth character 1) and a sixth character that identifies the migraine as occurring with migrainosus (additional code 1) or without migrainosus (additional code 9). Each one of these conditions is specified to avoid any confusion. You can see that the ICD transforms textual descriptions of health conditions to alphanumeric codes, and the hierarchy is the same as seen in these conditions. These are **mutually exclusive and exhaustive** groups, and nothing is left out since a code is provided for "others" also. Such detailed coding substantially reduces chances of any misunderstanding regarding the type of disease under consideration. Now, in place of long twined definitions that are liable to be interpreted differently by different workers, a code is enough to describe the disease. If such detailed specification of any disease is not available, a broad code such as G43 only for all migraines can be used. Code G is for diseases of the nervous system, and the subsequent characters serve to further specify the disease.

Because of the standardization introduced by ICD, the incidence and prevalence of diseases and other health problems can be monitored without fearing much about changing definitions, varying interpretations, and different nomenclatures in different countries and by different professionals at different points in time. Cause of death recorded in death certificates can also be interpreted uniformly around the world.

ICD is piloted by the World Health Organization (WHO) and is periodically revised as new diseases emerge and new knowledge about existing diseases is generated. The present classification is called revision 10 (named ICD-10), and the 11th revision is expected to be available in 2018. The codes given for migraine in one of the preceding paragraphs are as per ICD-10. ICD has several adaptations, such as for oncology, injuries, and primary care.

While detailed coding is a boon for complete specification of the exact disease, it also is a bane for many workers. Medically qualified persons are needed to specify the code, but more important is that many medical professionals too do not have adequate training to adopt these codes. Thus, many diseases get misclassified, and it is extremely difficult in a finished report to find the extent of misclassification. Because of this limitation, ICD is still not used widely, particularly in developing countries, where medical professionals are in short supply.

Full details of ICD are available at the WHO website [1].

## interpolation

Interpolation is the process of estimating the unavailable intermediary values on the basis of the available values. For this, the trend of values is identified, and this is used to generate the estimate of the intermediary values. This is nearly the same as imputation, but imputation is done for missing values, and interpolation is done for the values not observed or not reported. Imputation is done by using a statistical method that takes care of **sampling fluctuations**; interpolation is pure mathematics with no consideration of sampling.

Consider a simple example of a child's height of 84 cm at age 2 years and 94 cm at age 3 years. What is your best guess of height at age 2½ years? The most obvious answer is (84 + 94)/2 = 89 cm since 2½ is exactly in the middle of 2 and 3 years. This is the *linear* interpolation in the sense that it is based on the assumption that height grew at a uniform rate between 2 and 3 years. This is nearly so between these two ages—thus, this interpolation will not be wrong by too much. If a provision is made for slightly higher growth in the first 6 months than in the last 6 months of age between 2 and 3 years, the trend would need to undergo the revised interpolation. This might be, say, 89.3 cm. *Linear* interpolation of height at age

27 months would be 84 + 3 × (94 − 84)/12 = 86.5 cm, which again uses the assumption that the height increase of 10 cm during this period of 12 months is uniform—thus, 2.5 cm in 3 months. If that were not so, the interpolation would not be linear.

Interpolation can be used for creating 3-D anatomical models on the basis of images at different cross-sections, say, of ablation of an unresectable liver tumor [1]. Fu et al. [2] used interpolation to generate data on smoking and drinking at smaller geographical levels in India from survey data at a larger level. In both these studies, the algorithm is not as simple as the linear one we used in our illustration, but they illustrate how interpolation can be used in health and medicine.

## interquartile range, *see* variation (measures of)

## interrater reliability

Interrater reliability is the near-uniform assessment of the variable in question by multiple observers when done in identical conditions. *Rater* is a general term and can be used for observers, assessors, clinicians, laboratories, instruments, or any such entity that is used to measure the characteristics of the subjects. Thus, this has many names—interobserver reliability, interlaboratory reliability, interinstrument reliability, etc. However, human beings are particularly prone to errors and subjectivity, and interrater reliability has special significance when the observers are human beings. The terms **agreement** and **concordance** are also used for reliability depending on the context.

The score assigned by different examiners on papers submitted by students is a very convincing example of interrater reliability. When the same answers are scored by different examiners, they should ideally come up with the same scores for each student, and the differences across examiners should be minimal, if any. Similarly, when the same patient is assessed by three clinicians, blind to the assessment done by the others, they are reliable if all three reach the same conclusion. When aliquots of a blood sample are sent to four different laboratories, they should come up with the same values when using the same method or same instrument.

Assessment of agreement between two observers, two methods, etc. for quantitative measurements is discussed under the topic **agreement**. The term *interrater* is generally used when there are more than two observers. Much research uses multiple observers, and it is desirable that they are reliable so that the differential results cannot be ascribed to interrater disagreements. A separate study may be needed to assess reliability, in which all the observers are asked to measure the same subjects. If they are not reliable, focused training on this issue may help. Once their reliability is established, they can be used in research with confidence.

Interrater reliability for qualitative measurements is measured by **Cohen kappa** and for quantitative measurements by **intraclass correlation coefficient (ICC)**. Both of these are described in this volume under the respective terms along with how these values should be interpreted. The conditions under which they provide valid assessment are also stated. For qualitative measurements, **Bangdiwala *B*** can also be used in the case of **ordinal categories**. An account of various measures of interrater reliability has been provided by Hallgren [1].

High interrater reliability does not assure **validity**—high reliability can occur when all observers provide a better rating or a poorer rating than deserved, but it certainly increases confidence in the results. Low reliability indicates large measurement errors, whose effect can be low statistical **power** in a testing-of-hypothesis setup. Low reliability can occur due to poor scale, poor training, pliant characteristics of the subjects, variable response, etc. You can think of deleting the variable with low interrater reliability from your research, or replacing it with the more reliable ones.

## interval estimate, *see* confidence intervals (the concept of)

## interval scale, *see* scales (statistical)

## intervention studies, *see also* clinical trials, experimental studies

An intervention study is the one where the interest is in finding the effect of an intentional intervention on some specified outcome. Only human or man-made interventions are considered in this kind of study, and natural interventions, such as disasters and pollution, do not come into this fold. Contrast an intervention study with an **observational study** where naturally occurring events are studied.

The effect of an intervention could be adequately estimated only when the study is carried out in two groups—one with intervention and the other without intervention. When more than one intervention or grades of intervention are under study, accordingly more groups would be needed. These are called **arms** of the study. The average difference in the outcome in the two arms provides an estimate of the effect of intervention in one compared with the other. Efforts are made in an intervention study to control all other factors that can influence the outcome so that whatever effect is observed can be legitimately ascribed to the intervention. This is done by adopting a design that includes equivalent subjects in different arms. When controlling all factors is not feasible, as would happen in most situations, some are controlled by design as much as possible, and the effect of others is extricated by statistical methods such as regression.

Intervention studies in health and medicine are basically of two types. First are laboratory experiments such as on animals and on biological specimens, and the second are **trials** on patients and healthy subjects. Both these can be of several types. For example, trials can be for preventive and promotive intervention and can be done in communities, but most challenging are **clinical trials** done in clinics for assessing the efficacy and safety of newly devised regimens. For details, see the respective topics in this volume.

## interview data/survey, *see also* interviewing techniques

Interview is one of the three major methods of collecting medical data. The other two are examination and (laboratory and radiological)

investigations. Among minor methods are observations and records. All these methods complement each other in presenting a unified picture. However, generally, only interview is used in mass surveys. An example of an exception is the Health Interview and Examination Surveys carried out periodically in the United States and some other countries on a mass scale, where examination is also used.

Interview seems like the easiest and most inexpensive method of collecting health information. It is invasive of the time of the respondent but otherwise is a harmless procedure. The same cannot be said about examination and investigations. However, the information obtained by interview is the least reliable also. Interviewers are seldom trained to elicit exact information, and the respondents tend to vary their response depending on their mood, the context, and their reaction to the interviewer's approach. People tend to hide sensitive information such as on sexual abuses and injuries with legal implications. Even for information as benign as height and weight, there are instances when height is overstated and weight understated so that the body mass index on the basis of interview turns out substantially low compared with that obtained by actual measurements [1]. Interview-based measurements should not be used unless compelled by the circumstances. Results based on interview data can rarely be believed to be as good as those obtained by objective measurements. However, for aspects such as opinion, aptitude, and history, interview is just about the only alternative. Interview surveys carefully planned and carried out can yield useful information, and repeat surveys can point toward the trends (see, e.g., Ref. [2]).

Many large-scale surveys use interview as the sole method of collecting information. Demographic and Health Surveys carried out in many developing countries from time to time are an example of this methodology. These surveys have been very effective in delineating such diverse aspects of health as neonatal mortality [3] and knowledge and awareness about sexually transmitted diseases [4]. Recently, the Global Adult Tobacco Survey has been carried out in several countries to find the extent of use of various tobacco products in different segments of the population. This also is entirely interview based.

## interviewer bias, *see* bias in medical studies and their minimization

## interviewing techniques

Interviewing techniques comprise the ways to elicit a response from the subjects of interview. A good technique will ensure that correct and complete responses are obtained from all the subjects. This includes the method of approaching the subject, enlisting his/her confidence, establishing rapport, motivating him/her to devote time, convincing him/her of the utility of the interview, etc. The technique becomes important for health surveys, where sometimes, a person is required to answer a long series of questions. In a clinic, too, a patient is invariably asked about complaints, past history, health behavior, willingness to undergo certain medical or surgical procedures, etc. Unless correct and complete information is obtained, the data analysis, howsoever immaculate, is not going to yield valid results.

A cardinal property of a good interview technique is that the differences in the answers by different subjects are genuine and not ascribable to the language or content of the question, how you put the question, understanding of the subject, the length of the interview, inability to recall, unwillingness to answer, bias of either the interviewer or of the subject, etc. This is easy to accomplish, but errors can be minimized by adhering to the following simple rules.

Make sure that the instrument (**questionnaire/schedule**) is fully tested and standardized for the kind of subjects proposed to be interviewed. Sensitive questions such as on sexual encounters and involvement in crime may have to be reworded so that they are not embarrassing. Complex questions may have to be broken down into parts for easy understanding and easy questioning. These are not part of the interview technique but are stated here because of their importance in getting the right response. The interviewer should undergo training on techniques that can ensure correct response. This would include (i) conducting the interview in a conducive environment where the respondent feels comfortable; (ii) using the language and mannerisms of the subject proposed to be interview and establishing rapport; (iii) explaining the purpose of the interview and convincing him/her of how is this going to help; (iv) remaining neutral during the entire course of the interview; (v) not tweaking the questions meant to be stated verbatim; (vi) restricting the probing, if needed, to "what do you mean," "tell me more," etc. and not suggesting an answer; (vii) recording pertinent answers as in the case of *open-ended questions* and checking off the answer to *close-ended question* only after the respondent has an opportunity to listen to all possible options; and (viii) not passing judgment. These look like simple rules but could be difficult to follow in practice. Try to follow them as much as possible to get the correct response. Remember that you may never have another opportunity to get the right answers, and whatever answers are recorded will be analyzed as they are. If the data are wrong, do not expect right answers from the analysis of survey data.

For more details, see Miller et al. [1] and Fowler and Mangione [2].

## intraclass correlation, *see also* interrater reliability, agreement assessment (overall)

The intraclass correlation coefficient (ICC) is the measure of the degree of consistency or conformity between quantitative elements belonging to the same subgroup. This is especially suited to studying (linear) correlation between twins or other multiple births or between measurements of two eyes or two limbs, or other parts of the body of the same individual. One useful application of ICC is in assessing agreement between different observers and different methods when used on the same set of subjects where the observers and methods can be more than two. This application is discussed

under the topic **agreement** for a pair of measurements. ICC is also frequently used in assessing **interrater reliability**.

The meaning of intraclass correlation should be clear from the dot diagram in Figure I.5. Here, there are five observers (five dots for each subject) and six subjects. Each observer measures each subject (called *fully crossed*). You can see that the values are close to one another in each subject except subject no. 4. Because of similarity of values between observers for most subjects, the ICC would be high. This measures the degree of interrater reliability or agreement or concordance. The degree will further increase in our example if values for the fourth subject are also close to one another, and would be low if the values reported by different observers for most subjects are very different.

The computation of the ICC is slightly different from that of the product–moment **correlation coefficient**. Several variants are available that work in different situations (for example, observers are a random sample or not from a big pool). We are presenting the classical definition, which also seems to be the most acceptable and is applicable when the observers are fixed. The formula is relatively easy for a pair of values compared to multiple values.

intraclass correlation coefficient (a pair of readings):

$$r_I = \frac{2\Sigma_i(x_{i1}-\bar{x})(x_{i2}-\bar{x})}{\Sigma_i(x_{i1}-\bar{x})^2+\Sigma_i(x_{i2}-\bar{x})^2},$$

where

$x_{i1}$ is the measurement on the $i$th subject ($i$ = 1, 2, …, $n$) when obtained by the first method or the first observer,

$x_{i2}$ is the measurement on the same subject by the second method or the second observer, and

$\bar{x}$ is the overall mean of all $2n$ observations.

The denominator in intraclass correlation is different compared with the formula of **product–moment correlation**. Also, the mean used in the numerator is the overall mean in place of the subject mean.

intraclass correlation coefficient (several readings):

$$r_I = \frac{\Sigma_i\Sigma_{j\neq k}(x_{ij}-\bar{x})(x_{ik}-\bar{x})}{(K-1)\Sigma_i\Sigma_j(x_{ij}-\bar{x})^2}; \quad i=1,2,\ldots,n; \quad j,k=1,2,\ldots,K;$$

where $n$ is the number of subjects and $K$ is the number of observers or the number of methods to be compared. The mean $\bar{x}$ is calculated on the basis of all $Kn$ observations. Both these formulas are, in fact, sample estimates of the corresponding correlation in the population. A correlation of more than 0.75 is generally considered enough to conclude good agreement. A value less than 0.40 generally indicates poor agreement. A negative value of ICC indicates systematic disagreement.

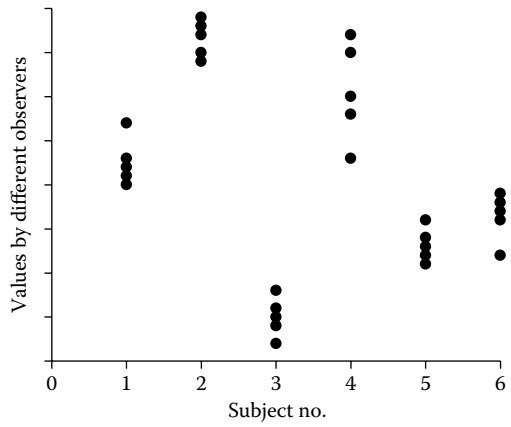

**FIGURE I.5** Illustration of intraclass correlation—values close to one another in each subject except subject no. 4.

The aforementioned formulas are for a fully crossed design. That is, the same set of observers is used for all the subjects. This is also called a two-way setup, as opposed to a one-way setup, in which each subject is assessed by a separate group of randomly drawn observers from a big pool. This is like having a pool of 200 nurses and randomly selecting 3 nurses to score subject 1, another 3 to score subject 2, etc. In the two-way setup also, one possibility is that you select $K$ observers randomly from a big pool, but the same $K$ observers are used throughout. In this case, observers would have a **random effect** because of random selection, and these formulas will not apply. If the observers are fixed and not randomly selected, these formulas are right, but in this case, you will not be able to generalize to any bigger group of observers.

### *ANOVA Formulation and Testing Statistical Significance of ICC*

For testing of significance, we use another formulation of ICC that is based on **analysis of variance** (ANOVA). This is on the premise that similar values across observers for the same subject would yield small within-subjects variance. Sounds reasonable! Between-subjects variance will remain whatever it is. Denote within-subjects variance by $\sigma_w^2$ and between-subjects variance by $\sigma_b^2$. A high value of between-subjects variance relative to the total variance is an indication that within-subjects variance is small, and the values within subjects are similar. This would mean high ICC. Under this formulation, thus,

$$\text{ICC: } \rho_I = \frac{\sigma_b^2}{\sigma_b^2+\sigma_w^2}.$$

This formulation is valid only when the observers are considered a random sample from the "population" of observers. This value of ICC cannot be negative, as opposed to the earlier formula for fixed observers, which can have a negative value. This value of ICC is interpreted as the proportion of the total variance accounted for by the between-subjects variation. Note again that a high value of this ratio would mean small within-subjects variance and, consequently, high intraclass correlation. The results of **one-way ANOVA** give the estimate of the ICC after some algebra as follows:

$$\text{estimated ICC: } \frac{\text{MSB}-\text{MSE}}{\text{MSB}+(K-1)\text{MSE}},$$

where MSB is the between-subjects mean square, MSE is the error mean square (this is the estimate of the within-subjects variance), and $K$ is the number of observers. To understand these **mean squares**, see that topic in this volume. If the observers disagree too much, MSE would be high, and ICC would be low.

This formulation highlights a limitation of ICC. This could be population specific. The between-subjects variance (MSB) could be high in the general population and low in the patients attending a particular clinic as they tend to be similar. Thus, an instrument could be judged reliable in one setup but unreliable in another setup. But there is a positive feature also. If you have five observers in one setup and three in another setup, the ICCs would still be comparable so long as the MSB is the same.

As an example of the use of ICC, consider a nationwide study by Nagler et al. [1] on variability between laboratories performing coagulation tests with identical platforms; prothrombin time, fibrinogen level, and other parameters were measured in a sample of 20 healthy subjects in eight selected laboratories. This variance across laboratories was substantial, and the ICC was low. This led to the conclusion that the standardization from one laboratory to the other is lacking, and efforts are needed to raise the level of standardization of structures and procedures involved in the quantification of coagulation factors.

In case of ICC, the interest would rarely be in the **null hypothesis** that ICC = 0. It would be whether it exceeds a given threshold or not. Thus, mostly, $H_0$: $\rho = \rho_0$ and the alternative $H_1$: $\rho > \rho_0$ (one-sided), and this can be easily tested by

criterion for testing ICC:

$$F = \frac{1+(K-1)\rho_0}{1-\rho_0} \times \frac{\text{MSB}}{\text{MSE}} \quad \text{with} \quad [(n-1), n(K-1)] \text{ df's.}$$

Use ***F*-distribution** to get the ***P*-value**. If it is less than the predetermined level of significance (say, less than 0.05), reject the null in favor of the alternative hypothesis; otherwise, do not.

For more details of ICC, see Shrout and Fleiss [2].

## intraobserver consistency/reliability, *see also* intraclass correlation

Intraobserver consistency is near equality of values in repeated measurements by one observer of the same characteristic of the same subject at the same point in time. This is also called intraobserver reliability. Repeated measurements can seldom be taken simultaneously at the same point in time in the same subject, but the idea here is measurements within a small period so that the value does not actually change. If an observer is asked to make three readings of diastolic blood pressure in the same subject in the same, say, sitting position after desired rest, the observer will be called consistent when the readings obtained are nearly the same every time. If an observer assesses the extent of burns of the same patient repeatedly within a period of, say 15 min, the answer should be the same. In the case of interpretation of an image, the same image can be given again and again to the same observer without even revealing that this is the same image. A good observer will give the same assessment every time even when, in this case, the time gap is large. The concern here is with the quality of the observer, but this can be extended to the quality of the tools or instruments or quality of laboratories. For example, when four aliquots of the same blood sample are blindly sent to the same laboratory for, say, finding the total cholesterol level, the results of all four should match. If the differences are wider than expected due to minor random variation, the quality of the laboratory is under suspicion.

Statistically, consistency means low variability, and **variance** is the natural criterion for assessing consistency in quantitative values. However, this measure heavily depends on the unit of measurement and the number of subjects. This also is easily distorted by a few outliers. A measure that is relatively independent of these ills is the correlation coefficient among the values reported by the observer on the same subject. This is described under the topic **intraclass correlation coefficient (ICC)**. In Figure I.5, substitute "observers" for "subjects" on the horizontal axis and values for different observers on the vertical axis, and you get an intraobserver consistency setup. Basically, these two setups are the same. Kraeutler et al. [1] used ICC for assessing intraobserver reliability of the radiographic diagnosis and treatment of acromioclavicular joint separations.

For qualitative measurements, intraobserver consistency is measured in terms of **Cohen kappa**. If you want to see an example of its actual use, see the work of Nepple et al. [2], who used Cohen kappa for assessing the intraobserver reliability of arthroscopic classification of acetabular rim labrochondral disease.

## inverse association

The term inverse association is used in several senses. (i) The first is when an increase in one is accompanied by a decrease in the other. Age and lung functions in adults are inversely associated. Since both are quantitative, the term generally used is inversely *correlated* in place of *associated*. This is the same as negative **correlation**. (ii) The second is regarding the association between the chances and not the values. Alzheimer's disease and cancer have been found inversely associated in the sense that Alzheimer's disease decreases the chance of cancer in a person and cancer decreases the chance of Alzheimer's disease [1]. They are much less likely to occur together. (iii) If one percentage rises out of the total, the other is bound to decline. If the percentage of deaths by communicable diseases decreases, as is occurring in most parts of the world, it is natural that the percentage of deaths by chronic diseases would increase. This stems from the fact that the sum total of probabilities of death by different causes is 1, and a fall in one will correspondingly cause a rise in the others. This is kind of obvious to statisticians but not so much to medical professionals. Under this paradigm, with increasing expectation of life almost everywhere, a rise in the percentage of deaths due to chronic diseases could be considered a welcome sign as less people are dying early due to infections, many of which inflict children.

Mathematically, though, there is a difference between negative and inverse. The negative of 3 is –3, whereas the inverse of 3 is 1/3. This kind of inverse association holds true for **odds ratio (OR)**. For a fourfold table with cell frequencies *a*, *b*, *c*, *d*, OR = *ad*/*bc*. If first row–first column is for presence of the **antecedent** and presence of disease, this is the OR for the presence of antecedent in diseased cases. Its mathematical inverse, *bc*/*ad*, is the OR for the absence of the antecedent in diseased cases. If the OR for positive electrocardiogram (ECG) in myocardial infarction (MI) is 4, the OR of negative ECG in MI cases is 1/4. The association between

MI and negative ECG is the inverse of the association between MI and positive ECG. This inverse is not in terms of the minus sign but in terms of the mathematical inverse. Similarly, if the **relative risk** (RR) of disease in exposed to nonexposed subjects is *r*, the RR in nonexposed to exposed subjects is 1/*r*. If the RR of oral cancer in regular users of smokeless tobacco to nonusers is 5.8, the RR of oral cancer in nonusers to users is 1/5.8. That is, nonuse of smokeless tobacco is inversely associated with the risk of oral cancer relative to its use.

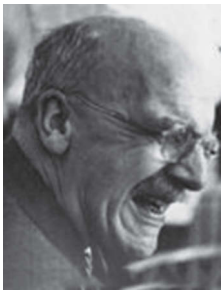
## inverse probability, *see* Bayes rule

## inverse sampling

Formally introduced by JBS Haldane in 1945 [1], inverse sampling is the process under which sampling continues till such time that a prefixed number of the outcomes of interest are available. This kind of sampling is advocated for rare outcomes since a fixed sample in this situation may not yield sufficient outcomes of interest for a reliable conclusion.



JBS Haldane

Suppose the interest is in adult cases of epilepsy. This is a rare condition, and even if a sample of few thousand is taken from the general population, or even from those coming to a hospital, the number of epilepsy cases may still be inadequate for any reliable conclusion. The sampling scheme in this situation can be to include any case of epilepsy seen in a clinic, and to continue to do so till, say, 30 cases of epilepsy are available. The number of outcomes of interest is fixed, but the sample size is not fixed in this case and is a **random variable** that depends on chance. You can see that this method of sampling counts the numbers and thus is applicable for events or attributes but not to quantitative outcomes. We cannot say that we will continue to sample till such time that the average direct bilirubin level is between 0.15 and 0.17 mg/dL. But we can say that we will continue sampling till such time that we have 50 cases with a high (say, >0.20 mg/dL) level of direct bilirubin. Such a cutoff converts the quantitative outcome to a qualitative outcome.

Inverse sampling is sometimes advocated for matched **case–control studies**, particularly when there are $K$ (>1) controls per case. In the usual case–control setup, there is a great likelihood that matching on selected predefined characteristics incidentally also matches the exposure under investigation. When matching exposure is found, the pair becomes redundant as it does not contribute to the discrimination under study. In this situation, the sampling may continue till such time that a control subject is found with different exposure. Keogh [2] has discussed this phenomenon and concluded that this inverse sampling offers improved statistical efficiency relative to a comparable study with a fixed number of controls per case.

The usual formulas for **standard errors (SEs)** and other estimates are based on **simple random sampling**. Those will not be applicable to inverse sampling. To work these out for a population proportion $\pi$, we need to consider what is called **a negative binomial distribution**.

Tian et al. [3] have worked out the SE and the confidence interval (CI) of relative risk under inverse sampling. Aggarwal and Pandey [4] compared the estimates of prevalence of leprosy in a population in India obtained by inverse sampling and cluster sampling. They found that the estimates are similar but the SE of the estimate obtained by inverse sampling was higher than obtained by cluster sampling. Thus, this scheme is not as efficient but can still be recommended in a setup where the disease of interest is rare.

## Ishikawa diagram

The Ishikawa diagram is a special type of diagram where potential causes of an outcome or steps of a process are organized in a *fishbone* structure for better understanding. This is also called a *cause–effect diagram*, although its application goes beyond this setup. It helps in sorting the causes or steps in useful categories so that there is no repetition, and the stipulation is that nothing is missed. It can also be used to structure a brainstorming session.

Kaoru Ishikawa

The diagram was devised by Kaoru Ishikawa in 1968 [2]. In Figure I.6 is such a diagram showing the process parameters that affect the critical quality attributes of water precipitation. Note its structure resembling bones of a fish. A new "bone" can be added as and when any new idea comes to mind that deserves to be considered. The length of the "spine" can also be increased when needed. This type of diagram is primarily a quality improvement tool and can be used in health and medicine also. Wong [3] has

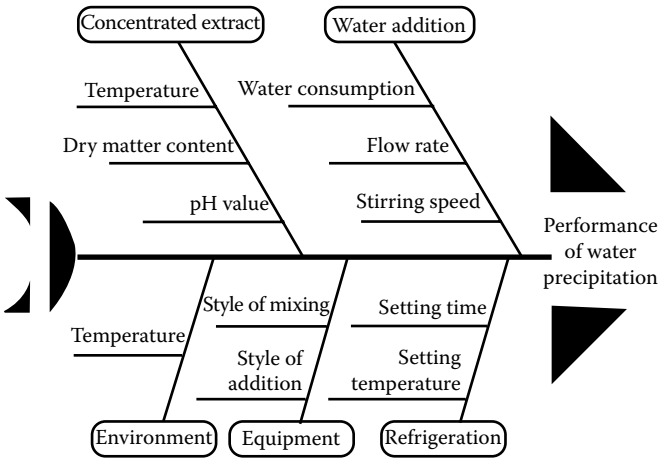

**FIGURE I.6** Ishikawa diagram of water precipitation process. (From Gong X, Chen H, Chen T, Qu H. *PLoS One* 2014 Aug 7;9(8):e104493. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC4125280/.)

discussed how Ishikawa diagrams can be used to assist the memory of clinicians while dealing with a case or to improve teaching and training. For example, it can be structured in a manner such that patient issues are on one side of the spine and care-provider issues on the other side. That can help in providing the required focus on different types of issues. One can use boxes or other markers to distinguish main causes from subcauses, as done in Figure I.6.

## item analysis

Item analysis is a set of statistical techniques used for assessing the efficiency of the items of a test to properly discriminate between the good and not-so-good outcomes. The results of item analysis rate the quality of the test for fair assessment. The analysis can also identify the items that are problematic in fair assessment. This analysis is generally used for developing and assessing the quality of educational tests in classrooms that could distinguish good students from not-so-good students, but the technique has found applications to multi-item medical tests also, for example, to grade disease, to grade quality of life after a surgery, to grade the knowledge regarding a particular health condition, etc. Such tests can be better understood as scales or instruments. For an application, see the work of Compton et al. [1], who have reported item analysis of multiple-choice questions on knowledge regarding mental illnesses.

Severity of disease in a patient can be assessed either by the total score in a test or externally by experts. If this is based on the total score, think of using **tertiles** to divide the subjects into three groups, namely, serious, moderate, and mild. Those who know tertiles will realize that this would classify the top one-third of patients as serious, the middle one-third as moderate, and the bottom one-third as mild. This may or may not actually be so but would serve the purpose of item analysis in most situations. If a large number of patients are available, these can be divided into five groups by **quintiles**. The following methods are described for three groups.

The first step in item analysis is to obtain the "difficulty index" of each item. In educational testing, this would mean the percentage of items answered wrongly. An item wrongly answered by less than 20% of students or more than 80% students is not considered a good item to discriminate between the good student and the poor student. This can be done only if you already know what the correct answer is and can be easily done for multiple-choice questions. Deletion of such items helps in reducing the length of the test, which also is a concern in test development. In medical testing, this translates into questions for, say, health assessment.

Next is the "discrimination index." This is the difference between the proportion of correct responses by serious cases and the proportion of correct responses by mild cases. The closer the value of this index is to 1.0, the more is its discrimination power. For example, if a question on previous history is answered "yes" as often by patients with mild disease as by patients with serious disease, the question has a low discrimination index for severity and is a candidate for deletion from the test.

Third is the **point-biserial correlation** between a patient's response (if dichotomous) on an item and his/her total score. If there are $n$ subjects, you will have $n$ pairs of values. If the item has a quantitative response such as pain score, this would be assessed by the regular product–moment **correlation coefficient**. The higher the correlation, the better the item in the sense that it is scored high for those who have a high score in total. Fourth is the distraction score. This is obtained for multiple-choice questions where some options are used as distracters. More low-score patients should select distracters as their answer than high-score patients.

There are other methods for assessing the quality of a test. These include the **reliability** of the test and its **validity**. They are for the test as a whole and not for individual items. More details of item analysis are provided by Koch [2].

## iterative procedure

An iterative procedure in biostatistics is finding the solution of an equation by trial and error, which requires that improved values are tried every time based on previous trials so that we can get closer and closer to the right solution. Obviously, this procedure is needed for those equations that do not have an explicit solution.

An iterative procedure is commonly followed to find the solution of **maximum likelihood** equations. These equations are derived to find the best estimates that fit the data. For example, sample mean $\bar{x}$ is a maximum likelihood estimate of the population mean μ of a Gaussian distribution. This is an explicit solution of the maximum likelihood equation and needs no iteration. But for the maximum likelihood estimates of the coefficients in **logistic regression**, there is no explicit solution, and we need to iterate to get a solution. In this

case, start with a plausible-looking value, plug it into the equation, find the error, revise the values, plug the revised value, and so on, till such time that the error becomes negligible. Various mathematical algorithms are available that guide us about how to find the error and how to revise the value for the next iteration. Successive iterations in most situations provide a closer solution, but sometimes, the iterations fail to narrow down the error, and it persists. In this case, we say that the iterations fail to *converge*, and no good estimate can be found.

Iteration is a fairly general procedure and has several other applications in the field of health and medicine. For example, iteration is used to reconstruct computed tomography images [1] and for other reconstruction techniques. The same sort of procedure is used in biostatistics, albeit for solving complex equations that do not have direct solutions.

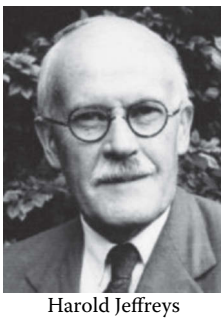
## Jeffreys interval for binomial π, *see also* Clopper–Pearson bound/interval

The Jeffreys interval is a slight modification of the **Clopper–Pearson interval** for the **binomial** probability π. This is sometimes preferred because this gives an interval with confidence closer to the desired level and has equal tails, whereas the Clopper–Pearson interval has unequal tails. The Jeffreys interval is best expressed in terms of the inverse of the **beta distribution** as

$$\text{Idf.Beta}(\alpha/2, x + ½, n - x + ½), \text{Idf.Beta}(1 - \alpha/2, x + ½, n - x + ½)$$

for confidence level $100*(1 - \alpha)\%$, where $x$ is the number of binomial "successes" out of $n$. This interval is symmetric for $x$ and $n - x$ in the sense that ½ is added to both. This is what tends to make this equal-tailed—each tail with probability $\alpha/2$. On the contrary, in the Clopper–Pearson interval, 1 is added to $n - x$ for the lower limit and to $x$ for the upper limit. Though exact, this kind of continuity correction in the Clopper–Pearson interval tends to yield an interval larger than needed, and this is not symmetric. The Jeffreys interval emerges from the work of Harold Jeffreys that culminated in his publication in 1946 [1] on estimation with invariant form for the prior probability.



Harold Jeffreys

The Jeffreys interval has Bayesian overtones with prior distribution being beta with parameters (½, ½). This is called the *Jeffreys prior.* After observing $x$ successes in $n$ trials, the distribution changes to beta $(x + ½, n - x + ½)$. When $x = 0$, the upper limit remains the same, but the lower limit is set to 0, and when $x = n$, the lower limit remains, but the upper limit is set to 1. This is the practice usually followed for confidence interval (CI) on binomial π because this is a probability that has natural bounds at 0 and 1.

See also **Wilson interval** for another kind of interval for binomial π.

## jitter graph/plot

A jitter graph is a plot where overlapping values are shown to be distinct by adding a small amount of noise to the data. In a **scatter diagram**, the values of $y$ on the vertical axis are plotted against $x$ on the horizontal axis. It is possible in your data that $y$ has same value for, say, fours person for the same value of $x$. In this case, these four points will be plotted one over the other, and it would look that this is just one point. Jitter helps to make it clear that these are four points without really disturbing the depiction of the relationship.

Overlapping could happen particularly when the value of $y$ is continuous but rounded off to a convenient number. Consider the birth weight of 1000 babies plotted against their birth order. Birth weight naturally would be recorded to, say, two decimal places. It is possible that 6 out of 1000 babies have birth order 1 and birth weight of 3.59 kg. In the scatterplot, these would be indistinguishable, and all six points will be at the same spot. To make them distinct in the plot, you can consider that these have birth weights (in kilograms) of 3.587, 3.358, 3.589, 3.590, 3.591, and 3.592. Then the overlap will be clear, as they will be slightly visible separately. Note that this jitter is not that much unjustified, because the value 3.59 in fact is a manifestation of values 3.586 to 3.595, as the weight is recorded to the nearest two decimals. We have systematically added 0.001 to the weight, but any random small quantity can be added to achieve jitter.

Consider the data in Table J.1 on blood creatinine level in kidney disease patients of different severity. These are values for a total of 43 patients, but some values are the same within each group. A scatterplot of these values is shown in Figure J.1a, where only 28 distinct values are seen. The other 15 values are overlaps and cannot be seen. After jitter, all 43 values can be seen (Figure J.1b). In this figure, the jitter is applied to the severity of disease since, in this case, slight left or right of mild is still mild, and the case is similar for moderate and serious disease groups. When any one variable is discrete as in this case, it is easy to apply jitter without affecting the meaning of the display.

**TABLE J.1**
**Blood Creatinine Levels in Male Adult Patients with Kidney Disease of Different Severity**

| Severity of Disease | Blood Creatinine Levels (mg/dL) |
|---|---|
| Mild | 1.3, 2.5, 1.8, 1.7, 1.4, 1.2, 1.8, 2.1, 1.7, 1.9, 2.2, 1.5, 1.7, 1.4, 2.0, 2.5, 1.8, 1.6, 2.0 |
| Moderate | 2.8, 3.2, 2.1, 2.7, 2.2, 2.9, 3.0, 3.4, 3.4, 2.9 |
| Serious | 3.9, 3.2, 3.7, 4.1, 4.5, 4.0, 4.3, 4.4, 4.2, 4.1, 3.7, 3.9, 3.2, 3.7, 4.0, 4.2, 3.8, 3.6, 4.0 |

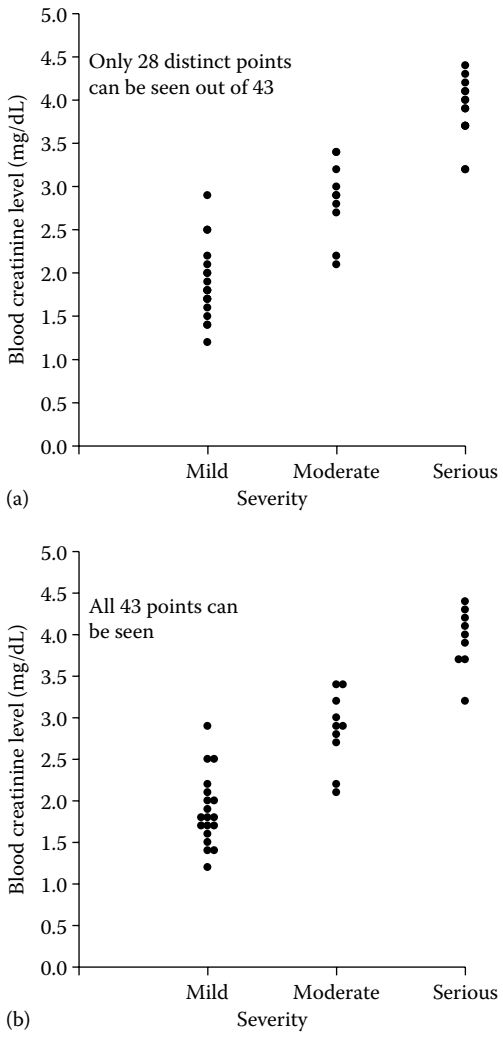

**FIGURE J.1** Plot of the data in Table J.1: (a) without jitter; (b) with jitter.

Jitter may not be needed if both the variables are continuous with a sufficient number of decimals. The need for this kind of adjustment arises generally when at least one variable is discrete. Jitter is only for display and not for analysis of data—the analysis continues to be on the actual values.

## joint distribution, *see* bivariate distributions, multivariate distributions

## J-shaped curve/distribution

A J-shaped curve arises when the values of one variable $y$ gradually decrease for increasing initial values of $x$ and then show a steep increase as the value of $x$ increases after a limit. A popular example

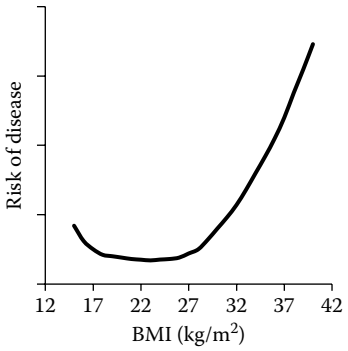

**FIGURE J.2** J-shaped curve between risk of disease and BMI.

is the risk of disease ($y$) and body mass index (BMI) ($x$). The risk of disease is relatively high when the BMI is low, say less than 18 kg/m$^2$; falls as the BMI increases; reaches a bottom when BMI is around 22–23 kg/m$^2$; and then increases as the BMI increases. (Although there is evidence that the risk remains low for BMI between 22 and 27 kg/m$^2$, we ignore this for our example.) This curve is shown in Figure J.2. The relationship between alcohol intake and risk of stroke also follows this pattern in many populations, where risk is slightly higher when no alcohol is taken and low for moderate drinking but steeply increases for heavy drinking. Nove et al. [1] examined maternal mortality in different age groups in 144 countries and noted a J-shaped curve because of high mortality among adolescents, again high at age 40 years or more.

In many applications, a higher value at initial values of $x$ is not seen, but the curve is still called J-shaped, although this is better considered an **exponential curve**. For example, bacterial growth over time, when unhindered, follows this kind of pattern. If the rise is slow with increasing $x$, it can still be possibly represented by an exponential curve by suitably choosing the parameters.

Figure J.2 is a curve and not a distribution, but it becomes a statistical distribution when the $y$-axis is the probability or the frequency or percentage. Thus, if the $y$-axis is the number of subjects and the shape is the same as in Figure J.2, this will be called a J-shaped distribution. This will not happen with BMI, because the number of people with high BMI does not increase as the BMI increases from 30 kg/m$^2$ onward, but can happen with some other variables.

You may occasionally find reference to a *reverse* J-shaped curve or distribution when low values carry much more risk than high values. This has been seen for baseline ankle brachial index and the hazard ratio of death in both men and women in the United States [2]. The authors called it a J-shaped distribution, but it actually is a reverse J-shaped curve.

# K

## Kaiser–Meyer–Olkin (KMO) measure

This is an index that compares the magnitude of observed correlations with the magnitudes of **partial correlations** in a multivariate setup, and is used to assess whether or not the data are adequate for **factor analysis**. Partial correlations are the correlations between two variables after removing the linear effect of the other variables. If the variables really share common factors, almost all the partial correlations should be small.

If the partial correlations are nearly equal to the (total) correlations, the value of the KMO index is nearly 0.5. Thus, the value of KMO should be more than 0.5, preferably more than 0.8, to indicate that most partial correlations are sufficiently small. Then, you can expect the existence of common factors as required for a successful factor analysis. KMO is calculated after a **Bartlett test** for sphericity rejects the null hypothesis of no correlations among the variables and assures that some correlations are present among the variables as required for trying factor analysis. If the Bartlett test reveals that significant correlations are not present, there is little justification to proceed with factor analysis.

Also called a measure of sampling adequacy, the KMO was initially proposed by Kaiser [1] in 1970 and modified by Kaiser and Rice [2] in 1974. Gonzáles et al. [3] used this measure for validation of an index of erectile function in Brazil, and Borg et al. [4] used this for a questionnaire to assess treatment outcomes of acetabular fractures in Sweden.

## Kaplan–Meier method, *see also* survival curve/function

The Kaplan–Meier method is a method to estimate the survival pattern of a group of subjects where the duration of survival is exactly measured on a continuous scale. On the other hand, the **life table method** is used for the analysis of survival when the survival is available in grouped data form. *Survival duration* is a generic term used for any duration, also popularly called time to event. These durations need special methods because (i) durations generally have highly skewed distribution and (ii) for some subjects, the complete duration is not available because of dropout, which can happen for various reasons, called **censored** data or incomplete segments. The method was developed by Kaplan and Meier in 1958 [1].

To understand this method, consider an example of 100 cervical cancer patients of whom 1 died after 1 month of enrollment, 4 died at 3 months, and 2 died at 7 months. Since 1 died out of 100 alive at 1 month, 4 died out of 99 alive at 3 months, and 2 died out of 95 alive at 7 months, the estimated survival probabilities are 99/100, 95/99, and 93/95, respectively at 1, 3, and 7 months. The denominator keeps on changing as mortality occurs as these are the conditional probabilities based on the persons surviving at the previous time points. The overall survival after 7 months is 93/100, which also can be obtained as 99/100 × 95/99 × 93/95. This product of the conditional probabilities is the basis for the Kaplan–Meier (K-M) estimate of survival probability, where the censored values are ignored after patients are last seen alive.

When the exact duration of survival is recorded, there is no need for an adjustment of the type used in the life table method. Instead, the censored observations are considered only till the time the subjects were last seen alive, and after that, they are ignored. The probability of survival is computed for each observed duration in place of each interval. Survival rate at time $t$ in this case is the proportion surviving longer than $t$. To estimate this, arrange the subjects according to the known duration of survival, including the censored duration. For $T$ distinct time points for which the duration of survival has been recorded, first obtain

$$p_t = \frac{n_t - d_t}{n_t}, \quad t = 1,\ 2,\ldots,\ T,$$

where

- $p_t$ is the proportion surviving the $t$th time point among those who survived the $(t-1)$st time point;
- $n_t$ is the number of subjects at risk of death at the $t$th time point, i.e., those who are still being followed up (this excludes those with incomplete segments, i.e., $n_{t+1} = n_t - c_t - d_t$)
- $c_t$ is the number of subjects with incomplete segments at time point $t$
- $d_t$ is the number who died at the $t$th time point

Then the estimated proportion surviving the $t$th time point is

Kaplan–Meier survival function at time $t$:

$$s_t = p_t p_{t-1} \ldots p_2 p_1;\ t = 1, 2, \ldots, T.$$

This is the estimated survival function in this case. It is computed for each unique time point. If a time point is applicable to two or more subjects, it is counted only once. This method requires the calculation of as many survival rates by the product rule given in the equation just mentioned as there are events. Hence, the K-M method is also called the **product limit** method. The larger the $T$, the smoother the survival curve. The K-M method for estimating survival probability at the last time point is usually very unreliable because of heavy censoring toward the end of the trial. The following example illustrates the method.

Consider the following data on survival time of 15 patients following radical mastectomy for breast cancer. The study started in January

**TABLE K.1**
**Illustration of Kaplan–Meier Method for Calculation of Survivors**

| Patient No. | Months of Survival | Serial Number of the Time Point $t$ | No. of Patients at Risk (at the Beginning of Time Point $t$) $n_t$ | Deaths at the $i$th Time Point $d_t$ | Number of Survivors $n_t - d_t$ | Proportion Survived $t$th Time Point $p_t$[a] | Proportion Survived since the Beginning $s_t$[b] | Number with Incomplete Segments $c_t$ | Number of Known Survivors $n_t - c_t - d_t = n_{t+1}$ |
|---|---|---|---|---|---|---|---|---|---|
| 1 | 6 | 1 | 15 | 1 | 14 | 14/15 = 0.933 | 0.93 | 0 | 14 |
| 2 | 8 | 2 | 14 | 1 | 13 | 13/14 = 0.929 | 0.87 | 0 | 13 |
| 3, 4, 5 | 20+ | 3 | 13 | 2 | 11 | 11/13 = 0.846 | 0.73 | 1 | 10 |
| 6 | 24+ | 4 | 10 | 0 | 10 | 10/10 = 1 | 0.73 | 1 | 9 |
| 7 | 25+ | 5 | 9 | 0 | 9 | 9/9 = 1 | 0.73 | 1 | 8 |
| 8 | 30+ | 6 | 8 | 0 | 8 | 8/8 = 1 | 0.73 | 1 | 7 |
| 9 | 35+ | 7 | 7 | 0 | 7 | 7/7 = 1 | 0.73 | 1 | 6 |
| 10, 11 | 37 | 8 | 6 | 2 | 4 | 4/6 = 0.667 | 0.49 | 0 | 4 |
| 12 | 38+ | 9 | 4 | 0 | 4 | 4/4 = 1 | 0.49 | 1 | 3 |
| 13 | 40+ | 10 | 3 | 0 | 3 | 3/3 = 1 | 0.49 | 1 | 2 |
| 14 | 42 | 11 | 2 | 1 | 1 | 1/2 = 0.50 | 0.24 | 0 | 1 |
| 15 | 45+ | 12 | 1 | 0 | 1 | 1/1 = 1 | 0.24 | 1 | 0 |

*Note:* "+" indicates that the duration of survival is at least this much (incomplete segments) for at least one patient.

[a] $p_t$ as in the formula given in the text.

[b] $s_t$ as in the formula in the equation in the text (for example, $s_3 = (11/13) \times (13/14) \times (14/15) = 0.73$).

2012 and continued till December 2015. Thus, the maximum follow-up was 4 years. However, many patients joined the study after January 2012 as and when radical mastectomy was performed.

Survival time (months):

6 8 20 20 20+ 24+ 25+ 30+ 35+ 37 37 38+ 40+ 42 45+

where "+" means that the patients are lost to follow-up or not followed up after this period. They are the incomplete segments. Their exact survival time is not known, but it is at least as many months as shown. The patients are deliberately ordered by survival time. This order is not important but makes the presentation simple. The sample size is small, and there are many incomplete segments. Both are undesirable for **survival analysis**, but the data are still adequate to illustrate the method.

The patients with incomplete segments do not contribute to the calculation of $s_t$ after they are lost. Thus, the rows such as those corresponding to duration 24–35 months in this case can be deleted, although Table K.1 has these rows for completeness. Note how $p_t$ is calculated for survival period of 20 months where there are two deaths and one incomplete segment. At this point, of the 13 patients, 11 survived and 2 died, and the patients with incomplete segments are not counted in this calculation. Thus, $p_3 = 11/13$. The other calculations are similar. The survival curve is shown in Figure K.1. The curve obtained by the life table method is also shown for comparison.

Since time is continuously observed in this setup, many deaths at one time point are shown by a stepladder. The median duration corresponding to 50% survival (0.5 on the $y$-axis) is nearly 37 months by this method. This is very different from the 43 months arrived at if the life table method is used.

Both the life table and K-M methods use all the censored durations, but the life table method assumes half intervals for censored observations. Thus, of the two, the K–M method is considered a better method. In any case, as you can easily appreciate, observation of values in intervals rather than exact values implies loss of information.

The validity conditions of K-M are that (i) censoring is unrelated to prognosis or survival in comparison with the other subjects in the group, (ii) the chance of survival of subjects enrolled early in the study is the same as that of those recruited late, and (iii) duration is exactly recorded and not in intervals.

If you want to see the K-M method in action, there are a large number of articles in the literature. One among them is by Takeda et al. [2], who used the K-M method to study the duration of continuation with a dorzolamide/timolol fixed-combination ophthalmic agent regimen in glaucoma patients who had been treated earlier with monotherapy.

A modification of the K-M method is when the data before reaching a certain landmark are ignored, for example, the events occurring between diagnosis and treatment. This is called **landmark analysis** and is discussed in detail by Dafni [3].

## Kolmogorov–Smirnov test

The Kolmogorov–Smirnov (K-S) test is used to find whether observed values fall into a specified **distribution** pattern (one-sample test), or whether the values in two groups follow the same pattern (two-sample test). This test is based on the maximum difference between the cumulative distributions (Figure K.2). This is a nonparametric test that can be used for any distribution, but the variable must be on a continuous scale.

In the case of one sample, this test computes the distances between the observed cumulative relative frequency and the cumulative probability expected under the specified distribution at each observed value. The specified distribution is the **null hypothesis** in this case that we would like to reject. This should be fully specified. If our sample of size $n$ has values ($x_1$, $x_2$, …, $x_n$), the cumulative relative frequency at $x_i$ is the number of values less than or equal to $x_i$ divided by $n$. This would be compared with the corresponding cumulative probability at $x_i$ of the specified distribution, and the difference is obtained. The K-S criterion is the maximum of these differences in absolute value. If the value of the criterion exceeds the value under the null hypothesis at a 5% level of significance, the null is rejected at this level. The values under the null are available in books and statistical software. This is valid for large $n$, but the

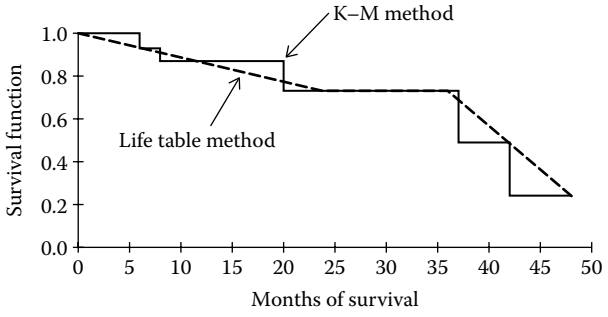

**FIGURE K.1** Survival function of breast cancer cases in our example: life table and K–M methods.

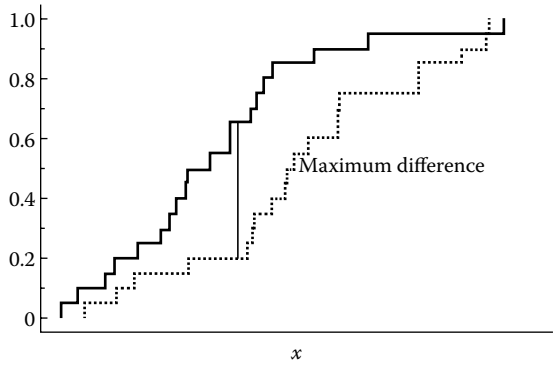

**FIGURE K.2** Maximum difference between cumulative distributions.

exact form is available for certain special cases. In fact, very large $n$ is generally required for a valid K-S test. The criterion was first proposed by Andrey Kolmogorov in 1933 [1], and the values of the criterion under the null were first tabulated by Smirnov in 1939 [2]. These tables became popular only after their publication in 1948 [3].

One practical problem with the one-sample K-S test is that the distribution under the null hypothesis must be fully specified including the values of its parameters. For example, if the specified distribution is Gaussian, its parameters are population mean and population variance, and both must be known. If not known, the usual criterion values under the null cannot be used; instead, they have to be worked out by simulations. When it is known that the distribution under the null is Gaussian, gamma, exponential, or any other, some other parametric test such as the **Anderson–Darling test** may be more powerful in the sense of its ability to detect a difference when really present.

The two-sample analogue of the K-S tests the hypothesis that the two samples come from the same distribution. The groups must be independent for this test. The test computes the differences in the cumulative relative frequencies in the two observed distributions at each observed value in either distribution. The sample sizes can be unequal, but these must be large for K-S test to be valid. The criterion in this case again is the maximum of the differences in the cumulative relative frequencies, as shown in Figure K.2. If the value of this criterion exceeds the value expected under the null (as tabulated by Smirnov), the null is rejected; otherwise, it is not.

The K-S test is conventionally used for uncensored exact continuous (ungrouped) values, but its variations for censored, grouped, or discrete data setups have also been derived [4].

The K-S test is commonly used to find whether the data are violating Gaussianity. This is required for many statistical procedures. For example, Altun et al. [5] used this on serum hepcidin levels and troponin levels in patients with non-ST-elevation myocardial infarction. If the values violate the Gaussian pattern, then nonparametric tests are used. However, just as for almost any statistical test, remember that small samples may not be able to detect a non-Gaussian pattern even if present.

## Kruskal–Wallis test

The Kruskal–Wallis (K-W) test is the nonparametric counterpart of the **one-way ANOVA *F*-test**. This is used to test whether the **central values** such as median in three or more independent groups are equal or not, with the condition that the shape of the distribution is nearly the same in all the groups. The $F$-test is valid only for data in a Gaussian (normal) pattern, but there is no such restriction for the K-W test. Minor violations of Gaussianity are permissible in the case of the $F$-test if the sample size is large, but if the violations are major and the sample size too is small, the K-W test is indicated in place of the $F$-test.

The K-W test was developed by William Kruskal and Allen Wallis in 1952 [1]. This basically is the same as the $F$-test for one-way layout but uses ranks of values instead of the exact values. The use of ranks makes it a nonparametric test and helps to dispense with the condition of Gaussianity.

Consider an example of the cholesterol level in isolated diastolic hypertensives, isolated systolic hypertensives, clear hypertensives, and controls. All subjects are adult females of medium build, the groups are matched for age, and they all belong to the same socio-ethnic group. Thus, the factors that may affect cholesterol level are controlled to a large extent. It is expected that the *pattern* of distribution of cholesterol level in different hypertension groups would be the same but not Gaussian. It is suspected that one or more groups may have measurements higher or lower than the others. The objective is to find whether or not the location (measured by the central values) differences between groups are statistically significant. Because the underlying distribution is not Gaussian, and if, in addition, the number of subjects in different groups is small, the conventional ANOVA cannot be used. The nonparametric K-W test is the right method for such a setup.

Denote the number of groups by $J$, each containing $n$ subjects. For simplicity, let the number of subjects be the same in each group, but that is not a prerequisite. Rank all $nJ$ observations jointly from smallest to largest. Denote the rank of the $i$th subject ($i = 1, 2, \ldots, n$) in the $j$th group ($j = 1, 2, \ldots, J$) by $R_{ij}$. Let the sum of the ranks of the observations in the $j$th group be denoted by $R_{\bullet j}$, i.e., $R_{\bullet j} = \Sigma_i R_{ij}$, If there is no difference in the location of the groups, then $R_{\bullet 1}$, $R_{\bullet 2}$, …, $R_{\bullet J}$ should be nearly equal and their variance nearly equal to 0. The following criterion exploits this premise:

$$\text{Kruskal–Wallis (K–W) test: } H = \frac{12}{nJ(nJ+1)} \frac{1}{n} \Sigma_j R_{\bullet j}^2 - 3(nJ+1).$$

When ties occur (two or more values are the same), the observations are assigned average ranks. In this case, the criterion changes slightly. For details, see Hollander and Wolfe [2]. Standard statistical packages automatically take care of such contingencies.

If the null hypothesis of equality of groups were true, the value of $H$ would be small. The distribution of the criterion $H$ under $H_0$ is known, and the $P$-value corresponding to the calculated value of $H$ for a set of data can be obtained. Again, it is better to leave it to a statistical software package to give the $P$-value. But it has limitations; for example, for three groups, the differences between the groups cannot be statistically significant by the K-W test unless $(n_1 + n_2 + n_3) \geq 7$ and at least two groups have two or more subjects. Software may give exact $P$-values for higher $J$ and higher $n$. If not, for four or more groups or any $n_j \geq 6$, the criterion $H$ in the preceding equation can be approximated by **chi-square** with $(J - 1)$ degrees of freedom (df's). In that case, reject $H_0$ if the calculated value of $H$ exceeds the critical value of chi-square at the desired significance level.

Pursuing the example cited earlier, consider cholesterol level in females with different types of hypertension and controls, as given in Table K.2, where the definition of various types of hypertension is also given. Isolated systolic and isolated diastolic hypertension are no longer considered benign conditions—they are recognized as cardiovascular risk factors. Also given in parentheses in this table are the joint ranks. The last column is the sum of the ranks ($R_{\bullet j}$) for the group. Note the split ranks at the tied values.

**TABLE K.2**
**Cholesterol Level in Women with Different Types of Hypertension**

| Hypertension Group | Total Plasma Cholesterol Level (mg/dL)[a] | | | | | Sum of Ranks |
|---|---|---|---|---|---|---|
| No hypertension—control | 221 | 207 | 248 | 195 | 219 | |
| (DBP < 90, SBP < 140)[b] | (8) | (2.5) | (16) | (1) | (7) | (34.5) |
| Isolated diastolic hypertension | 217 | 258 | 225 | 215 | 228 | |
| (DPB ≥ 95, SBP < 140) | (5) | (17) | (9) | (4) | (11) | (46) |
| Isolated systolic hypertension | 262 | 227 | 207 | 245 | 230 | |
| (DBP < 90, SBP ≥ 150) | (18) | (10) | (2.5) | (15) | (12) | (57.5) |
| Clear hypertension | 218 | 238 | 265 | 269 | 240 | |
| (DBP ≥ 90, SBP ≥ 140) | (6) | (13) | (19) | (20) | (14) | (72) |

*Note:* The hypertension categories are not exhaustive: For example, a subject with DBP = 92 and SBP = 138 mmHg would not be in this study.

[a] Rank of the value in the parentheses.

[b] DBP, diastolic blood pressure (mmHg); SBP, systolic blood pressure (mmHg).

In this case, $J = 4$ and $n = 5$. Using the sum of the ranks in the groups (last column), from the criterion given earlier:

$$H = \frac{12}{5\times 4(5\times 4+1)}\frac{1}{5}(34.5^2+46^2+57.5^2+72^2) - 3(5\times 4+1)$$

$$= 4.4.$$

Since the number of groups is four, we can use the chi-square approximation. A computer package gives $P = 0.2203$. This is not sufficiently small, and therefore, the null hypothesis of equality of locations of the groups cannot be rejected. Note that this conclusion is reached despite major differences in the value of $R_{\bullet j}$ in the four groups. The K-W test reveals that those differences in this example may have arisen from a sampling fluctuation when the groups actually have the same location.
