

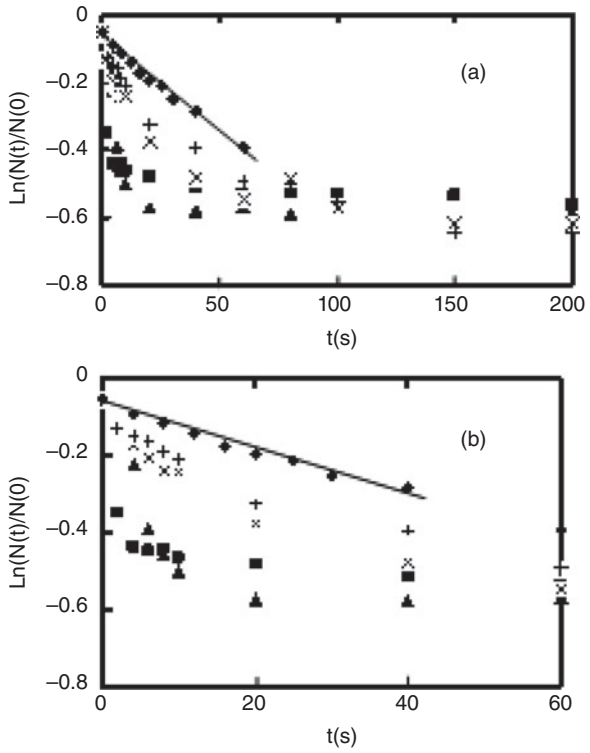

FIGURE 38.16 Plot of $\ln(N(t)/N(0))$ versus t for flocculation induced with an application of polyelectrolyte. The background solution of KCl is 1.0 M; $N(0) = 5.11 \times 10^7$ 1/cm^3. (a) The results for higher molecular weight of polyelectrolyte (MW = 4.9×10^6 g/mol). (b) Figure scaled up to 60 s. The solid line represents the regression line of the result of salt-induced coagulation taken from Fig. 38.13. Symbols: (□) 0.2 ppm, (+) 0.5 ppm, (▲) 1 ppm, (■) 3 ppm [14].

ratio of the rate of polymer flocculation and that of salt-induced rapid coagulation η, the effective layer thickness δ_H of adsorbed polymer flocculants can be evaluated by the following equation:

$$\eta = \frac{(a_0 + \delta_H)^3}{\alpha_T \cdot a_0^3} \tag{38.46}$$

The value of η is noteworthy. It was found to increase with an increase in polymer dosage [56–59]. Surprisingly, in some time, the value was found to be close to 100. At the same time, flocculation will cease immediately at high dosage. Our earlier studies revealed that the state of a polymer in a solution, rather than the equilibrium state of adsorption, is critical. Our recent work using polyelectrolyte with molecular weight of 4900 kDa demonstrated in Fig. 38.16 implies the possibility of stretching polymer by mixing will also contribute to the formation of floc. Thus, the estimated value of δ_h is much larger than the size of the same polymer obtained by viscosity and dynamic light scattering [14] as illustrated in Fig. 38.17.

38.6 CONCLUSION AND FUTURE PERSPECTIVES

One can immediately imagine that geometry of collisions will be an effective factor in the dynamics of flocculated suspension. However, it is not easy to obtain clear data. In this chapter, we introduced results obtained mainly in our laboratory.

Actually, the genetic structure is not merely the result of kinetics but will affect the kinetics profoundly. In the present chapter we assumed that flocs are monodispersed. Analysis of the effect of polydispersity and permeability is still in a primitive stage and future studies are needed to confirm these early theories.

Another major issue awaiting future research will be concentrated suspension.

ACKNOWLEDGMENT

The author expresses his gratitude to Dr. Motoyoshi Kobayashi and Mr. Takuya Sugimoto for fruitful discussion of collision dynamics. The work is partly founded by Kakenhi (Grant 222408025).

ANISOTROPIC GEL FORMATION INDUCED BY DIALYSIS

Toshiaki Dobashi and Takao Yamamoto
Graduate School of Science and Technology, Gunma University, Gunma, Japan

39.1 INTRODUCTION

Gels consist of a polymer network swollen by their medium. The cross-linking sites of a polymer network are usually dispersed randomly in gels, resulting in a macroscopically isotropic and homogeneous structure. This is because the maximum entropy of easily deformed polymer segments between cross-linking sites is obtained when the number of conformational states is maximum, specifically, in the isotropic and homogeneous states. In materials science and technology, however, it is sometimes important to control the anisotropic properties of materials. The anisotropy of gels is even more important in biological organisms, since gels in organisms such as those in muscles and blood vessels are anisotropic, having an advantage of function in organisms [1]. A crystal lens has anisotropy with an even gradient [2]. Therefore, anisotropy is often one of the required factors for artificial tissues and organs [3]. If polymer molecules in gels are rigid and strictly aligned in a particular direction, however, the entropy gain becomes smaller and the gel state becomes unstable. Therefore, various attempts to achieve a good balance between the abovementioned competitive effects, that is, an energetic penalty for an isotropic arrangement and an entropic penalty for molecular alignment, have been performed to obtain anisotropic gels [4–13].

Among the methods for preparing anisotropic gels, dialysis-induced gelation [14] has the advantage that the balance between the two effects is automatically obtained by self-organization and the gel formation, which is closely related to the appearance of anisotropy, can be analyzed by means of nonequilibrium thermodynamics [15]. In this method, polymer solutions are brought in contact with cross-linker solutions at an interface that is not permeable to polymer molecules but permeable to the solvent and medium, a solution of low-molecular-weight molecules including cross-linkers. Cross-linking starting from the interface enables us to obtain anisotropic gels. In Section 39.2, we describe the preparation of gels in detail and the resulting characteristics of the gels, focusing on the gelation process. In Section 39.3, a theoretical treatment of the analysis of gel formation process is provided. In Section 39.4, some of the applications reported previously and their potential uses are summarized.

39.2 DIALYSIS-INDUCED GELATION

39.2.1 Boundary Conditions

Dialysis-induced gelation is realized under various boundary conditions, as shown in Fig. 39.1. Figure 39.1a shows the most common means of dialyzing polymer solutions into a medium, where the boundary between the polymer solution and the medium is determined by the dialysis tube. Unless the resultant gel is too swollen or shrunk to detach itself from the dialysis tube, the boundary between the gel phase and medium is almost fixed during gelation. In Fig. 39.1b, a polymer solution is placed in a cell consisting of a set of circular parallel plates surrounded by a dialysis tube, and immersed in the medium. In this case, the boundary between the polymer solution and the resultant gel is partly fixed by the two plates and partly determined by the dialysis tube. In Fig. 39.1c, a polymer solution is sandwiched between a set of circular

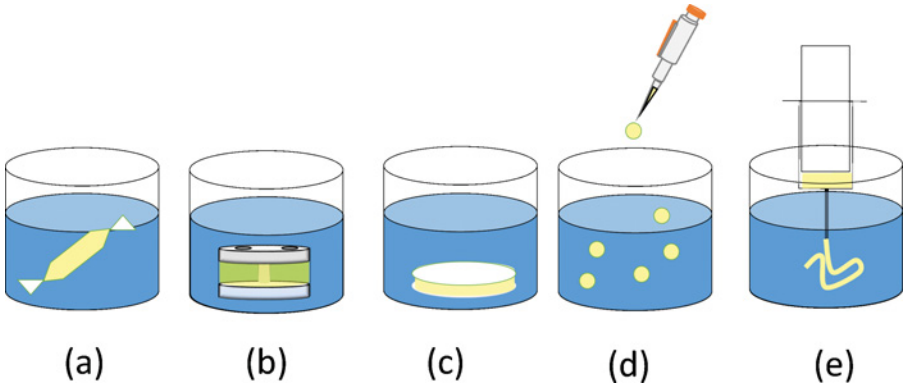

FIGURE 39.1 Illustration of dialysis-induced gelation by various methods under different boundary conditions.

parallel plates and immersed in the medium. Although there is no separation between polymer solutions and the medium, a thin gel membrane produced with the first contact of the polymer solution and the medium at the contact surface can serve as a dialysis tube, resulting in dialysis-induced gelation. The gelation shown in Fig. 39.1a–c is regarded as a process involving the growth of a gel layer toward the center. We also note that the geometry in (a) – (c) in Fig. 39.1 is cylindrically symmetrical. In Fig. 39.1c, we can use two parallel plates with various shapes to design different boundary conditions. For example, using square parallel plates, we obtain a geometrical condition having a fourfold rotation axis. If we drip a polymer solution into a medium, polymer molecules at the surface of the droplet cross-link on contact and the resulting thin concentric gel membrane serves as a spherical dialysis membrane [16], as shown in Fig. 39.1d. The geometry in this case is spherically symmetric. If we keep adding a polymer solution into the medium, we obtain a threadlike gel, as shown in Fig. 39.1e. In Figs. 39.1d,e, the position of the boundary surface between the initially yielded gel and the medium is maintained only when the cross-linking rate and cross-linking density at the surface are sufficiently large to maintain the shape. Otherwise, the polymer solutions dissolves in a large amount of the medium or the boundary largely deforms with time.

39.2.2 Birefringence of Dialysis-Induced Gel

Various combinations of rodlike or semiflexible polymer solutions, such as collagen, Curdlan, carboxymethylcellulose (CMC), chitosan, gelatin, polyglutamic acid, polylysine, arginic acid, and κ-carrageenan, and their appropriate media yield anisotropic gels, as shown in Fig. 39.2, under the boundary condition shown in Fig. 39.1a or c [17–24]. In all figures, black crossed lines are observed under crossed nicols. From optics [25], the symmetric axis of molecular alignment is in the radial direction. Among the combinations, the direction of molecular alignment was determined to be circumferential for the collagen and arginic acid systems [19,23]. A clear birefringence gradient is observed for all the gels. The turbid stripes observed in Figs. 39.2i and iii are attributed to the coupling of gelation and other physical phenomena such as phase separation. All the images observed under different boundary conditions, denoted as (a)–(e) in Fig. 39.1, exhibit

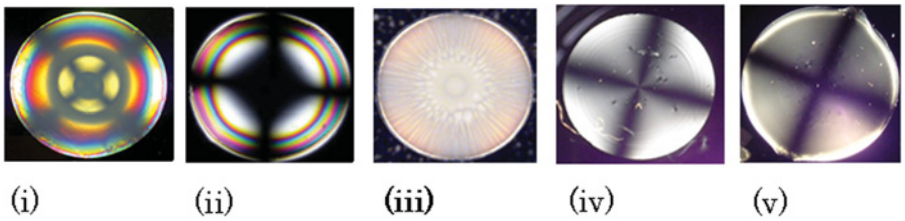

FIGURE 39.2 Gels observed under crossed nicols for polymer solution/medium systems using the boundary condition (a) or (c) in Fig. 39.1. The gels prepared under condition (a) were excised perpendicularly to the long axis of the dialysis tube, and the gels prepared under condition (c) were stripped off the plates. The photographs were taken from the top view: (i) Curdlan in NaOH solution/$CaCl_2$ solution (from Ref. 14, Fig. 2); (ii) DNA in buffer of pH 9.2/$CoCl_2$ solution (from Ref. 17, Fig. 1); (iii) CMC in pure water/$CaCl_2$ solution (from Ref. 18, Fig. 1); (iv) chitosan in acetic acid solution/NaOH solution (from Ref. 24, Fig. 1a); (v) myosin in pure water/glutaraldehyde solution. For a color version of this figure, see the color plate section.

clear birefringence (not shown). Therefore, the appearance of birefringence induced by dialysis should be a universal phenomenon. On the other hand, when we lower the concentrations of cross-linkers in the medium, the birefringence of the gels becomes weaker and finally disappears. These results suggest that a large chemical potential difference of polymer molecules at the interface between the polymer solutions and the medium is a necessary condition for yielding anisotropic gels.

39.2.3 Trigger for Gelation

Although the appearance of anisotropy is a common feature of dialysis-induced gelation, the cross-linking mechanism depends on the system. For example, the gelation of the solutions of DNA [17] and CMC [18] in Fig. 39.2ii and iii is induced by the cross-linking of polymer molecules by multivalent cations. Thus, the inflow of multivalent cations in the medium triggers gelation. In contrast to these systems, the gelation of the solution of chitosan in Fig. 39.2iv is induced by changing the pH of the solution to decrease the charge of polymer molecules to allow cross-linking due to hydrogen bonding. In this case, both the inflow and outflow of H^+ and OH^- from the polymer solution induce gelation. In Fig. 39.2i, the gelation mechanism is even more complex. Curdlan, (1→3)-β-D-glucan, is dissolved in an alkaline solution with a high pH. By lowering the pH of the solution, the Curdlan solution gels because the charge of Curdlan molecules is reduced, resulting in the disappearance of ionic binding sites and in a conformational change of Curdlan to induce cross-linking due to hydrogen bonding. The Curdlan solution also gels with cross-linkers of multivalent cations such as calcium cations. Therefore, when the Curdlan solution with a high pH is dialyzed into calcium chloride solution, both the inflow of calcium cations and the outflow of hydroxide ions induce gelation. The gelations by calcium-ion-induced cross-linking and hydrogen-bonding-induced cross-linking are competitive. As shown in Section 39.3, calcium-ion-induced cross-linking in the initial process and hydrogen-bonding-induced cross-linking in the late process are suggested from the results of a series of experiments and comparison with a theoretical argument. Interestingly, no calcium ions were detected in the polymer solution in the initial gelation, indicating that all the calcium ions in the inflow are used for cross-linking Curdlan to grow the gel layer. A dual cross-linking mechanism similar to that of the above-mentioned Curdlan system is also observed for DNA in a buffer of pH 9.2 dialyzed into a multivalent cation solution (Fig. 39.2ii) [9]. In this case, the pH of the solvent of DNA decreases, resulting in a decrease in the charge of DNA molecules and ultimately in the number of cross-linking sites during gelation. Although the mechanism of cross-linking is complex and depends on the system, gelation always consists of (1) irreversible molecular diffusion in both the polymer solution and the medium, (2) irreversible trans-interface molecular diffusion, (3) a reversible change in the conformation and charge of polymer molecules resulting from a change in the solvent composition, and (4) a reversible or irreversible molecular alignment starting from the interface between the polymer solution and the medium and the reversible or irreversible cross-linking of polymer molecules under the condition that the polymer solution is confined in a limited space.

39.2.4 Dynamics of Gelation

Figure 39.3 shows a typical example (chitosan in a low-pH solution dialyzed in a high-pH solution, as shown in Fig. 39.2iv, using square coverglasses as parallel plates) of the timecourse of anisotropic gelation. The front lines of the turbid gel layer and birefringent layer are traced under observation with open nicols and crossed nicols, respectively. To monitor the pH change, a small amount of litmus reagent is added to the chitosan solution, and the interface between the pink zone (acidic) and sky-blue zone (alkaline) is also traced during gelation. Clear boundaries between the layers with and without birefringence, between the turbid gel layer and the transparent sol, and between the pink zone and the sky-blue zone develop during dialysis. Figure 39.4 shows that during gel formation by the sandwich method, all the front lines of gelation, orientation, and pH change proceed simultaneously [24]. The mechanism of the synchronization of the motion of the front lines may be related to the gradient of the chemical potential of chitosan near the boundary layer. The results also indicate that anisotropic gelation can be traced by examining only the gel layer thickness x against the dialysis time t. Figure 39.5 shows the time course of x plotted using the scaled variables $\tilde{x} = x/R$ and $\tilde{t} = t/R^2$, where R is the radius of the parallel plates in Fig. 39.1c. The perfect superposition irrespective of the radius in the scaling plot and initial proportional relationship between $\tilde{x}^2$ versus $\tilde{t}$ (not shown) suggest a diffusion-limited process. Such a scaling relationship and the initial proportional behavior were observed for all systems previously reported. Thus, these characteristic behaviors are universal for dialysis-induced anisotropic gelation. On the other hand, the dynamics in the late process are different from each other and depend on the system.

39.3 THEORETICAL TREATMENT OF ANALYSIS OF DIALYSIS-INDUCED GELATION

The gelation mechanisms for the systems investigated so far are classified into four types; (1) gelation induced by the inflow of cross-linking agent, (2) gelation induced by a pH change due to both the inflow and outflow of ions, (3) gelation accompanied by a transition in mechanism, and (4) gelation induced by a dual mechanism.

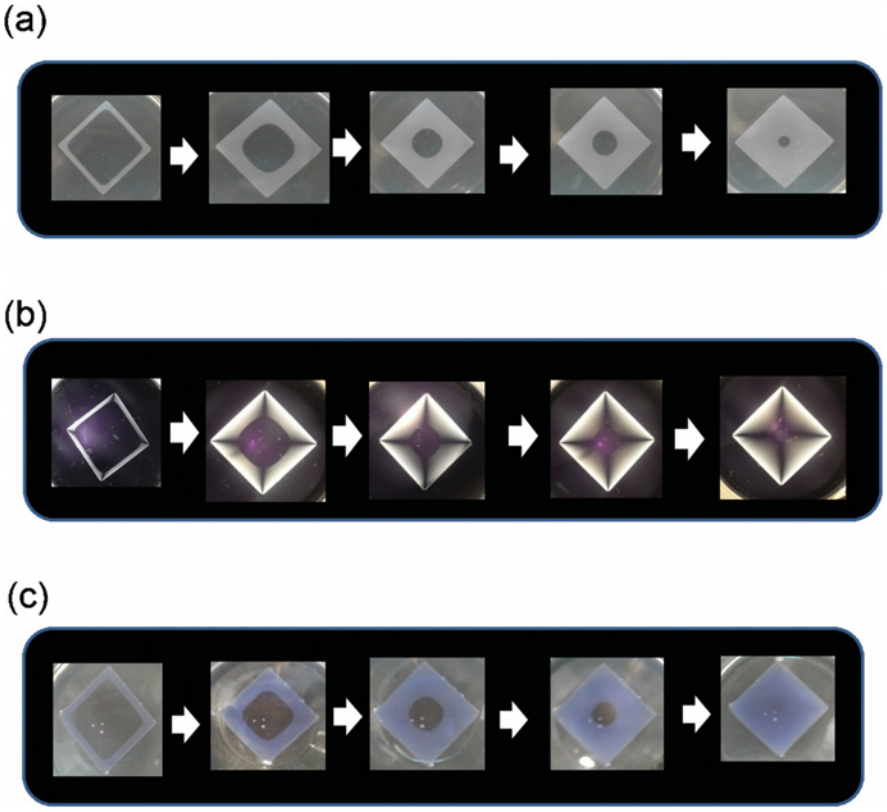

FIGURE 39.3 Development of birefringent, turbid, and sky-blue layers for the system of chitosan in acetic acid solution/NaOH solution under the square boundary condition in Fig. 39.2iv.

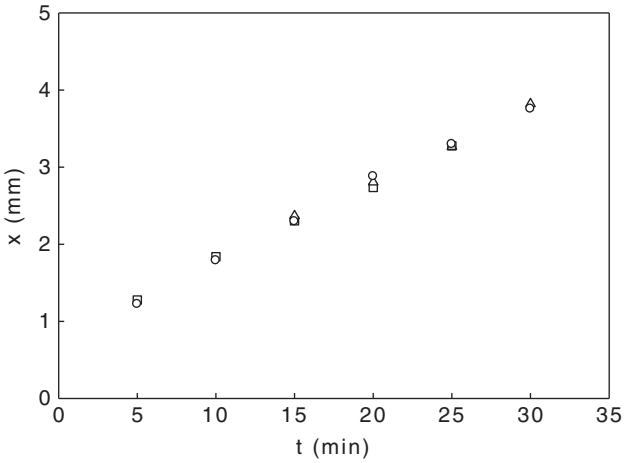

FIGURE 39.4 Timecourse of distance from edge of coverglass to interface between gel layer and sol core observed under open nicols (gel thickness) (∘), to interface between oriented layer and amorphous core observed under crossed nicols (oriented layer thickness) (□), and to interface between pink layer and sky-blue core dyed by litmus agent (△) (high-pH layer thickness) in immersion process of 200 μL of chitosan solution (1 wt% chitosan in 1 wt% aqueous acetic acid with 0.05 g/dL litmus agent) in 40 mL of 0.3 M NaOH for the system shown in Fig. 39.2iv. 39.3.1 Dynamics of Gelation Induced by a Cross-Linking Agent

The gelation of the solutions of DNA, CMC, and Curdlan (early stage) is induced by cations flowing from the medium into the inner polymer solution. The inflowing cations cross-link the polymers and serves as a cross-linking agent. Let

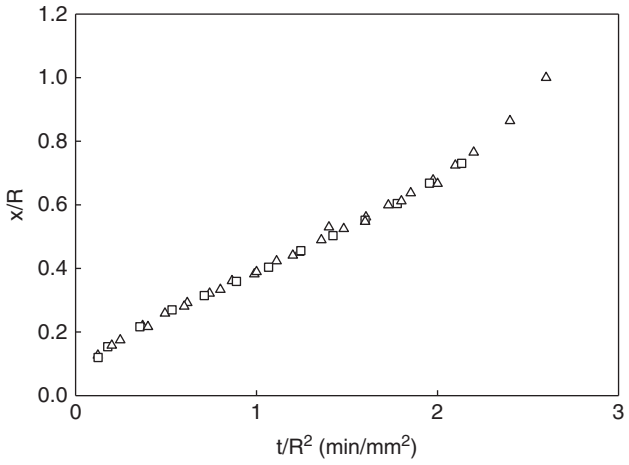

FIGURE 39.5 Timecourse of gel thickness in a scaled plot for system shown in Fig. 39.2iv. The diameters of the coverglasses are 12 mm (□), 15 mm (△), and 18 mm (∘).

us call the ion inducing the gelation by inflowing from the medium to the inner polymer solution the *inflow-ion*. The dynamics of the gelation is quantitatively explained by nonequilibrium thermodynamics based on the following assumptions [15]:

1. All the inflow-ions arriving at the inner polymer solution instantly cross-link with the polymers to produce a new gel layer.
2. The gel layer does not capture the inflow-ions as a sink, i.e., all the inflow-ions arrive at the inner polymer solution through the gel layer to realize a steady state.
3. The medium, gel and inner polymer solution are in local thermodynamic equilibrium at the boundary.

Assumption 1 ensures that the boundary between the gel layer and the inner solution is macroscopically sharp and that the gel formation dynamics can be visualized by tracking the motion of the boundary. The method in which the timecourse of the gelation is expressed by the boundary motion is called the *moving-boundary picture*.

Here, let us choose a system with cylindrical symmetry, specifically, the system sandwiched between two parallel circular glass plates with radius R. For a cylindrically symmetric system, the boundary is also cylindrically symmetric; the boundary is expressed as a circle concentric with the circular glass. The gel layer width x denotes the difference between the radii of the two circles. The relationship between the immersion time t and the gel layer width x is derived on the basis of nonequilibrium thermodynamics and assumptions 1–3.

As shown in Fig. 39.6, ρ_s, ρ_s', and ρ_0' denote the inflow-ion concentrations in the medium and in the gel layer at the boundaries with the medium and with the inner polymer solution, respectively. These concentrations are independent of the immersion time. The inflow-ion concentration ρ_0 in the inner polymer solution is zero because of assumption 3. The inflow-ion concentration at a distance r from the center of the cylinder is denoted by $\rho'(r)$, where $R - x \le r \le R$, $\rho'(R - x) = \rho_0'$, and $\rho'(R) = \rho_s'$.

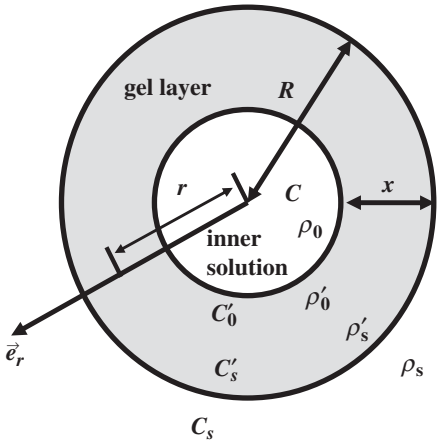

FIGURE 39.6 Upper view of dialysis system. The variables used to describe the theory are shown.

At the boundaries between the gel and the medium and between the gel and the inner polymer solution, the chemical potentials of the inflow-ion are balanced because of assumption 3:

$$\begin{cases} \mu_s^{\text{in}}(\rho_s) = \mu_G^{\text{in}}(\rho_s') \\ \mu_G^{\text{in}}(\rho_0') = \mu_0^{\text{in}}(0) \end{cases} \tag{39.1}$$

where μ_s^{in}, μ_0^{in}, and μ_G^{in} are respectively the chemical potentials of the inflow-ion in the medium, inner polymer solution, and gel layer. The cylindrical symmetry allows us to assume that the inflow-ion flux $\vec{j}^{\text{in}}$ is always along the radial direction and depends on only the distance r. Thus, we have

$$\vec{j}^{\text{in}} = -j^{\text{in}}\vec{\text{e}}_r \tag{39.2}$$

where j^{in} is the flux density and $\vec{\text{e}}_r$ is the unit vector along the radial direction. According to Fick's law, the velocity of the inflow-ion in the radial direction at a distance r is given by

$$v^{\text{in}} = -k^{\text{in}}\frac{\partial \mu_G^{\text{in}}(r)}{\partial r} \tag{39.3}$$

where k^{in} is the mobility of the inflow-ion and is assumed to be independent of the position in the gel layer. The flux density is given by

$$j^{\text{in}} = v^{\text{in}}\rho'(r) = -k^{\text{in}}\rho'(r)\frac{\partial \mu_G^{\text{in}}(r)}{\partial r}. \tag{39.4}$$

Assumption 2 requires that

$$\text{div}\vec{j}^{\text{in}} = -\frac{1}{r}\frac{\partial r j^{\text{in}}}{\partial r} = 0. \tag{39.5}$$

From the above equation, we obtain

$$j^{\text{in}}(r) = \frac{A}{r} \tag{39.6}$$

where A is a constant of integration determined by the boundary condition [Eq. (39.1)]. Using Eq. (39.4), we can rewrite Eq. (39.6) as follows:

$$-k^{\text{in}}\rho'(r)\frac{\partial \mu_G^{\text{in}}(r)}{\partial r} = \frac{A}{r} \tag{39.7}$$

Integrating both sides of the above equation from $r = R - x$ to $r = R$, we have

$$k^{\text{in}}[g^{\text{in}}(\rho'_s) - g^{\text{in}}(\rho'_0)] = A \ln \frac{R}{R-x} \tag{39.8}$$

where $g^{\text{in}}(\rho')$ is the partial pressure of the inflow-ion in the gel layer and is expressed in terms of the free energy satisfying

$$\mu_G^{\text{in}}(\rho') = \frac{\partial f_G^{\text{in}}(\rho')}{\partial \rho'} \tag{39.9}$$

as

$$g^{\text{in}}(\rho') = \rho' \mu_G^{\text{in}}(\rho') - f_G^{\text{in}}(\rho'). \tag{39.10}$$

Equation (39.8) gives the constant of integration as follows:

$$A = \frac{k^{\text{in}}[g^{\text{in}}(\rho'_s) - g^{\text{in}}(\rho'_0)]}{\ln \frac{R}{R-x}} \tag{39.11}$$

Therefore, the flux density j^{in} is given by

$$j^{\text{in}}(r) = \frac{k^{\text{in}}[g^{\text{in}}(\rho'_s) - g^{\text{in}}(\rho'_0)]}{\ln \frac{R}{R-x}} \frac{1}{r} \tag{39.12}$$

By denoting the number of inflow-ions required to produce a unit volume of the gel by ρ_G, we find that assumption 1 gives the relationship between the time interval dt and the width of the newly produced gel layer dx

$$2\pi R j^{\text{in}}(R) dt = \rho_G 2\pi (R - x) dx \tag{39.13}$$

From Eqs. (39.12) and (39.13), the time development equation of the gel width x is given by

$$\frac{dx}{dt} = K \frac{1}{(R-x) \ln \frac{R}{R-x}} \tag{39.14}$$

where

$$K = \frac{k^{\text{in}}[g^{\text{in}}(\rho'_s) - g^{\text{in}}(\rho'_0)]}{\rho_G} \tag{39.15}$$

Note that ρ_G is an increasing function of the concentration of the polymer in the inner solution since the number of cross-linking agent molecules required to cross-link the polymer increases with increasing number of polymer molecules in the inner solution. Thus, the coefficient K decreases with increasing concentration of the polymer in the inner solution.

In terms of the scaled time $\tilde{t} = t/R^2$ and the scaled width $\tilde{x} = x/R$, we have the following "universal" expression independent of the radius of the parallel plates, R:

$$\frac{d\tilde{x}}{d\tilde{t}} = K \frac{1}{(1-\tilde{x}) \ln \frac{1}{1-\tilde{x}}} \tag{39.16}$$

The solution to the above equation is given by

$$\frac{1}{2}(1-\tilde{x})^2 \ln(1-\tilde{x}) - \frac{1}{4}\tilde{x}^2 + \frac{1}{2}\tilde{x} = K\tilde{t} \tag{39.17}$$

The right-hand side (RHS) in the above equation, namely

$$\tilde{y}(\tilde{x}) \equiv \frac{1}{2}(1-\tilde{x})^2 \ln(1-\tilde{x}) - \frac{1}{4}\tilde{x}^2 + \frac{1}{2}\tilde{x} \tag{39.18}$$

is a universal function irrespective of the details of the system. Only the parameter K indicates the individuality of the gelation dynamics. The gelation dynamics of the DNA solution plotted in terms of the scaled time and the function $\tilde{y}$ is shown in Fig. 39.7. All the data for the low-pH DNA solutions (pH 6.8, 72, and 7.8) sit on the lines as shown in Fig. 39.7a.

In the initial stage of the gelation process, $\tilde{x} \approx 0$, we have $\tilde{y}(\tilde{x}) \approx \frac{1}{2}\tilde{x}^2$. Then, the square-root-type time development equation

$$\tilde{x} = \sqrt{2K\tilde{t}} \tag{39.19}$$

is obtained.

The square-root behavior appears since the gelation dynamics is inflow-ion-diffusion-limited. Diffusion process is governed by Fick's law, given by Eq. (39.3). The diffusion constant D conventionally characterizing diffusion is defined by the relationship between the flux and the concentration gradient as

$$D = D(\rho') = k^{\text{in}} \rho' \frac{\partial \mu_G^{\text{in}}(\rho')}{\partial \rho'} \vec{e}_r \tag{39.20}$$

Comparing the above equation with the flux expression [Eq. (39.4)], we have the concentration-dependent diffusion constant

$$D = D(\rho') = k^{\text{in}} \rho' \frac{\partial \mu_G^{\text{in}}(\rho')}{\partial \rho'} \tag{39.21}$$

For simplicity, instead of the above "precisely defined" diffusion constant, we focus on the "mean" diffusion constant

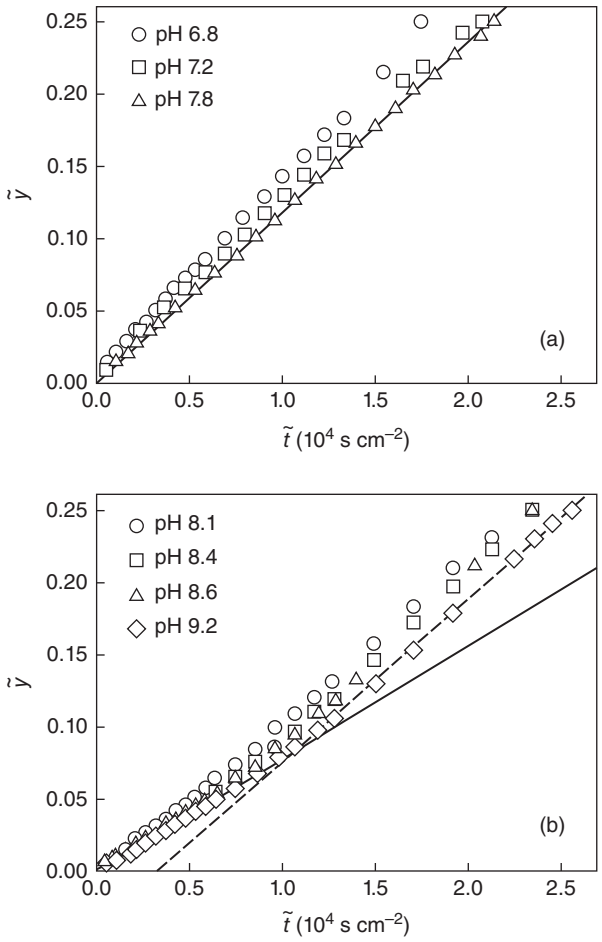

FIGURE 39.7 Gel formation process of DNA solution immersed in $AlCl_3$ solution expressed by the function $\tilde{y}(\tilde{x})$ against the scaled time $\tilde{t}$. The results for DNA solutions with various pH in the range of pH 6.8–9.2 are shown. (From Ref. 9, Fig. 6.) Reprinted with permission from the American Chemical Society.

defined by

$$\bar{D} = \frac{1}{\rho_s' - \rho_0'} \int_{\rho_0'}^{\rho_s'} D(\rho) d\rho \tag{39.22}$$

This equation is rewritten as follows:

$$\bar{D} = \frac{1}{\rho_s' - \rho_0'} \int_{\rho_0'}^{\rho_s'} D(\rho) d\rho = \frac{1}{\rho_s' - \rho_0'} \int_{\rho_0'}^{\rho_s'} k^{\text{in}} \rho \frac{\partial \mu_G^{\text{in}}(\rho)}{\partial \rho} d\rho$$

$$= k^{\text{in}} \frac{1}{\rho_s' - \rho_0'} [g^{\text{in}}(\rho_s') - g^{\text{in}}(\rho_0')]$$

$$= \frac{\rho_G}{\rho_s' - \rho_0'} K \approx \frac{\rho_G}{\rho_s'} K \approx \frac{\rho_G}{\rho_s} K \tag{39.23}$$

From the above equation and the definition of K, we have the following relationship:

$$\bar{D} \approx \frac{\rho_G}{\rho_s} K \tag{39.24}$$

39.3.2 Dynamics of Gelation Induced by pH Change

The gelation of chitosan solution is induced by a pH change. The gelation dynamics induced by a pH change involves ions (e.g., H^+) flowing out of the inner polymer solution to the medium as well as inflow-ions (e.g., OH^-) since both the inflow of ions in the medium and the outflow of ions in the inner polymer solution can change the pH of the inner polymer solution. Let us call the ion inducing gelation by outflowing from the inner polymer solution the *outflow-ion*. The ion outflow reduces the number of inflow-ions ρ_G required to produce a unit volume of gel. Combining the time development equation of ρ_G with the time development equation of the boundary [Eq. (39.16)], we derive the pH-change-type gelation dynamics [26].

New assumptions, namely, that (4) the gel layer does not capture the outflow-ions as a sink, that is, that all the outflow-ions arrive at the medium through the gel layer to realize a steady state; (5) the inner polymer solution is always in thermodynamic equilibrium; and (6) the flows of the inflow-ion and the outflow-ion do not affect each other, are added to assumptions 1–3. Assumption 5 implies that the concentration of the outflow-ion in the inner polymer solution is uniform. The concentration of the outflow-ion in the inner solution is denoted by $C(t)$. As shown in Fig. 39.6, C_s' and C_0' denote the outflow-ion concentrations in the gel layer at the boundaries with the medium and inner polymer solution, respectively. Since the volume of the medium is quite large, the concentration of the outflow-ion C_s in the medium is expected to always be zero. The outflow-ion concentration at a distance r from the center of the cylinder is denoted by $C'(r)$, where $R - x \le r \le R$.

At the boundaries between the gel and the medium and between the gel and the inner polymer solution, the chemical potentials of outflow-ions are balanced because of assumption 3

$$\begin{cases} \mu_s^{\text{out}}(0) = \mu_G^{\text{out}}(C_s') \\ \mu_G^{\text{out}}(C_0') = \mu_0^{\text{out}}(C(t)) \end{cases} \tag{39.25}$$

where μ_s^{out}, μ_0^{out}, and μ_G^{out} are, respectively, the chemical potentials of outflow-ions in the medium, the inner polymer solution, and the gel layer. Note that these chemical potentials are expected to be independent of the inflow-ion concentration from assumption 5. The outflow-ion flux $\vec{j}^{\text{out}}$ is also along the radial direction and depends only on the distance r

$$\vec{j}^{\text{out}} = j^{\text{out}} \vec{e}_r \tag{39.26}$$

where j^{out} is the flux density. The velocity of the outflow-ion in the radial direction at a distance r is given by

$$v^{\text{out}} = -k^{\text{out}} \frac{\partial \mu_G^{\text{out}}(r)}{\partial r} \tag{39.27}$$

where k^{out} is the mobility of the outflow-ion and is assumed to be independent of the position in the gel layer. The flux density is given by

$$j^{\text{out}} = v^{\text{out}} C'(r) = -k^{\text{out}} C'(r) \frac{\partial \mu_G^{\text{out}}(r)}{\partial r} \tag{39.28}$$

Assumption 4 requires that

$$\text{div}\vec{j}^{\text{out}} = \frac{1}{r} \frac{\partial r j^{\text{out}}}{\partial r} = 0. \tag{39.29}$$

From the above equation, we obtain

$$j^{\text{out}}(r) = \frac{B}{r} \tag{39.30}$$

where B is constant of integration determined by the boundary condition. Following the procedure by which the constant A is derived, we have

$$B = \frac{k^{\text{one}}[g^{\text{one}}(C_s') - g^{\text{one}}(C_0')]}{\ln \frac{R}{R-x}} \tag{39.31}$$

where $g^{\text{one}}(C')$ is the partial pressure of the outflow-ion in the gel layer and is given by

$$g^{\text{out}}(C') = C' \mu_G^{\text{out}}(C') - f_G^{\text{out}}(C') \tag{39.32}$$

with the free energy satisfying

$$\mu_G^{\text{out}}(C') = \frac{\partial f_G^{\text{out}}(C')}{\partial C'} \tag{39.33}$$

Here, we use assumption 5, from which the chemical potential of the outflow-ion can be assumed to depend on only the concentration of the outflow-ion and not on that of the inflow-ion. Since the concentration of the outflow-ion in the medium is zero, we can expect that C_0' is also zero. This means that $g_G^{\text{out}}(C_0') \approx g_G^{\text{out}}(0) \approx 0$ and

$$B = -\frac{k^{\text{out}} g^{\text{out}}(C_0')}{\ln \frac{R}{R-x}} \tag{39.34}$$

Then, the flux density j^{out} is obtained as

$$j^{\text{out}}(r) = \frac{-k^{\text{out}} g^{\text{out}}(C_0')}{\ln \frac{R}{R-x}} \frac{1}{r} \tag{39.35}$$

Since the concentration of the outflow-ion in the inner polymer solution is reduced by flow of the outflow-ion and the gel layer does not capture the outflow-ions, we have

$$\pi(R-x)^2 dC = -j^{\text{out}}(R) 2\pi R dt \tag{39.36}$$

Then, using Eqs. (39.35) and (39.36), we have the time development equation for $C(t)$;

$$\frac{dC(t)}{dt} = -2 \frac{k^{\text{out}} g^{\text{out}}(C_0')}{(R-x)^2 \ln \frac{R}{R-x}} \tag{39.37}$$

In terms of the scaled variables $\tilde{t}$ and $\tilde{x}$, the above equation is rewritten as

$$\frac{dC(\tilde{t})}{d\tilde{t}} = -2 \frac{k^{\text{out}} g^{\text{out}}(C_0')}{(1-\tilde{x})^2 \ln \frac{1}{1-\tilde{x}}} \tag{39.38}$$

Note that the scaled gel width $\tilde{x}$ is changing with time, as shown by Eq. (39.16).

The pH change is induced by neutralization by inflowing of the inflow-ions. The number of the inflow-ions required to neutralize the inner solution is proportional to the concentration of the outflow-ions in the inner solution. Hence, ρ_G is expressed as [26]

$$\rho_G = \alpha C \tag{39.39}$$

where α is a positive constant. The above equation indicates that the number of the inflow-ions required to produce a unit volume of gel decreases with increasing immersion time since the concentration C decreases owing to the outflow of ions in the inner solution.

To discuss the dynamics of the gelation induced by a pH change, we take the time development of ρ_G into account. The gelation dynamics is expressed by the simultaneous equations Eqs. (39.16), (39.25), (39.38), and (39.39). To obtain the solution to these equations, we must obtain the thermodynamic functions, the partial pressures g^{in} and g^{out}, and the chemical potentials, μ_0^{in}, μ_G^{in} μ_s^{in}, μ_0^{out}, μ_G^{out}, and μ_s^{out}. In the simplest case, we adopt the ideal gas picture for the inflow-ions and the outflow-ions. Then, the partial pressures are given by

$$\begin{cases} g^{\text{in}}(\rho') = k_B T \rho' \\ g^{\text{out}}(C') = k_B T C' \end{cases}, \tag{39.40}$$

and the relationships between the concentrations at the boundaries are given by

$$\begin{cases} \rho_s' = \rho_s, & C_s' = C_s = 0 \\ \rho_0' = \rho_0 = 0, & C_0' = C \end{cases} . \tag{39.41}$$

From Eqs. (39.39)–(39.41), since the coefficient K given by Eq. (39.15) is expressed as

$$K = K(\tilde{t}) = \frac{\gamma \rho_s}{\alpha C(\tilde{t})} \tag{39.42}$$

with

$$\gamma = k^{\text{in}} k_B T \tag{39.43}$$

and

$$-k^{\text{out}} g^{\text{out}}(C_0') = -\beta C(\tilde{t}) \tag{39.44}$$

with

$$\beta = k^{\text{out}} k_B T \tag{39.45}$$

the simultaneous equations expressing the gelation dynamics [Eqs. (39.16) and (39.38)], are rewritten as

$$\begin{cases} \dfrac{d\tilde{x}}{d\tilde{t}} = \dfrac{\gamma \rho_s}{\alpha C(\tilde{t})} \dfrac{1}{(1-\tilde{x}) \ln \dfrac{1}{1-\tilde{x}}} \\ \dfrac{dC(\tilde{t})}{d\tilde{t}} = -\dfrac{2\beta C(\tilde{t})}{(1-\tilde{x})^2 \ln \dfrac{1}{1-\tilde{x}}} \end{cases} . \tag{39.46}$$

For the initial conditions

$$\begin{cases} C(0) = C_{\text{init}} \\ \tilde{x}(0) = 0 \end{cases} \tag{39.47}$$

the solution to $\tilde{x}(\tilde{t})$ is given by

$$\tilde{z}\left(\tilde{x}; \frac{2\beta}{K_{\text{init}}}\right) = K_{\text{init}} \tilde{t} \tag{39.48}$$

where

$$K_{\text{init}} = \frac{\gamma \rho_s}{\alpha C_{\text{init}}} \tag{39.49}$$

and

$$\tilde{z} = \tilde{z}(\tilde{x}; h) = \int_0^{\tilde{x}} \frac{(1-u) \ln \dfrac{1}{1-u}}{1 - h \ln(1-u)} du \tag{39.50}$$

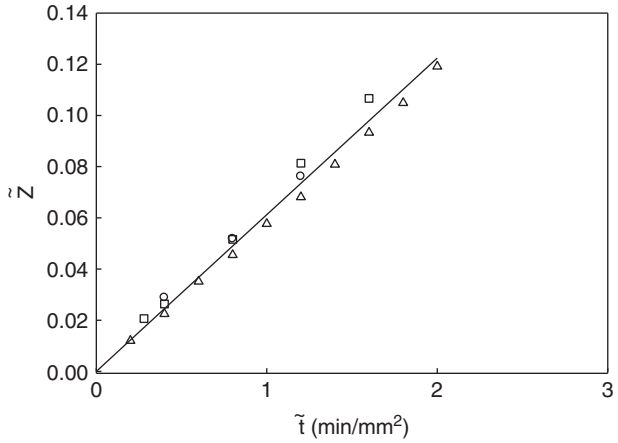

FIGURE 39.8 Gel formation process of chitosan solutions with chitosan concentrations 0.5 % (∘), 1.0% (□), and 1.5% (△) expressed by the function $\tilde{z}(\tilde{x})$ against the scaled time $\tilde{t}$. (From Ref. 27, Fig. 5.) Reprinted with permission from the American Chemical Society.

Equation (39.46) or the solution [Eq. (39.48)] is expressed in terms of only the scaled variables $\tilde{t}$ and $\tilde{x}$. Hence, the scaling relation with respect to the radius R holds even in the pH-change-induced gelation dynamics. The scaling relation showing that the gelation dynamics is expressed in terms of the scaled variables $\tilde{t}$ and $\tilde{x}$ is expected to hold universally since the scaling relation is unaffected by details of the thermodynamic functions for the ions. One significant feature of the time development equation [Eq. (39.48)] is that the equation is independent of the polymer concentration in the inner solution. This is a characteristic feature of the gelation dynamics of pH-change-induced gelation, and, generally, of the thermodynamic-state-change-induced gelation. The independence was experimentally verified by analyzing the gelation of chitosan solution, as shown in Fig. 39.8 [27].

The timecourse of the gelation dynamics induced by a pH change expressed by Eq. (39.48) is different from that induced by inflowing cross-linking agents expressed by Eq. (39.17). The deviation from the cross-linking-agent-induced gelation dynamics is characterized by the parameter h in the function $\tilde{z}$; $\tilde{z}(\tilde{x}; 0) = \tilde{y}(\tilde{x})$. For small values of $\tilde{x}$, the $h \ln(1-u)$ term in the denominator of the integral in Eq. (39.50) is negligible; $\tilde{z}(\tilde{x}; h) \approx \tilde{y}(\tilde{x})$ for $\tilde{x} \approx 0$. Therefore, the timecourse in the early stage is the same as that for the cross-linking-agent-induced gelation:

$$\tilde{y}(\tilde{x}) = K_{\text{init}} \tilde{t}. \tag{39.51}$$

Experimentally, the coefficient K_{init} is obtained from the slope of the initial line of the plot of $\tilde{t}$ versus $\tilde{y}$. The coefficient K_{init} is proportional to the concentration of the inflow-ion in the medium and to the reciprocal of the initial concentration

of the outflow-ion in the inner polymer solution. These features were experimentally verified by analyzing the gelation of chitosan solution [26,27]. Note that $K_{\rm init}$ is independent of the concentration of the polymer in the inner solution, unlike in the case of cross-linking-agent-induced gelation.

In the late stage, where $\tilde{x} \approx 1$, the function $\tilde{z}$ asymptotically behaves as

$$\tilde{z} \approx a + \frac{K_{\rm init}}{2\beta}\left(\tilde{x} - \frac{1}{2}\tilde{x}^2\right), \tag{39.52}$$

where a is a constant. Then, the time course of gelation in the late stage is expressed as

$$\tilde{x} - \frac{1}{2}\tilde{x}^2 = 2\beta\tilde{t} + b \tag{39.53}$$

where b is a constant. The $\tilde{t}$ -linear behavior of $\tilde{x} - \frac{1}{2}\tilde{x}^2$ is a characteristic feature of the late stage. β is obtained from the slope of the linear relationship.

39.3.3 Dynamics of Gelation Accompanied by Transition in Mechanism

Although in the cross-linking-agent-induced gelation, ions in the inner solution also flow out to the medium, the outflow does not affect gelation. However, the outflow of ions in some cases changes the gelation mechanism. During the dialysis of Curdlan solution, the pH decreases with the outflow of ions in the inner solution. This decrease in the pH changes the gelation mechanism from the cross-linking-agent-induced type to the pH-change-induced type. Let us denote the scaled time at which the gelation mechanism changes by $\tilde{t}_c$, and C and $\tilde{x}$ at $\tilde{t}_c$ by C_c and $\tilde{x}_c$ respectively.

In the early stage, i.e., $0 \le \tilde{t} \le \tilde{t}_c$, the dynamics of the gelation is expressed by

$$\tilde{y}(\tilde{x}) = K\tilde{t}. \tag{39.54}$$

The concentration C varies with the elapsed time in accordance with the differential equation

$$\frac{dC(\tilde{t})}{d\tilde{t}} = -\frac{2\beta C(\tilde{t})}{(1-\tilde{x})^2 \ln\dfrac{1}{1-\tilde{x}}}. \tag{39.55}$$

From Eqs. (39.54) and (39.55), we derive the relationship between $\tilde{C}$ and $\tilde{x}$ as

$$\tilde{x} = 1 - \left(\frac{C}{C_{\rm init}}\right)^{\frac{K}{2\beta}}. \tag{39.56}$$

Then, in terms of the transition concentration C_c of the gelation dynamics, the scaled transition width $\tilde{x}_c$ is expressed as

$$\tilde{x}_c = 1 - \left(\frac{C_c}{C_{\rm init}}\right)^{\frac{K}{2\beta}} \approx 1 - \left(\frac{C_c}{C_{\rm init}}\right)^{\frac{\gamma\rho_s}{2\beta\rho_G}}. \tag{39.57}$$

For the transition width, the scaling holds. The transition width increases with increasing initial concentration $C_{\rm init}$ of the outflow-ion and with increasing concentration ρ_s of the inflow-ion.

In the late stage, namely, $\tilde{t}_c \le \tilde{t}$, the dynamics of the gelation is expressed by $\tilde{z}$. Since in this case, the elapsed time is long, the late-stage behavior of $\tilde{z}$ appears; the time development of $\tilde{x}$ is given by the asymptotic form

$$\tilde{x} - \frac{1}{2}\tilde{x}^2 = 2\beta\tilde{t} + b \tag{39.58}$$

39.3.4 Dynamics of Gelation Induced by Dual Mechanisms

In the case of the gelation of DNA solution by aluminum ions, the pH change is induced by ions flowing from the inner solution to the medium and it decreases the number of cross-linking sites of DNA. The decrease in the number of cross-linking sites changes ρ_G from a large value in the early stage to a small value in the late stage. The plot of $\tilde{t}$ vs $\tilde{y}$ is linear in each stage, but its slope differs. Denoting the scaled crossover time from the early stage to the late stage by $\tilde{t}_c$, we obtain the gelation dynamics as [9]

$$\begin{cases} \tilde{y}(\tilde{x}) = K_1\tilde{t} & (0 \le \tilde{t} \le \tilde{t}_c) \\ \tilde{y}(\tilde{x}) = K_2\tilde{t} + (K_1 - K_2)\tilde{t}_c & (\tilde{t}_c \le \tilde{t}) \end{cases}, \tag{39.59}$$

where K_1 and K_2 are respectively the slopes in the early and late stages, and $K_1 < K_2$. As shown in Fig 39.7b, the two-stage gelation behavior appears for the high-pH DNA solution [9].

The time development of the concentration of outflow-ions in the inner solution is governed by Eq. (39.55). Then, the scaled width $\tilde{x}_c$ at the crossover time is expressed by

$$\tilde{x}_c = 1 - \left(\frac{C_c}{C_{\rm init}}\right)^{\frac{K_1}{2\beta}} \tag{39.60}$$

where C_c is the outflow-ion concentration when ρ_G changes. Then, the crossover time is given by

$$\tilde{t}_c = \frac{1}{K_1}\tilde{y}(\tilde{x}_c) = \frac{1}{K_1}\tilde{y}\left(1 - \left(\frac{C_c}{C_{\rm init}}\right)^{\frac{K_1}{2\beta}}\right) \tag{39.61}$$

39.4 APPLICATIONS OF DIALYSIS-INDUCED ANISOTROPIC GELS

Gels showing anisotropy are useful in various applications. Dialysis-induced gelation has been applied for both industrial and biological uses. One team of investigators prepared double-network hydrogels with extremely high mechanical strength containing a synthetic liquid crystalline polyelectrolyte, poly(2,2′-disulfonyl-4,4′-benzidine terephthalamide) (PBDT), using a similar methodology [8,28]. Another group used dialysis-induced anisotropic gelation to control the hierarchical structure of cell scaffolds as a template for constructing artificial tissues that mimic for native tissues [29]. Microfluidic devices have been used to precisely regulate the shape and size of cell scaffolds and to construct engineered tissues in which the arrangement of cells and cell scaffolds was controlled. That group also found that an anisotropic collagen scaffold is useful for bone cell growth.

It is challenging to develop materials consisting of biomolecules without damaging their unique biofunctions, since toxic materials can be selectively adsorbed on them. As a typical example, carcinogenic agents and environmental hormones having planar aromatic groups intercalate with DNA double helices [30,31], thereby inhibiting the interpretation of the hereditary code [32]. This specific property of DNA can be used as for developing the most efficient selective adsorbents for such specific toxic agents. For this application, DNA must be in a water-insoluble state [33, 34]. The water-insoluble anisotropic gel prepared from double-helical DNA by simple dialysis is considered to be an adsorbent with which toxic agents can be extracted effectively (an advantageous gel property) and detected even when agents produce no color in the visible wavelength range (an advantagous birefringent property).

GELS

ETSUO KOKUFUTA

Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan

40.1 INTRODUCTION

The study of gels was one of the most advanced areas in polymer science in the 1990s. According to the terminology of polymers and polymerization processes in dispersed systems (IUPAC Recommendations 2011) [1], a *gel* is defined as "nonfluid colloidal network or polymer network that is expanded throughout its whole volume by a fluid." Along this definition, we can visualize a variety of gels, so that at first the most familiar gels are taken as examples to outline the general characteristics of gels. Here let us look at silica gel, agarose gel, and polyacrylamide gel with respect to their structural characteristics. As shown in Fig. 40.1, silica gel is formed of a colloidal network in which small silica particles are three-dimensionally connected with each other. Perhaps the siloxane bond (≡Si—O—Si≡) plays an important role in forming network junction points on the surface of each particle. The dispersed phase of silica gel is a gas (air), and this type of gel is referred to as *aerogel*. Both agarose and polyacrylamide gels have a covalent polymer network and are defined as *polymer gels*. However, there is a difference in the formation of the network junction points. In the case of agarose gel, the polymer network forms through the physical aggregation of polymer chains, caused by helix formation, which results in regions of local order acting as the network junction points. Agarose is soluble in water at temperatures above 65°C, and the solution (sol) is gelated by cooling during which the helix formation takes place. On further heating the gel becomes sol, indicating that the regions of local order are thermally reversible. Thus, in this case the resulting swollen network may be termed a *thermoreversible gel*. The network of polyacrylamide (PAAm) is formed by cross-linking polymer chains. *N*,*N*′-Methylenebisacrylamide (Bis) is a cross-linker that connects the polymer chains via the covalent bond; thus PAAm gel is not thermoreversible. Agarose and PAAm gels, in which the swelling agent is water, therefore both are defined as *hydrogels.* Although the IUPAC recommendation [1] has provided the definition of a wide range of gels (e.g., soap gels, phospholipids, clays, V_2O_5 gels, and globular or fibrillar protein gels), this chapter focuses on the hydrogels in which the network is formed via cross-linking of synthetic polymer chains with a suitable cross-linking agent. The reason is that many gels of this sort undergo a *volume phase transition* (VPT) in response to an external stimulus, studies of which have contributed to a great advance in our knowledge of polymer gels. The author aims to provide a good understanding of VPT in synthetic polymer gels from different perspectives.

40.2 OUTLINE OF VOLUME PHASE TRANSITION (VPT)

The swelling of polymer gels, such as that observed when rubber is placed in benzene, has long been a well-known phenomenon. As early as 1948, researchers [2] performed a detailed study of the swelling behavior of cellulose xanthate gels in dilute salt solutions. Others [3,4] also made great contributions to understanding the swelling behavior of ionic and neutral gels. In early studies by these pioneers, however, little attention paid to the existence of a critical endpoint in the phase equilibria, although in 1968 two authors [5] published a theoretical paper on this subject. The earliest report of the VPT in a gel was in 1978 by Tanaka [6], who discovered a

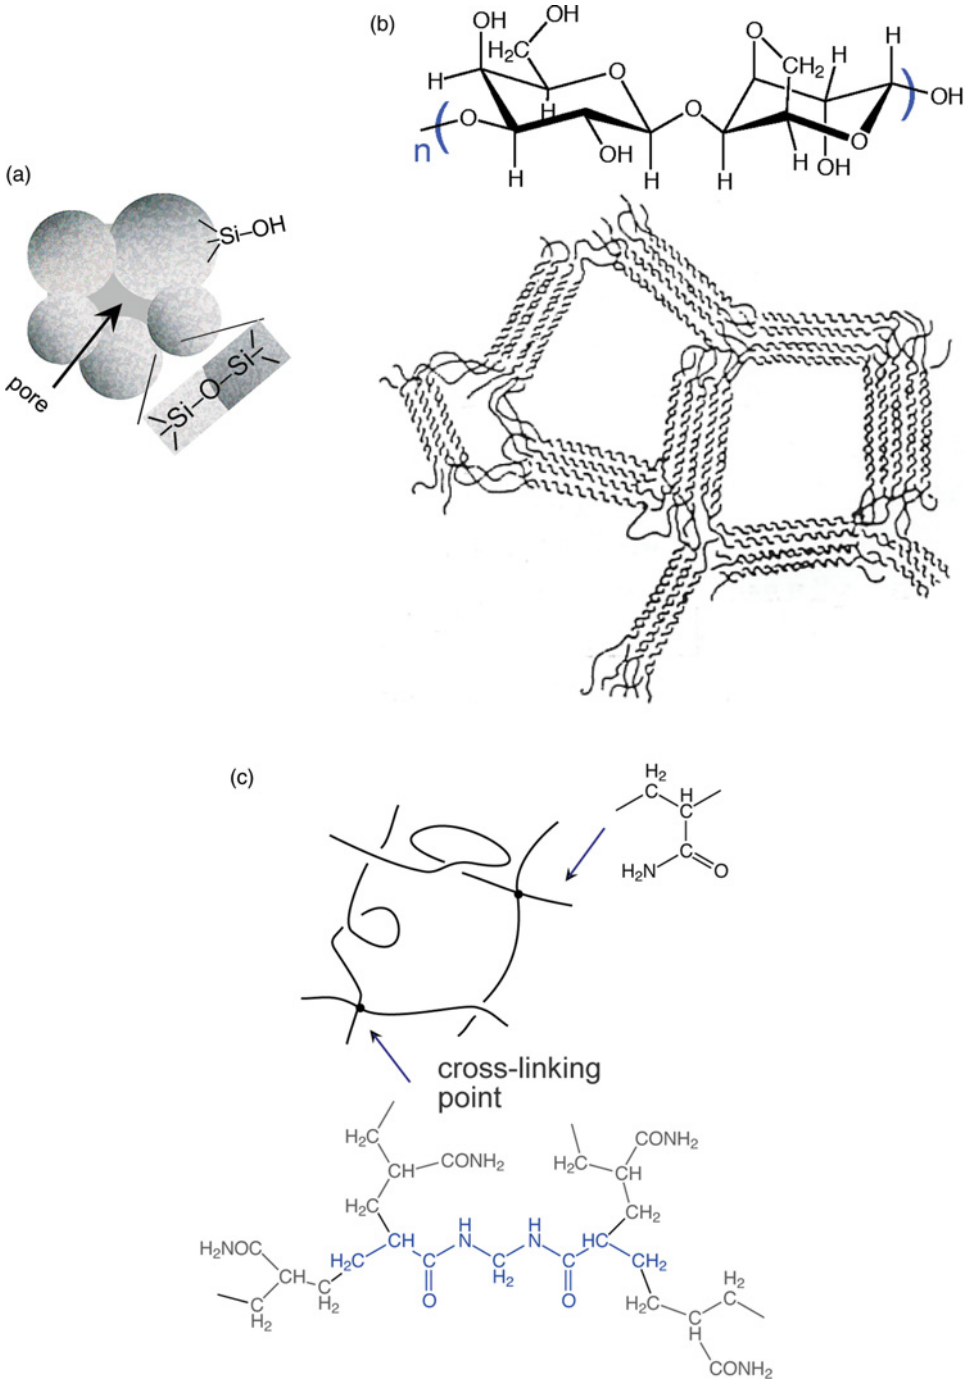

FIGURE 40.1 Schematic illustration of silica gel (a), agarose gel (b), and polyacrylamide gel (c). In (c) the polyacrylamide (PAAm) chains are covalently crosslinked with *N*,*N*′-methylenebisacrylamide (Bis) (see chemical structure of cross-linking point).

discontinuous volume collapse of PAAm gels in acetone–water mixtures when varying the temperature or the composition of the mixture. This phenomenon is now referred to by the acronym VPT (or simply as *phase transition*) of gels and is observed in many gels of synthetic and natural polymers. The VPT is accompanied by reversible, discontinuous (or in some cases, continuous) volume changes, often as large as several hundred times, in response to small variations in the solution conditions surrounding a gel. Variables that trigger the VPT include solvent composition, salt concentration, pH, temperature, and small electric fields. Figure 40.2 outlines the VPT of a gel cylindrical in shape [7], which was prepared in

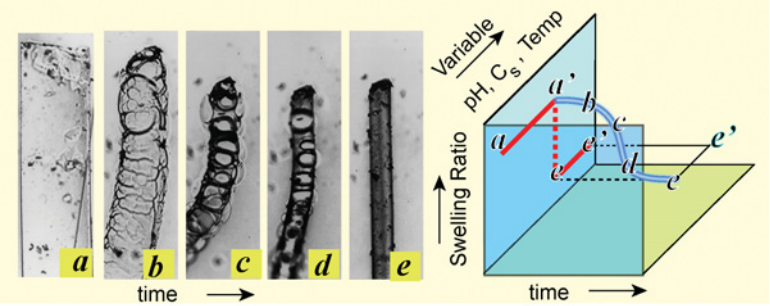

FIGURE 40.2 Volume phase transition (VPT) of a gel in response to a small change of the valuables that are the solution conditions surrounding the gel. Heavy line passing through points a, a', e and e' denotes the equilibrium swelling curve (equilibrium swelling ratio versus valuable). Thin line shows the kinetics curve of the shrinking transition process, in which points a ($\approx a'$) to e ($\approx e'$) correspond to the pictures on the left. (Adapted from Kokufuta 2005 [7].)

a glass capillary with an inner diameter of d_0 (0.29 mm in this case). The gel sample was removed from the capillary, cut into an appropriate size, and purified via repetition of swelling and shrinking in a large volume of the solution for measurement. In this figure, component a shows the gel in the swollen state, which continues until point a', where the gel starts the VPT (shrinking transition in this case). Segments b–d show the process of the VPT, and e is the gel in the fully collapsed state where the size or volume of the gel no longer changes when the surrounding condition such as temperature or pH (i.e., variables) is changed. A heavy line in the 3D graph denotes the equilibrium swelling curve, in which a broken line shows the VPT. A thin line shows the kinetic curve of the VPT. Note that in this chapter, unless otherwise noted, the equilibrium swelling ratio is given as d/d_0 or V/V_0 ($\equiv (d/d_0)^3$), where d denotes the equilibrium diameter of the gel, d_0 is the diameter of the gel when it was prepared, and V and V_0 are the gel volume in the equilibrium state and at the preparation, respectively. Also note that the gel diameters (d_t) during the VPT cannot be precisely determined when bubbles appear on the surface of the gel. At that time, an average value, obtained from the diameters at many positions (usually >10) of the gel, was used as the diameter at time t if we have to investigate the swelling and shrinking kinetics of gels.

40.3 THEORIES OF VPT

For theoretical interpretation of the swelling behavior of gels, it is convenient to imagine that there exists an analogy between swelling equilibrium and osmotic equilibrium. Then it is assumed that the polymer network might play multiple roles as a solute, osmotic membrane, and also pressure-generating device through polymer–solvent mixing effects, network elasticity, and electrostatic interactions of the fixed charges with counterions. According to this consideration, Flory proposed an equation to describe the osmotic pressure (Π) of a gel as a sum of three contributions [3]: $\Pi = \Pi_{\text{mix}} + \Pi_{\text{elas}} + \Pi_{\text{ion}}$, where Π_{mix} represents the contribution from polymer–solvent mixing, Π_{elas} is the elastic contribution due to deforming the network chain from its reference state, and Π_{ion} is the contribution arising from the difference in mobile ion concentrations between the gel and bulk phases. Although Flory's description did not suggest that gels undergo a VPT, Tanaka and his coworkers [7, 8] made several modifications of it to explain their experimental results demonstrating the phase transition in the polymer gels in which the network has a slight amount of charge. Their mathematical description is

$$\Pi = -\frac{N_A kT}{\upsilon_s}\left[\varphi + \ln(1-\varphi) + \frac{\Delta F}{2kT}\varphi^2\right] + \nu kT\left[\frac{\varphi}{2\varphi_0} - \left(\frac{\varphi}{\varphi_0}\right)^{1/3}\right] + \nu f kT\left(\frac{\varphi}{\varphi_0}\right) \tag{40.1}$$

where N_A = Avogadro's number, k = Boltzmann's constant, T = absolute temperature, υ_s = molar volume of the solvent, φ = volume fraction of the network, φ_0 = volume fraction of the network under the theta condition in which the cross-linked chain takes a random walk configuration, ΔF = free-energy change associated with formation of a contact between polymer segments in the network, ν = number of effective chains per unit volume at $\varphi = \varphi_0$, and f = number of counterions per effective chains in the network. It is clear that the first, second, and third terms in Eq. (40.1) are related to Π_{mix}, Π_{elas}, and Π_{ion}, respectively [e.g., 10].

Osmotic pressure Π must be zero when the gel is in equilibrium with the surrounding solvent. Zero osmotic pressure is also necessary for the free energy (F_g) of the gel to be minimized, since $\Pi = -\partial F_g/\partial V$, where V is the volume of the gel and is proportional to φ_0/φ. Using Eq. (40.1), such

conditions may be expressed as

$$\tau \equiv 1 - \frac{\Delta F}{kT} = \frac{\nu v_s}{N_A \varphi^2}\left[(2f+1)\left(\frac{\varphi}{\varphi_0}\right) - 2\left(\frac{\varphi}{\varphi_0}\right)^{1/3}\right] + 1 + \frac{\varphi}{2} + \frac{2\ln(1-\varphi)}{\varphi^2} \tag{40.2}$$

where parameter τ ($= 1 - \Delta F/kT$) is called the *reduced temperature*, which changes with temperature and solvent composition. The equation then determines the equilibrium network concentration as a function of τ. For certain values of τ, however, Eq. (40.2) is satisfied by three values of φ, corresponding to two minima and one maximum of the free energy. The value of φ corresponding to the lower minimum represents the equilibrium value. A discrete volume transition occurs when the two free-energy minima have the same value. Figure 40.3 shows typical swelling curves calculated for an ionic gel as a function of f. In calculations of the equilibrium swelling ratio (φ_0/φ) by Eq. (40.2), Tanaka et al. used $\varphi_0 = 0.5$ and $\nu v_s/N_A\varphi^3 \approx 10$ (i.e., $\nu v_s = 7.5 \times 10^{24}$) [8]. The former value was obtained by assuming that monomers and cross-linkers would be polymerized during gelation in a random-walk fashion to form a network, while the latter was chosen so as to fit the theoretical curves with the experimental data that are obtained from partially hydrolyzed PAAm gels. As can be seen from Fig. 40.3, an increase in f causes a drastic change in both V/V_0 and τ at the transition.

A more detailed comparison of experimental results with the theoretical description was undertaken using a gel composed of *N*-isopropylacrylamide (NIPAAm) and sodium

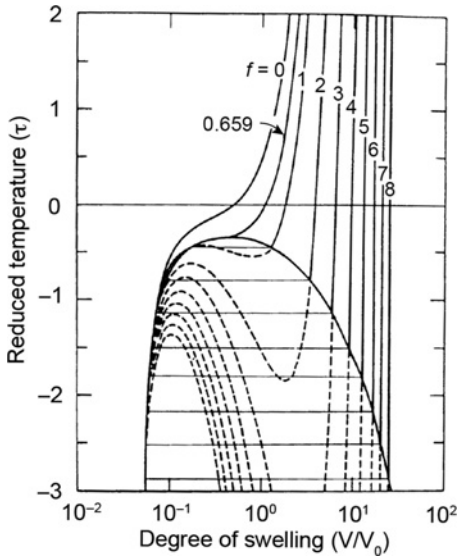

FIGURE 40.3 Relationship between equilibrium degree of swelling ($V/V_0 \approx \varphi_0/\varphi$) and reduced temperature as a function of the numbers (f) of ionized groups per effective chains. (Adapted from Kokufuta 2001 [10] in which the original drawing in [8] was modified with the permission of Prof. T. Tanaka.)

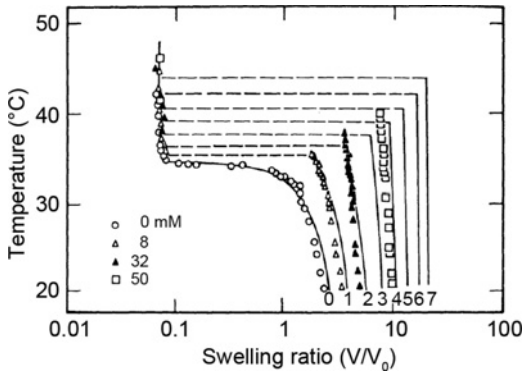

FIGURE 40.4 Temperature dependence of swelling ratio for ionic NIPAAm gels with different amounts of COONa groups. Numbers in the figure denote the f value that is the number of counterions per chain. The curve of $f = 0$ was obtained so as to fit the calculation to the experimental dada (circles) through freely choosing the parameters in Eq. (40.3), which were then used in the calculation of the other curves ($f > 1$). Plots with different symbols are experimental results for the COONa concentrations in mM. (Adapted from Kokufuta 2001 [10] in which the original drawing in [9] was modified with the permission of Prof. T. Tanaka.)

acrylate (NaAAc) [9]. As will be mentioned later, NIPAAm yields thermosensitive polymers or gels; the former undergoes a phase separation, and the latter experiences a volume collapse (shrinking transition) in water on heating to about 32°C. Thus, as shown in Fig. 40.4, the hydrogel without NaAAc (i.e., pure NIPAAm gel) undergoes a continuous VPT at around 34°C. However, an increase in the amount of copolymerized NaAAc causes a large volume change at the transition. At the same time, an increase in transition temperature (T_V) is observed. To compare these results with the theoretical description, term $\Delta F/kT$ (i.e., χ parameter) in Eq. (40.2) was rewritten as $\chi = \Delta F/kT = (\Delta H - T\Delta S)/2kT$. Thus, Eq. (40.2) becomes

$$\frac{1}{T} = \frac{\Delta S}{\Delta H} + \frac{k}{\Delta H}\left\{\frac{\nu v_s}{N_A\varphi^2}\left[(2f+1)\left(\frac{\varphi}{\varphi_0}\right) - 2\left(\frac{\varphi}{\varphi_0}\right)^{1/3}\right] + 1 + \frac{\varphi}{2} + \frac{2\ln(1-\varphi)}{\varphi^2}\right\} \tag{40.3}$$

In calculating the swelling ratio as a function of temperature, the following approach was used in [9]. The equilibrium swelling ratio was calculated using the relation $V/V_0 = \varphi_0/\varphi = (d/d_0)^3$, where d is equilibrium gel diameter and d_0 (1.35 mm) is the inner diameter of the capillary utilized in the gel preparation. Parameter φ_0 (~ 0.07) was obtained from the experimental asymptotic value of V/V_0 at high temperatures (see V/V_0 at temperatures above 35°C). Also, ν (1.0×10^{22} L^{-1}) was from the amount of cross-linker by considering that one cross-linker provides two effective chains in the network at maximum, and ΔH (-8.7×10^{-14} erg) was the literature value [9]. It should

be noted that, because (1) NIPAAm gels in water exhibit an endothermic shrinking on heating ($\Delta H > 0$), but (2) an exothermic swelling on cooling ($\Delta H < 0$) (for example, see Ref. 11, in which references to earlier work may be found), the calculation focuses on the swelling transition. Also note that the ΔH value is based on "one unit" of NIPAAm chains in the gel network; therefore, ΔH becomes 5.3 kJ per unit mole. In addition, it was assumed in [9] that since the transition temperature T_V is determined principally by the $\Delta H/\Delta S$ ratio, ΔS is approximately equal to $\Delta H/T_V$ and the curvature of a swelling curve is determined mainly by the value of ΔH. Taking these observations into account, they obtained the theoretical swelling curve for the NIPAAm gel. However, the estimated theoretical fit was rather poor; for example, the calculated curve predicts much smoother change than the measured curve near the transition region (data not shown). Thus, as the second approach, an attempt was made to estimate the parameters from the experimental dada for the neutral NIPAAm gel by a curve-fitting technique. The results of the best fit gave the following values: $\Delta H = -5.4 \times 10^{-11}$ erg, $\Delta S = -1.8 \times 10^{-13}$erg.K^{-1}, $\nu = 1.2 \times 10^{24}$ L^{-1}, and $\varphi_0 = 0.07$. Using these parameters, the swelling curves for ionic NIPAAm gels with COONa (8–50 mM in preparation) were calculated (see the solid curves in Fig. 40.3). The calculated curves well reproduced the experimental data for the ionic gels; however, the values obtained from the two-parameter fit for ΔH and ν were significantly greater than the values determined from independent measurements. For this discrepancy, Tanaka et al. mentioned the following reasons. In modeling, the effects of loops, free branches, non-Gaussian properties of chains (due to self-avoiding random walk, and stretching limit due to finite length of the chains), polydispersity of chains, and other factors were not considered. Moreover, in this author's opinion, for ionic gels, it also neglected the charge–charge interaction and counterion condensation, which may affect the actual value of osmotic pressure [7,10].

After publication of the Tanaka team's papers (mainly Refs. 6, 8, and 9), there have been many arguments concerning Flory's description. At the same time, several authors proposed modified models for the VPT in gels. A team of coworkers [12] have developed a theory with a quasi—chemical lattice mode for the mixing term Π_{mix}; however, Guassian chains are still assumed, and therefore it is difficult to fit experimental results with a single set of parameters over the entire range of swelling. Another group of coworkers [13] employed a lattice–fluid model to overcame difficult use of the lattice-based mixing term. They derived interaction energy from the various cohesive energy densities in the system that fits the experimental results. But their model, although sensitive to the fact that gels swell under pressure in an attempt to increase entropy, overestimates this effect. Another team [14] used a virial-type expression for mixing term Π_{mix} according to two investigators [15] who studied the temperature dependence of the hydrophobic interaction between molecules in water. Also, an elastic expression that accounts for the limits of elongation was employed. They can predict continuous transitions that become discontinuous upon ionization (see Fig. 40.4), but as yet several adjustable parameters are needed. More details for these modifications are presemted in the literature [10].

Before discussing the disagreement between prediction and observation in terms of the above models including Tanaka's descriptions, we have to determine why ionic gels collapse with rising temperature. In general, osmotic pressure increases not only with increasing concentration of counterions, but also with rising temperature. In order to resolve this conflict, one may assume that *hydrophobic interaction* is competitive with osmotic pressure arising from counterions. Nevertheless, it is preferable to discuss whether the concept of osmotic pressure is adequate. With respect to this subject, another team [4] argued that the Donnan distribution could not give even a rough approximation. Then they proposed a theory based on random coil model in which the charge interaction along a chain was calculated by the Debye–Hückel theory. This was taken over by Hasa–Ilavsky–Dusek (HID) theory [16], in which the elastic term was modified by considering the influence of charges on the deformation of the network. A mathematical description of the HID theory [17] was

$$\begin{aligned}\Pi = &-\frac{RT}{v_s}\left[\ln(1-\varphi)+\varphi+\chi\varphi^2\right] - RT\varphi_o \\ &\times\left[\varphi^{1/3} - \frac{\varphi}{2} + \frac{3}{5n\varphi^{1/3}} + \frac{99}{175n^2\varphi^{1/3}} + \frac{513}{875n^3\varphi^{5/3}}\right] \\ &+ \frac{RTf_m\rho\varphi}{M_0} - \frac{N_A\nu Z^2 e^2 f_m^2}{3D\varphi_0\left\langle R_0^2\right\rangle^{1/2}\varphi^{4/3}}\left[\frac{2.5A}{1+A} - \ln(1-A)\right]\end{aligned} \tag{40.4}$$

and

$$A = \left[\frac{9DkTM_0}{\pi N_A e^2\left\langle R_0^2\right\rangle f_m\rho}\right] \tag{40.5}$$

Here, f_m is the mole fraction of ionic monomer unit in the network, ρ the density of the dry gel, Z the degree of polymerization of the chain in the network, e the electronic charge, D the dielectric constant of solvent, $\left\langle R_0^2\right\rangle$ the mean-square end-to-end distance, and M_0 the average molecular weight of copolymer unit [i.e., $M_0 \approx f_m M_i + (1-f_m)M_n$, where M_i and M_n are the molecular weight of the ionic and the neutral monomer unit in the network, respectively]. It is clear that Eq. (40.4) includes the term due to the electrostatic interaction between the fixed charges that was ignored in Tanaka's description based on Flory's theory. In addition,

the elastic term in Eq. (40.1) was modified in Eq. (40.4). Therefore, one may expect that the prediction of swelling degree ($1/\varphi$) as a function of f_m from Eq. (40.4) would be better than that from Eq. (40.3). However, it was concluded that neither the Flory nor the HID theory could provide a reasonable approach for predicting the swelling degree for polyelectrolyte gels in which the network is composed of different ratios of *N,N*-dimethylacrylamide (DMAAm) (neutral monomer) and 2-acrylamide-2-methylpropanesulfonic acid (AMPS) (ionic monomer). Nevertheless, we must remember the essential difference between the approaches of Flory and Katchalsky for the swelling of polymer gels. Flory considered that a lightly cross-linked ionic gel closely resembles a Donnan membrane system, while such a gel in the Katchalsky treatment was considered to be an extension of the corresponding polyion (see Fig. 40.5). The latter allows us to discuss the swelling and shrinking behaviors of polymer gels in terms of attractive and repulsive interactions between segments or functional groups in the network.

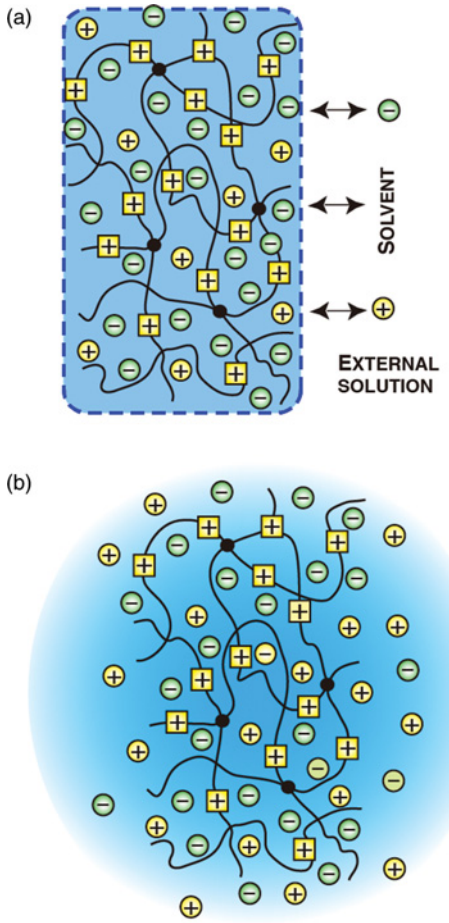

FIGURE 40.5 Schematic representations of a cationic gel based on Flory's model (a) and Katchalsky's model (b). The fixed charge is represented by a square with a plus sign, while circles with minus and plus signs denote counterion and byion, respectively. (Adapted from Kokufuta 2005 [7].)

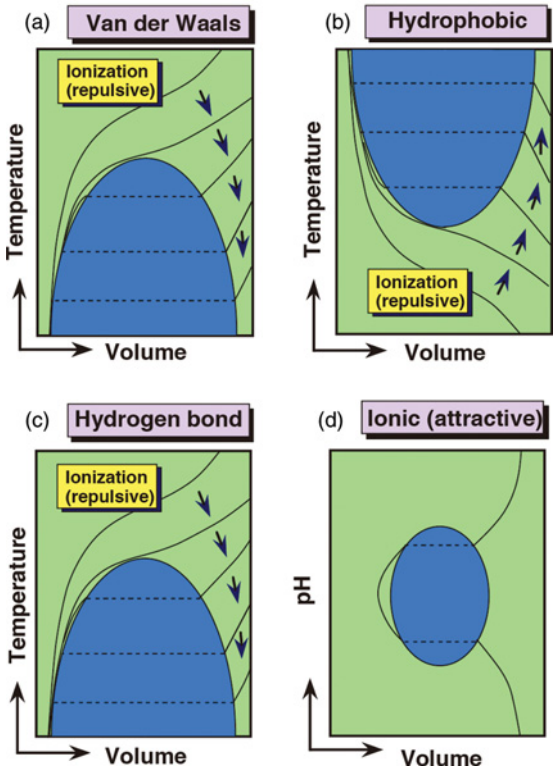
40.4 UNDERSTANDING VPT AT THE MOLECULAR LEVEL

Although there is much debate about a theoretical explanation of the VPT in gels, a large number of data have been accumulated in experiments with various gel systems. It is therefore important to draw a generalized perspective about the phase transition from experimental data. This may be achieved through classification of the experimental swelling curves. We have tried to present a "unified" model of gel transitions, with an addition of an example for volume transition in a gel driven by hydrogen bonding [18]. Then, the gel volume phase transitions were classified into four types (see Fig. 40.6) by considering the following attractive forces that act to shrink the polymer network: ionic, hydrophobic, van der Waals, and hydrogen bonding. When a repulsive force,



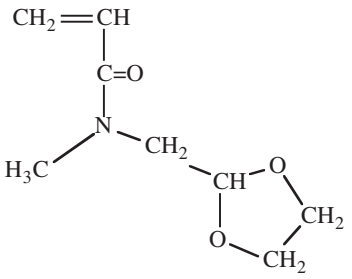


FIGURE 40.6 Four types of intermolecular forces that play an important role in the VPT of gels. When such attractive forces as van der Waals interaction (a), hydrophobic interaction (b), hydrogen bonding (c), and electrostatic interaction (d) become stronger than the repulsive electrostatic force, the gels start the transition. An increase in the ionization degree causes the increase in the gel volume at the transition. For more details, see text. (Adapted from Ilmain et al. 1991 [18].)

usually electrostatic in nature, overcomes an attractive force such as hydrogen bonding or the hydrophobic interaction between the network chains, gel volume should increase discontinuously in some cases and continuously in others. The variables triggering the VPT influence these intermolecular forces and thereby the "balanced state" of the attractive and repulsive forces. One study [18] erred several times in citing references as well as in giving an example for a gel system in which the van der Waals force becomes dominant as the attractive force. However, this classification serves as a good guide for discussing whether the main factor consists in swelling or collapsing a gel. For example, the polyampholyte network in a bulk gel [19,20] or in a microgel [21] collapses at a pH (isoelectric point) at which the network-bound positive and negative charges balance each other (see Fig. 40.6d). For the VPT of this sort, it has been pointed out that Flory's theory is not available [19]. Another example is that the VPT of a poly(ethylenimine) (PEI) gel is well explained in terms of a balance between the attractive hydrogen bonding and the cationic charge repulsion [7,22]. In addition, anionic surfactants such as sodium dodecyl sulfate (SDS) effectively collapsed the PEI gel due not only to the neutralization of the cationic charges but also to hydrophobic interaction.

In Fig. 40.6 the hydrophobic interaction must be defined in a category different from the other three intermolecular attractive forces. Since the studies on the thermodynamics of nonpolar solvation in the mid-1940s [23], the standard model for the hydration of nonpolar solute species has emphasized enhancement of the solvent water structure hydrating the solute. The exact nature of this structural ordering has remained unclear, but it is not disputed that the nonpolar solvation process results in a net loss of entropy. This entropic mechanism for association of nonpolar moieties subsequently became central to models of protein folding and stability following the seminal work of Kauzmann in 1959 [24], who argued that a structural interpretation of the thermodynamic data could be developed by considering the hydration of the polar and nonpolar molecular groups that constitute proteins. In the area of polymer gels, the main issue regarding hydrophobic interaction, which initially attracted the most attention, seems to be in understanding the phase transition of NIPAAm gels. In general, gels swell on heating, an example of which is shown in Fig. 40.3. In contrast, the NIPAAm gels undergo the swelling transition on "cooling" (Fig. 40.4), the process of which is an exothermic ($\Delta H < 0$), but $\Delta S < 0$. Such negative enthalpy and entropy changes may be rationalized by assuming that an "icelike structure" is stabilized in the neighborhood of nonpolar solutes—thus the heat evolved may be attributed to the latent heat of freezing of "icebergs" that represent regions of crystalline order and whose formation, therefore, leads to a loss of entropy. The tendency of nonpolar solutes to aggregate in aqueous media reduces the number of water molecules in their immediate vicinity and leads to "melting icebergs." This provides the driving force toward such aggregation and has been referred to as the *hydrophobic bond* [24]. These considerations are elementary, as mentioned above, but allow us to understand the difference between diagrams (b) and (a), as well as (b) and (c) in Fig. 40.6. For the NIPAAm gel network whose monomer unit is composed of a hydrophilic amide moiety and hydrophobic isopropyl and methylene moieties, it is not so simple to understand and interpret the phase transition mechanism at the molecular level. Indeed, the phase transition of gels and the phase separation of polymers, based on *N*-propylacrylamides and *N*-propylmethacrylamides, are dependent on the structure of the constituent monomers (see Fig. 40.7) [11,25]. These results indicate that we must consider (1) amide–amide and amide–water hydrogen bonding and (2) a possible hydrogen bonding of solvent water with the H–C bond of the alkyl groups, in terms of water clustering around both the alkyl and the amide groups. In addition, it has been suggested that the effects of R and R′ on the *electronic structure* of $R{-}C(=O)NH{-}R'$ seem to play an important role in these hydrogen bond formations [25]. In the case of a gel based on *N*-(1,3-dioxolan-2-ylmethyl)-*N*-methylacrylamide (DIOMMA) whose chemical structure is given by

a rise in temperature leads to the volume collapse in water but the swelling in alcohols [26]. This opposite trend in the thermal properties in water and in alcohols was discussed in terms of polymer–polymer, polymer–solvent, and solvent–solvent interactions. However, in more detail, the two oxygen atoms in the dioxolane moiety seem to cause clustering of water molecules, which hinders hydrophobic association in the network. Indeed, with increasing temperature, the degree of swelling of DIOMMA gel in water quasi-monotonically decreases up to near 60 °C and gradually levels off to a constant value at about 70°C, the results of which are clearly different from the volume changes of the other *N*-alkyl acrylamide gels such as NIPAAm gels. In alcohols such as methanol and ethanol, the DIOMMA gel network is under a collapsed sate, probably due to the solvent-mediated hydrogen bounding at a low temperature range (<25°C). However, such hydrogen bonds are broken on heating, and at the same time the network is solvated via hydrogen bonding between the OH and amide groups. All the above discussions were based on the results obtained

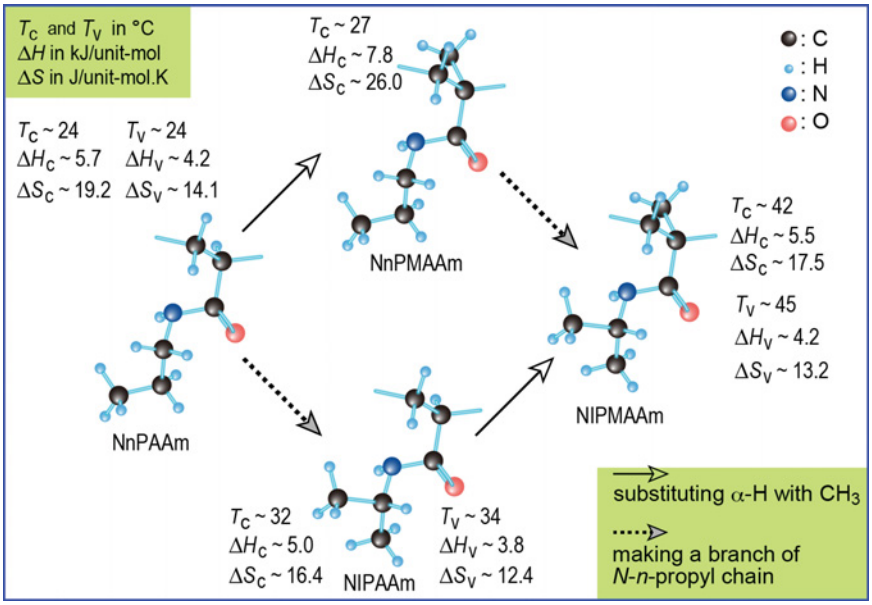

FIGURE 40.7 Systematic comparison of the effects of α-methyl group and sidechain branching on the phase separation of polymers, as well as on the VPT of gels, based on *N*-propylacrylamide or methacrylamide monomers: *N*-isopropylacrylamide (NIPAAm), *N*-isopropylmethacrylamide (NIPMAAm), *N*-*n*–propylacrylamide (NnPAAm), and *N*-*n*-propylmethacrylamide (NnPMAAm). T_c denotes the phase separation temperature, and ΔH_c and ΔS_c ($= \Delta H_c/T_c$) are the enthalpy and entropy change during the phase separation, respectively. Similarly, T_v is the volume phase transion temperature, ΔH_v and ΔS_v ($= \Delta H_v/T_v$) are the enthalpy and entropy change during the VPT, respectively. Note that the phase separation of the polymer or the collapse transition of the gel in water on heating is the endothermic process, so that $\Delta H > 0$ and $\Delta S > 0$. All the data were determined by heating DSC measurements of the polymers or the gels so as to avoid the effect of the concentration. In the case of NnPMAAm, the data for the gel are not shown because the gel could not be prepared because of a low water solubility of the monomer [11]. (Adapted from Kano & Kokufuta 2009 [11] and Kokufuta et al. 2012 [25].)

with techniques such as Fourier transform infrared (FTIR) or attenuated total reflectance (ATR)-FTIR spectroscopy, ^{1}H-NMR spectroscopy, and differential scanning calorimetry (DSC). Almost all the important studies are included in the literature [11,25,26].

40.5 EFFECTS OF DISTRIBUTION OF IONIC OR HYDROPHILIC MONOMER UNITS WITHIN THE NETWORK

It was previously mentioned that there are two models for understanding ionic gel transitions: (1) Flory theory based on classical Donnan method and (2) Katchalsky theory based on random-coil model in which the charge interaction along a chain was considered. However, it is difficult to determine which model is realistic, as can be seen from certain experiments [17]. Here, it is shown that studies on the effect of charge distribution within the network provide an answer to this question. For this, we synthesized four ionic gels composed of NIPAAm and AAc residues (NIPAAm:AAc ratio of the feed ≈10:1 by moles the monomers or repeating units) using the following approaches [27]: (1) for gel I, the redox polymerization of an aqueous solution containing NIPAAm, AAc, and Bis which can be initiated by a pair of ammonium persulfate (APS, initiator) and *N,N,N′,N′*-tetramethylethylenediamine (TMED; accelerator); (ii) for Gel II, the physical entrapment of poly(AAc) by Bis-crosslinked NIPAAm gel, the preparation method of which is the same as that in (i) except for the use of poly(AAc) instead of the AAc monomer; (iii) for Gel III, the gelation of an aqueous solution containing poly(NIPAAm) and poly(AAc) by γ-rays from ^{60}Co under conditions where no complexation occurs between poly(NIPAAm) and poly(AAc); and (iv) for Gel IV, the γ-ray irradiation of an aqueous solution of poly(NIPAAm–co–AAc). Figure 40.8 shows the temperature dependence of the normalized equilibrium diameters (d/d_0) at pHs 3 and 10 for Gels I and II as the example. At pH 10 at which the COOH groups of the AAc units are fully ionized ($COOH + NaOH \rightarrow COO^- + Na^+ + H_2O$), a marked difference due to the AAc distribution was observed between G I and G II. The localized COO^- ions in G II are

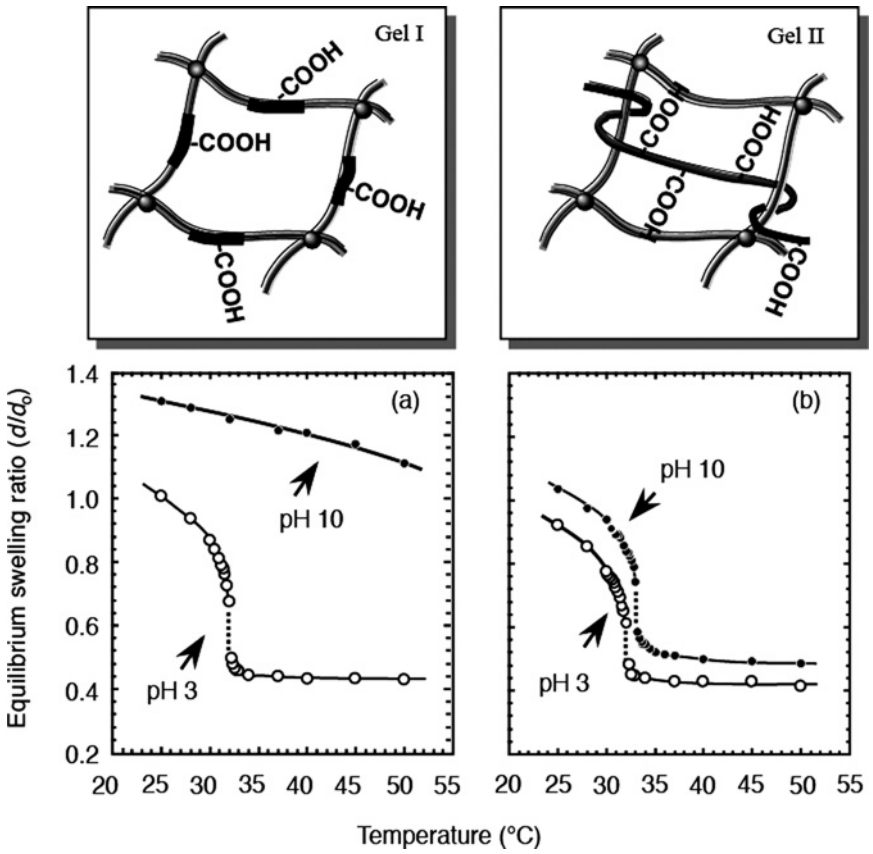

FIGURE 40.8 Temperature dependence of normalized equilibrium diameters (d/d_0) at pH 3 and 10 for Gel I (a) and Gel II (b). Poly(AAc) with MW = 450,000 was used for the preparation of gel II. (Adapted from Kano & Kokufuta 2009 [11] and Kokufuta et al. 2012 [25].)

not effective in preventing the thermally induced gel collapse at temperatures above T_v. This clearly indicates the effect of microscopically created charge inhomogeneity on the VPT. Since there is little disagreement between the T_c and T_v values for the polymers and gels of NIPAAm (see Fig. 40.7), a similar molecular mechanism may be predicted in the phase separation and the volume transition. For Gel II composed of ca. 90 % of Bis-crosslinked "pure" NIPAAm chains, it is predictable that its VPT behavior is not so different from those of poly(NIPAAm) and NIPAAm gel, even at pH 10 where the incorporated poly(AAc) chains (ca. 10 % in unit mole base) are fully ionized. Indeed, at pH 10 Gel II underwent a VPT at a temperature near to the T_c or T_v (~33°C) of the NIPAAm polymer and gel. The same result has been obtained by a comparison of Gels III and IV (see [27]). In addition, when the swelling curves of Gel II were studied at pHs 3 and 10 as a function of the molecular weight of the entrapped poly(AAc), the following results have been obtained: (i) The increase in the molecular weight at pH 10 brought about an increase in the gel volume over the temperature range of 25 °C to 50 °C; and (ii) at pH 3 and at temperatures $< T_v$, the gel volume decreased with increasing molecular weight of the entrapped poly(AAc). Therefore, it has been clear at the molecular level that the charge distribution has a marked effect on the swelling of NIPAAm-based polyelectrolyte gels.

In the above example, we looked at the case where the charges that cause a repulsive force are localized in the network. Now, it is interesting to see what is happening in the network into which neutral polymer chains that do not undergo hydrophobic association are physically immobilized. For this, two NIPAAm-based gels were prepared: One consists of the copolymer of NIPAAm and vinyl pyrrolidone (VP), and the other is the NIPAAm gel with immobilized poly(VP) [7]. The amount of VP monomer or repeating VP unit was varied from 0 to 50 mol %. As can be seen from Fig. 40.9, the copolymerization of a hydrophilic VI monomer causes a rise in T_v, and simultaneously extends a range of temperatures at which a large volume change takes place. By the immobilization of poly(VP), however, there is little change in T_v, although an increase in the gel volume under a fully collapse state is observed. This is the case, even when 50 % of poly(VP) was immobilized. These results clearly indicate that the distribution of "neutral but hydrophilic" chain

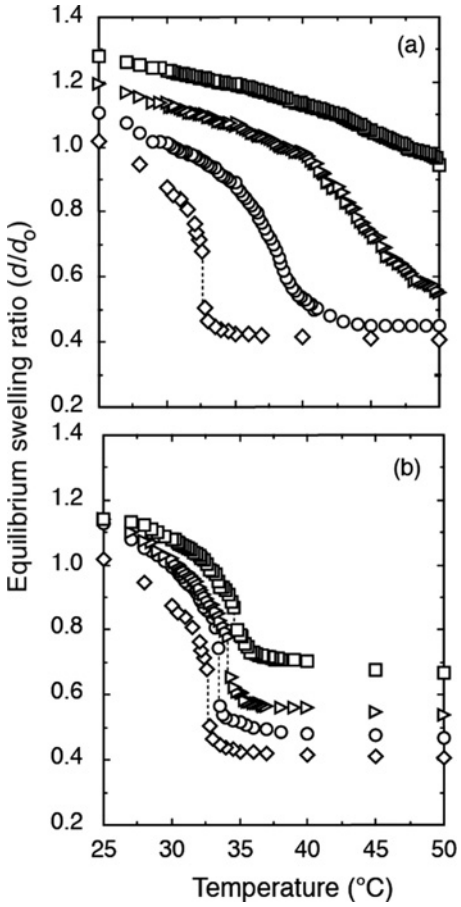

FIGURE 40.9 Temperature dependence of normalized equilibrium diameters (d/d_0) for NIPAAm gels with copolymerized VP (a) as well as with immobilized poly(VP) with MW = 360,000 (b). Contents of VP monomer or VP unit in the pregel solution: (rhombus) 0 mol%, (circle) 10 mol%, (right-pointing triangle) 30 mol%, and (square) 50 mol%. The measurements were carried out in pure water. (Adapted from Kokufuta 2005 [7].)

segments within the NIPAAm network plays an important role in the association of hydrophobic chain segments. Then, it is natural to conclude that the charged segments affect the VPT in polyelectrolyte gels through both the long-range Coulombic interaction and the hydrophilic nature.

40.6 EFFECTS OF COIL-TO-HELIX TRANSITION IN POLYPEPTIDE GELS

We have attempted to see the VPT in gels through force balance approach (FBA) that is based on the balanced state of the attractive and repulsive forces between the constituent polymer chains in the network. In other words, this is to draw analogies between the behavior of uncross-linked and cross-linked polymers in a solvent. Here it is demonstrated that the FBA successfully accounts for the VPT of polypeptide hydrogels [28]. Polypeptides in aqueous solutions are known to adopt three different conformations (α-helix, random coil and β-sheet structures) depending on pH, temperature and additives. Circular dichroism (CD), optical rotatory dispersion (ORD) and ^{1}NMR techniques are often used for investigating the polypeptide conformations in solutions. However, such techniques are less helpful for the gels that are prepared via cross-linking of polypeptides with a suitable agent such as glutaraldehyde (GA). This is mainly due to the difficulty to handle them in the measurements. In particular, CD and ORD are unable to use for the gels that become opaque in their preparations or measurements. Even in such a case, however, the FBA allows us to discuss the gel volume transition in terms of the conformation change of the peptide chain in solutions. For example, as shown in Fig. 40.10, a hydrogel obtained from poly(α-L-lysine) (α-PLL) by cross-linking with GA shows little change of the volume at the pH range (see Fig. 40.10c) at which the polymer undergoes a coil-to-helix transition. However, α-PLL gel undergoes a VPT at pH at which the polymer had adopted α-helix conformation (Fig. 40.10e). The gel after the transition further collapses upon heating even in the temperature region (Fig. 40.10g) where the polymer adopts the β-sheet structure. In the case of racemic poly(α-DL-lysine) (α-PDLL) that does not adopt any secondary structure in the pH and temperature ranges studied, the gel shows the VPT similar to those of α-PLL gel. However, the pH range causing the gel collapse is wider than that for α-PLL gel (Fig. 40.10d–f). Moreover, the magnitude of the volume changes with temperature is larger for α-PDLL gel than for α-PLL gel, although the fully collapsed volume for former at high temperatures (e.g., 60°C) is larger than that for the latter. These results indicate that the formation of the helical segments in the cross-linked chain has little effect in the gel collapse, but their association by attractive force causes the gel to shrink. The attractive interactions are mainly due to the hydrogen bonding, but hydrophobic interactions between the lysine sidechains should be considered [28].

40.7 EFFECTS OF SURFACTANT BINDING

It has been mentioned that the distribution of network charges strongly affects the VPT of ionic NIPAAm gels. This can be observed in the case of ionic surfactant–bound NIPAAm gels [7,29]. Ionic surfactants such SDS and sodium dodecylbenzene sulfonate (NaDBS) are bound to neutral NIPAAm polymers and gels, by which they are converted into a polyelectrolyte [30–32]. To the polymer the binding takes place at critical aggregation concentration (CAC). This causes an elevation of lower critical solution temperature (LCST $\equiv T_c$) as a result of electrostatic repulsion between the charges of the polymer-bound surfactant micelles. Similarly, an increase in T_v as well as in the swelling ratio at T_v can be observed

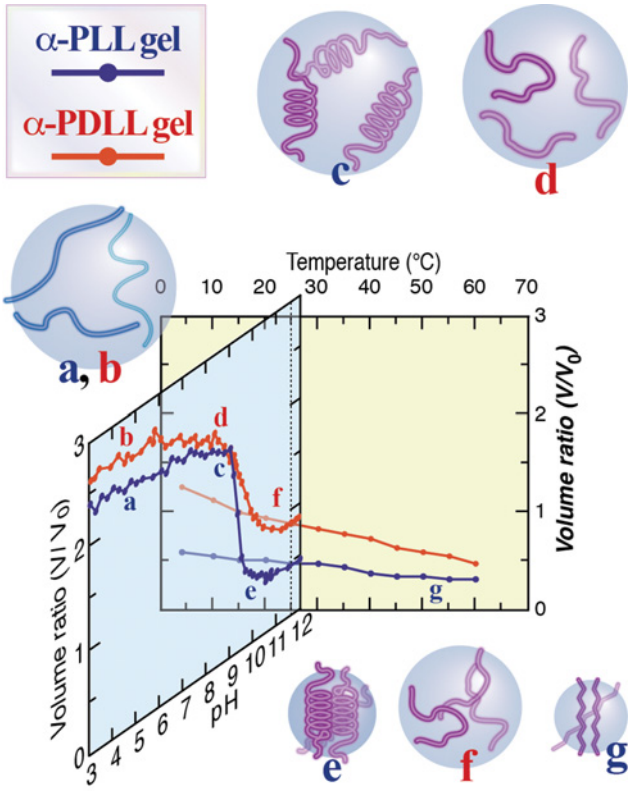

FIGURE 40.10 Schematic representation of poly(lysine) gel collapse in response to pH and temperature. The volume ratio (V/V_0) was calculated by $V/V_0 = (d/d_0)^3$ from the data obtained by initially increasing the pH or temperature of the outer solution. Sample: α-PLL gel (dashed line) and α-PDLL gel (gray solid line). The predicted conformations in the cross-linked polymer chains are as follows: for α-PLL gel, random coils (a), partially formed helices before their association (c), associated helices (e), and β-structure (g); and for racemic α-PDLL gel, random coils (b), collapsed coils before their association (d), and associated collapsed coils (f). (Adapted from Kokufuta et al. 2011 [28].)

in surfactant-bound NIPAAm gel systems. A few studies [33, 34] attempted to describe the VPT behavior in connection with the formation of surfactant micelles in the gel. However, quantitative analysis for the amount of bound surfactants, followed by a careful comparison of the surfactant-bound NIPAAm gel and the AAc-copolymerized NIPAAm gel, both of which have almost the same charge density (0.16 ± 0.02), has raised the questions as to why (1) the volumes of the surfactant-bound gels are much smaller than those of the copolymer gel and (2) the T_v of the former is higher than that of the latter (see Fig. 40.11a). A rise in temperature causes a slight increase in the network charges, which can be accurately determined from surfactant uptake by the gel [35]; however, the differences that are mentioned in questions 1 and 2 above cannot be understood in the common knowledge of ionic gel transitions. Therefore, answers to these questions would help clarify the nature of swelling forces in ionic gels, including the surfactant-bound gels. Now, let us assume that surfactant molecules bind only to the polymer networks within a layer of the gel near the surface but not to all of the networks in the body of the gel (Fig. 40.11b). The reason is that charges of the surfactant-bound layer seem to hinder further diffusion into internal parts of the gel of the surfactant molecules with charges of the same sign. Thus, a NIPAAm gel with bound surfactants is seemed to resemble a sort of "composite" polyelectrolyte gel consisting of cross-linked polymer chains with different amounts of ionizable groups. Since, as shown in Fig. 40.11a, the T_v of the pure NIPAAm gel is lower than those of three ionic NIPAAm gels, part *c* (in Fig. 40.11b) without bound surfactants should collapse at temperatures slightly higher than T_v, but parts *a* and *b* remain in the swollen state. We usually define T_v as the temperature at which a gel discontinuously and completely collapses; therefore, the experimentally determined T_v of a surfactant-bound gel is governed primarily by the degree of ionization in part *a*, but not in parts *b* and *c*. However, the swelling ratio as the overall gel volume is strongly affected by changes in the degree of ionization in part *b*. Even if part *a* is maintained at the same level of ionization in both the SDS- and NaDBS-bound gels, in this case the level in part *b* for the former is higher than that for the latter. Then, we can see from the features in Fig. 40.11a that (1) the SDS-bound gel exhibits a high degree of swelling compared with the NaDBS-bound gel, and (2) the total change in the gel volume at T_v for both surfactant-bound gels is smaller than that for the copolymer gel with a homogeneous charge distribution as a result of random copolymerization of AAc monomers.

Measurement of the spatial distribution of surfactant concentration within the gel phase should provide direct evidence for the local surfactant binding as assumed above. For this purpose NaDBS is an appropriate surfactant because it has the phenyl group, which exhibits an absorption band in the UV range. Figure 40.11c shows typical examples of the position dependence of transmittance (PDT), the results of which were obtained with the sample gel disks with bound NaDBS. The gel disks with a thickness of ~0.2 μm were obtained by cutting a cylindrical gel rod using a microtome, after confirming that the surfactant binding had attained equilibrium. The scanning was performed from the right-hand end to the left-hand end of each gel disk. Two wavelengths, 261 nm and 400 nm, were used to measure the PDT. Since NaDBS has no absorption at 400 nm, the transmittance at this wavelength varies depending on the sample thickness. Therefore, the PDT at 400 nm should be used as a control. PDTs (segments *a* and *b* in Fig. 40.11c) are the results obtained using wet and dry gels with an initial diameter (d_0) of 2 mm, respectively. The wet gel sample was fully swollen in pure water prior to contact with the NaDBS solution, whereas the dry gel was directly treated with the surfactant solution without swelling procedure (for more details, see

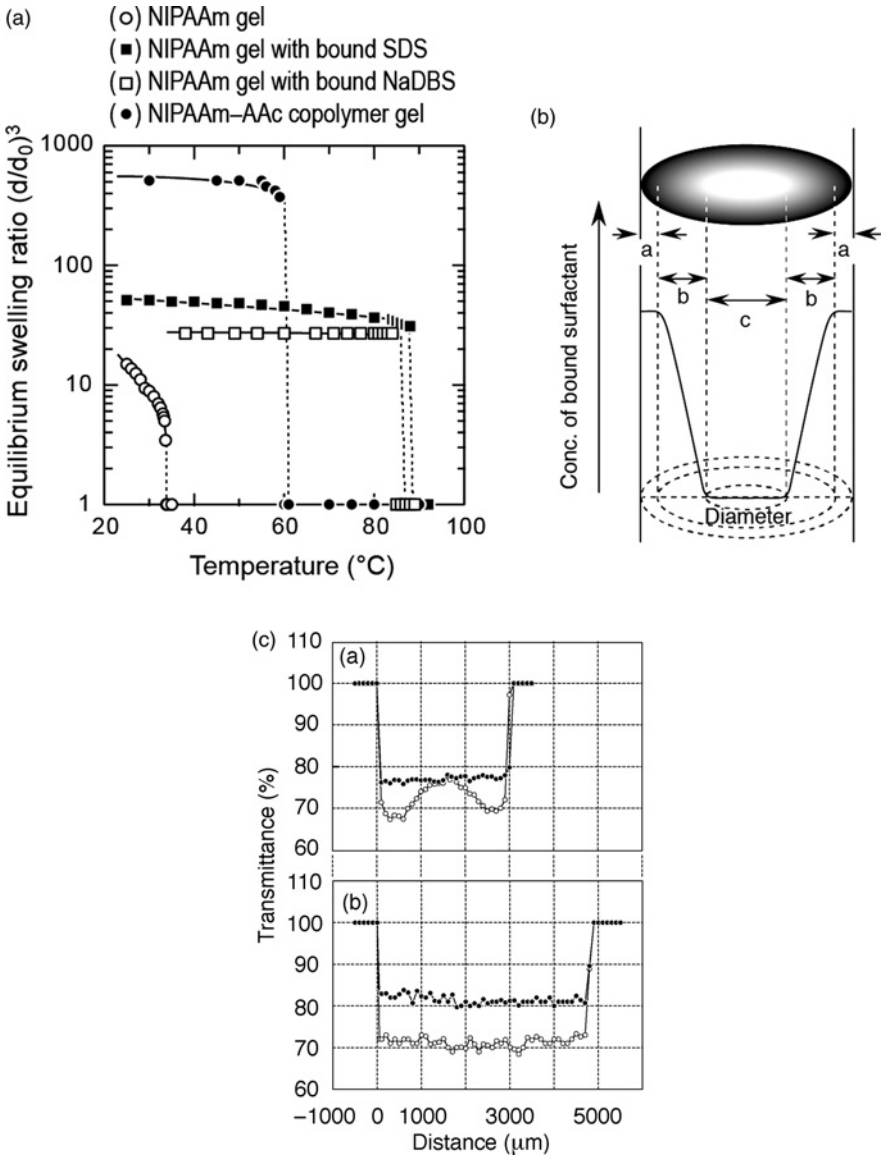

FIGURE 40.11 Several important features of surfactant-bound NIPAAm gels. (a) Comparison of equilibrium swelling curve for pure NIPAAm gel with those for ionic NIPAAm gels with bound NaDBS and SDS as well as with copolymerized AAc. The charge densities based on moles of ionized groups (sulfate, sulfonate, and carboxylate ions) per mole of NIPAAm plus Bis (cross-linker) are 0.16 ± 0.02 for both surfactant-bound gels; and 0.18 for NIPAAm-AAc copolymer gel as a control sample. The former was determined from the surfactant uptake by the pure NIPAAm gel at 25°C and at initial surfactant concentrations >20 mM. (b) Schematic representation for a cylindrical gel with inhomogeneously bound surfactant molecules. A horizontal sectional view of a cylindrical gel after attainment of a saturated level of surfactant binding is illustrated together with a concentration profile of bound surfactant: *a*, part with a saturated level of bound surfactants; *b*, part in which the surfactant concentration gradually decreases toward the center; and *c*, part in which there is no bound surfactant (i.e., corresponding to neutral gel). (c) Position dependence of transmittance (PDT) for cylindrical wet gel disk (*a*) and dry gel disk (*b*) with a saturated level of NaDBS binding. The diameter (d_0) before the surfactant binding was 2 mm each for both gels. Wavelengths used for the measurements: 261 nm (open circles) and 400 nm (filled circles). (Adapted from Kokufuta 2005 [7] and Kokufuta et al. 1997 [29].)

Experimental Section in Ref. 29). In PDT (*a* in Fig. 40.11c), a rapid decrease in transmittance at both ends was observed when using the wavelength at 261 nm. However, the transmittance increased gradually and became constant when the scanning point approached the central core of the gel disk. On the other hand, the transmittance at 400 nm was almost constant, independent of the position. Therefore, it is evident that the surfactant molecules bound strongly only around the gel walls. This conclusion can be supported by PDT (*b* in Fig. 40.11c) for the dry gel in which we did not observe specific position-dependent changes in transmittance at 261 nm. In the case of the dry gel, the surfactant solution permeated throughout the gel phase, such as by taking up water by a sponge, thus allowing the surfactant molecules to bind to the network without distribution, at least within the resolution (30 μm) of our microscopic spectroscopy, the value of which is dependent on the size of the beam going through the gel disks. Thus, a marked difference can be observed in the diameters of the surfactant-bound wet and dry gels; specifically, the distance between the right- and left-hand ends, which is larger for the dry gel than for the wet gel, although their diameters in the preparation were identical with each other. As a result, it becomes apparent that the VPT in surfactant-bound ionic NIPA gels is obviously affected by the inhomogeneously distributed charges. The same conclusion has been obtained from experiments with NIPAAm microgels to which NaDBS had been bound [36]. If the osmotic pressure due to mobile counterions plays an important role in the VPT of polyelectrolyte gels, one would expect there to be little influence on the inhomogeneity of charge distributions within the gel. Thus, the results presented here may provide a key to consider whether or not the VPT of polyelectrolyte gels is governed by osmotic pressure. Then it is logical to consider that the nature of NIPAAm gels with ionic surfactants is explained well in terms of the Katchalsky model not based on the osmotic pressure arising from counterions.

40.8 NETWORK INHOMOGENEITY AND SWELLING–SHRINKING KINETICS

We have looked at the influence of the homogeneity of the ionic or strongly hydrophilic monomer units in the network on the VPT in gels. Here let us consider in a wide sense the structural inhomogeneity of the network, namely, network inhomogeneity. According to the definition of gels, many sorts of gels are inhomogeneous in the structure of their networks; for example, see agarose gel in Fig. 40.1. However, in the case of polymer gels it seems that network homogeneity is governed mainly by the distribution of cross-linking points within the network. Indeed, a microscope laser light-scattering study [37] showed a fluctuating speckle pattern due to highly nonuniform spatial distributions of polymer network concentration and cross-linking density in a Bis-cross-linked NIPAAm gel. These inhomogeneities were then considered to have two origins: (1) the dynamic critical fluctuations of the polymer solution at the onset of gelation and (2) the domain formation due to the microphase separation, both of which are directly related to the phase equilibrium properties of the gel during the gelation process. Such fluctuations of polymer density are permanently frozen in the gel structure. In addition to these permanent spatial fluctuations, a polymer network undergoes thermal dynamic concentration fluctuations. Therefore, the nature of gel inhomogeneities can be accounted for in terms of three (two static and one dynamic) types of fluctuation. The conventional technique of dynamic light scattering (DLS) can now be used to study the structural inhomogeneity of gels [38]. The DLS data may be analyzed by the partial heterodyne method [39].

It is obvious from the above that the network homogeneity affects the VPT in gels. However, a question remains regarding a correlation of the swelling–shrinking kinetics of gels with their microscopic structures. Before discussing this issue, we must know the swelling and shrinking kinetics of gels. One group of coworkers [40–42] have studied a theory of the swelling-shrinking kinetics of gels and compared it with their experiment results. Then, the characteristic time (τ) taken for a gel to swell or shrink was given by

$$\tau \propto l^2/D \tag{40.6}$$

where l denotes the characteristic linear dimension of the gel and D is the collective diffusion coefficient of the networks. This equation means that the time for a gel to swell or shrink depends on its size, such as the radius of a spherical gel. Thus, the gels seem to undergo a fast volume change as the term l in Eq. (40.6) is reduced. A candidate falling into this criterion would be gel particles with diameters in the range of several tens to several hundreds of nanometers, often referred to as *microgels* or *nanogels*. However, the swelling–shrinking kinetics of such gel particles has not yet been studied in detail through the direct measurement of particle sizes as a function of time, probably because of the lack of experimental techniques. Indeed, the fast kinetics of microgels has been predicted from the studies of (1) the diffusion rate of solutes into or out of the gel particles (e.g., [43]) and (2) the permeation rate of solvents through the pore formed among the gel particles [44]. Another candidate seems to be macroporous gels having a large pore size, a high pore volume, and a high specific surface area, a good example of which is the opaque gels obtained via the gelation of NIPAAm at temperatures above the LCST or T_v [45–48]. The observed rapid volume change of such macroporous gels was then interpreted by assuming that their bodies are made up of minute domains of densely and sparsely cross-linked gel networks; therefore, the term l in Eq. (40.6) should be reduced.

A technique for achieving fast deswelling kinetics of NIPAAm gels without relying on reduction of l in Eq. (40.6) has been reported [49]. This was based on the use of a macromonomer that is composed of a NIPAAm mainchain and a vinyl group at one end; thus cross-linking with Bis yields a gel network to which many graft NIPAAm chains are bound, that is, a comb-type grafted NIPAAm gel. The gel obtained was transparent in appearance, like conventional Bis-crosslinked NIPAAm gels, but exhibited a very rapid rate of shrinking in response to a change in temperature of 10–40°C. Since the shrinking rate was found to vary depending on the length of graft chains, it was concluded that the thermal collapse of graft chains "bound to the network" plays a key role in the overall gel collapse. This should be distinct from the dynamic property of conventional gels, which is dominated by the diffusion-limited transport of polymeric components of the network in a solvent as characterized by the term D in Eq. (40.6). Then, it is logical to assume that the network homogeneity causes fast deswelling kinetics. This assumption was confirmed by using chemical and radiation cross-linked gels [50]. More specifically, four gels cylindrical in shape were prepared by two different methods: (1) γ-ray irradiation to aqueous solutions of poly(NIPAAm) or poly(NnPAAm) (for their structures, see Fig. 40.7) and (2) redox polymerization of NIPAAm or NnPAAm monomer using Bis as the cross-linker. There were a few differences in the swelling kinetics among these gels. However, a marked difference was observed in the shrinking processes, the rate of which was faster in the order of radiation cross-linked NIPAAm gel > radiation cross-linked NnPAAm gel > chemically cross-linked NnPAAm > chemically cross-linked PNIPAAm gel. This difference was discussed in terms of the microscopic structure of the gels, which was studied by DLS. It was found that the static inhomogeneities frozen in the chemically and radiation cross-linked gels play a key role in their shrinking kinetics.

40.9 MICROGELS

The terms *microgels* and *nanogels* have been used in the previous sections [36,43,44]. Both terms were also used in many papers dealing with the gel particles with diameters in the range of several tens to several hundreds of nanometers, as was mentioned previously. However, in IUPAC Recommendations 2012, nanoparticle is defined as "particle of any shape with dimensions in the 1×10^{-9} and 1×10^{-7} m range (i.e., 1 nm $\sim$ 100 nm)" and this is the case for "nanogel" (see pp. 393–394 in Ref. 51). According to this, some of the important features of microgels will be discussed at the end of this chapter. The contents are mainly limited to microgels based on NIPAAm because almost all of the previous sections have focused on the VPT in "bulk" gels of this sort.

In 1987 Tanaka et al. prepared microgels with a swollen diameter of 0.4 μm (400 nm) by cross-linking NIPAAm with Bis in a sorbitan monolaurate/water mixture as the polymerization medium [52]. To the best of the present author's knowledge, this is the first report on NIPAAm microgels. While different polymerization mediums were used to prepare NIPAAm microgels, two other researchers [53] reported a simple technique for synthesizing monodisperse aqueous NIPAAm latex particles. They demonstrated that the latex dispersions can be obtained by "tumbling" a 5-mL vial containing aqueous solutions consisting of different amounts of NIPAAm, Bis, and an initiator such as potassium persulfate. The polymerization was done at temperatures (e.g., 70°C) that are higher than the LCST or T_v. The latex particles obtained were swollen to about 1 μm in diameter at low temperatures but were contracted by a factor of ~10 in volume, when the temperature was raised above the LCST. It seems that this work facilitates further studies on NIPAAm based-microgels, mainly because of its simple preparation method, as well as the thermal behavior of latexes similar to those of bulk NIPAAm gels and NIPAAm polymers in water. In addition, it should be noted that NIPAAm microgels have slight positive or negative charges arising from polymerization initiators. Therefore, microgel dispersions allow us to use the techniques such as DLS, static light scattering (SLS), electrophoretic light scattering (ELS), and potentiometic and colloid titrations, which are important tools in the study of colloid dispersions. Therefore, many studies have been performed with NIPAAm-based microgels with and without other comonomer units, almost all of which were reviewed in 2000 by Pelton [54], who attempted to discuss the temperature dependence of particle size in terms of the theories of VPT based on the Flory theory, but not on the Katchalsky theory. Also, it was mentioned that the electrophoretic behavior of NIPAAm gel particles is well accounted for in terms of a"charged surface model" established by Pelton and his coworkers, but not of "free-draining model" for polyelectrolyte coils. However, more recent studies [55,56] with ionic or amphoteric NIPAAm microgels clearly demonstrated that their electrophoretic behavior must be discussed in terms of free-draining model, at least in a swollen state. In addition, it seems that "charged hairy surface-layer model" proposed by Ohshima [57, 58] provide a good discussion of the electrophoretic results of NIPA microgels that are in the collapsed state.

In several studies in the 2000s, geometric characteristics of NIPAAm-based microgel particles were investigated. For example, we carefully compared the DLS and SLS results of various microgels based on NIPAAm and concluded that the surfaces of swollen microgel particles were decorated with attached dangling chains, while the microgels with the surface to which oppositely charged polyions are bound are spherical in shape and there are no dangling surface chains [59] (see Fig. 40.12). The structure of microgel particles as

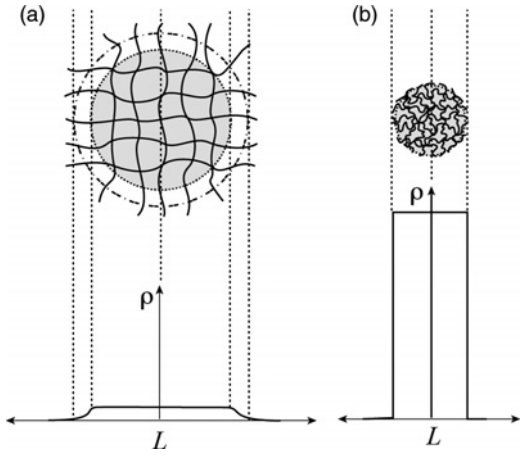

FIGURE 40.12 Schematic representations for a microgel particle in a swollen state (a) and a fully collapsed state (b). The degree of collapse pictured is 0.5 in diameter (L). The polymer density (ρ) was assumed to be constant within the main body (gray circles) of the gel particle, that is, random distribution of cross-linked polymer chains. Ratio of radius of gyration (mean-square radius; R_g from SLS) to hydrodynamic radius (R_h from DLS) is larger than 0.775 for (a), but equal or close to 0.775 for (b). Note that the theoretical R_g/R_h ratio for densely packed spheres becomes 0.775. (Adapted from Kokufuta et al. 2007 [59].)

shown in Fig. 40.12b has also been suggested by the studies [60, 61] of poly(vinyl alcohol) microgels obtained by γ-ray irradiation. Therefore, the size or volume changes of microgel particles in response to small variations in the solution conditions (temperature, pH, salt concentration, etc.) may be discussed in terms of the Katchalsky model (see Fig. 40.5). Then, the complex formation between NIPAAm-based ionic microgels with opposite charges, as well as between an anionic or cationic microgel and oppositely charged linear polyions, provide the key to understanding the mechanism of polyelectrolyte complex formation in water [62–64]. The main reason is that the charges within the internal part of microgels can prevent the aggregation of gel particles, on addition of oppositely charged microgels or polyions. This is the case even when a 1:1 stoichiometric polyelectrolyte complex forms in water, in which the linear polyion complexes are aggregate with each other. As a result, we may study the 1:1 stoichiometric microgel complexes by using techniques such as SLS, DL,S and ELS.

40.10 CONCLUSIONS

This chapter has covered a relatively mature area of polymer gels; however, the fruits of the studies on the VPT in the gels have brought to developments in stimuli-responsive materials. On the other hand, there are extremely many kinds of gels according to the IUPAC definition [1], so that gels composed of materials with self-assembled fibrillar networks were not covered in this chapter. Nevertheless, the understanding of the VPT with such a way as FBA (force balance approach) would provide a key for "controlling" molecular self-assembly, in particular in aqueous systems. Hopefully, the discussions in this chapter can lead to an understanding of the scientific principles governing response driven functions leading to future technologies.

GEL CRYSTALS

TSUNEO OKUBO

Institute for Colloidal Organization, Hatoyama 3-1-112, Uji, Kyoto 611-0012, Japan

41.1 INTRODUCTION

Gel crystals are grouped into three systems: (I) crystal-like ordering of gel spheres (particles) in suspension state, (II) gels containing interior crystal arrays of colloidal particles, and (III) crystal-like arrays of gel spheres formed at the plane and curved interfaces (see Fig. 41.1). All of these systems are quite interesting because of their structure and function are similar to those of biological assemblies such as skin and crystalline lens. Furthermore, most gels are highly sensitive to the external fields and atmospheres. Typical gel spheres in type I are cross-linked linear-type polymers. Recently, many kinds of core–shell-type gel spheres have been prepared. Mixtures of the gel spheres and colloidal hard spheres are also interesting. Spheres of type II gel crystals will be distributed in the gas, liquid, or solid state. Many kinds of interfaces of type III gel crystals are also available on the gas-, liquid- or solid-state spheres (particles) or plates. Here, most studies have focused on type I gel crystals formed from spherical gel particles. However, anisotropic and also monodisperse particles are very exciting to study because of their specific functions and propertird in gel crystals.

First, let's discuss type I gel crystals: the gel particle crystals. In general, polymer solution, which is composed of linear-type polymers and their solvents, is *transparent*. The main cause for the transparency is the fact that the size of the unit's polymer dynamic thermal motion, which is close to the size of these type I gel crystal monomer units, is very small compared with the light wavelengths and is rather close to the size of solvents (see Fig. 41.2). There exist no *interfaces* between the polymer solutes and solvents, since the monomer units and solvent molecules exchange their locations rather freely by their thermal motion. On the other hand, colloidal dispersions of hard spheres are composed of the large solid particles and very small of medium-sized molecules. The sizes of typical colloidal particles are dimensionally close to or larger than those of the light wavelengths, and 100–1000-fold larger than those of the medium molecules. Thus, colloidal dispersion is *turbid* except for those in the refractive-index-matched condition between particles and medium. In other words, turbid dispersion supports the existence of the *interfaces* in a sense of colloid chemistry.

Most colloidal particles in water, on the other hand, get negative charges on their interfaces by two mechanisms: (1) *dissociation of ionizable groups* introduced to the interfaces from the initiators during polymerization of monomers, and (2) the *preferential adsorption of ions* from suspension in order to reduce the high free-energy level at the particle–water interfaces. Typical examples of the latter are the colloidal crystallization of monodispersed gold and silver particles. They acquire negative charges *spontaneously*, when they disperse in water, and then they always show negative ζ-potential in suspension state. However, these particles should have no charges on the sphere surfaces when the spheres do not come in contact with water [1]. The charges on a colloidal sphere are introduced spontaneously when the amount of charge is not sufficient for the stabilization of dispersion, whereas the charges are bound with their counterions when the charge amount on a colloidal sphere is excessive. This *charge renormalization effect* has been discussed by various researchers [2–5].

The ionic groups at the interfaces leave their counterions in the medium phase, and these excess charges accumulate near the interface, forming an *electrical double layer*. The

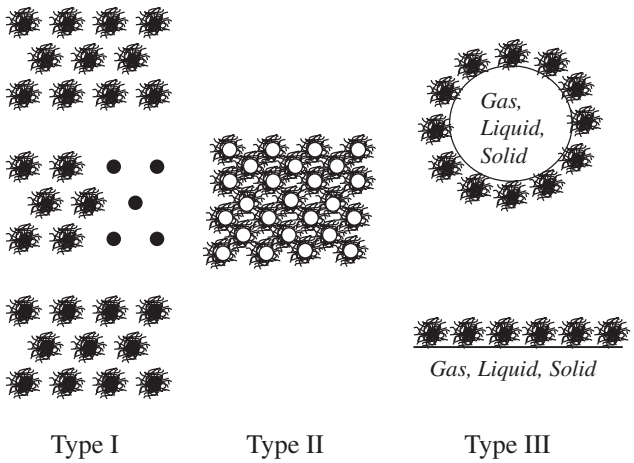

FIGURE 41.1 Types of gel crystals.

counterions and coions in the diffuse region are distributed according to a balance between the thermal diffusive forces and the forces of electrical interaction with colloidal particles. The impact of the electrical double layers on colloidal crystallization has been clarified by many researchers [1–28]. Giant sizes of colloidal single crystals [20–29] have been formed in the exhaustively deionized and diluted suspension of colloidal spheres [20,29–31]. Colloidal crystals are beautiful and fantastic with respect to their iridescent structural colors, since the interparticle distance is just in the range of light wavelengths and each single crystal reflects light in different colors as a result of Bragg diffraction. From our experience, the colloidal spheres smaller than ~40 nm in diameter hardly form crystal structures even though the spheres are monodisperse and the suspensions are deionized exhaustively because of the very vigorous Brownian thermal motion of such small spheres and the difficulty in the formation of the electrical double layers. Colloidal crystals were not formed for the monodisperse and 29-nm spheres at any sphere concentrations, despite the formation of the typical liquid-like structures, *ordered liquid* [32]. The electrical double layers might not be formed firmly when the sphere size is not large enough relative to the size of simple electrolytes and/or medium-sized molecules, since the interfaces between the spheres and the solvent molecules are not formed firmly.

Now, most gel dispersions are also turbid, and characteristically they appear to be just in between *linear-type polymer solution* and *colloidal dispersion* as schematically represented in Fig. 41.2. When the degree of cross-linking is quite low, then the gels will behave like polymer solutions, whereas the gels will behave as colloidal particles as their degree of cross-linking increases. Crystallization of thermosensitive gel spheres of poly(*N*-isopropylacrylamide), pNIPAm and their mixtures with other colloidal spheres has been studied in aqueous media by several research groups hitherto (see also Table 41.1) [33–51]. Especially in the authors' previous papers [48–51], the important role of the electrical double layers on the crystallization of gel spheres has been demonstrated, for the first time, using the monodisperse thermosensitive gel spheres of poly(*N*-isopropylacrylamide) ranging from 0.5 mol% to 10 mol% in the degree of cross-linking and also ranging from 200 to 600 nm in gel size in their hydrated and swollen states.

Type I gel crystals are really crystal, where the gel spheres move with the translational and rotational modes by the thermal energy $k_B T$ but retain their equilibrium positions. On the other hand, thermal movement of type II gel crystals is greatly restricted. Type II gel crystals, gels containing crystal structure, however, may be much more useful in order to build up the external field responsible optical devices, because the contraction and/or extension of gels, which is one of the most interesting function, is significant compared with other types of gel crystals.

41.2 GEL SPHERES USED FOR TYPE I GEL CRYSTALS

One of the most familiar gel spheres of type I gel crystals is thermosensitive polymer gel spheres, pNIPAm gels. Table 41.2 shows several characteristics of a series of poly(*N*-isopropylacrylamide) gel spheres, pNIPAm(200-0.5), pNIPAm(200-2), pNIPAm(200-5), pNIPAm(200-10), pNIPAm(400-5), pNIPAm(600-5), and pNIPAm(1500-5). Here, the first and second numbers in parentheses indicate the rough values of sphere size at 20°C in nanometer scale and the degree of cross-linking in mol%, respectively. The sphere size, d_0 estimated from the dynamic light-scattering measurements, decreased sharply as the suspension temperature increased. The temperatures of the transition were around 33°C for each sphere. Deionized stock suspensions, with their concentrations ranging from ∼2 to 4 wt%, emitted strong iridescent colors at 25°C. The densities of the gel spheres in the suspension state (ρ) were estimated from the reflective spectroscopy by the author's group, for the first time. The ρ-value is obtained from the ratio of the gel concentration in weight percent divided by that in volume percent. The density increased sharply as the suspension temperature increased. At an elevated temperature the gel spheres must be highly compact with the polymer chains and colloidal interfaces forming firmly. The ρ-value of the gel spheres increased as the degree of cross-linking and/or size of spheres increased. The ζ-potentials were negative and decreased slightly as the degree of the cross-linking and/or sphere size increased. These results are consistent with the colloidal nature of the gel spheres; specifically, the water–gel interfaces form more firmly as the sphere density increases. The negative charges on the gel interfaces originate mainly from the charges from the initiator used, potassium persulfate in the polymerization processes and also from the spontaneous charging at the interfaces between the gel spheres and water as was described in Section 41.1.

The volume fraction of gel spheres, ϕ-values, are estimated from the l-values using Eq. (41.1) [52]:

$$l = 0.904 \times d_0 \times \phi^{-1/3} \tag{41.1}$$

The characteristic values of *cationic* gel spheres, lightly cross-linked poly(2-vinyl pyridine) spheres, AIBA-P2VP [53], and lightly cross-linked poly(2-vinyl pyridine) stabilized with poly (ethylene glycol), PEGMA-P2VP [54], are given in Table 41.2. The diameters were measured using various techniques, including scanning electron microscopy (SEM), laser diffraction particle size analyzer method (LDPS), electrophoretic light-scattering measurements (ELS), and dynamic light-scattering measurements (DLS). The mean size of PEGMA-P2VP gel spheres d_0 decreased slightly when the degree of cross-linking increased from 0.1 to 1 mol%, which is consistent with the dependence of the degree of cross-linking of pNIPAm gel spheres. Zeta-potentials of AIBA-P2VP increased as degree of cross-linking decreased, whereas those of PEGMA-P2VP decreased. One cause will be due to the fact that AIBA-P2VP is softer and contain a more amount of water molecules within a gel sphere compared with PEGMA-P2VP, since the effective density of AIBA-P2VP gel spheres (ρ) is small compared with that of the corresponding PEGMA-P2VP, especially at low degree of cross-linking. When the gel spheres are soft, the ionic groups contacting with water molecules and then number of the ionized groups should increase.

The ρ-values of AIBA-P2VP and PEGMA-P2VP increased with increasing degree of cross-linking and were insensitive to the sphere concentration as is shown in Tables 41.1 and 41.2. The ρ-values of PEGMA-P2VP gel spheres were slightly larger than those of AIBA-P2VP and also increased with increasing degree of cross-linking. The ρ-values of pNIPAm gel crystals were quite insensitive to the sphere concentration. The density of AIBA-P2VP in the dried state should be close to that of PEGMA-P2VP, since most of the content of both gel spheres is P2VP polymer. The specific density of PEGMA-P2VP was measured to be 1.1 in mean value [53,54]. Thus, the volume fractions of the AIBA-P2VP gel polymers and water in suspension state are evaluated to be 0.74 (=0.81/1.1) and 0.26, 0.64 (=0.7/1.1) and 0.36, and 0.45 (=0.51/1.1) and 0.55, for AIBA-P2VP(1), AIBA-P2VP(0.5), and AIBA-P2VP(0.1), respectively [53]. Furthermore, the volume fractions of the PEGMA-P2VP gel polymers and water in suspension state are estimated to be 0.75 (=0.83/1.1) and 0.25, 0.66 (=0.73/1.1) and 0.34, and 0.85 (0.93/1.1)

TABLE 41.2 Characteristics of AIBA-P2VP and PEGMA-P2VP Gel Spheres at 25°C

				Critical conc. Melt. (wt%)		l_D (nm)	
Gel spheres	d_0 (nm)	ζ-Pot. (mV)	ρ	With resins		Without resins	Ref.
AIBA-P2VP(0.1)	170	+60	0.51	0.2	0.8	44.6	53
AIBA-P2VP(0.5)	170	+58	0.70	0.18	0.5	64.0	53
AIBA-P2VP(1)	180	+47	0.81	0.7	1.5	81.5	53
PEGMA-P2VP(0.1)	400	+16.0	0.83	1.1	1.2	260	54
PEGMA-P2VP(0.5)	390	+21.9	0.73	0.7	1.0	230	54
PEGMA-P2VP(1)	385	+22.7	0.93	0.7	1.0	260	54

and 0.15, respectively, for PEGMA-P2VP(0.1), PEGMA-P2VP(0.5), and PEGMA-P2VP(1) [54]. This means that the quarter volume of a gel sphere is filled with water in suspension state. Clearly, AIBA-P2VP and PEGMA-P2VP are very hard and close to the typical colloidal hard spheres. pNIPAm gel spheres and the core–shell-type gel spheres, for example, have been studied intensively in deionized water and at room temperature [55–67].

41.3 PHASE DIAGRAM AND MORPHOLOGY OF TYPE I GEL CRYSTALS

Close-up color pictures of colloidal single crystals of pNIPAm(200-5) gels in a test tube are shown in Fig. 41.3 [48]. Images (a) and (b) identify deionized and salt-containing suspensions, respectively. The giant single crystals of several 10s of millimeters, which are composed of gel spheres, were observed especially in the low gel concentrations and in the deionized state with the coexistence of the ion exchange resins. There are two kinds of single crystals, which were recognized macroscopically, by the naked eye: (1) red, blue, yellow and blocklike crystals and (2) pillarlike ones. (1) The formers form from the *homogeneous nucleation mechanism* in the bulk phase far from the cell wall. The color change from the reddish to bluish or bluish (or greenish) to reddish in a single crystal is due to the change in the incident angles of light through the curved wall of the test tube. When a test tube is rotated slowly, the single crystals exhibiting the strong iridescent colors disappeared suddenly, but the other single crystals appeared in the other places. These iridescent colors are clearly ascribed to Bragg diffraction of the incident light through the crystals. The single crystals are packed densely separated with the grain boundaries, and the appearance and disappearance of the crystals take place depending on the Bragg diffraction conditions. On the other hand, the pillarlike crystals grow from the *heterogeneous nucleation mechanism* along the cell wall. It should be noted here that each single crystal of the typical colloidal spheres is surrounded by grain boundaries and packed densely [16,20,29,30,68]. The morphology of the single crystals of the gel spheres is quite similar to that of the typical colloidal spheres [3,16,20–23,29–31,69–74]. Large single crystals were observed in the rather diluted gel suspensions *in the presence of salt*, for the first time. For typical colloidal hard spheres, large single crystals are not formed with salt systems. In other words, gel crystals are rather insensitive to the salt addition compared with typical colloidal sphere system.

Figure 41.4 is a phase diagram of the crystallization of pNIPAm(200-5) at 25°C [48]. The figure also shows the size of single crystals very roughly corresponding to the size of the open circles. Solid circles show the colloidal liquid state. Concentrations of the diffusible simple ions (most of them will be hydronium and hydroxide ions in aqueous media) in suspension with and without ion exchange resins in the figure are estimated to be approximately 2×10^{-7} M and 1×10^{-6} M, respectively, from the conductance measurements and the authors' experience [30, 31]. Clearly, the critical concentration of melting (or crystallization) increased by the addition of a small amount of sodium chloride. The phase diagram of the gel spheres is also very similar to those of typical colloidal spheres, polystyrene, colloidal silica, and PMMA spheres, for example [20,22,31,72,73], although the absolute values of the corresponding volume percents (vol%) of pNIPAm(200-5) are 10-fold higher than those of typical colloidal spheres. This difference in the critical concentrations supports the idea that the crystallization takes place by the

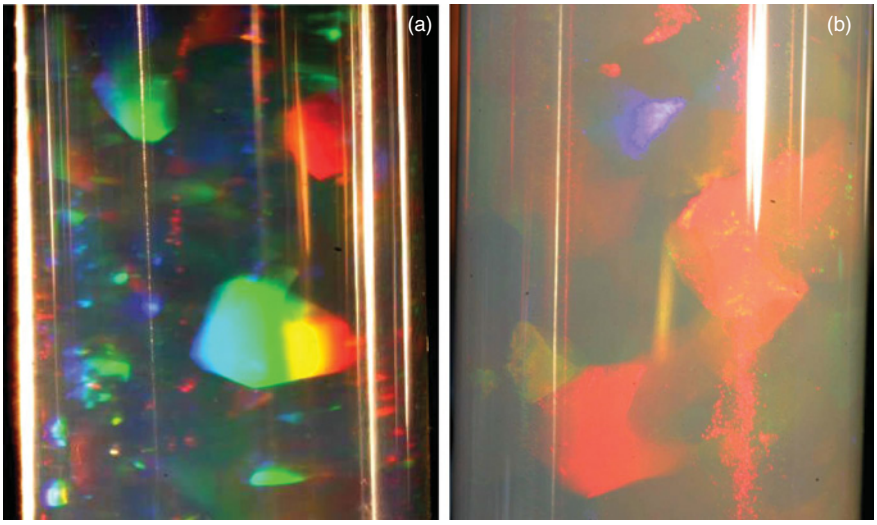

FIGURE 41.3 Close-up color images of PNIPAM(200-5) in a test tube: (a) [PNIPAM(200-5)] = 0.116 wt%, with resins, at 25°C; (b) 2.82 wt%, [NaCl] = 3.5×10^{-5} M, at 25°C. For a color version of this figure, see the color plate section.

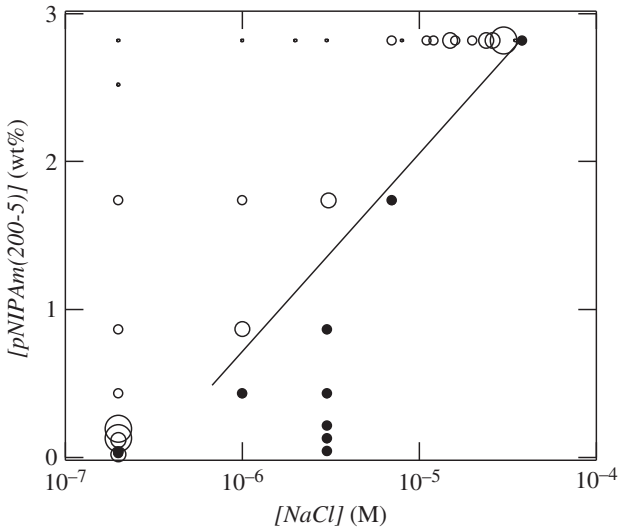

FIGURE 41.4 Phase diagram of colloidal crystal of PNIPAM(200-5) gel spheres as a function of salt concentration at 25°C. White circles–crystal, size of circles shows rough values of crystal size; black circles—liquid. (Adapted from Okubo 2002 [43].)

incomplete electrical double layers from the *vague interfaces* of gel spheres compared with the firm interfaces of the typical colloidal spheres.

The mean size of the single crystals observed macroscopically changed as a function of the concentration of pNIPAm gel spheres. Several important findings are summarized [48–51]. *First*, size of single crystals of pNIPAm(200-10) from the homogeneous nucleation mechanism decreased sharply as gel concentration increased. *Second*, the very large single crystals formed at the gel concentration slightly higher than the critical concentration of crystallization at 20°C especially for pNIPAm(200-10), which is quite similar to the observation of typical colloidal spheres. This is due to the fact that the sphere–solvent interfaces form firmly when the degree of cross-linking is large. *Third*, crystal size versus concentration profiles of pNIPAm(200-10) were almost completely insensitive to the suspension temperature between 20 °C and 45°C, whereas the profiles of pNIPAm having low degree of cross-linking were sensitive to the suspension temperature. This result also supports the theory that the intergel repulsion of pNIPAm(200-10) is strong compared with that of gels having lower degrees of cross-linking.

Size of single crystals of pNIPAm(400-5) from the homogeneous nucleation mechanism increased gently as gel concentration increased, and the largest single crystals formed at the gel concentration around 2 wt% at 20°C and then the crystal size decreased again gently. At high temperatures the crystals' maximum size was not observed in the range of concentrations examined. These gentle concentration dependences of crystal size of pNIPAm(400-5) are different from those of the typical colloidal dispersions and also those of small gel spheres, where very large single crystals formed at the sphere concentration slightly higher than the critical concentration of melting and crystal size decreased sharply as the sphere concentration increased. Concentration dependences of pNIPAm(600-5) spheres are complex. At 20°C and 33°C the largest crystals appeared at the gel concentration close to the critical concentration of melting, but their size decreased gently as sphere concentration increased. At 45°C, crystal size increased gently with sphere concentration, and the maximum size of crystals usually forms around ≥4 wt%. Thus, the concentration dependences of the crystal size of pNIPAm(400-5) and pNIPAm(600-5) are gentle and different from the other small gel spheres such as pNIPAm(200-5). These results support the assumption that the crystals of large gel spheres are not so stable compared with the small gel spheres. In general, the relative contribution of the electrical double layers (l_D) against the sizes of gel spheres (d_o) decreases as the gel size increases.

Another team of investigators [75] proposed the reentrant order–disorder transition from their theoretical study as a function of gel sphere concentration. Two other investigators [76] reported the supporting data using static (SLS) and dynamic light-scattering (DLS) technique. This author believes the polydispersity index of the gel spheres to be most important for phase transitions.

41.4 LATTICE STRUCTURE OF TYPE I GEL CRYSTALS

SLS measurements of deionized suspensions of the thermosensitive gels of poly(*N*-isopropylacrylamide) with various degrees of cross-linking and sizes were made at 20°C and 40°C [77]. Sharp scattering peaks are observed in the scattering curve and they were assigned to the face-centered cubic (fcc) and/or body-centered cubic (bcc) lattices in the distribution of gel spheres. The fcc and bcc crystal structures formed in the stable and unstable conditions respectively; thus, the former formed more favorably at high sphere concentrations and/or low temperatures. The closest intersphere distances were much longer than the hydrodynamic diameters of the gel spheres, especially at low sphere concentrations. These experimental results emphasize the important role of the extended electrical double layers in the crystallization of gel spheres, although the contribution of double layers in gel systems is weak compared with that in the typical colloidal spheres.

Figure 41.5 shows examples of the static light-scattering intensities, with $I(q)$ as a function of scattering vector q for pNIPAm(200-5) at 0.3 wt% and at 40 °C [77]. Sharp blue and the broad red curves indicate data for the coexistence of suspensions with and without ion exchange resins. These suspensions are *crystal* and *liquid*, respectively. Very sharp peaks appeared for the crystals. The light-scattering

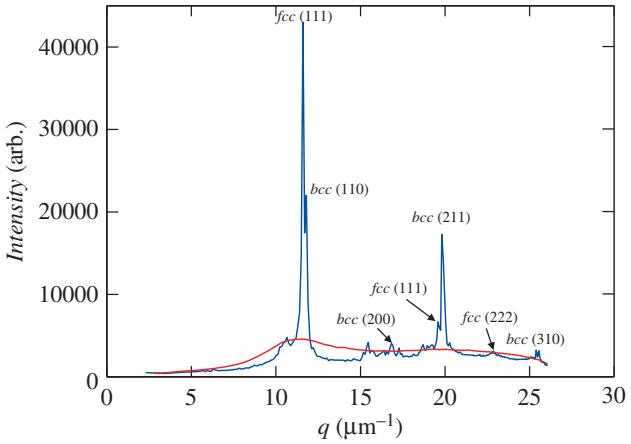

FIGURE 41.5 Scattering intensity of aqueous suspensions of pNIPAm(200-5) as a function of scattering vector at 40°C, 0.30 wt%. Blue curve–with ion exchange resins; red curve–without resins.

intensity measurements were made at intervals of half of a degree (0.5°). However, this interval was not always narrow enough for the determination of very reliable values of the peak scattering vector q_m. Similar profiles in the intensity of scattered light showing the peaks have been reported for typical colloidal crystals of hard spheres in deionized aqueous suspensions. However, most of the experiments of hard spheres were made for the much lower sphere concentrations than the gel systems [78–81].

Assignment of the respective peaks q_m to the crystal planes was made from comparison of the observed peak vectors with the calculation from $q_{h,k,l} = 2\pi/a(h^2+k^2+l^2)^{1/2}$, where h, k, and l are Miller's indices and a is the unit cell size. During crystallization and the aging process it is highly plausible that several kinds of single crystals having the same crystal lattice structures but slightly different lattice spacing values form. The quite low rates of crystallization of pNIPAm gels were compared with those of typical colloidal spheres such as colloidal silica spheres (see Section 41.5). Only the high and main peaks were assigned to be the reflections of face-centered cubic (fcc) and body-centered cubic (bcc), lattices as is shown in Fig. 41.5. The Bragg distances (d_B) were evaluated from the q_m values using Bragg equations, $d_B = 2\pi/q_m$. The nearest-neighbored intersphere distance (l), which is given by $(3/2)^{1/2}d_B$, agreed satisfactorily with the corresponding l_0-values calculated from the sphere concentration. In this work, l_0-values were calculated assuming the simple cubic lattice in the sphere distribution, although the real crystals of gel spheres are fcc and/or bcc lattices. Differences in the l_0-values among the simple cubic fcc and bcc lattices at the same sphere concentration are within 3%, corresponding to the experimental errors in SLS measurements. The peaks are sharp and the background intensity is low. Thus, there should not be a significant difference between the profiles in the structure factor $S(q)$ and the intensity of scattered light $I(q)$:

$$I(q) = P(q)\,S(q) \tag{41.2}$$

Here, $P(q)$ is the single-particle form factor, and can be estimated experimentally from the $I(q)$ measurements on the same suspension but in the presence of salt, for example.

The scattering curve of the gel suspensions without resins shown in red in Fig. 41.5 showed rather broad main and further broad second peaks. The fcc and bcc crystals coexisted. Clearly, very sharp double peaks appeared at low q in the figure, and were assigned to the (111) and (110) reflections of fcc and bcc lattices, respectively. Most other peaks were then assigned rather accurately as is shown in Fig. 41.5. The difference in peak scattering vectors between the (111) reflection of fcc and (110) of bcc was only 1–2° in scattering angle. The agreement between the observed distance and the calculation from the sphere concentration is satisfactory when the experimental errors of the SLS measurements are taken into account. The red scattering curve in Fig. 41.5 demonstrates, on the other hand, that the suspension without resins is the typical *liquid* or *disordered liquid* structure.

Sharp reflection peaks were observed for pNIPAm gel suspensions especially at high gel concentrations and high suspension temperature. The primary peak wavelength (λ_p) in the reflection spectroscopy of colloidal crystals at the scattering angle of 90° is estimated from the nearest-neighbor intersphere distance (l) of the face-centered- and/or body-centered-cubic lattices, which are most familiar types of lattice structures in colloidal crystals [52]:

$$\lambda_p = nl/0.6124 \tag{41.3}$$

Here, the refractive index (RI) of the liquid (n) is given as follows:

$$n = \phi \times (\text{RI of gel sphere}) + (1-\phi) \times (\text{RI of water}) \tag{41.4}$$

In our experiments gel sphere concentrations are not so high, and n is safely assumed to be that of water, 1.33. Thus, l-values are estimated from reflection spectroscopy.

The nearest-neighbor intergel sphere distance (l) is in a linear relationship with the reflection peak wavelengths given by Eq. (41.3). The lattice spacing of gel sphere crystals does not change with variation of suspension temperature, because the lattice spacing is determined by sphere concentration or sphere number in suspension, and *not by gel size*. Insensitivity of the lattice spacing of the thermosensitive gel sphere crystals on suspension temperature was supported experimentally by others [67] as well as the present authors. Temperature

dependence of the lattice spacing of type II gel crystals is substantial [82], since the lattice spacing changes following variation in gel size.

41.5 KINETICS OF TYPE I GEL CRYSTALLIZATION

The size of the colloidal single crystals from the homogeneous nucleation L is estimated by Scherrer's equation from the half-width of the reflection spectrum [83, 84]

$$L \propto n\,(\Delta q)^{-1} \tag{41.5}$$

where n is the number of the order in the Bragg equation. q is the scattering vector, and Δq denotes $q_l - q_s$, with q_l and q_s referring the largest and smallest wavelengths corresponding to the half-width of the reflection peak. It should be noted here that Eq. (41.5) is derivable by assuming the existence of a powderlike random distribution of a large number of colloidal crystals in the reflection volume. However, this assumption is difficult to maintain, since the most dense planes of the colloidal single crystals tend to orient parallel to the cell plane.

The peak intensity I of the reflection spectra is approximated by Eq. (41.6) [26,81]

$$I \propto N_{\text{cryst}} L^3 \propto L^3 \tag{41.6}$$

where N_{cryst} is the number of single crystals in the reflection volume, which is directly proportional to the number concentration of crystals in the final stages of crystallization, being equal to the total number of nuclei that were formed in the whole course of crystallization. The crystal growth rate v is evaluated from the cube-root plot of the reflection intensity using Eq. (41.6) or the half-width of the reflection peak using Eq. (41.5).

Most kinetic measurements on colloidal crystallization, including gel sphere crystallization, have included observation of an induction period, after which the crystal growth started especially in the diluted suspensions. This observation supports the assumption that the kinetics of colloidal and gel crystallization is explainable by the classical diffusive crystallization theory, including nucleation and crystal growth processes. The number of nuclei that germinate per unit time, the nucleation rate v_n is given by

$$v_n = N_n / t_i \tag{41.7}$$

where N_n is the total number of nuclei that are formed during the nucleation process and t_i is the induction period. Here, we assume that the number of nuclei equals the number of single crystals formed. The number of spheres per mean size of single crystals N_c is given for the cubic lattice by

$$N_c = 2^{1/2} L^3 / l^3 \tag{41.8}$$

where L and l are the mean size of single crystals formed and the closest intersphere distance, respectively. The total number of colloidal spheres (N_T) in a unit volume is $\phi/[(4/3)\pi(d_0/2)^3]$. Then, v_n is given as follows:

$$v_n = N_T / N_c t_i \tag{41.9}$$

The size of a single crystal is highly polydisperse, as has been observed previously [20]. Therefore, clear-cut separation of the nucleation step from the crystallization process will be difficult, and the nucleation reaction may remain even in the crystal growth period. Furthermore, Ostwald ripening of the crystals, that is, further growth of large crystals and disappearance of small ones, has not been observed for many colloidal crystallization systems.

According to two investigators [83,84], the crystal growth rate v is given by

$$v = v_\infty \left[1\text{-}\exp(-\Delta\mu / k_B T)\right] \tag{41.10}$$

Here, $\Delta\mu$ is the chemical potential difference between the crystal and liquid phases and is given by Eq. (41.11)

$$\Delta\mu = \mu_{\text{cryst}} - \mu_{\text{liq}} \tag{41.11}$$

$\Delta\mu > 0$ means that the crystallization will proceed. We should note that Eq. (41.12) holds [71]:

$$\Delta\mu / k_B T = \ln(\phi / \phi_c) \sim \sigma \tag{41.12}$$

where σ is the relative supersaturation given by $(\phi - \phi_c)/\phi_c$. From Eqs. (41.10) and (41.12), we can derive the following equation:

$$v = v_\infty [1\text{-}\exp(-\sigma)] \tag{41.13}$$

Equation (41.13) is further simplified as follows:

$$v = v_\infty - v_\infty \phi_c / \phi \tag{41.14}$$

Equation (41.14) often holds in our experiments for typical colloidal hard spheres [81,85–92]; v_∞ is given by Eq. (41.15):

$$v_\infty = 4D_0 / \xi \tag{41.15}$$

Here, D_0 is the diffusion coefficient of spheres and ξ is the mean diffusion length (path) in the crystallization suspension. The unit of gel concentration in the kinetic study should be a volume fraction (or volume percent) instead of a weight percent as is shown in Eqs. (41.12) and (41.14), for example.

Crystal growth rate coefficients, k ($= v/L_\infty$) of the crystallization of a series of thermosensitive gel spheres of pNIPAm are shown in Fig. 41.6 [93]. Crystallization of colloidal silica

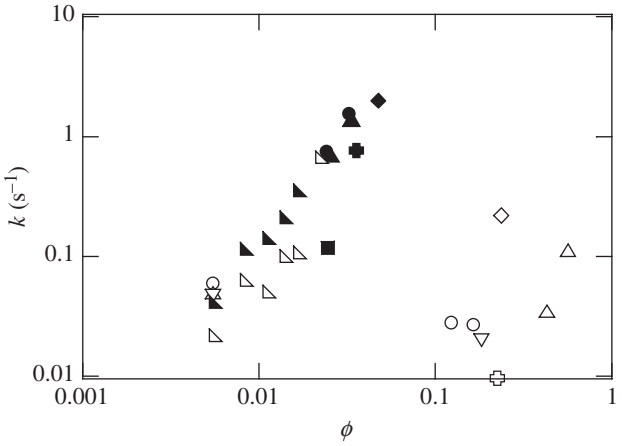

FIGURE 41.6 Rate coefficients, k in the crystallization of PNIPAM and CS83 spheres at 20°C (open symbols) and 45°C (solid symbols). (200-10) circles, (200-5) broad crosses, (200-2) triangles, (200-0.5) squares, (400-5) reversed triangles, (600-5) diamonds, CS83 triangle flags.

spheres are also compared. The k-values of gel and silica systems increased sharply as the sphere concentration and suspension temperature increased. The k-values of gel system were insensitive to the degree of cross-linking in the range from 2 to 10 mol% of cross-linker against amount of the monomer in mole, and decreased sharply when the degree of cross-linking decreased further to 0.5 mol%. The k-values increased as gel size increased. The k-values of gel systems at 20°C were small and observed only at very high sphere concentrations in volume fractions, whereas those at 45°C were high and close to those of silica systems. Induction time t_i, after which crystallization starts, increased as the degree of cross-linking increased and/or the gel size decreased at any temperatures, when comparison was made at the same gel concentration. The t_i-values at 45°C were high and decreased sharply with increasing sphere concentration, whereas those at 20°C were high only at very high sphere concentrations. These kinetic results support the theory that the electrical double layers play an important role in gel crystallization in addition to the excluded volume of gel spheres. It is deduced further that the electrical double layers of the gel system form from the vague interfaces (between gel and water phases) compared with those of typical colloidal hard-sphere system.

41.6 ROLE OF ELECTRICAL DOUBLE LAYERS ON TYPE I GEL CRYSTALLIZATION

Colloidal crystallization of typical colloidal hard spheres in aqueous and polar organic solvents takes place by the thermal fluctuation of the spheres and the extended electrical double layers. In other words, electrostatic repulsive intersphere interactions exist. In the deionized state, the electrical double layer is very thick and the intersphere repulsive forces prevail over a long distance as much as micrometers, although the forces become weak. Formation of the crystal-like ordering is nicely explained with the *effective soft-sphere model*. The effective diameter d_{eff} of the spheres includes the Debye screening length l_D and is given by the diameter d_0 plus twice the Debye length in Eq. (41.16). Here, d_0 of gel spheres is assumed to be very close to the hydrodynamic diameter measured by the dynamic light-scattering spectroscopy:

$$d_{\text{eff}} = d_0 + 2 \times l_D \tag{41.16}$$

Debye screening length is given by Eq. (41.17)

$$l_D = (4\pi e^2 n / \varepsilon k_B T)^{-1/2} \tag{41.17}$$

where e is the electronic charge, ε is the dielectric constant of the solvent, and n is the concentration of "diffusible" or "free-state" cations and anions in suspension. Thus, n is the sum of the concentrations of diffusible counterions, foreign salt, and both hydronium and hydroxide ions from the dissociation of water. The maximum value of l_D in water is ~1 μm, which is estimated from Eq. (41.17) by taking $n = 2 \times 10^{-7}$ (mol dm^{-3}) $\times N_A \times 10^{-3}$ cm^{-3}, where N_A is Avogadro's number. When d_{eff} is shorter than the intersphere distance l, a gaslike distribution is observed. When d_{eff} is comparative to, or a bit shorter than, the intersphere distance, the distribution of spheres is usually liquidlike. When the effective diameter is close to, or larger than, the observed intersphere distance, crystal-like ordering is formed. This effective soft-sphere model has been supported by systematic comparison between d_{eff} and l values. According to the effective soft-sphere model, l is close to d_{eff} in crystal suspensions.

The ratio of the Debye screening length (l_D) against the hydrodynamic diameter (d_0) size l_D/d_0 is given in Table 41.1 [48–51]. This ratio is an important parameter to know for the relative contribution of the Debye screening effect against the excluded-volume effect. The l_D/d_0-values increased sharply as gel concentration decreased and/or temperature increased. The ratio l_D/d_0 at 1 wt% increased as gel size increased at any temperature. The main cause for these tendencies is due to the fact that the density of the gel spheres increased with increasing size as is seen in Table 41.1. The colloidal interfaces should be formed more easily for more compact gel spheres. Interfaces between the gel spheres and medium-sized molecules will be located slightly inward from the outside edge of the gel spheres. The crystallization of pNIPAm gels takes place by the significant contribution of the extended electrical double layers in addition to the excluded-volume effect, especially at low gel concentrations, at low temperatures, at high degrees of cross-linking of gel spheres, and further at large gel spheres. This indicates further that

the gel spheres share interfaces with bulk water phase. In other words, simple ions inside a gel sphere are placed under restraint from free diffusion in part, although most simple ions and water molecules are able to diffuse rather freely inside the gels.

The l_D/d_0 ratios are calculated to be 0.45, 0.38, and 0.26 for the crystals of AIBA-P2VP(1), AIBA-P2VP(0.5), and AIBA-P2VP(0.1), respectively, at approximately 8–10 wt%, from Table 41.2 [53]. The ratios are calculated to be 0.65, 0.59, and 0.68 for the suspensions of PEGMA-P2VP(0.1), PEGMA-P2VP(0.5), and PEGMA-P2VP(1) at approximately 5 wt%, respectively [54]. These results support the theory that the cationic gel spheres AIBA-P2VP and PEGMA-P2VP have *interfaces* with water phases but the thickness of the electrical double layers are not so large compared with the anionic charged gel and colloidal hard spheres even in the deionized suspension. The other reason for the smaller the electrical double layers is due to the fact that both cationic gel spheres AIBA-P2VP and PEGMA-P2VP are still large in size compared with typical pNIPAm gel spheres. Furthermore, the fact that the calculation of the l_D/d_0 of AIBA-P2VP and PEGMA-P2VP was made at rather high sphere concentrations, must be another important cause. In conclusion, it is clear that the crystallization of the cationic gel spheres takes place by the important contribution of the *extended electrical double layers* in addition to the *excluded-volume effect* of the gel spheres themselves, although the interfaces of gel spheres with water come to be vague, especially when the degree of cross-linking is low. Two coworkers [94] measured simultaneous static and dynamic three-dimensional cross-correlated light scattering of concentrated pNIPAm microgels in dimethyl formamide. They found that the microgel structure is different from that of hard spheres as the cross-link density decreases, leading to a fuzzy particle surface with dangling polymer chains.

41.7 RIGIDITY OF TYPE I GEL CRYSTALS

According to a discussion in one study [95], the nearest-neighbor intersphere distance l is given by Eq. (41.18) in the sedimentation equilibrium

$$(l - l_m)/l_m = (\sigma_{\text{eff}}\, g\, \phi_m/G)(h - h_m) \qquad (41.18)$$

where l_m and ϕ_m indicate the lattice spacing (nearest-neighbor intersphere distance) and the sphere concentration (in volume fraction) at the midplane of the suspension column in the sedimentation equilibrium, respectively; h and h_m are the heights of the arbitrary layer and midplane; g is the gravitational constant; σ_{eff} is the difference in the specific densities of pNIPAm gel spheres minus that of water in the suspension state; and G is the rigidity (Young's elastic modulus) of gel crystal.

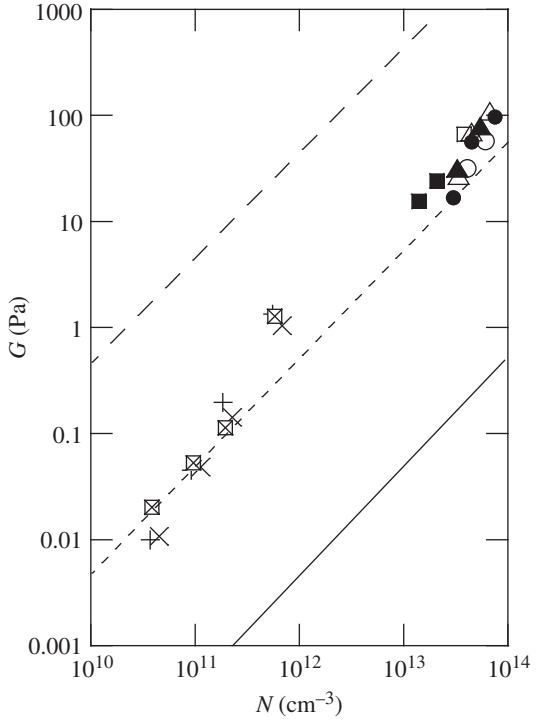

FIGURE 41.7 Log G versus log N plots of pNIPAm(200-2) (open circle), pNIPAm(200-5) (triangle), pNIPAm(200-10) (square), AIBA-P2VP(0.1) (solid circle), AIBA-P2VP(0.5) (solid triangle), AIBA-P2VP(1) (solid square), PEGMA-P2VP(0.1) (plus sign), PEGMA-P2VP(0.5) (cross sign), and PEGMA-P2VP(1) (cross sign in square), $b = 1$ (solid line), 0.1 (short broken line), 0.01 (long broken line).

The G-values thus estimated are shown in Fig. 41.7 as a function of number density of the gel spheres N. As have been discussed in the literature [95,96], the order of magnitude of the modulus G is approximated in terms of the magnitude of the thermal fluctuation δ of a sphere as

$$G \cong f/l \cong (k_B T/ < \delta^2 >)/l \qquad (41.19)$$

where f is the force constant, l is the intersphere distance, δ is the thermal fluctuation of a sphere in the effective potential valley, k_B is the Boltzmann constant, and T is the absolute temperature. Introducing a nondimensional fluctuation parameter b for $<\delta^2>^{1/2} / l$, the modulus is obtained as a linear function of N [96,97]:

$$G \cong N k_B T/b^2 \qquad (41.20)$$

When $b = 1$, Eq. (41.20) gives the elastic modulus of an ideal gas having the same sphere concentration. Lindemann's law of crystal melting tells us that $b < 0.1$ holds for a stable crystal. Short and long dashed lines in Fig. 41.7 represent $b = 0.1$ and 0.01, respectively. It is clear that all the G-values of pNIPAm gel spheres shown by open symbols are located around the short dashed line. The solid symbols in Fig. 41.7

show the *G*-values of the cationic gel spheres, lightly cross-linked poly(2-vinylpyridine) stabilized with poly(ethylene glycol), PEGMA-P2VP measured by the microscopy in the sedimentation equilibrium [54]. Most *G*-values of PEGMA-P2VP spheres also located around short dashed lines, and the slope of the observed log *G* values against log *N* plots seems slightly larger than that of the short dashed line. Thus, there exists no difference in the elastic properties between anionic pNIPAm and cationic AIBA-P2VP and PEGMA-P2VP gel spheres. Most of *G*-values of the typical colloidal crystals are located between the short dashed and long dashed lines [21–23]. The *b*-values of pNIPAm gel spheres estimated from the *G*-values using Eq. (41.20) were $0.05 \sim 0.07$, $0.05 \sim 0.09$, and $0.05 \sim 0.15$, repectively. These results on *G*- and *b*-values of pNIPAm gel crystals support the notion that the elastic properties of gel crystals is not essentially different from those of typical colloidal crystals and further metals, polymers, and other materials [96, 97]. These experimental results also emphasize that the gel crystals are soft compared with those of typical hard-sphere systems and that the role of the extended electrical double layers for the crystallization of gel spheres is important but weak compared with that of hard colloidal spheres.

41.8 TYPE II GEL CRYSTALS

One team of investigators [98] have studied this field for a long time. They prepared crystal arrays of polystyrene spheres (150 nm in diameter) first in aqueous media and then polymerized the suspension with 50% *N*-vinylpyrrolidone, 17% acrylamide, 4.5% *N*,*N*-methylene bisacrylamide, and 1% benzoin methylether [98]. The gels maintained the crystal structure of spheres and the extinction peak wavelength did not change as a result of gelation. The peak wavelength shifted toward a shorter one by a uniaxial strain in the plane of the film, and extinction spectra recovered again when stress was relieved. The same team prepared the thermosensitive gels containing crystal arrays of polystyrene spheres in the interior of the gel [99]. Lattice spacing changed with gel temperature quite sharply. Inverse opal structure was observed to have a periodically ordered porosity, endowing type II hydrogels with structural colors based on Bragg diffraction of light. We should note that the porous hydrogels exhibit a rapid change in volume in response to environmental variations [100–110], pH, ionic concentration, and temperature, for example. Type II gel crystals in organic solvents were prepared by another team [66, 67].

41.9 TYPE III GEL CRYSTALS

Studies of adsorbed and stabilized emulsions or forms by solid colloidal particles were reported [111, 112], for example, more than a century ago. Silica sols, carbon black, and polystyrene particles were used as emulsifiers to preparestable oil-in-water and water-in-oil emulsions [113,114]. Studies on stabilizing forms by the mixtures of solid particles with surfactants and/or surface-active polymers have been performed [113,115,116], but few reports of foams stabilized only by solid particles have appeared in the literature [111,113,117–120]. One team [111,112] found the formation of highly stable foams adsorbed and stabilized gel spheres with *ordered* polystyrene spheres in water. The suspensions emitted light induced by Bragg diffraction of the incident white light and were stable for more than one year. In another study pH-sensitive liquid marbles were prepared by adsorption of poly(2-vinylpyridine) spheres on the liquid water [123]. Adsorption of cross-linked poly(2-vinylpyridine) on the surfaces of gold particles was studied [124].

41.10 TYPE III GEL CRYSTALLIZATION OF GEL AGGLOMERATES DURING DRYNESS

Drying patterns of gel sphere suspensions of pNIPAm [125–128], AIBA-P2VP [129], and PEGMA-P2VP [130] were studied on a coverglass, a watchglass, and a Petri glass dish. Formation of the monodispersed agglomerated particles and their ordered arrays were observed. Figure 2.8 shows typical examples of the following microscopic drying structure patterns: (a) flickering *ordered spokelines*, (b) *ordered rings*, (c) *net* structure, and (d) *lattice* like ordered structures of the agglomerated particles. The net and lattice structures formed more favorably at high degrees of cross-linking, at high gel concentrations, and/or at high temperatures. By the addition of sodium chloride, very large dendritelike and net structures of the large agglomerated particles formed at 20°C and 45°C, respectively. The importance of the coordinated convectional flow of the agglomerated particles during the drying processes is supported for the ordered array formation. The role of the electrical double layers around the agglomerated particles and the interaction of the particles with the substrate surfaces during dryness are also important for the ordering. These microscopic drying patterns of gel spheres were very characteristic to the gel systems and differ from those of linear-type polymers and also from typical colloidal spheres.

41.11 CONCLUSIONS AND FUTURE PERSPECTIVES

The critical concentration of melting of type I gel crystals is quite sensitive to the ionic concentration of the gel suspension, as is clear in the sharp change in the critical concentration of melting both with and without the resins. Furthermore, the morphology of the single crystals of gel spheres surprisingly resembles those of typical colloidal spheres such as

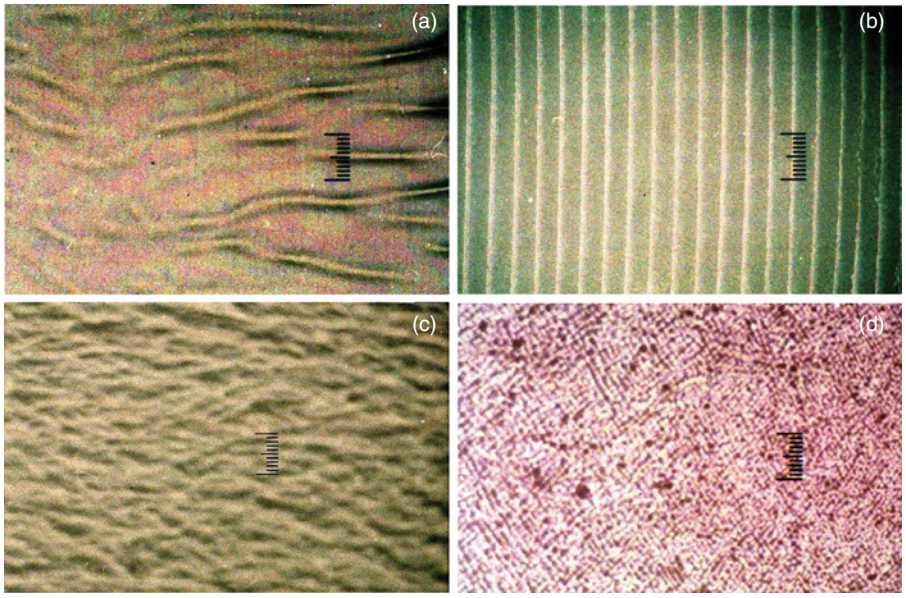

FIGURE 41.8 Typical microscopic drying structures of (a) *ordered spokelines*, (b) *ordered rings*, (c) *net* structure, and (d) *lattice* like ordered structures of the agglomerated particles of gel spheres. polystyrene and colloidal silica spheres, for example. Turbidity of the liquid-state suspensions of the gel spheres was high and similar in extent compared to that of the typical colloidal spheres having hydrodynamic size similar to that of the gels. Turbidity itself of the gel supports the theory that there exists a certain interface separating two phases, namely, gel spheres and medium-sized molecules having different refractive indices, respectively. This work clearly demonstrates that the crystallization of the gel spheres especially in the deionized aqueous system takes place by the excluded-volume effect of the gels, and also by the contribution of the extended electrical double layers formed around each gel spheres.

Most researchers, including the present authors, have believed that the gel spheres of pNIPAm do not form interfaces with water phase because of the significant diffusion of water and ionic species through the gels. We should note here that a group of researchers [45, 46] found that the nearest-neighbor intergel distances in the crystal structures of core–shell spheres, having pNIPAm as a shell at rather high sphere concentration without resins, were slightly larger than the hydrodynamic size of the gels. They attributed this difference to the existence of the local charges on the gel spheres, which originated from the charges of initiators used during polymerization of the core–shell spheres. Their explanation is correct, the current authors believe. Additionally, their experiments also support the importance of the electrical double-layer effect on the crystallization, although the extent of the contribution of double layers is small from their experimental condition *without deionization* of the suspension. The present authors' most recent experiments have been made in the deionized condition, where the contributions of electrical double layers are substantially high. The important contribution of the electrical double layers to crystallization is clearly demonstrated by the crystallization at 45°C, where the excluded diameter of the gel spheres (d_0) is very small compared with the intersphere distance (l).

Crystallization phenomena of the mixtures of pNIPAm gels and colloidal silica spheres were studied in the deionized state by the authors' group [43, 44]. The crystallization was discussed by the coupling effects of the extended electrical double layers around the colloidal silica spheres and the excluded-volume effects of the pNIPAm gels. Contribution of the electrical double layers around the gels was not discussed in this chapter. However, the contribution of the electrical double layers must be discussed anew for these systems too. The pNIPAm gel spheres contain many water molecules in the inner region of the sphere, especially at low temperature as described above. Then, the gel spheres in the suspension state will be assumed to be in *liquid phase*, which is distinguished from the bulk water phase. It is highly plausible that the gel spheres and water molecules interact strongly with each other by the solvation and polar–polar interaction between gels and water, for example, and behave as a kind of *liquid* different from the bulk water. In other words, the gel suspensions will be a *microemulsion* system, where

the electrical double layers extend from the liquid-phase spheres.

In this work, the excluded diameter of the gel sphere is assumed to be equal to the hydrodynamic diameter estimated from the dynamic light-scattering measurements. If the excluded diameter were sensitive to the ionic concentration of the suspensions, especially at low temperatures (e.g., 25°C), the possibility of crystallization caused by the extension of the gel spheres themselves still remains, even in the deionized state. In other words, the possibility of crystallization taking place only by the excluded-volume effect still remains at low temperatures. However, at high temperatures (e.g., 45°C), gel size is fairly small compared with the intergel distances by the substantial shrinking of the gels, and the contribution of the excluded-volume effect becomes quite small. Thus, crystallization at high temperatures should not take place without the contribution of the electrical double layers. Measurements of the hydrodynamic diameter of gel spheres in deionized state and at very low concentrations, where no two (or more) gel spheres interact with each other, are, therefore, important for further clarification of the gel crystallization process.

OLEIC ACID-BASED SURFACTANTS AS COST-EFFECTIVE GEMINI SURFACTANTS

KENICHI SAKAI AND MASAHIKO ABE

Department of Pure and Applied Chemistry, Faculty of Science and Technology, Tokyo University of Science

42.1 INTRODUCTION

Gemini surfactants, consisting of two monomeric surfactants linked by a spacer, are an important class of functionalized amphiphilic molecules with remarkable physicochemical properties. The physicochemical aspects of the aqueous solution properties of gemini surfactants have been reviewed in the literature [1–3]. Generally, when compared with conventional monomeric surfactants, the corresponding gemini surfactants give (1) a lower critical micelle concentration (cmc), (2) a lower surface tension measured at the cmc, (3) spontaneous formation of vesicles and/or wormlike micelles even at relatively low concentrations, and (4) a lower Krafft temperature and good water solubility in the case of ionic gemini surfactants. These physicochemical properties allow for the reduction of total consumption of chemicals in waterborne industrial products, and therefore, gemini surfactants are called "environmentally friendly materials." Nevertheless, the number of commercially available gemini surfactants is very limited. We note that, as far as we are aware, only four gemini surfactants are commercially available in Japan at present. Their chemical structures are shown in Fig. 42.1. This difficulty in providing a wide variety of gemini surfactants to the markets arises from their high selling price. In order to facilitate the widespread use of gemini surfactants in a variety of applications, the development of low-cost strategies for the synthesis and purification of gemini surfactants is essential.

On the basis of this background, oleic acid–based gemini surfactants have been developed by our research group. Oleic acid is the basis of human sebum and stratum corneum cell lipids, and hence, it is a biocompatible, ecological, and relatively low-cost material. Indeed, from the standpoint of its chemical structure, we hypothesize the following two points: (1) it is possible to modify the *cis* double bond with various kinds of headgroups through relatively simple chemical reactions to achieve cost-effective syntheses, and (2) it is possible to introduce a hydrophobic chain at the terminal carbonyl group via the amide or ester bonding. These two synthetic strategies allow for the design of a wide variety of gemini surfactants, as well as for control of the hydrophilic/hydrophobic balance of the surfactants by variations in the hydrophobic chain length and the type of headgroup. Both of these features are advantageous to the development of environmentally friendly surfactants for a wide variety of industrial products. In this chapter, we review recent developments of oleic acid–based gemini surfactants and their physicochemical properties.

42.2 SYNTHESES AND MOLECULAR STRUCTURES

The chemical structures of the oleic acid–based gemini surfactants developed by our research group are shown in Fig. 42.2. These include anionic phosphate-type [4], sulfonate-type [5], carboxylate-type [6, 7], cationic quaternary ammonium-type [8], nonionic sugar-type [9], and polyoxyethylene-type [10] surfactants. These surfactants are also categorized into three groups from their synthetic

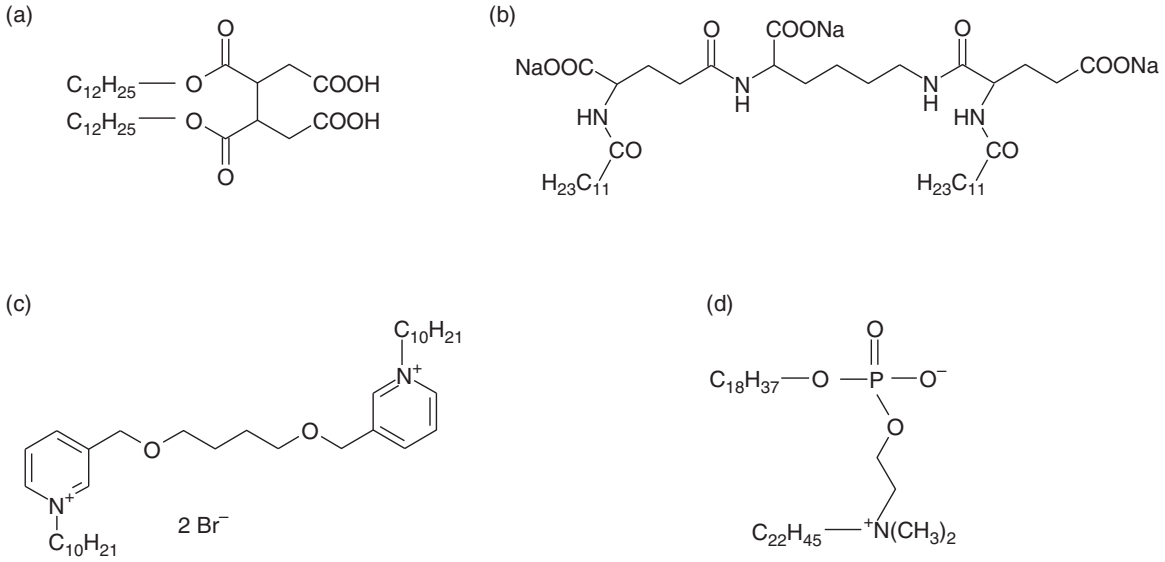

FIGURE 42.1 Chemical structures of commercially available gemini surfactants: (a) dicarboxylic acid–type anionic gemini surfactant (Gemsurf, Chukyo Yushi); (b) glutamic acid–based anionic gemini surfactant with a lysine spacer (Pellicer, Asahi Kasei Chemicals); (c) dipyridinium-type cationic gemini surfactant (Hygenia, Tama Kagaku Kogyo); (d) phosphate–quaternary ammonium-type zwitterionic gemini amphiphile (Vinoveil, NOF).

aspects, as shown in Fig. 42.3. The three synthetic routes are as follows: (1) the oxidation of the *cis* double bond to yield dihydroxy compounds (phosphate-, carboxylate-, and polyoxyethylene-types), (2) the one-step oxidation of the *cis* double bond to introduce a sulfonate headgroup, and (3) the reaction of the *cis* double bond with a peroxide to yield epoxy compounds (quaternary ammonium and sugar types).

These surfactants exhibit the following general features relevant to their chemical structures:

1. With the exception of the carboxylate-type gemini surfactants, it is not possible to introduce two identical headgroups to the *cis* double bond of oleic acid (9 and 10 positions). The introduction of two nonidentical headgroups into the 9 and 10 positions proceeds unselectively, resulting in a mixture of two regioisomers. For example, in the case of the phosphate-type gemini surfactant, the phosphate group is unselectively introduced to either the 9 or 10 position, and the final product obtained is a mixture of these regioisomers.
2. In view of the reaction mechanisms, one of the symmetric/asymmetric headgroups is generally in an *anti* position with respect to the other headgroup. This means that the final product is a mixture of enantiomers of each regioisomer. For example, the phosphate-type gemini surfactant is composed of two regioisomers and their respective enantiomers (9*R*,10*R* and 9*S*,10*S*). We have used such mixtures when studying the physicochemical properties of these surfactants.
3. The change in length of the hydrophobic chain covalently bound to the terminal carbonyl group results in a change in the geometric symmetry of the surfactant molecules.

42.3 DILUTE AQUEOUS SOLUTION PROPERTIES

We have studied dilute aqueous solution properties of oleic acid–based gemini surfactants by means of, for example, static surface tension, conductivity, pyrene fluorescence, dynamic light scattering (DLS), and cryogenic transmission electron microscope (cryo-TEM) measurements. Here, as a typical example, static surface tension data obtained for the aqueous solutions of the carboxylate-type gemini surfactants (abbreviated as "CC-9,9-Es*n*," where *n* is the length of the hydrocarbon chain covalently bound to the terminal carbonyl group of oleic acid) are shown in Fig. 42.4 [6]. These measurements were performed at pH 9 in the presence of 10 mmol dm^{-3} NaCl. Neither precipitation nor phase separation was seen in these aqueous solutions because two carboxylic acid headgroups are expected to be fully deprotonated at this pH. In the region of low surfactant concentrations, the surface tension decreases sharply with increasing concentration and attains a breakpoint. The surfactant concentration corresponding to this breakpoint is assumed to be the cmc or the critical association concentration (cac) of each surfactant. This is a general behavior we can see in aqueous surfactant systems.

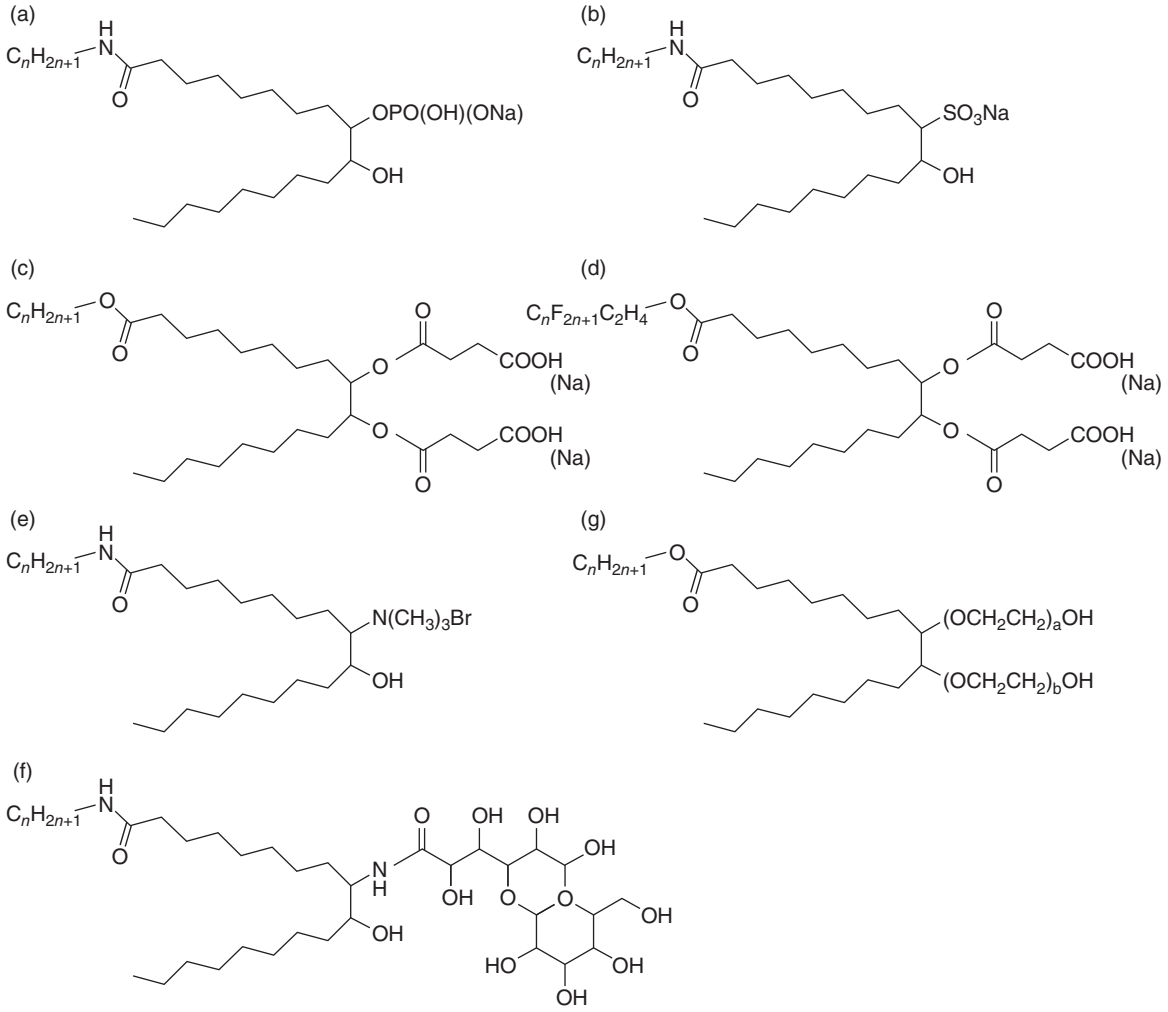

FIGURE 42.2 Chemical structures of oleic acid–based gemini surfactants developed by our research group: (a) phosphate-type anionic surfactant (POH-9,9-Am*n*, n = 6,8,10); (b) sulfonate-type anionic surfactant (SOH-9,9-Am*n*, n = 8,10); (c) carboxylate-type hydrogenated anionic surfactant (CC-9,9-Es*n*, n = 6,8,10); (d) carboxylate-type partially fluorinated anionic surfactant (CC-9,9-EsH2F*n*, n = 4,6,8); (e) quaternary ammonium-type cationic surfactant (NOH-9,9-Am*n*, n = 8,10,12); (f) sugar-type nonionic surfactant (LacOH-9,9-Am*n*, n = 10); (g) polyoxyethylene-type nonionic surfactant (EO*m*-9,9-Es*n*, $m = a + b$ = 10,20,30, n = 10).

The surface tension data allow us to calculate some physicochemical parameters: the surface excess concentration estimated at the cmc (or cac) (Γ_{cmc} or Γ_{cac}) and the occupied area per molecule adsorbed at the air-aqueous solution interface (A_{cmc} or A_{cac}) are calculated from the following equations [11]:

$$\Gamma_{\text{cmc(cac)}} = -\frac{1}{2.303iRT}\left(\frac{d\gamma}{d\log C}\right)_T \tag{42.1}$$

$$A_{\text{cmc(cac)}} = \frac{1}{N_A\Gamma_{\text{cmc(cac)}}} \tag{42.2}$$

where γ is the equilibrium surface tension measured at a surfactant concentration of C, T is the absolute temperature, N_A is the Avogadro constant, and R is the gas constant. In this particular case, the number of adsorption species [i in Eq. (42.1)] is assumed to be 1 in the presence of 10 mmol dm^{-3} NaCl. We also calculated pC_{20} for each surfactant. Here the C_{20} is defined as the surfactant concentration that produces a reduction of 20 mN m^{-1} in the surface tension of an aqueous solution of 10 mmol dm^{-3} NaCl ($pC_{20} = -\log C_{20}$), and therefore, this value is indicative of an efficiency in lowering the surface tension [11].

The physicochemical parameters calculated for the aqueous CC-9,9-Es*n* systems are summarized in Table 42.1. The corresponding data reported for the other series of oleic acid–based gemini surfactants are also shown in this table. It is clear that an increased hydrophobic chain

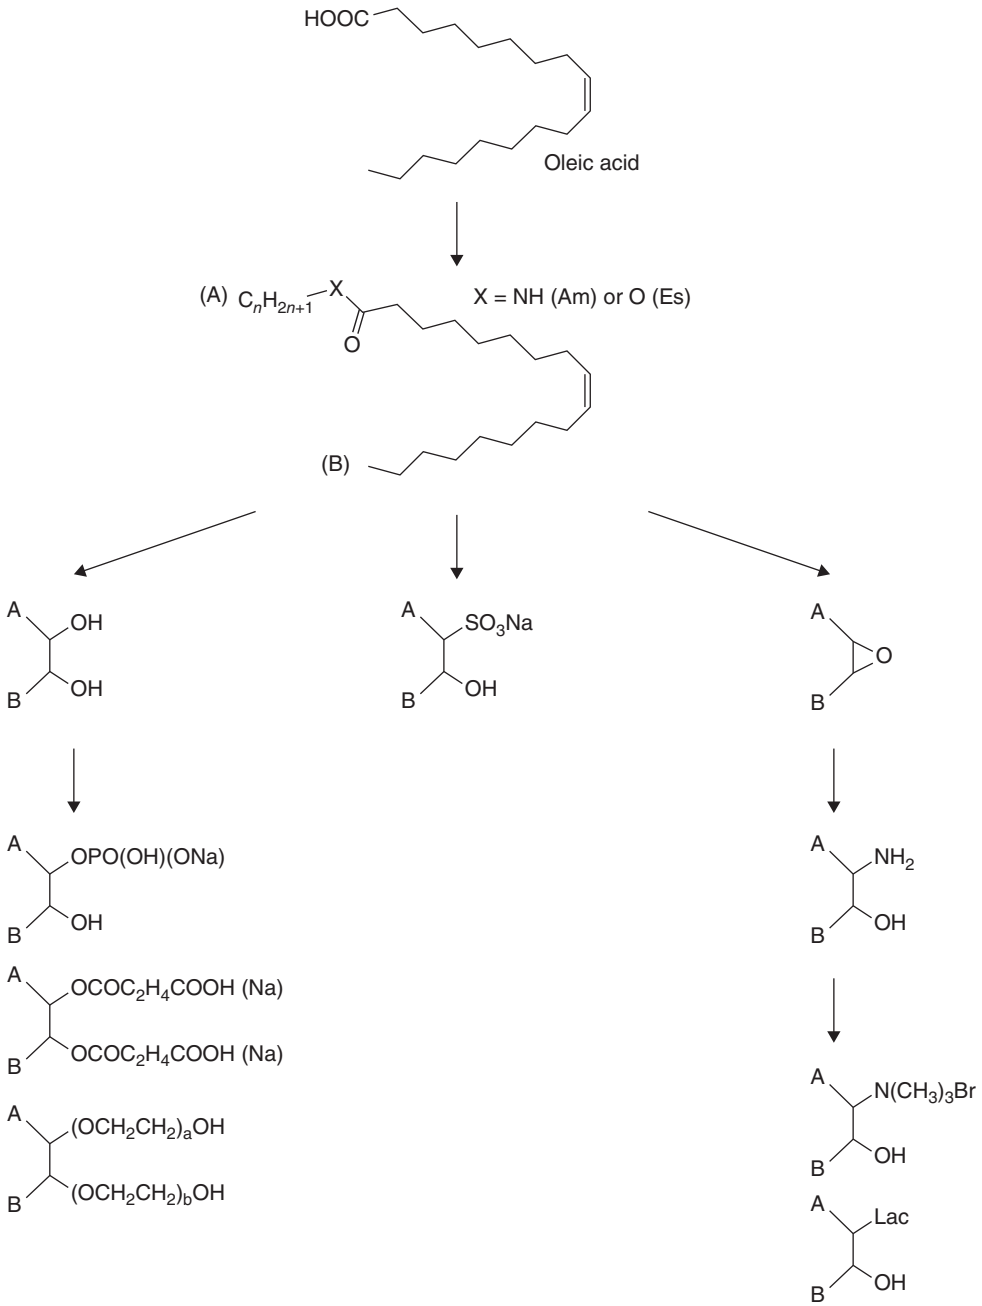

FIGURE 42.3 Synthetic routes of oleic acid–based gemini surfactants.

length results in lower cmc (cac) and larger pC_{20} values for all of the surfactant series. In addition, except the quaternary ammonium-type cationic surfactants (NOH-9,9-Am*n*), the increased hydrophobic chain length also results in larger Γ_{cmc} (Γ_{cac}) and hence smaller A_{cmc} (A_{cac}) values. These results are reflective of the increased hydrophobic character of the gemini surfactants with increasing their hydrophobic chain length. This logically leads to the formation of a closely packed monolayer film at the air–aqueous solution interface, although within our experimental resolution the resulting γ_{cmc} (γ_{cac}) data are almost unchanged as a function of their chain length. The decreased Γ_{cmc} (and increased A_{cmc}) observed for the aqueous NOH-9,9-Am*n* systems may result from the occurrence of steric hindrance between longer-chain molecules adsorbed at the air–aqueous solution interface [8].

It has been reported that molecular symmetry of gemini surfactants plays a significant role in their aqueous solution properties [12]. In order to assess this effect, we have synthesized a petroselinic acid–based sulfonate-type gemini

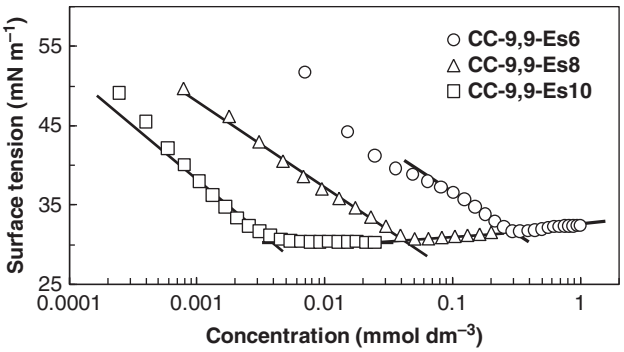

FIGURE 42.4 Static surface tension of aqueous CC-9,9-Es*n* (n = 6,8,10) solutions as a function of their concentrations. The surfactant solutions contained 10 mmol dm^{-3} NaCl as a background electrolyte, and the solution pH was fixed at 9. (This figure is reproduced from Ref. 6 with copyright permission from the Japan Oil Chemists' Society.)

surfactant (abbreviated as SOH-12,6-Am10 in Table 42.1) and compared the aqueous solution properties with those for the corresponding oleic acid–based surfactant (SOH-9,9-Am10) [5]. The hydrocarbon chain length of petroselinic acid is the same as oleic acid, but the *cis* double bond lies at the 6–7 position, which is different from that for oleic acid (9–10 position). As a result, the total number of methylene units is identical for the two surfactants ($\alpha + \beta = 28$, where α and β are the chain lengths from the headgroups), but the degree of molecular symmetry differs (i.e., $\alpha/\beta = 19/9 = 2.1$ for SOH-9,9-Am10 and $\alpha/\beta = 16/12 = 1.3$ for SOH-12,6-Am10, respectively). Cleary, the increased molecular symmetry results in (1) lower cac, (2) lower γ_{cac}, (3) greater Γ_{cac} (and hence smaller A_{cac}), and (4) greater pC_{20} values. These results suggest that SOH-12,6-Am10 exhibits greater surface activity as compared with SOH-9,9-Am10. We assume that the more symmetric analog (SOH-12,6-Am10) provides greater hydrophobic environments within the molecule.

The combination of DLS and cryo-TEM measurements has provided the information about the molecular assemblies spontaneously formed in dilute aqueous solutions of the oleic acid–based gemini surfactants. In most cases, relatively small micellar assemblies are suggested to be formed in such aqueous solutions (CC-9,9-Es*n* (n = 6,8) [6], CC-9,9-EsH2F*n* (n = 4,6,8) [7], and NOH-9,9-Am*n* (n = 8,10,12) [8]), but larger assemblies are also observed in some cases. For example, one of the phosphate-type surfactants (POH-9,9-Am8) forms vesicular assemblies under certain experimental conditions (see a cryo-TEM image; Fig. 42.5) [4]. Generally, gemini surfactants give a larger packing parameter than monomeric ones [13], and hence molecular assemblies with lesser positive curvature tend to be formed even just above the cmc (or cac). We also note that the formation of premicelles is suggested for the cationic oleic acid–based gemini surfactants (NOH-9,9-Am*n*) at concentrations below their cmc [8].

42.4 TEMPERATURE–CONCENTRATION PHASE BEHAVIOR WITH WATER

We have studied the temperature–concentration phase diagrams of binary mixtures of oleic acid–based gemini surfactants with water [7]. The surfactants used here were carboxylate-type gemini surfactants with disodium salts; one is the series of partially fluorinated surfactants (abbreviated as "CC-9,9-EsH2F*n*", where n is the fluorocarbon chain length = 4,6,8) and the other is CC-9,9-Es8 as an example of the corresponding hydrogenated surfactants. The number of studies focusing on the phase diagrams of partially fluorinated gemini surfactants in a wide range of temperatures and concentrations is very limited because of the synthetic

TABLE 42.1 Physicochemical Parameters Calculated for Aqueous Solutions of Oleic Acid–Based Gemini Surfactants

	cmc (or cac) (mmol dm^{-3})	γ_{cmc} (or γ_{cac}) (mN m^{-1})	Γ_{cmc} (or Γ_{cac}) (μmol m^{-2})	A_{cmc} (or A_{cac}) (nm^2)	pC_{20}	Conditions	Ref.

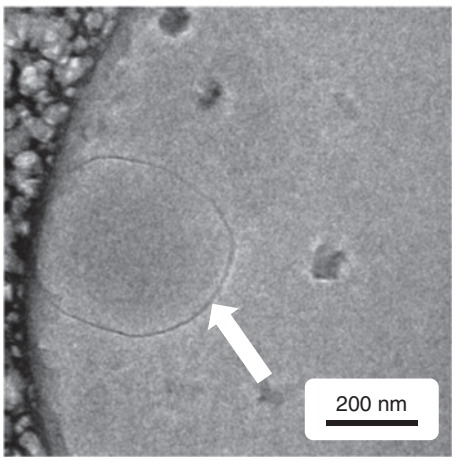

FIGURE 42.5 A cryo-TEM image obtained for the aqueous solution of POH-9,9-Am8. The surfactant concentration was set at 64 × cac in the presence of 100 mmol dm^{-3} NaCl at pH 7. (This figure is reproduced from Ref. 4 with copyright permission from Elsevier.)

difficulties of such surfactant samples. The aqueous phase behavior was characterized with a combination of visual appearance, polarized optical microscopy (POM), and small-angle X-ray scattering (SAXS) data.

The resulting temperature–concentration phase diagrams of CC-9,9-EsH2F*n* and CC-9,9-Es8 are shown in Fig. 42.6. Several phase states, including micellar solution phase (W_m), hexagonal phase (H_1), bicontinuous cubic phase (V_1), and lamellar phase (L_α), were observed along with coexistence of these phases in certain regions. A middle phase (M) is also seen in the phase diagram of CC-9,9-Es8. We found the following features in these diagrams [7]:

1. The increased surfactant concentration yields molecular assemblies with lesser positive curvature. The increased surfactant concentration leads to an increased counterion concentration, a decreased repulsion between ionic headgroups, and hence a decreased cross-sectional area of the headgroups [14, 15]. This change leads to an increased packing parameter of the surfactants [13], and hence we see molecular assemblies with lesser positive curvature at high concentrations.
2. Assemblies with lesser positive curvature tend to be formed at higher temperatures. This is rationalized by the fact that the increased temperature results in a decreased hydrophilicity of the headgroups, leading

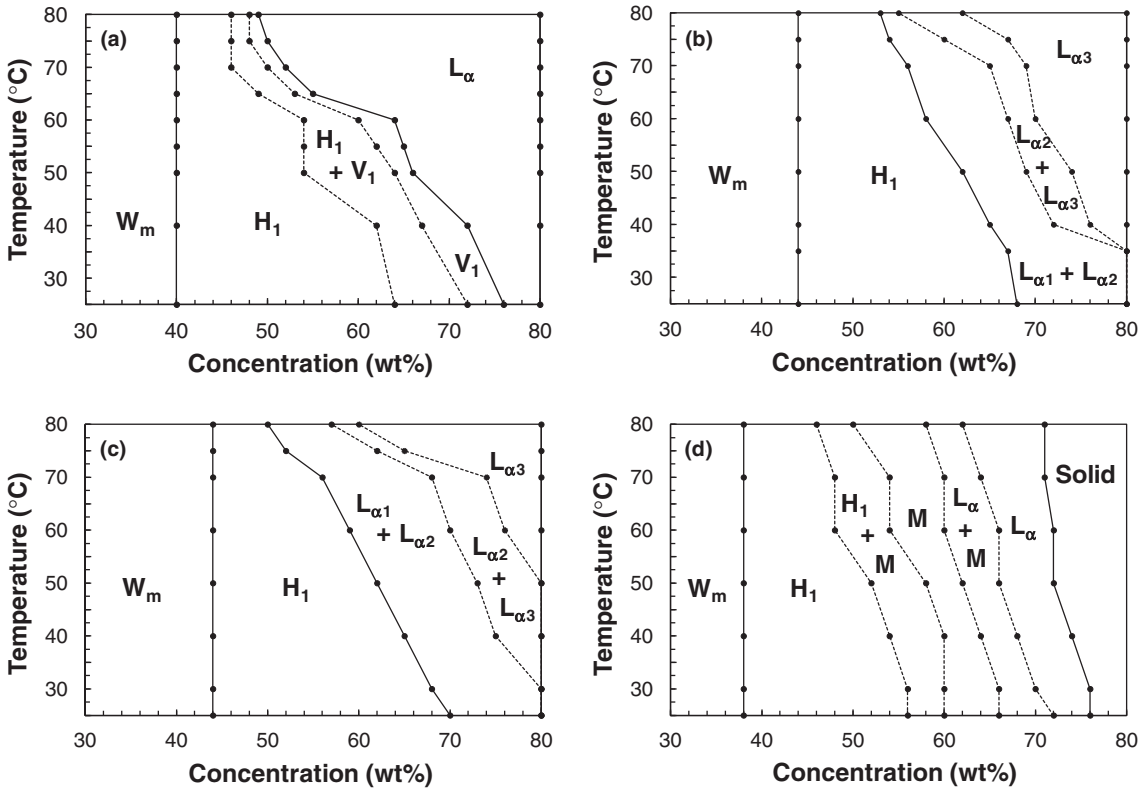

FIGURE 42.6 Temperature–concentration phase diagrams of (a) CC-9,9-EsH2F4, (b) CC-9,9-EsH2F6, (c) CC-9,9-EsH2F8, and (d) CC-9,9-Es8. The surfactant samples used in this study were disodium salts. (This figure is reproduced from Ref. 7 with copyright permission from the Japan Oil Chemists' Society.)

to a decreased cross-sectional area of the surfactants. Similar temperature-induced phase transitions have been observed in the amino acid–based monomeric and gemini surfactant systems [15].

3. The shorter fluorocarbon chain analog tends to form assemblies with greater positive curvature such as H_1 and V_1 phases, whereas the longer fluorocarbon chain analog tends to form assemblies with lesser positive curvature such as L_α phase.
4. The hydrogenated surfactant can form liquid crystals more effectively than the partially fluorinated surfactants. For example, the W_m–H_1 phase transition concentration is observed to be lower for CC-9,9-Es8 than for the three CC-9,9-EsH2F*n* samples. It seems likely that this property results from the ease of molecular packing of the hydrogenated surfactant. In other words, close molecular packing is inhibited in the CC-9,9-EsH2F*n* systems because of the limited miscibility between fluorocarbon and hydrocarbon units. The following two results are also rationalized by this interpretation: (1) two-phase separation of white solids from a solution phase is observed only in the CC-9,9-EsH8 system; and (2) the temperature-induced phase transition occurs more drastically for CC-9,9-EsH2F*n* than for CC-9,9-EsH8 because of the ease of molecular motion of the partially fluorinated surfactants within their assemblies.

42.5 CHARACTERIZING INSOLUBLE MONOLAYER FILMS FORMED AT THE AIR–WATER INTERFACE

The oleic acid–based carboxylate-type gemini surfactants (CC-9,9-Es*n*) exhibit pH-dependent protonation–deprotonation behavior in aqueous media [6]. In alkaline solutions, the surfactants can lower the surface tension as well as form molecular assemblies, as mentioned in Sections 42.3 and 42.4. Under acidic or neutral conditions, the surfactants are intrinsically insoluble in aqueous media and form a monolayer film at the air–water interface when they are spread on the water surface from volatile solvents (e.g., chloroform).

Figure 42.7 shows the surface pressure–area (π–A) isotherm data obtained for the three analogs of CC-9,9-Es*n* at pH 6–7 [6]. The surface pressure increases gradually with decreasing molecular area. No phase transition points are seen in these π–A isotherm data. Interestingly, each π–A isotherm attains a critical point in the range of the molecular area of 0.5–0.7 nm^2, and then the surface pressure becomes constant, even when the molecular area is further decreased from the critical point. On the basis of these data, the following two points are suggested. *First*, at a given surface pressure, the molecular area increases with an increase in the chain length (n). This is an opposite trend from that for the data shown in Table 42.1, where the occupied area (A_{cmc} or A_{cac}) estimated from the static surface tension data at pH 9 decreases with n. This suggests that the geometric molecular volume is a critical factor in determining the degree of molecular packing in the intrinsically insoluble pH region, whereas the intermolecular hydrophobic interaction plays a crucial role at pH 9. *Second*, the absolute slope of the π–A isotherm in the vicinity of the critical point is larger for the longer-chain analog than for the shorter one. This may indicate that, although the molecular area increases with increasing chain length at a given surface pressure, the degree of homogeneity of the monolayer film increases with increasing chain length.

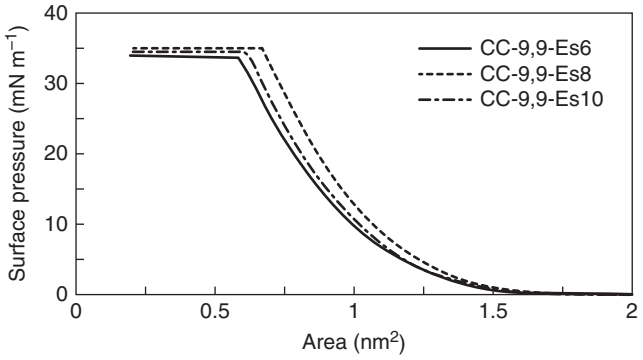

FIGURE 42.7 π–A isotherms of CC-9,9-Es*n* (n = 6,8,10) at pH 6–7 in the absence of added electrolytes. (This figure is reproduced from Ref. 6 with copyright permission from the Japan Oil Chemists' Society.)

Infrared external reflection (IER) measurements provide further insights regarding the chain conformation of the surfactant molecules adsorbed at the air–water interface [16]. The typical IER spectra for CC-9,9-Es8 are given in Fig. 42.8 [6]. The characteristic absorption peak appears in the range of 2920–2930 cm^{-1}, which originated from the CH_2 asymmetric stretching vibration of the hydrocarbon chains. The wavelength gradually shifts toward lower values with an increase in the sample volume spread on the water surface. This primarily suggests that the increased molecular density results in a change of the hydrocarbon chains from *gauche*-to-*trans* conformations.

42.6 ADSORPTION CHARACTERISTICS AT SOLID–AQUEOUS SOLUTION INTERFACES

The adsorption of gemini surfactants at solid–liquid interfaces has been reported by a number of researchers through measurement of adsorption isotherms [17–20] and the study of adsorbed layer morphologies [19–23]. Key findings include the facts that (1) the adsorption plateau region (i.e., saturation) appears at much lower concentrations when compared with the corresponding monomeric surfactants [17],

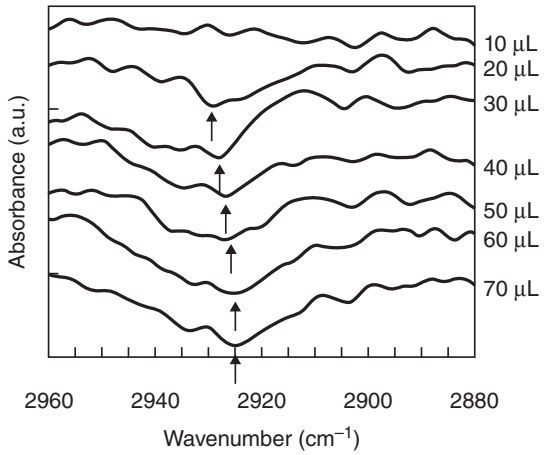

FIGURE 42.8 Infrared external reflection spectra of monolayer films of CC-9,9-Es8 formed at the air–water interface. The effects of molecular packing on the chain conformation were studied by changing the sample volume of the CC-9,9-Es8 chloroform solution (0.1 mmol dm^{-3}) spread on the water surface in the range 10–70 μL. The aqueous solution pH was set at 6–7 in the absence of added electrolytes. (This figure is reproduced from Ref. 6 with copyright permission from the Japan Oil Chemists' Society.)

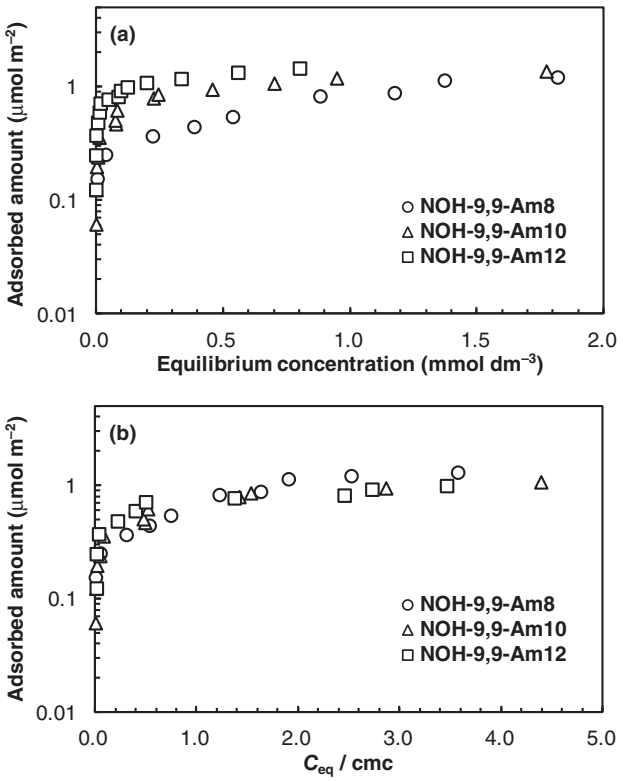

FIGURE 42.9 Adsorption isotherms of NOH-9,9-Am*n* (*n* = 8,10,12) on colloidal silica particles as a function of (a) equilibrium concentration of NOH-9,9-Am*n* (= C_{eq}) and (b) C_{eq}/cmc. (This figure is reproduced from Ref. 8 with copyright permission from the Japan Oil Chemists' Society.)

which reflects their remarkably lower cmc; (2) a higher adsorption density in the saturation region can be expected for gemini surfactants (in particular those having a short spacer unit such as C_2H_4) as compared to monomeric ones when we compare the adsorption data (in mol m^{-2}) normalized by the number of hydrocarbon chains [17]; and (3) as a result of their increased packing parameter, gemini surfactants yield surface aggregates with reduced positive curvature when compared to the corresponding monomeric surfactants [21].

We have characterized the adsorption of the oleic acid–based quaternary ammonium-type gemini surfactants (NOH-9,9-Am*n*, where *n* is the length of the hydrocarbon chain bound to the terminal carbonyl group of oleic acid) at the silica–aqueous solution interface [8]. The adsorption isotherms of these surfactants on colloidal silica particles are shown in Fig. 42.9. When the amount of surfactant adsorbed is replotted as a function of the equilibrium surfactant concentration (C_{eq}) normalized by the cmc, it is obvious that the shape of the adsorption isotherms of the three surfactants is qualitatively similar. Briefly, at relatively low concentrations (in the region of C_{eq}/cmc < 0.1), an increase in C_{eq} results in a steep increase in the amount of surfactants adsorbed, after which adsorption becomes more gradual at relatively high concentrations (in the region of C_{eq}/cmc > 0.1). An increased NOH-9,9-Am*n* chain length results in a shift to a lower equilibrium concentration at which adsorption starts to increase sharply, clearly being reflective of the lower cmc of the longer-chain analogs. The adsorption isotherms suggest that two adsorption processes are present. At low equilibrium concentrations the cationic surfactants are electrostatically adsorbed onto the negatively charged colloidal silica particles, while at high equilibrium concentrations, hydrophobic intermolecular interactions play a dominant role in surfactant adsorption.

The adsorption isotherms also allow us to calculate the occupied area per surfactant molecule adsorbed at the silica–aqueous solution interface. The adsorbed amount estimated at the cmc is in the range of 0.7–0.8 μmol m^{-2} for all of the NOH-9,9-Am*n* samples. This corresponds to an occupied area of 2.1–2.4 nm^2. Assuming that the surfactants form a complete flat bilayer at the silica–aqueous solution interface, the "actual" occupied area is estimated at 4.2–4.7 nm^2. These values are significantly higher than the occupied area per surfactant molecule adsorbed at the air–aqueous solution interface (Table 42.1), indicating that the adsorption density of NOH-9,9-Am*n* on colloidal silica parties is lower than that at the air-aqueous solution interface.

We have assessed the morphology of surfactant assemblies formed at the silica–aqueous solution interface [8], by means of soft-contact atomic force microscopy (AFM) imaging technique [24]. As a result, no significant surface features could be discerned in this case, indicating the formation of

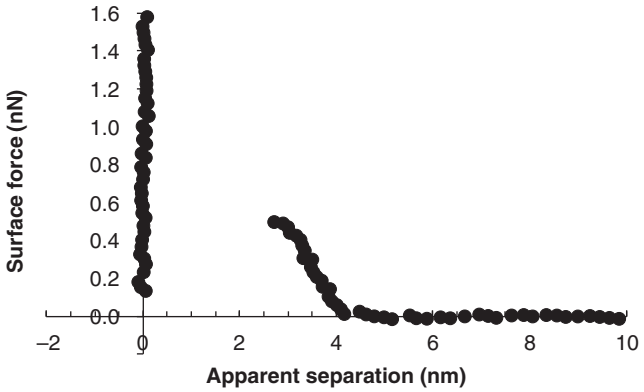

FIGURE 42.10 Force–distance data obtained for the NOH-9,9-Am10 aqueous system. The surfactant concentration was set at 10 × cmc. A flat silica plate was used as a solid substrate. (This figure is reproduced from Ref. 8 with copyright permission from the Japan Oil Chemists' Society.)

planar aggregates (i.e., a bilayer). This is consistent with the general trend observed for gemini surfactants [21].

AFM force curve measurements further provide structural information on the molecular assemblies formed at solid-solution interfaces. A typical force–distance curve obtained for the NOH-9,9-Am10 system is shown in Fig. 42.10 [8]. The shape of the force–distance curve suggests the repulsive interaction to originate from steric interactions arising from the NOH-9,9-Am10 molecular aggregates formed on the silica surface. The push-through distance (∼2.7 nm in this case) provides a measure of the adsorbed layer thickness under application of normal pressure. This distance is smaller than the hydrodynamic diameter of the NOH-9,9-Am10 micelles (∼5–7 nm). This suggests that, assuming bilayer formation, the hydrocarbon chains of the opposing molecules are interpenetrated to a certain degree as a result of the pressure applied normal to the surface.

It should be noted that the force–distance curve shown in Fig. 42.10 differs significantly from those reported in the previous paper [20], where force curves in aqueous solutions of the cationic gemini surfactant 1,2-bis(dodecyldimethylammonio)ethane dibromide in the presence of 10 mmol dm^{-3} NaBr were measured. In that case, compression of the surfactant layer resulted in a two-step repulsive interaction, where one stage was a relatively long-range repulsion and the other was a steeply increasing short-range repulsion. The first push-through, observed after the long-range repulsion, was ascribed to collapse of the weakly adsorbed surfactant layer on the tip, whereas the second push-through, observed at shorter separations, resulted from collapse of the surfactant layer formed on the solid substrate. The absence of the steep short-range repulsion in the NOH-9,9-Am10 system suggests, therefore, that steric repulsion against normal pressure is reduced as compared to the conventional gemini surfactant system. In addition, it was not possible to detect any long-range electrostatic repulsion in the current system, which may be due to collapse of the NOH-9,9-Am10 layer on the cantilever tip under normal pressure. It seems likely that this phenomenon reflects the lower adsorption density and/or the looser molecular packing arrangement of NOH-9,9-Am10, which is attributed to the asymmetric structure.

42.7 CONCLUDING REMARKS

In this chapter, we have presented the physicochemical properties of the oleic acid–based gemini surfactants recently developed in our research group. Basically, these surfactants exhibit excellent surface activities in aqueous solutions and tend to form molecular assemblies with less positive curvature. This molecular association occurs not only in aqueous bulk solutions but also at solid-aqueous solution interfaces. These behaviors follow general trends we can see in typical gemini surfactant systems. We can also see notable differences between our oleic acid–based surfactant systems and typical gemini surfactant systems. For example, we found the lower adsorption density and the looser molecular packing arrangement of our oleic acid–based surfactants adsorbed at the solid–aqueous solution interface. Such differences arise from the asymmetric headgroup and tail structures of our surfactants.

The oleic acid–based gemini surfactants have been synthesized using the reduced cost strategy; however, their selling prices are still higher than those of conventional monomeric surfactants. We anticipate, therefore, that these surfactants will find application in the formulation of high-performance chemical products in fields such as cosmetics, personal care, and medical applications. Our preliminary experiments have demonstrated that some of the oleic acid–based gemini surfactant samples exhibit excellent biodegradability and low (or no) skin irritant effects. This feature will also help us to find suitable applications of these surfactants.

FUNCTIONAL HYDROGEL MICROSPHERES

Daisuke Suzuki, Takuma Kureha, and Koji Horigome
Graduate School of Textile Science & Technology, Shinshu University, Ueda, Nagano, Japan

44.1 INTRODUCTION

Polymer hydrogel microspheres (known as *microgels*) are spherical objects comprising cross-linked polymeric networks swollen by water. Typical microgels are approximately 10–1000 nm in size, and are dispersed in a solvent. Microgels have been extensively researched in previous decades, as their "smart material" properties are beneficial in numerous technologies such as drug and gene delivery [1–4]; chemical and biological separation [5, 6]; sensors [7, 8]; templates or stabilizers for inorganic nanoparticles [9–12]; photonic crystals [13–16]; and smart particulate emulsifiers [17–19]. Most microgels share a number of properties with macrogels; specifically, their physicochemical properties respond to external stimuli such as pH, temperature, light, presence of biomolecules, and salt concentration. This stimuli-responsive property of microgels enables many of the abovementioned applications. In addition, the colloidal nature of microgels confers tremendous advantages over macrogels. For example, microgels rapidly respond to external environmental changes because of of their high surface:volume ratios.

Probably the best known and most widely studied microgels are the poly(*N*-isopropylacrylamide) or pNIPAm microgels. Chains of pNIPAm demonstrate a thermoresponsive property, altering from coiled to globular at the lower critical solution temperature (LCST) of around 32°C in pure water [20, 21]. Thus, pNIPAm microgel undergoes a volume phase transition (VPT) at around the LCST of pNIPAm linear chains [22]. In contrast, pH-responsive microgels have been synthesized from polyelectrolyte microgels, and many researchers have already copolymerized charged monomers in microgels. For instance, by precipitation polymerization in several alcohols, researchers have fabricated monodispersed and pH-responsive microgels from acrylamide, methacrylic acid, and the cross-linker methylenebisacrylamide (BIS) [23, 24]. Naturally, because the presence of electrolytes in microgel dispersions affects the electrostatic interactions among the microgels, polyelectrolyte microgels also depend on salt concentration. This chapter introduces functional microgels and overviews their synthesis, characterization, and applications.

44.2 MICROGEL SYNTHESIS

An important consideration in microgel synthesis is to ensure their monodispersity and prevent their coagulation. Microgels can be synthesized in three ways: (1) from monomer, (2) from polymer, and (3) from macrogel. In general, monodispersed microgels cannot be obtained by methods 2 and 3; thus, microgels are usually prepared from monomers, which permits monodispersed microgels if the polymerization is sufficiently precise. Thermosensitive microgels are most commonly fabricated by precipitation polymerization. Briefly, microgel formation requires that the synthesized polymer is insoluble under the polymerization conditions, whereas the monomer is soluble. For instance, pNIPAm microgels form when precipitation polymerization is performed in water at 70°C, since pNIPAm is water-insoluble at high temperatures [20, 21]. Microgels of pNIPAm chains cross-linked by BIS were first reported in 1986 [25]. In this method, the monomers and cross-linkers are completely dissolved in water. The mixture is usually bubbled with nitrogen gas to purge oxygen from the solution, and then heated to a

Encyclopedia of Biocolloid and Biointerface Science, Volume 1, First Edition. Edited by Hiroyuki Ohshima.

temperature above the LCST of pNIPAm. Finally, polymerization is initiated by adding a water-soluble initiator such as potassium persulfate (KPS) to the reactor.

Thermosensitive microgels prepared by precipitation polymerization become aggregated by homogeneous nucleation. Besides pNIPAm microgels, precipitation polymerization is applicable to other acrylamide derivatives such as *N*-isopropylmethacrylamide (NIPMAm) whose LCST is ~44°C in aqueous media [26–28]. The polymerization is usually conducted at high temperature, which liberates sulfate radicals from compounds such as ammonium persulfate or KPS. The sulfate radicals attack monomers such as NIPAm, initiating radical propagation and chain growth. Once the polymer chain reaches a critical length, it collapses onto itself, producing precursor particles. The chain collapses because the polymerization temperature exceeds the LCST of the polymer. The precursor particles grow by aggregation with other precursor particles. As the aggregated precursor particles coalesce, the charged chain ends become concentrated at the surface. Therefore, the charge imparted by the initiator stabilizes the microgels once they have reached a critical size. The size of the resultant microgels can be controlled by polymerization temperature, surfactant addition, and copolymerization. Cross-linkers are required to prevent microgels from dissolution as the mixture is cooled below the LCST. In particular, multiresponsive microgels can be formed by copolymerizing ionic monomers with NIPAm or NIPMAm.

Even the simplest pNIPAm microgel contains two chemical species (NIPAm and cross-linker), and many of the fascinating microgels contain multiple monomers. The presence of more than one monomer introduces complexity in any free-radical copolymerization because each monomer exhibits a unique reactivity. For example, it is commonly accepted that the cross-linker BIS polymerizes faster than NIPAm during precipitation polymerization. Consequently, the cross-link density is higher in the polymer that forms first than in the last, and the exterior of the microgel is less cross-linked than the microgel core [29].

The desired functionality of microgels is achieved by correct design and control of microgel structure. Among the most widely studied structures are the core–shell microgels, which are broadly divisible into two classes: (1) the *solid core*, which is surrounded by a hydrogel shell [30–34], and (2) the *entire structure*, which consists of hydrogel [35–41]. In class 1, the core usually comprises solid materials such as polystyrene and silica particles. The hydrogel shell is then introduced by seeded precipitation polymerization. One team of investigators synthesized polystyrene core–pNIPAm hairy particles by living radical graft polymerization [34]. The hydrogel shell of the hairy particles is not cross-linked; thus, the thermoresponsive behavior of the particles is uniquely different from that of conventional solid core–hydrogel shell microgels.

The second class of core–shell microgels contains hydrogel in both the core and the shell. Core–shell microgels synthesized by precipitation polymerization were first reported by Lyon et al. [35]. During this polymerization, preformed deswollen hydrogel cores are surrounded by hydrogel shell with a structure or functionality that is the same as or different from that of the core. This technique enables control of the radial distribution of the functional groups in the microgels, and the display of interesting properties. Because the shell can be synthesized by introducing different comonomers to the core, core–shell microgels can undergo multiple phase transition behaviors with increasing temperature [35]. Furthermore, core–shell microgels form the basis of hollow hydrogel capsules [36]. In this case, the core and shell are prepared with a degradable and nondegradable cross-linker, respectively. Following core degradation, the microgels are extensively purified by centrifugation to remove the degraded linear polymer chains from the core.

Recently, our group reported different types of composite microgels containing solid material. Polymer particles are commonly produced by dispersion polymerization. In principle, the conditions for successful dispersion polymerization are simple, requiring a steric stabilizer and solvent that dissolves the monomer but precipitates the polymer. First, we used pNIPAm microgels as stabilizers during alcoholic dispersion polymerization of styrene (Fig. 44.1) [42]. The size, size distribution, and morphology of the

resultant polystyrene particles depend on the size and concentration of the microgels. In particular, polystyrene particles coated with PNIPAm-based microgels were observed using scanning electron microscopy (SEM; see Fig. 44.1). Multilayered composite microgels have also been synthesized by surfactant-free seeded emulsion polymerization [43]. Electron microscopic observations of these composite microgels reveal a distinct solid shell of oil-soluble chemical species (glycidyl methacrylate, in this case), while surface analysis reveals a hydrogel layer surface (Fig. 44.2).

44.3 MICROGEL CHARACTERIZATION

This section briefly overviews the frequently used techniques for characterizing microgels. Since microgels are colloidal in nature, they can be characterized according to their size, polydispersity, and shape and state of dispersion/flocculation. Moreover, microgels also possess gel properties; therefore, equally important features are degree of swelling and network structure.

The size, size distribution, and shape of microgels are usually determined from optical microscopy. Microgels with diameters approximating or largely exceeding 1 μm are generally considered suitable for observation by optical microscopy. Improved spatial resolution for smaller microgels is achieved by confocal microscopy. In this technique, microgels are labeled by fluorescence dyes such as rhodamine or by quantum dots incorporated into the microgel's network [44]. Notably, the behavior of microgels dispersed in water can be studied by the same optical methods [26].

If higher resolution is required, the applied microscopies require radiation of much smaller wavelengths. Thus far, dried (solid) microgels have usually been characterized by electron microscopy. For example, SEM and transmission electron microscopy (TEM) can identify the size, polydispersity, and shape of microgels in the dry state. Furthermore, depending on the sample preparation and the resolution of the microscope, information on the surface structure is obtainable. In particular, TEM has often been used to investigate microgels hybridized with metal nanoparticles. Because of the large electron density differences between metal nanoparticles and polymer components, even comparatively small metal nanoparticles embedded in rather large microgels can be imaged with high resolution [45]. A typical SEM image

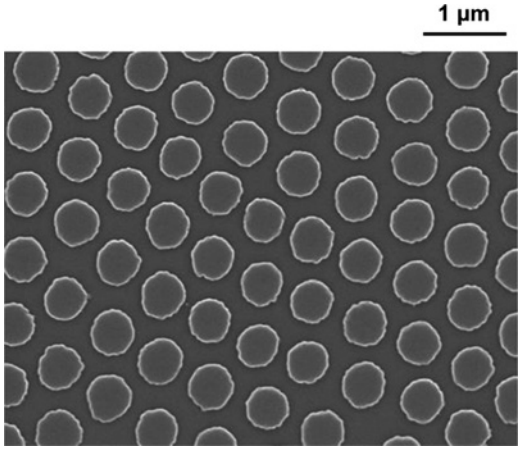

FIGURE 44.3 SEM image of pNIPAm microgels dried on polystyrene substrate at 25°C. [Reprinted with permission from Ref. 46. Copyright (2011) American Chemical Society.]

of pNIPAm-based hydrogel spheres is shown in Fig. 44.3 [46].

One drawback of electron microscopy is that it reveals the nearly deswollen state of microgels. For many purposes, the collapse of microgels under the high vacuum of the microscope is undesirable, and the microgels should be imaged in the swollen state. In such cases, cryo-TEM offers a valuable alternative. In this technique, microgel dispersions are quickly frozen at low temperatures (e.g., with liquid butane or propane cooled with liquid nitrogen). If the cooling rates are sufficiently high, the structure in the solution is frozen and the water in the microgel samples is vitrified. Since the temperature, pH, and ionic strength of the initial microgel dispersion are alterable, cryo-TEM allows microgel imaging under different conditions determined by the initial state.

Another frequently used microscopy method is atomic force microscopy (AFM). In contrast to optical and electron microscopes, the sample is imaged by AFM in a purely mechanical way. Microgel height is determined from the repulsive and attractive interactions between the sample surface and the resulting cantilever displacement. Similar to electron microscopy, AFM conducted in air provides images of nearly collapsed microgels. However, solubilized samples can be studied using AFM in a liquid cell. Recently, the VPT of thermoresponsive microgels was monitored by AFM [47, 48].

Microgels have also been characterized by light scattering and spectroscopy. Because the available information depends on the light wavelengths, microgels in water can be characterized from various perspectives. For example, the size and polydispersity of microgels dispersed in water may be studied by dynamic light scattering (DLS). Since parameters such as temperature, pH, and ionic strength of the dispersion medium can be readily varied, DLS is ideally suited to investigate the behavior of responsive microgels. For instance, DLS obtains the swelling curves of thermoresponsive microgels. First, the microgel size is calculated as the hydrodynamic diameter (or radius). The hydrodynamic diameters D_h of microgels are determined from the measured diffusion coefficients using the Stokes–Einstein equation. Subsequently, the swelling capacity of responsive microgels is quantified by the swelling ratio α:

$$\alpha = \frac{V(T)}{V_0} = \left(\frac{R_h(T)}{R_{h,0}} \right)^3 \tag{44.1}$$

In this equation, $V(T)$ and V_0 are the microgel volumes at temperature T and in the fully swollen state, respectively. Because microgels are nearly spherical [49], α can be determined from the respective hydrodynamic radius R_h rather than from the volume V.

In contrast, small-angle scattering (SAS) of X rays and neutrons enable structures to be studied on a local length scale [50–52]. This localization relates to the enhanced range of scattering vectors available in experiments involving X rays and neutrons, whose de Broglie wavelength is much smaller than the wavelength of lasers used in light-scattering setups. Therefore, light-scattering experiments yield the overall microgel size, while SAS provides structural parameters at the nanometer scale. For instance, the network correlation length ξ is determined from SAS measurements of microgels [53–55].

The electrostatic properties of colloids influence their colloidal stability and interactions with dissolved polymers and surfaces. The fascinating electrical properties of microgels arise from covalently bonded electrically charged groups contributed by the polymerization initiator. The electrical properties of microgel dispersions have been characterized from their electrophoretic mobility, which determines the zeta-potential replaced with the surface potential of the particles. Although constructed from cross-linked and hydrated polymers, microgels possess no definite solid–liquid interfaces; thus, they cannot be characterized by the ζ-potential. Hence, Ohshima's theory has been applied to the electrophoretic mobility of microgels [56–59]. In addition, microgels are soft, ion-penetrable particles, and their electrophoretic mobility also provides morphological information. Ohshima and colleagues theoretically described the electrophoretic mobility of latex particles covered by ion-penetrable surface layers [60–62]. This theory was initially developed for biocolloids. The total particle potential is contributed by both the surface charge layer and Donnan potential. Ohshima's model has been successfully applied to core–shell composite particles such as polystyrene latex covered by pNIPAm hydrogel layers [60–62]. The theory yields two important parameters: the volume density of fixed ionic groups bound within the surface charge layer (N) and

the softness parameter ($1/\lambda$). The model is governed by the following equations:

$$\mu = \frac{\varepsilon_r \varepsilon_0}{\eta}\left(\frac{\psi_0/\kappa_m + \psi_{DON}/\lambda}{1/\kappa_m + 1/\lambda}\right) + \frac{ZeN}{\eta^{\lambda^2}} \tag{44.2}$$

$$\psi_0 = \frac{kT}{ve}\left(ln\left[\frac{ZN}{2\nu n} + \left\{\left(\frac{ZN}{2\nu n}\right)^2 + 1\right\}^{1/2}\right] + \frac{2\nu n}{ZN}\left[1 - \left\{\left(\frac{ZN}{2\nu n}\right)^2 + 1\right\}^{1/2}\right]\right) \tag{44.3}$$

$$\psi_{\mathrm{DON}} = \frac{kT}{ve} ln\left[\frac{ZN}{2\nu n} + \left\{\left(\frac{ZN}{2\nu n}\right)^2 + 1\right\}^{\frac{1}{2}}\right] \tag{44.4}$$

$$\kappa_m = k\left[1 + \left(\frac{ZN}{\nu n}\right)^2\right]^{1/4} \tag{44.5}$$

where ε_r, ε_0, η, and e are the relative permittivity, permittivity in vacuum, viscosity, and electronic charge, respectively; κ_{m} is the reciprocal of the double-layer thickness within the surface charge layer. The Donnan potential of the surface charge layer and the potential at the boundary between the surface layer and the surrounding solution are given by ψ_{DON} and ψ_0, respectively. Z and ν are the charge numbers and valencies of the ionized groups within the surface layer and the electrolyte, respectively. λ denotes the friction experienced by the liquid flowing through the surface layer. The softness parameter λ^{-1} approaches zero as the particles become more rigid. N and n are the number densities (m^{-3}) of charged groups in the surface charge layer and electrolyte ions, respectively, and k is the Boltzmann constant.

44.4 FUNCTIONAL MICROGELS

This section summarizes some important functional microgels, which have been developed mainly by our group and synthesized by precipitation polymerization.

44.4.1 Hybrid Microgels

Hybrid microgels comprise metal nanoparticles embedded in polymer microgels. Monodispersed inorganic nanoparticles are synthesized in situ by reduction of precursor ions immobilized in the polymer networks of the microgel. Under these conditions, pNIPAm-based microgels containing functional groups behave as reactors for synthesizing inorganic nanoparticles [9–11]. By changing the microgel composition, metal nanoparticles of varying size are obtained [9]. Hybrid microgels are attractive functional material candidates, since they combine the features of soft microgels (such as high colloidal stability and stimuli-responsiveness) with the optical, electronic, and magnetic properties of metal nanoparticles. The synthesis of metal nanoparticles (CdS, fluorescent and nonfluorescent Ag, and Fe_3O_4) in poly(NIPAm-acrylic acid-2-hydroxyethyl acrylate) microgels has been comprehensively investigated [9,63]. Others [11,64] discussed how the volume transition of the pNIPAm shell modulates the catalytic activity of metallic nanoparticles in polystyrene core–pNIPAm shell particles. They also demonstrated the catalytic efficacy of thermosensitive Au-pNIPAm yolk shell hybrid particles in the reduction of aqueous 4-nitrophenol and nitrobenzene, and that temperature enhances catalysis sensitivity [65]. We have reported on microgels hybridized with in situ synthesized inorganic nanoparticles, where microgels of different structure templates exhibit tunable properties [10,66–69]. The thermosensitivity of such hybrid microgels manifests as color change. By controlling the interparticle interactions between the nanoparticles embedded in the microgel, we can alter the surface plasmon resonance absorption of Au and Au/Ag nanoparticles (Fig. 44.4) [10,67]. Another template enabled the fabrication of a hybrid microgel wherein a stable Au nanoshell was formed in situ at a rigid core surface [66]. We have also demonstrated the formation of colloidal crystals of core–shell hybrid microgels by thermal annealing [69]. Here, the hybrid microgel architecture was constructed in multiple synthetic steps to homogenously localize the Au nanoparticles within the microgels (Fig. 44.5). Novel assemblages that exploit this hybrid structure will be useful for creating complex, tunable optical materials with periodic refractive index over multiple length scales.

In addition to the abovementioned reports, microgels hybridized with metal nanoparticles have been extensively applied to tuning optical properties [70–74] and catalysis [75–80].

44.4.2 Janus Microgels

Janus particles are particles with chemically different hemispherical surfaces [81]. The synthesis of rigid Janus particles has markedly progressed, and we believe that the synthetic method is now established [82]. Therefore, future research will focus on applications rather than production of these particles. As mentioned above, microgels are soft agglomerates of cross-linked polymer networks, and highly swollen in appropriate solvent. Recently, our group has created its first Janus microgels [83, 84], which are cationic on one side and anionic on the other. The hydrophilicity of the entire microgel is tunable by external stimuli such as pH and temperature. We are currently engaged in controlling the shape of microgel assemblies by their stimulus-responsive

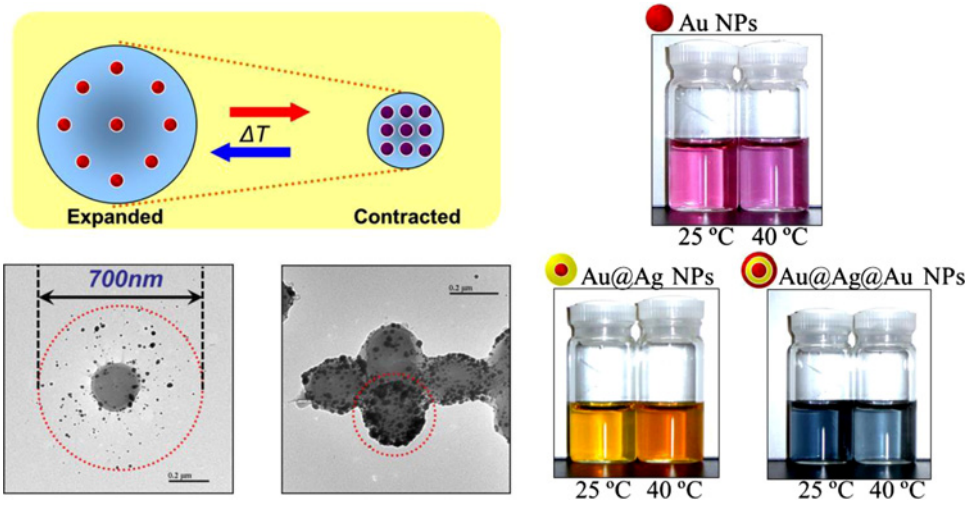

FIGURE 44.4 As the temperature changes, the microgel swells and shrinks, altering the relative distance between metallic nanoparticles suspended in the polymer matrix, the interaction of their surface plasmons, and thus their optical properties. The rightmost frames show the color differences at 25°C and 40°C (left and right, respectively, in each frame) for samples loaded with gold nanoparticles (top), gold–silver core–shell nanoparticles (bottom left), and gold–silver–gold multishell nanoparticles (bottom right). properties; our Janus microgels can assemble into A-B_A-B_A-B-type strings via attraction between cationic and anionic hemispheres. This arrangement is crucially different from the A-B_B-A-type clusters formed by non-charged/onesided charged amphiphilic Janus particles. First, temperature- and pH-responsive microgels were constructed from NIPAm and acrylic acid (AAc) monomers. NIPAm-*co*-AAc microgels were prepared by aqueous free-radical precipitation polymerization. Oil-in-water (o/w)-type Pickering emulsions were formed by stirring a mixture of aqueous microgel dispersion and hexadecane at room temperature. Here, the microgels behaved as particulate stabilizers. Subsequently, one hemisphere of the microgels was modified with ethylenediamine at the oil–water interface. At pH 5, almost all of the carboxyl groups in the microgel were highly deprotonated, and the charge was distributed

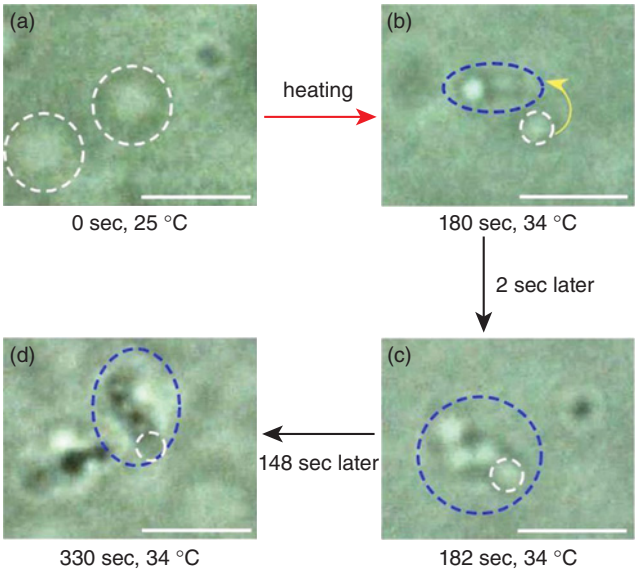

FIGURE 44.6 Temperature-induced assembly of Janus microgels traced by optical microscopy. All scale bars are 5 μm. (a) At 25°C, pH = 3, and salt concentration = 10 mM, Janus microgels exist in a swollen state. (b) Dispersion immediately jumped from 25°C to 34°C. The microgels contracted as they dehydrated. Thus, the deswollen microgels have assembled into strings 180 s after the temperature jump. Here, the microgel (delineated by the white circle) is just attaching to the microgel trimer (delineated by the blue circle). (c) A microgel tetramer forms 2 s later. homogeneously across the microgel surface. However, at pH 3, although the vast majority of AAc carboxyl groups were protonated, anionic sulfate groups released from the initiator were active throughout the microgel, and the amine groups became positively charged over a single hemisphere. Thus, dipolar Janus structures were fabricated by changing the pH. Generally, microgels are colloidally stabilized by steric hindrance; however, they are influenced by electrostatic attractive forces. Our Janus microgels were colloidally stable at 25°C and pH 3, but they were flocculated above 34°C at the same pH. These behaviors were revealed by DLS. Interestingly, the flocs showed a stringlike structure under optical microscopy (Fig. 44.6). The advantages of Janus microgels are as follows:

1. *Variable Stimulus-Responsive Properties*. Radical precipitation polymerization yields many types of stimulus-responsive microgels.
2. *Reversible Dispersion/Flocculation Behavior*. pNIPAm microgels are known to reversibly disperse and flocculate [46]. The colloidal stability of such microgels can be controlled by varying the external stimuli such as temperature and pH.
3. *Biocompatibility*. To date, several types of biocompatible microgels have been fabricated from natural polymers. These advantages suggest a role for Janus microgels in precisely controlled particle clusters, microfluidic devices, microactuators, and model colloids for molecular science.

44.4.3 Oscillating Microgels

Different from conventional stimuli-responsive microgels, novel oscillating microgels with periodically changing physicochemical properties have been developed by our group and others. Oscillations are automatic; specifically, the microgels periodically swell/deswell in the absence of externally stimulated on/off switches [85–87]. This section summarizes some recent advances in this new class of microgels.

Oscillating microgels are fabricated by anchoring functional species with periodically changeable properties to the microgels. If the microgel is to synchronize with pH-oscillating reactions, the functional group should be a carboxyl or amine group. For example, poly(NIPAm-*co*-AAc) microgels synthesized by precipitation polymerization are synchronized with the bromate–sulfite pH–oscillating reaction [85].

In our research, microgels were synchronized with the redox oscillation of the Belousov–Zhabotinsky (BZ) reaction by covalently bonding the metal ion catalyst of the BZ reaction to the microgel [86, 87]. Aqueous free-radical precipitation polymerization, by which stimuli-responsive microgels are synthesized, is also beneficial for synthesizing monodispersed microgels. To this end, ruthenium (4-methyl-4′-vinyl-2,2′-bipyridine)bis(2,2′-bipyridine)bis(hexafluorophosphate) monomer [denoted as $Ru(bpy)_3$ monomer], NIPAm, and cross-linker BIS are dissolved in water, and polymerization is initiated by injecting a cationic initiator solution (e.g., V50) into the mixture at 70°C [86, 87]. Polymerization usually requires about 6 h to complete. During the polymerization, 50–60% of the $Ru(bpy)_3$ monomer is incorporated into the resultant microgels with the $Ru(bpy)_3$ moieties fixed in the reduced $Ru(bpy)_3^{2+}$ state [88]. The loss of $Ru(bpy)_3$ monomer during polymerization is attributable mainly to the hydrophilicity of the monomer. The LCST of highly charged pNIPAm linear chains is much higher than that of pure pNIPAm. Consequently, the poly(NIPAm-*co*-$Ru(bpy)_3$) chains are forced into the coiled state during polymerization, even at 70°C, and are not incorporated by microgels. The $Ru(bpy)_3$ monomer also faces shrinkage of the hydrodynamic diameters of the microgels during polymerization; the effect is similar to that of ionic surfactants in precipitation polymerization [88]. Moreover,

by changing the ionic strength, monomer concentration, and initiator concentration, we can control the microgel size. To date, monodispersed microgels of hydrodynamic diameter 100–800 nm have been prepared in their swollen states. Currently, to achieve the swelling/deswelling volume oscillation, the metal catalyst of the BZ reaction must be immobilized within polymer chains of microgels.

How the oscillatory behavior of microgels is regulated must be clarified. Oscillatory behavior is governed by the conditions of the involved chemical reactions. The reaction temperature and the concentrations of the reacting chemical substrates essentially determine the oscillatory characteristics of the chemical reaction itself (such as the induction period, oscillation amplitude, oscillation period, and waveform). The state of the microgel network structure (i.e., whether the polymer chain is coiled or globular) should also dynamically affect the chemical reactions via a feedback effect. In the next three subsections, the features of oscillating microgels are clarified by summarizing the effects of the abovementioned primary influencers of oscillatory behavior by focusing on the BZ reaction. To simplify the discussion, we assume that all reaction solutions are mechanically stirred, although mechanical stirring is another important mediator of oscillatory behavior.

In general, the oscillations in the BZ reaction are preceded by an induction period, as shown in Fig. 44.7. In practical applications, the induction period of the oscillating microgels must be controlled as precisely as possible. This induction period depends on the types and concentrations of the chemical substrates (i.e., metal ion catalysts, oxidizing and reducing reagents, strong acids), and on the temperature and stirring rate [89]. The induction period of the BZ reaction is most likely explained by a critical concentration of the organic brominated species [mainly bromomalonic acid

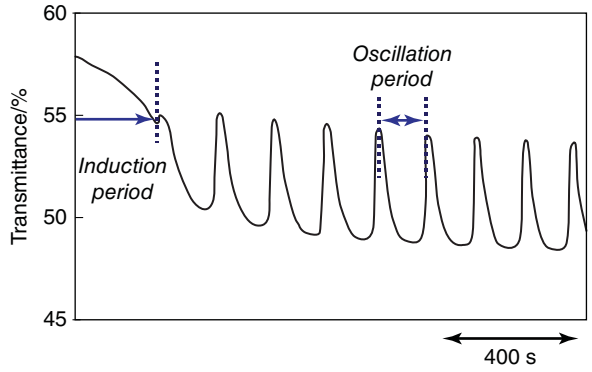

FIGURE 44.7 Typical profile of cyclic optical transmittance by oscillating microgels. To observe transmittance changes originating from microgel oscillation, measurements were made relative to an isosbestic point (570 nm) of the Ru^{II} and Ru^{III} states. [Reprinted with permission from Ref. 91. Copyright (2008) American Chemical Society.]

(BrMA)] that triggers oscillation [89, 90]. The effect of initial substrate concentrations on the induction period of the oscillating microgels is less easily clarified, but has been investigated by varying substrate concentration while other parameters are fixed [91]. For oscillating microgels containing immobilized metal ion catalysts, the induction period also strongly depends on the microgel network structure [88]. Figure 44.8 plots the induction periods of microgel oscillations, and those of the conventional BZ reaction without microgels, at 25°C. In all cases, the chemical reagents in the BZ

reaction are malonic acid (MA), sodium bromate ($NaBrO_3$), and nitric acid (HNO_3), and the oscillating microgels represent 1 mol% and 10 mol% cross-linked (by BIS cross-linker) polymer. As the cross-link density increases, the induction period of the microgels markedly lengthens, as is evident from Fig. 44.8. From a hypothesis proposed earlier [90], we relate the induction period of the oscillating microgel system to the immobilization of the metal ion catalysts in the microgels. BrMA must be produced at lower rate than in the BZ reaction with nonimmobilized catalysts, because the diffusion constants of the chemical substrates and intermediates are reduced in the microgel networks. Moreover, increasing $[NaBrO_3]_0$ extends the induction period of the oscillating microgels, but does not affect the induction period in bulk solution (Fig. 44.8b). Again, the induction period is related mainly to the critical BrMA concentration, which is known to depend on $[NaBrO_3]_0$ [89,90]. The differing induction period between the oscillating microgels and the bulk solution might be related to additional factors such as the concentrations of metal ion catalyst and MA. In fact, as $[NaBrO_3]_0$ increases, the tendency for the induction period to lengthen strengthens with decreasing concentration of metal catalyst in the BZ reaction with nonimmobilized cerium ions [90]. The relationship between induction period and temperature has also been clarified [88]. The induction period is longer in the oscillating microgels than in the conventional BZ reaction at all temperatures below the VPTT (volume phase transition temperature) of the microgels. In addition, at all temperatures, the induction period of the microgels is extended with increasing cross-link density. All of these results can be attributed to $Ru(bpy)_3$ immobilization within the cross-linked network structures [91]. The mechanism underlying the induction period of oscillating microgels is complex, and requires further investigation.

The short swelling/deswelling oscillation period of microgels is very difficult to follow by DLS. Thus, oscillation amplitudes at different hydrodynamic diameters were estimated from diameter changes between the reduced Ru^{II} state and the oxidized Ru^{III} state at the same temperature [86,88,91]. The hydrodynamic diameters of poly(NIPAm-*co*-$Ru(bpy)_3$) microgels as functions of temperature were measured by DLS, and are plotted in Fig. 44.9. Since the BZ reaction proceeds only at high salt concentration, the HNO_3 concentration exceeded 0.3 M in all solutions. The deswelling curves almost coincide when small quantities (<0.12 mol%) of $Ru(bpy)_3$ are immobilized, as shown in Fig. 44.9a. In contrast, when 0.34 mol.% of the $Ru(bpy)_3$ monomer is incorporated into microgels, the transition temperature is higher for the oxidized Ru^{III} state than for the reduced Ru^{II} state. Comparing parts (b) and (c) of Fig. 44.9, we note that the shift in transition temperature enlarges as the amount of $Ru(bpy)_3$ monomer immobilized in the microgels increases from 0.56 mol% to ~1 mol%. From these data, we can roughly estimate the volume changes in the oscillations.

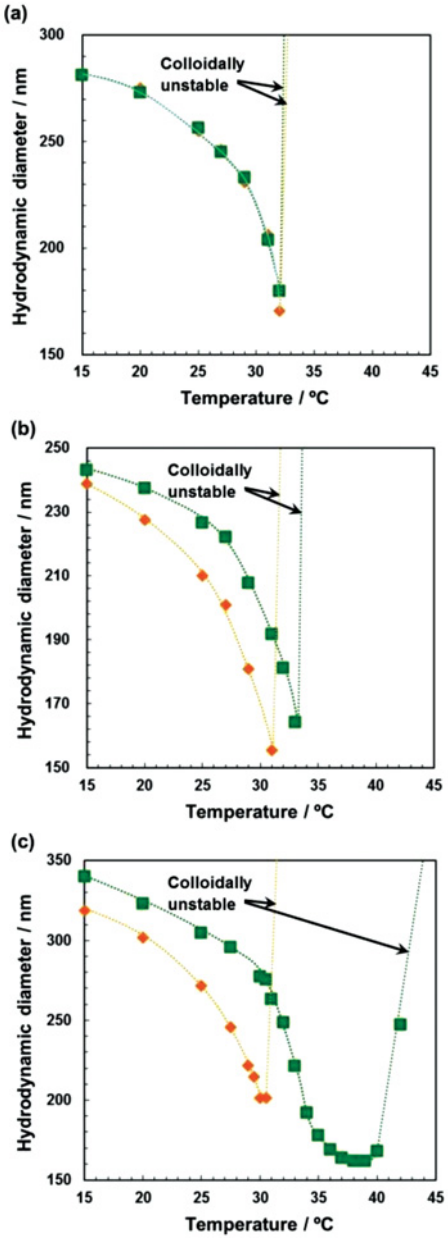

FIGURE 44.9 Relationship between hydrodynamic diameter of microgels and temperature, measured by DLS. BIS cross-linked poly(NIPAm-*co*-$Ru(bpy)_3$) microgels in the reduced Ru^{II} state are suspended in solution with 1 mM Ce^{III} and 0.3 M HNO_3 (orange diamonds), and in the oxidized Ru^{III} state in solution with 1 mM Ce^{IV} and 0.3 M HNO_3 (green squares). Samples contain (a) ~0.1 mol.%, (b) ~0.6 mol.%, and (c) ~1.0 mol.% $Ru(bpy)_3$ monomer. [Reprinted with permission from Refs. 88 and 99. Copyright (2008 and 2010) American Chemical Society.]

For instance, at a constant temperature of 30°C, the volume of the oscillating microgels changes by ~40% (Fig. 44.9c).

Since hydrodynamic diameters are not easily measured by real-time DLS, oscillation amplitudes are monitored by

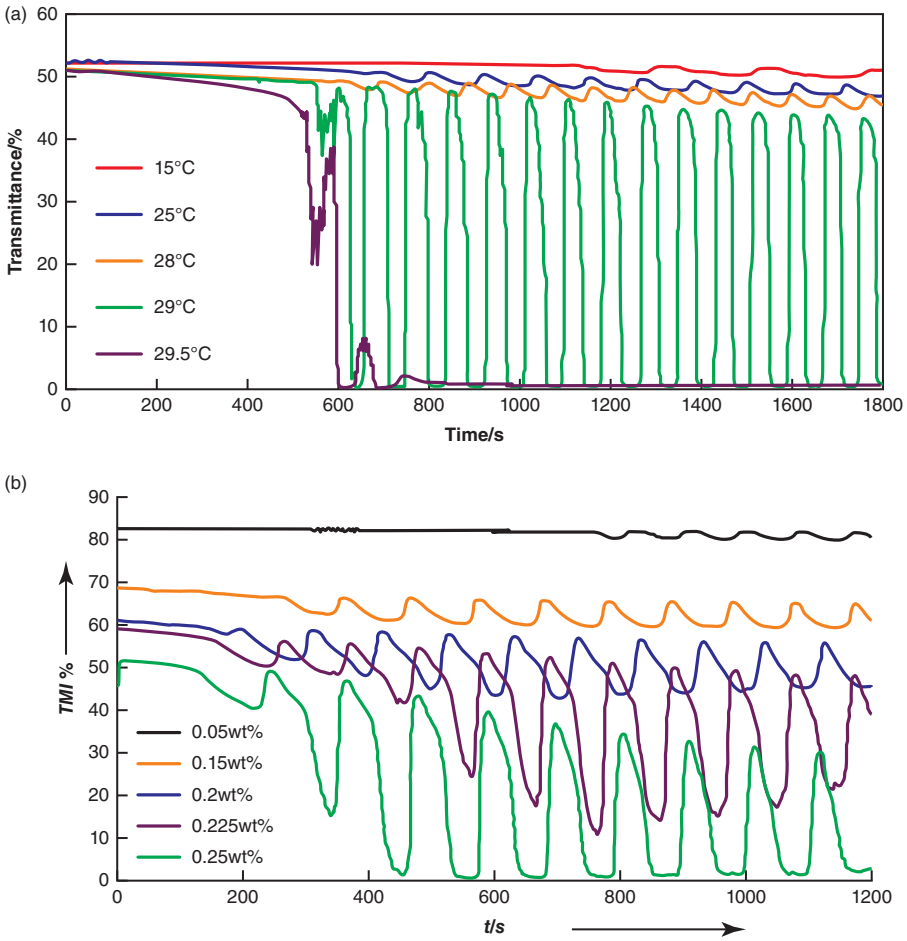

FIGURE 44.10 Profiles of cyclic optical transmittance of BIS cross-linked oscillating microgel dispersions. Profiles are measured at (a) different temperatures and (b) different microgel concentrations. [Reprinted with permission from Refs. 86 and 88. Copyright © 2008 Wiley-VCH. Copyright (2008) American Chemical Society.]

changes in the optical transmittance of dispersed microgels. The results are plotted in Fig. 44.10. The oscillation amplitudes in the microgel volume and optical transmittance are related, because the swelling determines the scattering intensity and the optical transmittance. Below the transition temperature (15–28°C; Fig. 44.10a), the oscillation amplitude of the optical transmittance slightly increases with increasing temperature, mainly because the hydrodynamic diameter shift between the Ru^{II} and Ru^{III} states increases, as shown in Fig. 44.9b,c.

Note that the oscillation amplitude of the redox potential in the bulk solution of the BZ reaction depends on the concentrations of initial substrates and the $Ru(bpy)_3$ catalyst [92]; thus, the $Ru(bpy)_3$ catalyst exists partially in the reduced Ru^{II} state and partially in the oxidized Ru^{III} state at the same time. Moreover, using isothermal titration calorimetry and ultrasensitive differential scanning calorimetry, one team of investigators [93] reported that less heat was released by the oscillating microgel system than by a bulk solution of the BZ reaction, because the chemical reaction in the former is restricted by the hydrogel network structure. Consequently, the DLS-derived results of Fig. 44.9 might overestimate the amplitude of the volume oscillation.

Although the overall BZ reaction involves more than 80 elementary reactions, understanding how the overall oscillation period P_{osc} is affected by the chemical reaction conditions is a worthwhile pursuit. Similar to the induction period mentioned above, the P_{osc} of the BZ reaction depends on the initial substrate concentrations, temperature, and stirring rate. Moreover, when oscillating microgels are involved, the P_{osc} should also be affected by metal–catalyst–immobilization. To investigate this effect, we compared the P_{osc} of microgel oscillations with those of the bulk solution of the BZ reaction. First, with the temperature fixed at 25°C, the dependence of P_{osc} on initial substrate concentration was determined. As shown in Fig. 44.11, the P_{osc} clearly differs between

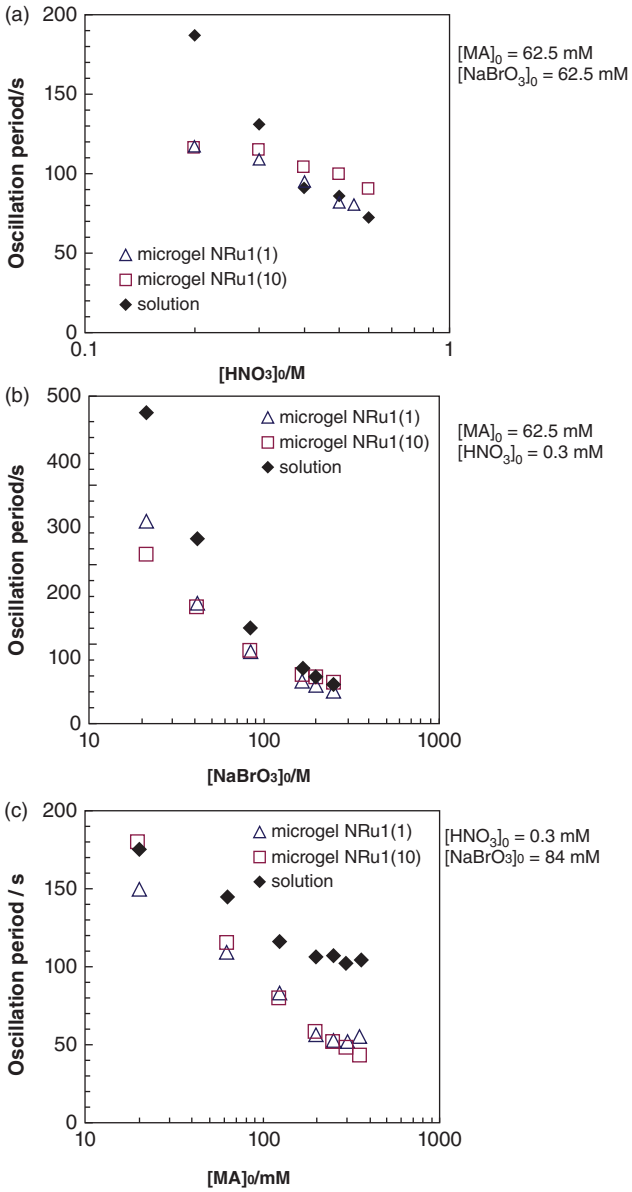

FIGURE 44.11 Effect of initial substrate concentration on oscillation period of the bulk solution system (black diamonds), 1 mol.% BIS cross-linked oscillating microgels (blue triangles), and 10 mol.% BIS cross-linked oscillating microgels (red squares). FIGURE 44.12 Arrhenius dependence of oscillation frequency (F_{osc}) of BIS cross-linked oscillating microgels: 1 mol.% (black diamonds), 4 mol.% (red squares), and 10 mol.% (blue triangles). Control measurements of the BZ reaction without microgels are also shown (orange circles). [Reprinted with permission from Ref. 88. Copyright (2008) American Chemical Society.]

the bulk solution and the microgel dispersion. In all cases, P_{osc} reduces as the initial substrate concentration increases. Unlike the situation in the bulk solution, the relationship between P_{osc} and substrate concentration in the dispersed oscillating microgels is strengthened for MA, but weakened for HNO_3 and $NaBrO_3$. Large differences in P_{osc} between the bulk solution and the oscillating microgels also appear at high $[MA]_0$ and low $[HNO_3]_0$ or $[NaBrO_3]$, but not at higher $[HNO_3]_0$ or $[NaBrO_3]_0$. Although the aforementioned results cover only a subset of the possible phenomena, they may be useful for qualitatively controlling the P_{osc}.

Next, we describe how the cross-link density of oscillating microgels alters the P_{osc}. For this purpose, we analyze three types of oscillating microgels with different cross-link densities. For convenience, the analyzed variable is the oscillation frequency, F_{osc} (= $1/P_{osc}$). As shown in Fig. 44.12, the F_{osc} of the bulk solution of the BZ reaction increases with increasing temperature according to Arrhenius' law [94,95]. Below the transition temperature, the oscillating microgels also follow the Arrhenius law [88]. In contrast, the F_{osc} decreases near the transition temperature, and the corresponding plots deviate from the Arrhenius equation. The reasons for this phenomenon will be explained later. The F_{osc} of the oscillating microgels apparently exceeds that of the bulk solution. Moreover, at low temperatures (e.g., 15°C), the F_{osc} increases with increasing cross-link density of the microgels, but remains almost unchanged near the transition temperature (around 25°C). This phenomenon reflects the thermoresponsive properties of oscillating microgels, specifically, at 15°C when all microgels are highly swollen, the mesh size of the microgel network structure may monotonically decrease as the BIS feed increases. In contrast, near the transition temperature, changes in BIS feed may scarcely alter the mesh size. Thus, the oscillation period of the microgels clearly depends on their cross-linked network structure. Notably, the network structure also changes during swelling/deswelling

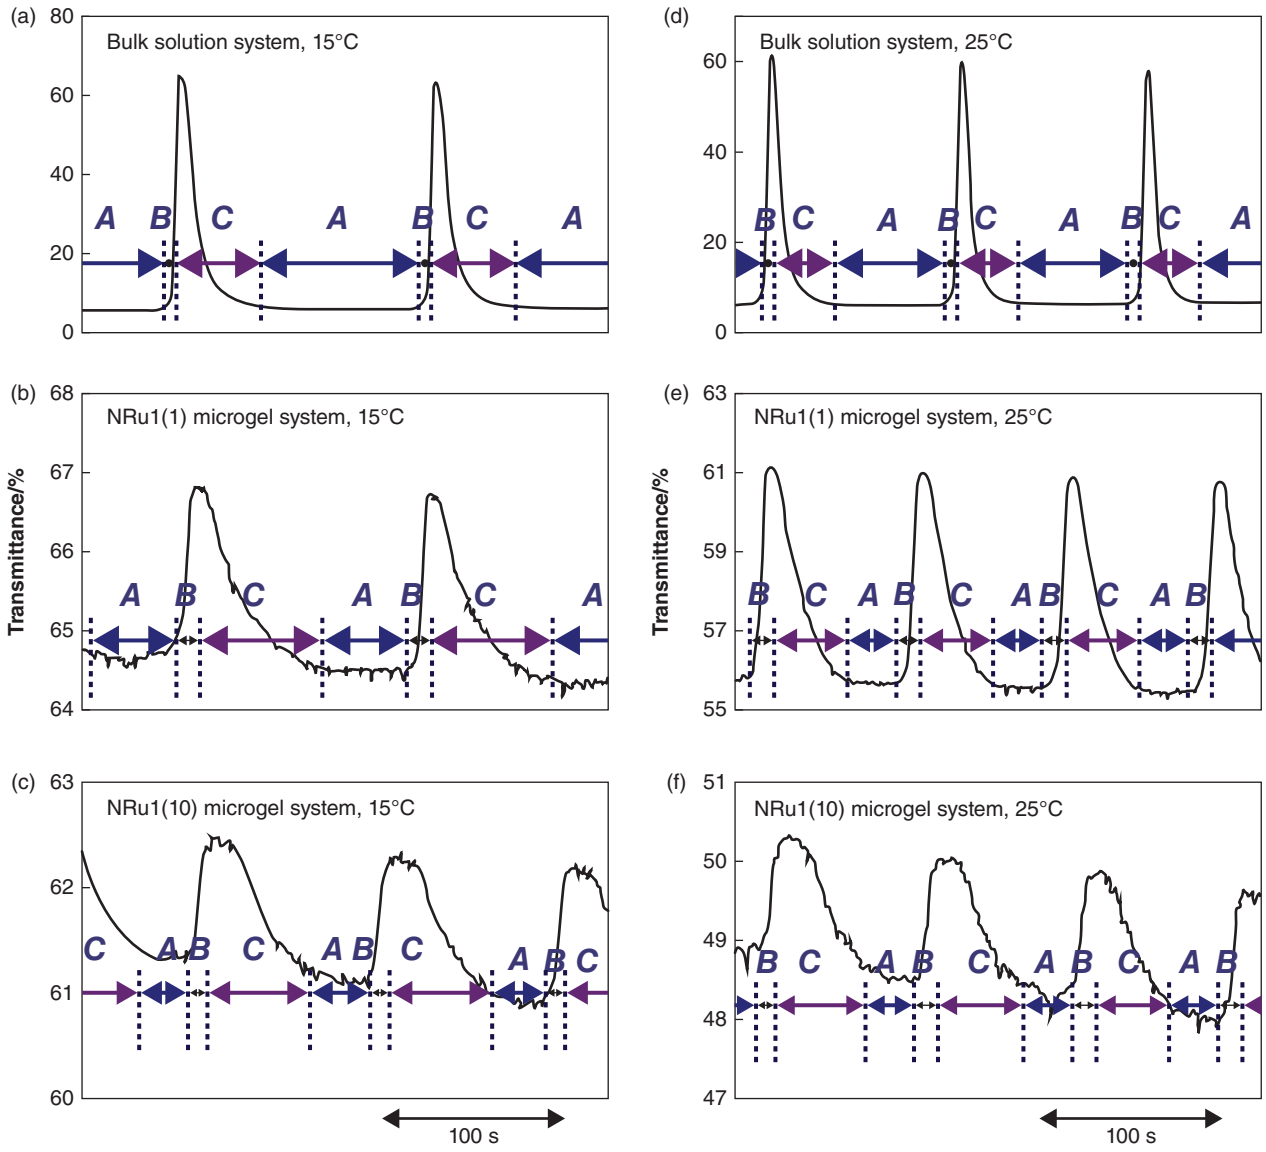

FIGURE 44.13 Typical oscillation waveforms of bulk solution (a,d), 1 mol.% BIS cross-linked oscillating microgels (b,e), and 10 mol.% BIS cross-linked oscillating microgels (c,f). The profiles were measured at 15°C (a–c) and 25°C (d–f). [Reprinted with permission from Ref. 88. Copyright (2008) American Chemical Society.]

volume oscillations of the microgels, suggesting that chemical changes respond to feedback from mechanical changes. Although this effect has yet to be clarified, the network structure undoubtedly plays an important role in controlling the F_{osc} of the oscillating microgels.

To better understand the mechanisms that alter the period of oscillating microgels, the waveforms observed in bulk solution were compared with those obtained from microgels. The oscillations were compared by dividing their waveforms according to the three main processes of the FKN mechanism: consumption of bromide ion (process A), autocatalytic reaction of bromous acid accompanied by catalyst oxidation (process B), and organic reaction accompanied by catalyst reduction (process C) [96, 97]. This division of the typical waveforms is depicted in Fig. 44.13. At a given temperature, the durations of processes B and C relative to the oscillation period (i.e., B/P_{osc}, and C/P_{osc}) are longer for the oscillating microgels than in bulk solution. In addition, at 15°C these ratios enlarge with increasing cross-link density of the oscillating microgels, but remain almost constant at 25°C. Since processes B and C involve catalytic reactions, these findings reflect the immobilization of the $Ru(bpy)_3$ catalyst in the microgels. For the same amount of catalyst, the rate of an immobilized catalytic reaction is lower than that of a

soluble catalytic reaction. In contrast, the A/P_{osc} values of the oscillating microgels are smaller than those in bulk solution, although the reason for the smaller values is unclear. The abovementioned pair of contrasting events alters the P_{osc} of the oscillating microgels. The waveforms of the volume oscillation and the bulk solution of the BZ reaction are also affected by initial substrate concentration [91]. In particular, the prolongation of process C imposed by the abovementioned cross-linking effect [88] reduces with increasing initial MA concentration, resulting in a different dependence for each substrate.

This section has described how the swelling/deswelling oscillation (i.e., volume oscillation) of oscillating microgels synchronizes with chemical reactions such as the BZ reaction. We now explore another oscillating behavior, namely, the flocculating/dispersing oscillation of microgels [86, 87]. This oscillatory behavior has been previously reported in a pH-oscillating system [85].

As shown in Fig. 44.10a, the oscillation amplitude of the optical transmittance increases with increasing temperature within the range 15–28°C [88]. This amplitude increase arises from the increased deviation in hydrodynamic diameter between the $Ru(bpy)_3^{2+}$ and $Ru(bpy)_3^{3+}$ states at constant temperature (Fig. 44.9). At 29°C, a dramatic change in amplitude and waveform appears, and oscillations disappear at 29.5°C. Considering the hydrodynamic diameters plotted in Fig. 44.9, these dramatic changes must be associated with colloidal stability differences between the $Ru(bpy)_3^{2+}$ and $Ru(bpy)_3^{3+}$ states. Under these conditions, the high salt concentration negates the electrostatic repulsion, and the microgels in the reduced $Ru(bpy)_3^{2+}$ state become flocculated. The microgels exist in a deswollen state and lack the repulsive interaction of steric hindrance that originates at the exterior of hydrated polymer chains.

Next, recognizing that colloidal stability is sensitive to microgel concentration, we investigated the effect of microgel concentration on the oscillations at constant temperature [86]. The results are plotted in Fig. 44.10b. From this figure, the optical transmittance apparently depends on microgel concentration. The amplitude and waveform of the optical transmittance dramatically change only at higher microgel concentrations, indicating that the microgels are repeatedly flocculated and redispersed under these conditions.

Moreover, the optical transmittance and redox potential of the microgel dispersion were measured simultaneously [88]. Here, increased redox potential implies increased concentration of oxidized $Ru(bpy)_3^{3+}$ catalyst. As shown in Fig. 44.14a, the transmittance curve overlaps the redox potential curve at low temperatures, indicating that the swelling/deswelling volume oscillation of the microgels is synchronized with the cyclic chemical reaction. In contrast, as shown in Fig. 44.14b,c, the transmittance curve deviates from the redox potential curve at higher temperatures, indicating a flocculating/dispersing oscillation of the microgels.

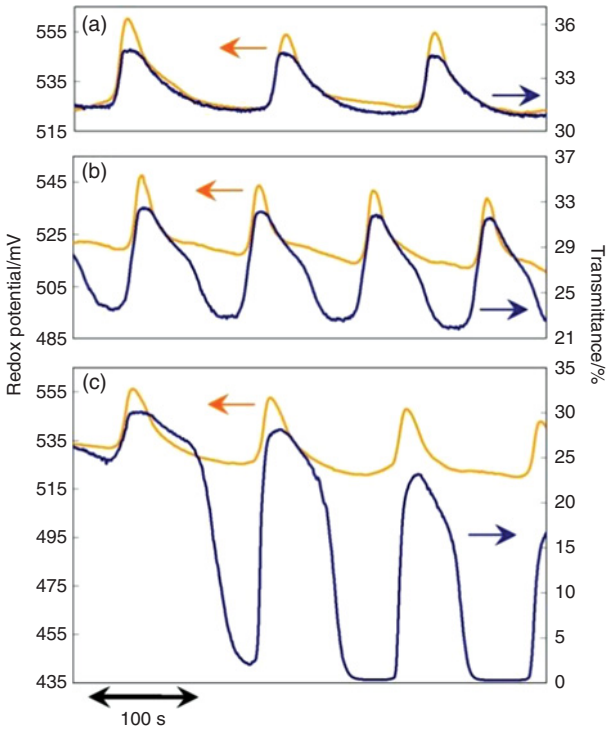

FIGURE 44.14 Simultaneous measurements of redox potential (orange) and transmittance (blue) of 1 mol.% BIS cross-linked oscillating microgel at different temperatures: (a) 25°C, (b) 27°C, and (c) 27.5°C. [Reprinted with permission from Ref. 88. Copyright (2008) American Chemical Society.]

Note that the transmittance decreases sharply when a high proportion of the catalyst exists in the reduced $Ru(bpy)_3^{2+}$ state, further indicating that the large decreases manifest from microgel flocculations. Here, the flocculations are redispersed because the microgel does not lie in a deep potential minimum; hence the flocculations are weak and reversible [98].

Furthermore, as shown in Fig. 44.15, the microgels oscillate in both volume and flocculation/dispersal behavior [87,99]. At low temperature (20°C), the waveform is shaped similar to that of typical BZ reactions detected by optical transmittance and redox potential changes. Thus, the oscillating viscosity in the microgel dispersion is due to swelling/deswelling oscillation of the microgels. As shown in Fig. 44.15a, the viscosity is high when the microgels exist in a swollen state at point (i) and low in the deswollen state at point (ii). In contrast, the waveform shape dramatically alters at higher temperature (23°C; Fig. 44.15b). Considering the abovementioned optical transmittance and redox potential data, the oscillating viscosity in the dispersion may be reasonably attributed to the flocculating/dispersing oscillations of the microgels. In this case, the smaller peak is attributed to a simple volume oscillation of each microgel from point (i) to point (ii) in Fig. 44.15b. The succeeding amplitude spike

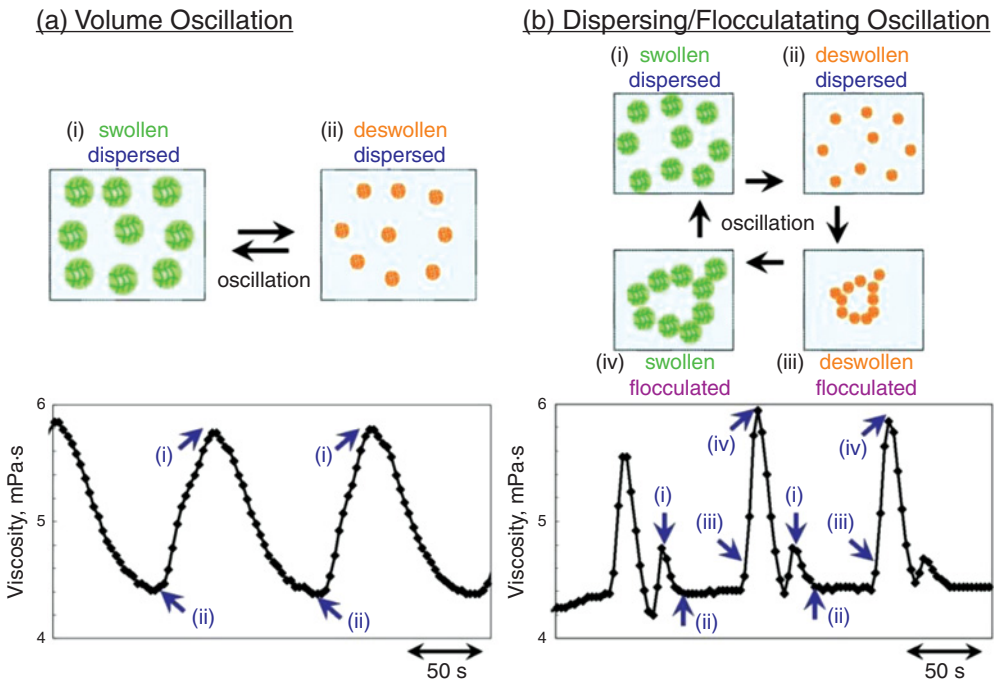

FIGURE 44.15 Profiles of cyclic viscosity in oscillating microgel dispersions: (a) swelling/deswelling (volume) oscillation of microgels at 20°C; (b) dispersing/flocculating oscillation of microgels at 23°C. [Reprinted with permission from Ref. 87. Copyright (2009) American Chemical Society.]

arises from flocculation of the microgels at point (iii), where the flocs become sufficiently large for detection by optical transmittance. Flocculation persists until colloidal stability is recovered through hydrating and swelling at point (iv). The viscosity of the dispersion is then decreased as the flocs redisperse. At minimum viscosity, redispersal may be complete. The swelling/deswelling cycle of the microgels then repeats. Consequently, the behavior of the flocculating/dispersing oscillation is better revealed by rheological measurements than by transmittance measurements [87]. Large amplitudes of viscosity oscillation have also followed the induction of large swelling/deswelling volume oscillations in microgels incorporating many $Ru(bpy)_3$ complexes [99].

More recently, we obtained high-amplitude swelling/deswelling oscillations by introducing a hierarchical structure into an artificial muscle constituting a high-volume fraction of swollen microgels [100]. The microgels used in this analysis were fabricated by copolymerizing NIPAm, $Ru(bpy)_3$, *N*-(3-aminopropyl) methacrylamide hydrochloride (APMA), and cross-linker by free-radical precipitation polymerization. Reversible high-amplitude oscillations were induced in the macrogel by dispersing/flocculating oscillations of the constituent microgels. Although microgel motions are restricted in macrogels, slight cross-linking in the macrogel should permit some movement. The amplitude of the macrogel is much larger than that of unstructured gel. We believe that the autonomously oscillating soft actuators prepared by this simple fabrication process are suitable for practical use in micropumps.

44.5 CONCLUDING REMARKS

This chapter has summarized the behaviors of stimulus-responsive microgels with particular focus on hybrid microgels, Janus microgels, and oscillating microgels. We consider that research into these emerging functional microgels has taken its initial steps. As fundamental research progresses and the technology develops, hydrogels will make valuable theoretical and practical contributions to colloid, polymer, and materials chemistry.

HYDROPHILIC–LIPOPHILIC BALANCE (HLB): CLASSICAL INDEXATION AND NOVEL INDEXATION OF SURFACTANT

YUJI YAMASHITA AND KAZUTAMI SAKAMOTO

Department of Pharmaceutical and Life Sciences, Faculty of Pharmacy, Chiba Institute of Science, Choshi, Chiba 288-0025, Japan

45.1 INTRODUCTION

In the last few decades, many polyoxyethylene (POE)-type surfactants have been investigated for their fundamental properties such as melting point and solubility in water or oil, and their practical properties such as clouding temperature, solubilization, liquid crystal formation, and emulsification. These properties were studied systematically and classified with respect to the hydrophilic–lipophilic balance (HLB) of the surfactant. Development of this "HLB concept" would be one of the greatest contributions possible with the advancement of practical usage of POE surfactants in the industrial fields. Table 45.1 lists applications corresponding to the HLB number range.

The HLB number is an index of the affinity of a surfactant toward a solvent; for example, a high HLB number indicates that the surfactant is more attracted to water (is water-soluble). It is well known as a practical example of the HLB number that the type and appropriate amount of POE surfactant can be estimated to emulsify a kind of oil-in-water (o/w) solution. In addition, the HLB number shows a good correlation with the clouding temperature and phase inversion temperature (PIT), and has provided significant benefit to the development of advanced emulsification technology. The HLB number scale, introduced by Griffin, was the first successful attempt at quantitative characterization of the POE surfactants, while classification of surfactants by HLB number in some instances does not help one to predict the optimum emalsification.

Initially, Griffin established the HLB number by his extensive experiments using POE surfactants; therefore, HLB calculation cannot be assumed to work for general surfactants other than those of the POE type. It is understood that the POE chain has a unique interaction with water molecules, characterized by a decrease in temperature with conformational change and dehydration. Furthermore, use of the HLB number in practical applications can be fraught with difficulty as there are no accountable adjustments of POE–water interactions relating to the effects of additives, temperature, self-organization, and so on in the HLB number calculated by the equations provided. The HLB number and its calculation are certainly convenient and applicable to mixture properties exclusively for POE surfactants but do not always provide a correct HLB value for non-POE surfactants. Consequently, a surfactant suitable for application cannot become widespread in the marketplace even if it has excellent properties.

From this perspective, we attempted to review the classical HLB number and the substantial issues involving basic properties and applications. By reconsidering the HLB number, we introduced our most recent studies on the hydrophilic–lipophilic nature of the surfactant.

45.2 CALCULATIONS OF HLB NUMBER

Various equations used to calculate the HLB number have been proposed over the past 50 years. The first and still most commonly used equation was proposed by Griffin

TABLE 45.1 HLB Numbers and Corresponding Applications

HLB number range	Corresponding application
1.5–3	Antifoaming agent
1–4	Emulsifier for w/o emulsions
6–8	Wetting agent
10–13	Emulsifier for o/w emulsions
13–15	Detergent
15–18	Solubilizer

[1]. This equation expresses the structural balance between hydrophilic and lipophilic groups in a surfactant molecule as numeric index from 0 to 40 on the basis of emulsification examination using trial POE surfactants. This equations is useful for POE surfactants; specifically, the HLB numbers of the POE alkyl ethers (C_mEO_n) are given by the following equation, where the HLB number equals the weight fraction of oxyethylene (POE) moiety in the molecule:

$$\text{HLB} = \frac{\text{POE(wt\%)}}{5} \tag{45.1}$$

As mentioned above, these numbers are obtained from empirically emulsifying examinations, and thus this equation can be utilized as a reliable and convenient tool for industrial applications. On the other hand, Griffin also obtained another equation to calculate the HLB number for fatty-acid esters chemically bonded with polyalchohols as follows [2]

$$\text{HLB} = 20 \times \left(1 - \frac{S}{A}\right) \tag{45.2}$$

where S and A are the saponification and acid numbers of the ester, respectively. The HLB number given to polyglycerol fatty-acid ester as a representative for this equation frequently shows different solution properties from C_mEO_n, even though their HLB numbers appeared to be equivalent. So that it is difficult to apply HLB numbers for that mixed-surfactant system as their values are assigned from different equations.

Davies' method [3, 4], which is one of the traditional methods used to calculate HLB, is based on the unit value given to the each functional group as either a hydrophilic or a hydrophobic element, and HLB of the molecule can be calculated as a summation of whole unit values:

$$\text{HLB} = 7 + \sum(\text{unit value of hydrophilic group}) + \sum(\text{unit value of lipophilic group}) \tag{45.3}$$

The representative unit values are shown in Table 45.2. This versatile equation is able to calculate the HLB number even for ionic surfactants, although the resulting HLB value might not predict the properties of the surfactant solution.

TABLE 45.2 Representative Unit Values Used in Davies Equation

Hydrophilic group	Unit value	Lipophilic group	Unit value
$-SO_4Na$	38.7	CH_3-	−0.475
–COONa	19.1	$-CH_2-$	−0.475
$-(CH_2-CH_2-O)-$	0.33	–	–
–OH	1.9	–	–

Another important equation commonly used for HLB calculation is based on the *organic conceptual diagram* [5]. Initially, the primary objective of this method was to identify the complex properties of organic compounds via intermolecular interactions. The conceptual diagram consists mainly of an *organic value* (OV) and an *inorganic value* (IV), which respectively relate to the intermolecular force generated by van der Waals interactions and electrostatic interactions, and the combination of two values corresponds to the HLB number:

$$\text{HLB} = \frac{\Sigma\,\text{IV}}{\Sigma\,\text{OV}} \times 10 \tag{45.4}$$

The representative organic and inorganic values are shown in Table 45.3.

Let us compare the HLB numbers of $C_{12}EO_n$ calculated by Eqs. (45.1), (45.3), and (45.4). Figure 45.1 shows the change in HLB number as a function of the EO chain length (n). As expected, the HLB number monotonically increases with n, suggesting that the hydrophilicity of $C_{12}EO_n$ increases. However, there are discrepancies of HLB values between equations which disperse further by increasing EO numbers. Namely for $C_{12}EO_5$, the Griffin's HLB value is 10.8, whereas the Davies's equation (3) gives 4.9 which underestimates in comparison to the Griffin's equation. On the other hand, the HLB value calculated from the organic conceptual diagram's equation (4) is 21.1 contrastively overestimating. No matter what correct HLB value is, it is a fact that these different equations resulted to the different answers. This is a crucial problem when industrial applications are exercised, because more or less we rely on the HLB number of the surfactant regardless of their origin.

TABLE 45.3 Representative IV and OV Used in Organic Conceptual Diagram [6]

Functional group	IV	OV
C	0	20
$-(CH_2-CH_2-O)-$	60	−10
–OH	100	0
–O–	20	0
–COOH	150	0
$-NH_2$	70	0

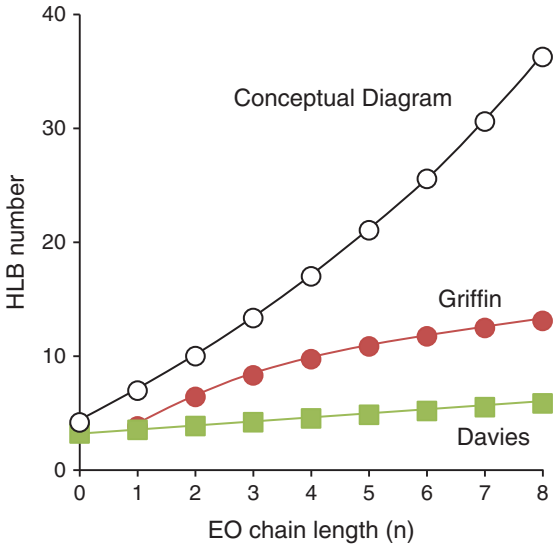

FIGURE 45.1 Comparison of HLB numbers calculated by Eqs. (45.1), (45.3), and (45.4). The HLB number is plotted agains the EO chain length (n) for $C_{12}EO_n$.

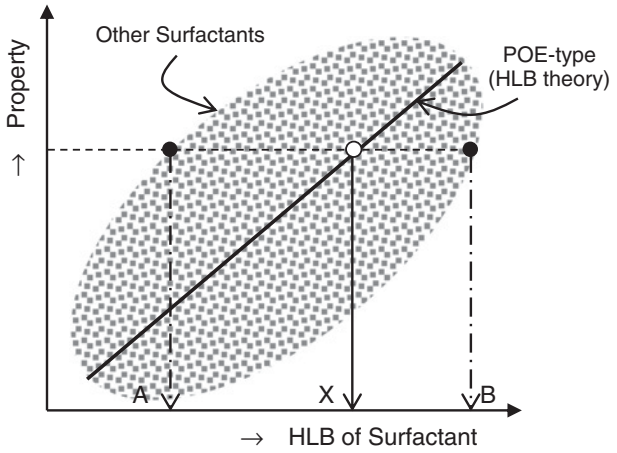

FIGURE 45.2 Correlation diagram of HLB number and property of surfactant. POE-type surfactants have mutual linear relationships, while the ellipsoidal region corresponds to the relationship with the other surfactants. Even if a specific property is required, several surfactants can be adapted (A or B and so on).

45.3 PRACTICAL SIDE OF HLB THEORY

Despite the recent market trend favoring ecofriendly (environmentally friendly) surfactants to replace petroleum-derived materials, POE surfactants are still predominant. One reason is that there is no sufficiently accurate index (corresponding to the HLB number for POE surfactants) to define the intrinsic properties of prospective surfactants, and therefore it should be difficult to obtain the intended properties and state of the solution. Careful thought and constructive examination will be needed to fill this gap. As an example, there is an interesting phenomenon in which polyglycerol fatty-acid esters in diluted solutions show a specific clouding point (CP) within the limited range of hydrophilic–lipophilic balance, which is incompatible with POE surfactants [7]. Furthermore, there have been two reports of phase inversion temperature (PIT) found in a polyglycerol-type surfactant–w/o ternary system, where the HLB of the polyglycerol-type surfactant was tunable by temperature [8, 9]. This implies that polyglycerol-type surfactants possess similar basic properties such as CP and PIT but differ from POE surfactants in this way. In summary, the HLB concept was established for POE surfactants that function within the family of POE structures, but there must be a way to correlate the HLB concept with the surfactants of different chemical species in order to compare or combine functions altogether.

Figure 45.2 shows a conceptual representation of the HLB concept. The horizontal axis (X; abscissa) represents the HLB number of a surfactant and the vertical one (Y; ordinate) represents a property of the surfactant solution such as clouding point, phase inversion temperature, phase state, and so on. The proportional line in the figure represents a relationship between Y and X for POE surfactants. This line can enable one to predict properties of the POE surfactant solution if the respective HLB values are given. On the other hand, for most (non-POE) surfactants, HLB numbers corresponding to the specific properties of their solutions deviate from the pattern shown as A, B, and so on in Fig. 45.2. Thus it would be difficult to predict the properties on the basis of the HLB number. In such cases, to obtain the desired property of the surfactant solution, one could choose a specific surfactant from among the POE-type surfactants (HLB=X in Fig. 45.2) and still have several choices for the other surfactants (HLB=A or B or another option). Although conceptually explained here, the phrase "HLB dependence" possibly fails to adequately assess the HLB aspect in order to utilize the surfactant in developing a real formulation.

45.4 EVALUATION OF HYDROPHILICITY AND LIPOPHILICITY

A surfactant consists of hydrophilic and lipophilic groups that are covalently bonded. Therefore it is conceivable that using a single method might not ensure accurate characterization of the nature of every functional group. Chromatography has been applied for evaluation of the surfactant, and there have been many studies on the polarity [10–12] and hydrophilicity–lipophilicity [13] of surfactants using reversed-phase chromatography. However, this method was unable to establish a practical index because of the limited number of surfactants used, as this was a labor-intensive and time-consuming task. However, we have proposed a novel

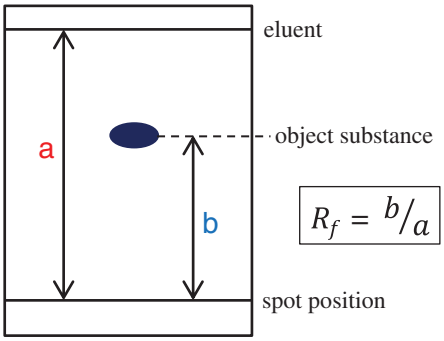

FIGURE 45.3 R_f measurement using TLC plate.

method using thin-layer chromatography (TLC), and systematically evaluated ionic and nonionic surfactants [14]. In addition, we ensured that this TLC method was consistent with the HPLC method. Another team of investigators [15] examined our TLC method for POE alkyl ethers and confirmed it to be compatible with the calculated HLB numbers of these surfactants.

On the basis of these studies, we have attempted to develop this TLC method theoretically. The originality and ingenuity in our study have enabled us to use two TLC plates with different polarities, normal and reverse phases, to obtain the individual R_f values as seen in Fig. 45.3. The intrinsic capacity constant (k) of a surfactant is calculated by use of the following equation:.

$$k = \frac{1}{R_f} - 1 \tag{45.5}$$

Thus, each k value is obtained for the normal and reverse phases, and their ratio (k_N/k_R : k_N for normal phase, k_R for reverse phase) is regarded as a *correlation index of hydrophilicity–lipophilicity*. The selection and combinatorial approach of the TLC plate (stationary phase) and the mobile phase lead to a comprehensive index that includes contributions of every functional group of the surfactant molecule partitioning in the mobile phase and interacting with the stationary phase. By using a given eluent as the mobile phase, in addition, we can estimate the effect of solvation of the object substance. Eventually, the following new index, *integrated surfactant potency* (ISP), representing surfactant properties, will be introduced as functions of k_N and k_R:

$$\text{ISP} = f\left(\frac{k_N}{k_R}\right) \tag{45.6}$$

This expression seems to be similar to the HLB calculation using the organic conceptual diagram [5], whereas our proposed method enables the empirical analysis of a substance itself.

TABLE 45.4 HLB Numbers of Various Lauroyl Amino Acids

Amino Group	Abbre.	HLB (Davies)
Glycine	L-Gly	12.5
Alanine	L-Ala	11.7
Vaine	L-Val	10.6
Leucine	L-Leu	10
Isoleucine	L-lle	10
Phenylalanine	L-Phe	8.7
Tryptophan	L-Trp	9.6
Serine	L-Ser	15
Proline	L-Pro	10.6
Aspartic acid	L-Asp	15.6
Glutamic acid	L-Glu	14.7

45.5 TLC EVALUATION OF AMINO ACID-DERIVED SURFACTANTS

To confirm the validity of this TLC method, the new index, k_N/k_R, was examined using the amino acid–derived surfactants in comparison to the HLB number calculated from Davies' theory [Eq. (45.3)]. The surfactants used consist of lauroyl (C_{12}) group as lipohilic group and different kinds of amino acids as hydrophilic group (Table 45.4), and the TLC measurements were carried out at room temperature using a methanol/water mixture [80/20 (v/v)] as eluent.

The hydrophilicity of the surfactant is remarkably sensitive to the type of amino acid used, resulting in the different HLB numbers as seen in Table 45.4. The hydrophilic–lipophilic property of the surfactant is well defined by Davies' theory for the homolog of the amino acid surfactants. Figure 45.4 shows a plot of k_N/k_R against the HLB number, where the k_N/k_R tends to increase with higher HLB numbers.

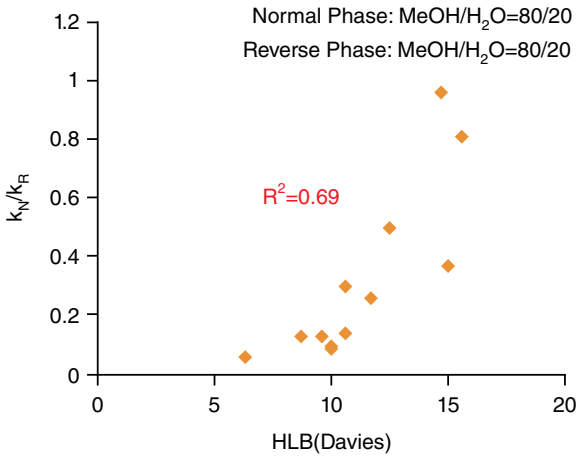

FIGURE 45.4 Relationship between HLB number calculated by Davies' theory [Eq. (45.3)] and the empirical new index, k_N/k_R. The eluent is a methanol/water mixture (80/20 in volume) for both TLC plates.

The correlation coefficient is 0.69, indicating a fair correlation. Although this evaluation system was not sufficiently verified in terms of the eluent, stationary-phase dissociation of ionic amino acid moieties, this TLC method can be a useful tool in determining the surfactant property, and further development must be done to establish as a novel indexation system.

45.6 CONCLUSIONS

In this chapter, we reviewed the classical HLB number theory and its calculations, and pointed out the problems that might be encountered in real manufacturing processing. In particular, the different equations lead to different HLB numbers, which must place the desired properties of the formulation at risk. To resolve such an unnoticed or overlooked misfit between the HLB number and the solution properties, and applications such as emulsification, a new method has been proposed by using the chromatography technique. Instead of the HLB number, we proposed an original and useful index, termed *integrated surfactant potency* (ISP). The appropriate formula of ISP is being investigated in detail and will be standardized for all surfactants by modifying the eluent and the stationary phase. In addition, ISP will potentially be able to predict properties of the surfactant solution such as critical micellar concentration (cmc), clouding temperature, and liquid crystal structures associated with the hydrophilic–lipophilic balance of the surfactant. It is our objective to establish this TLC method to be utilized in many industrial fields to offer solutions with proper selection of surfactants.

INSULIN FIBRILLATION AND ROLE OF PEPTIDES AND SMALL MOLECULES IN ITS INHIBITION PROCESS

VICTOR BANERJEE AND K.P. DAS

Department of Chemistry, Laboratory of Protein Chemistry, Bose Institute, Kolkata, West Bengal, India

46.1 INTRODUCTION

46.1.1 Protein Fibrillation

Proteins are the key members of complex molecular networks of the living organism, controlling the processes taking place in the cell. To carry out their task, proteins must remain in their folded conformation that usually corresponds to the thermodynamically most stable state. During their lifecycle, proteins experience stress conditions, which may perturb the folded native conformation. When these natively folded proteins are converted into nonnative *cross-β-sheet*-fold fibrous structures in different stress conditions, their functional properties are lost forever. This process is called *protein fibrillation* or, more commonly, *amyloid* like aggregation. Matthias Schleiden first coined the term *amyloid* in 1838 to describe an amylaceous component of a plant. Later, in 1854, Rudolph Virchow used the term to describe the high-nitrogen-content deposits seen in liver autopsy [1]. Since then the term *amyloid* has been used to refer to high proteinaceous deposits.

Under normal aggregating conditions, proteins usually form amorphous structures. However, protein fibrillation leads to protein aggregates having a well-defined organized structure. So far numerous proteins are found to form fibrous structure despite the lack of any amino acid sequence homology among them and thus, it is said to be an intrinsic property of a protein [2, 3]. Interestingly, fibrils of all these proteins share a common structural trait [4–6] and go through a common pathway for adaptation of such an ordered structure. A typical fibrillation process involves nucleation phase followed by fibril growth and formation of matured fibrils [7, 8]. In the nucleation phase only minute amounts of fibrils form, which eventually act as catalyst for development of fibrils in the elongation phase. When most of the proteins converted into fibrils, the process reaches equilibrium. The length of the nucleation and the elongation phase depends on the stress conditions and the proteins under study [8–10]. The presence of preformed fibrils or foreign surfaces, such as nanoparticles, can influence the fibrillation kinetics by catalyzing the nucleation phase at these interfaces [11–13]. Unfolded and aggregated proteins are usually evacuated from the cell by the quality control management system of the body through proteolytic cleavage by enzymes. Nonetheless, the aggregated fibrous forms of proteins are often resistant to these enzymes and thus a burden to the system. These aggregates elicit toxicity to the cellular environment [14].

46.1.2 Diseases Associated with Protein Fibrillation

In humans, more than 40 diseases are known to be related to protein fibrillation [4, 14, 15]. A selected list of some of these diseases is given in Table 46.1, along with the names of the specific proteins as the predominant components of the deposits. Each disease is synchronized to the fibrillation of a specific protein at a specific location. For example, amyloid β-peptide (Aβ) fibril in the brain is closely linked to Alzheimer's disease. Among the amyloid diseases,

TABLE 46.1 Some Amyloid Related Diseases and Their Respective Precursors and Amyloid Fibril Forming Proteins

Amyloid diseases	Precursor proteins	Amyloid proteins
Alzheimer's disease	Amyloid precursor protein	Aβ peptides
Spongiform encephalopathies	Prion protein (PrPc)	PrPsc
Primary systemic amyloidosis	Immunoglobulin light and heavy chains	AL and AH
Senile systemic amyloidosis	Wild-type transthyretin	ATTR
Hemodialysis-related amyloidosis	β2-microglobulin	Aβ2M
Hereditary nonneuropathic systemic amyloidosis	Lysozyme	ALys
Type 2 diabetes	Pro-IAPP	IAPP or "amylin"
Injection-localized amyloidosis	Insulin	AIns
Secondary systemic amyloidosis	(Apo) serum amyloid A	Serum amyloid A
Familial amyloid polyneuropathy I	Transthyretin variants	ATTR
Familial amyloid polyneuropathy II	Apolipoprotein A1	AApoA1
Familial amyloidosis	Fibrinogen $\alpha\alpha$A-chain)	AFib

Parkinson's disease and Alzheimer's disease rank among the most weakening and socially troublesome diseases of the modern world [16]. So far, no definitive treatment plan exists for amyloid diseases, although Alzheimer's disease drug candidates aiming to reduce the amount of protofibrillar aggregates of Aβ are reported to be under clinical trial [17]. Disease caused by fibrillation of a given protein may show variations in terms of phenotypes and incubation periods and is assumed to be connected to the structural isoforms, also known as *morphologies* [18].

46.1.3 Fibrillation of Insulin

Insulin is a 51-residue protein hormone, produced naturally in the islets of Langerhans in the pancreas. It forms fibrillar structures in different stress conditions, such as low pH, high temperature, and low concentration of denaturants [9]. Insulin is a major α-helical protein composed of two chains, A and B, which are interconnected by two disulfide linkages. Chain A of insulin consists of two helical segments, A2–A8 and A13–A20, and chain B includes a region of extended structure B1–B8. The α-helical region between residues B9–B19 and B20–B23 is a β-turn region, and B24–B28 residues form another extended strand [19]. The key step in the fibrillation process of this protein is the conversion of its α-helical secondary structure into β-sheet configuration [10]. Insulin exists as a hexamer, tetramer, trimer, or monomer depending on the solution condition [10, 20, 21]. Dissociation of the native oligomer into monomer is the primary stage of insulin amyloidosis. Afterward, monomeric insulin partially unfolds and triggers the fibril formation. Insulin fibril formation may depend on many factors. Even different batches of insulin isolated from the same source may show variation in fibrillation propensity [19]. This variation is attributed to the presence of different amount of preformed fibril nuclei in the insulin samples [19]. Ionic strength, viscosity, pH of the solution, and external temperature also influence the process [19]. The specific residues, which are involved in interaction in this process, have been extensively researched [19, 22]. Conformational displacement of the *C*-terminal portion of the B chain partially exposes the hydrophobic residues, including A2, A3, B11, and B15, which play a critical role in this process [22]. Like other fibrils, the core structures of insulin fibrils contain *cross-β-sheets*, where β-strands run perpendicular to the fibril axis. Details of the mechanism of insulin fibrillation and the structure of insulin fibrils are described in Sections 46.1.3.3 and 46.1.3.4, respectively.

46.1.3.1 Problems Associated with Insulin Fibrils. Insulin plays a crucial role in carbohydrate metabolism in the human body. Many diseases have been linked to the nonregulatory production of insulin and its nonfunctionality due to formation of fibrils. Literature shows increasing evidence of insulin amyloids in clinical situations [23–26]. Fibril formation of insulin poses a problem as it reduces the therapeutic efficiency of injectable insulin used to treat type 2 diabetes. Insulin fibrils could also be found in the body of patients taking repeated insulin injections to fight against type 2 diabetes [24, 27]. Such patients are susceptible to have insulin fibril deposits in various body parts such as shoulders [26], arms [28], thighs [24, 25], and abdominal walls [28, 29] at or around the site of injections. These fibrils were also observed to be formed irrespective of the source and type of insulin [23–27].

46.1.3.2 Study of Insulin Fibrillation. Congo red and Thioflavin T (ThT) are the most widely used probes to detect the presence of insulin fibrils under in vitro conditions [30]. These two probes are specific to amyloid like fibrils. On binding to fibrils, fluorescence emission intensity of ThT enhanced significantly. Kinetics of insulin fibrillation is also monitored by measuring the fluorescence emission intensity enhancement of ThT. Time course of insulin fibrillation observed using ThT fluorescence usually shows a sigmoidal

profile (Fig. 46.1a). This profile consists of a lag phase followed by an exponential growth phase, which eventually levels off (Fig. 46.1a). The lag phase signifies the nucleation step of insulin fibrillation where a number of temporal conformers of insulin appeared. In the latter (exponential growth) phase, the rapid increase in fluorescence emission intensity indicates growth of fibrils, and the saturation in intensity level represents equilibrium in fibril growth. The time profile fits nicely to Eq. (46.1), which leads to the computation of the lagtime and the apparent fibril growth rate constant [10]:

$$Y = \frac{A_2 - A_1}{1 + \exp\left[\dfrac{(t_0 - t)}{\mathrm{x}}\right]} + A_2 \qquad (46.1)$$

In this equation, A_1 is the initial fluorescence, A_2 is the maximum fluorescence, t_0 is the time when fluorescence has reached the half- maximum; $1/x = k$ is the apparent rate constant of the fibril growth; and lagtime is approximated by $t_0 - 2x$.

Secondary structure of insulin during fibrillation has been monitored using CD and FTIR spectroscopy. Since insulin is a major α-helical protein, it shows a characteristic W-shaped spectrum in CD measurement with two negative ellipticities at $\sim$ 210 nm and $\sim$ 224 nm (Fig. 46.1b). In the course of fibrillation, these two negative ellipticities converge into one point that is around $\sim$ 218 nm, and the shape of the spectrum changes to U (Fig. 46.1b). The change in the CD spectrum is due to formation of a β-sheet structure. In case of FT-IR, a peak shift is observed in the amide I region from 1654 to $\sim$ 1630 cm^{-1} on conversion into fibrils (Fig. 46.1c) [20, 31]. Scanning electron microscopy, transmission electron microscopy, atomic force microscopy, and other microscopic methods are now used to study the insulin fibril morphology [10, 20, 32]. Atomic force microscopy is used to measure the tensile strength of insulin fibrils appearing in different conditions [33]. A representative TEM image of insulin fibril is shown in Fig. 46.1d.

46.1.3.3 Mechanism of Insulin Fibrillation. The ordered aggregation process of insulin proceeds through multiple steps with different temporal and length scales of conformational changes. When the concentration of intermediates with partially unfolded structures exceeds the critical value, the nucleation process starts. These intermediate conformers are similar to the premolten globule states [4]. Insulin in fibrillation condition shows a novel partial fold, which is similar to those observed in the NMR studies of two disulfide insulin analogs [34,35]. The fibrillation proceeds via dissociation of the native oligomer to monomer followed by partial unfolding to initiate the formation of fibrillation nucleus. Hence, unfolding of the monomer triggers the association process. In 2004 two authors proposed that the exposure of hydrophobic residues of the disordered regions of A and B chains of the insulin is the cause of aberrant self-association of the monomerc insulin [22]. The *C*-terminal segment of chain B is disordered, and partial opening of this region opens up the hydrophobic aromatic amino residues of B24–B26. These residues are further involved in the formation fibril nucleus of nonnative β-sheet structure.

It is very difficult to determine the size of the nucleus as it is a transient intermediates in the aggregation pathway. Hence, different biophysical techniques have been used to trap and identify the fibril nucleus. On the basis of aggregation kinetics, some of the nucleus sizes were determined and it was found that there might be variation in size and shape of the nucleus depending on the protein sequence and conditions. These nucleus sizes range from monomer to hexamer. For polyglutamine protein, the nucleus is monomeric and that of β2-microglobulin is of hexameric in nature [36, 37]. In 2005, Ahmad et al. characterized the soluble insulin oligomers, which may be the fibril nucleus [38]. They used H/D exchange kinetics to explore the solvent exposed regions of those soluble oligomers. They probed the surface hydrophobicity of these early oligomers with ANS fluorescence. This study highlighted the presence of at least two major populations of oligomeric forms in between native monomer and the mature fibrils. Nonetheless, the shape of this oligomeric nucleus remained elusive. In 2007, another group, using the SAX technique, characterized those oligomers [39]. They showed it is helical in shape. This study was very important in terms of rational design of drugs. Nayak et al. [40] proposed a model for insulin fibril nucleus based on their SANS study and the previous study by Vestergaard. They proposed that the fibril nucleus is the end-on association of three cylindrical insulin dimers, which then associated inside on orientation to form larger fibrils. It is interesting to note that insulin exists as a zinc-coordinated circular hexamer in vivo as compared to linear hexameric nucleus in vitro [40].

46.1.3.4 Structure of Insulin Fibrils. Structural studies of amyloid have involved several biophysical techniques, such as X-ray fiber diffraction, electron microscopy, atomic force microscopy, and more recently solid-state nuclear magnetic resonance and electromagnetic resonance [41, 42]. These studies showed that fibrils are long, straight, and unbranched. These are composed of smaller protofilaments, which are subunits consisting of amyloid fibrils. The number of protofilaments may vary in a fibril structure depending on the precursor protein [43, 44]. These protofilaments are often twisted around one another to form mature fibril [45–47]. The internal structure of protofilaments of amyloid fibrils showed a "cross-β" pattern in an X-ray diffraction study [48]. This was further confirmed by studying fiber diffraction of synthetically designed peptide fibrils [49, 50]. The pattern indicates that these fibrous molecules share a core structure consisting of a β-sheet conformation where the hydrogen bonding

(Adapted from Jimenez et al. 2002 [43], p. 9196. © The National Academy of Science; reproduced with permission.) (b) Fibril model of insulin A and B chains of insulin molecule are shown in pale red and pale blue, respectively. The LVEALYL segment, which forms the spine of the fibril, is in dark blue. The SLYQLENY segment, from the A chain, which forms auxiliary sheets to the spine of the fibril, is in dark red. Disulfide bonds are shown in yellow. (Adapted from Ivanova et al. 2009 [53], p. 18990. © The National Academy of Science; reproduced with permission.)

direction runs parallel to the fiber axis and the β-strands are perpendicular, much like the steps of a ladder.

On the basis of this cross-β pattern, Jimenez et al. proposed a model of insulin fibril using 3D-cryo-EM reconstruction [43]. The probable schematic model of four protofilament form of insulin is presented in Fig. 46.2. Mass-spectrometric analysis of the insulin fibrils showed that the disulfide bonds of the native insulin remain intact in its fibrillar form [43]. The interchain disulfide bond requires the strand to run in parallel, and the intrachain disulfide bond initiates curvature into the strand. The basic shape of the protofilament remains the same irrespective of any polypeptide chain. Volume calculations advocate that each insulin occupies two β-strand layers. For simplicity, all chains are shown in parallel packing, although alternate molecules could be antiparallel. The twist of the fibrils reported is left-handed [51,52]. To pack insulin protofilaments together in a consistent interface, the protofilament twist must follow the overall twist of the fibril. Hence, protofilaments also have left-handed helical twist.

Later, Ivanova et al. proposed the insulin fibril structure based on X-ray fiber diffraction and mass per unit length and the crystal structure of LVEALYL [53]. They found that this single segment could nucleate and inhibit the insulin fibrillation in a mole-ratio-dependent manner. Thus, it must be the central core of the cross-β spine of the insulin fibrils. The X-ray diffraction pattern of insulin fibrils showed that fibrils were β-sheet in nature and parallel to the fiber axis. There are two pairs of sheets with different sheet-to-sheet distance. The chain B segment LVEALYL was used as the molecular basis of the steric zipper spine of insulin fibrils. This segment is in helical conformation in the native insulin and thus converts into extended β-strand. The disulfide bonds that connect chains A and B force the A chain to convert into an extended β-strand. LVEALYL segment also gives a structural template to the extended segment LYQLENY of chain A. The spine of this model makes up four β-sheets (Fig. 46.2b). The structures of the inner two β-sheets, which form the streic zippers, overlay on the crystal structure of LVEALYL (Fig. 46.2b). The outer two β-sheets formed from the extended segment LYQLENY of chain A (Fig. 46.2b). The *N*- and *C*-termini retain the native like structure. This model is in good agreement with the earlier model proposed by Jimenez et al. and Ionescu-Zanetti et al. [43, 52]. The model provides a high-resolution structural basis of insulin fibrils, which cannot be obtained by low-resolution density map analysis. However, these models are limited to the structure of matured fibrils only.

Small-angle X-ray scattering gave insights into the structure and assembly of amyloid fibrils formed by insulin

in its early stage of fibrillation [39]. For the first time, the study reveals the oligomeric assembly of insulin fibrils. The SAX study proposed that insulin fibrils are assembled from a helical fibrillation precursor composed of five to six insulin monomers, which corresponds to the fibril nucleus. The mature amyloid fibril is composed of three individual filaments that wrap around one another [39]. However, the SAX study of the fibrils formed by α-synuclein revealed a contrasting structure in which a single filament appeared to make up the mature fiber. Nayak et al. also proposed a model of insulin fibril nucleus, which is basically an end-on associated form of three dimmers of insulin [40]. More recently, Kurouski et al. probed an insulin fibril surface by tip-enhanced Raman spectroscopy (TERS) [32]. The insulin fibril surface consists of 34% β-sheet and 66% α-helix and unordered structure [32]. Residues C, F and W are found to be frequent in the β-sheet region, whereas P was only found in the α-helix and unordered region of the fibril. The study corroborates well with the existing model proposed by Jimenez et al. in 2002 [32].

46.2 PREVENTION OF INSULIN FIBRILLATION

46.2.1 General Strategies to Prevent Insulin Fibrillation

Various small molecules have been used to prevent insulin fibrillation. The rationales behind the use of those small molecules are different in each case. One early strategy was to promote the self-association of insulin. Since insulin must be transformed into a monomer before the onset of fibrillation, the self-association of insulin was promoted by the addition of Zn^{2+} or Ca^{2+} to stabilize its hexameric structure [54, 55]. Polyhydroxy compounds, such as carbohydrates, glycerol, and amphiphilic block copolymers, attenuate the penetration of water into the hydrophobic core by forming a protective layer around the surface of the insulin. They also reduce the number of unwanted hydrophobic interactions and thus act as amyloid inhibitors [56, 57]. Betaine, trehalose, and citrulline also inhibited insulin fibrillation, presumably by a similar mechanism [58]. These strategies were very general and have their shortcomings. The hexameric insulin has a low rate of adsorption in the bloodstream. Its larger size impedes its adsorption. Hence, insulin must dissociate to a dimeric or a monomeric state for effective transport and activity [59, 60]. Therefore, addition of metal ions may have increased the stability of insulin but at the same time, they also decrease the functional activity of the protein. Polyhydroxy compounds require a high-molar-excess concentration to execute inhibitory activity, which may elicit unwanted immune responses. Consequently, these are not suitable for a drug candidate. Biocompatible peptides are suited for this job. However, they do have limitations, the most common one is their instability in hydrolysable conditions. In Section 46.2.2 we discuss the design of peptide-based inhibitors and the role of other small molecules in insulin fibrillation.

46.2.2 Peptide-Based Inhibitors of Insulin Fibrillation

Since peptides can be nontoxic, they may not turn on the unwanted immune response and thus have a good potential to become suitable drug candidate. Now many research groups are exploring peptide-based inhibitors [20, 61, 62].

46.2.2.1 Hybrid Peptides Designed as Inhibitors of Insulin Fibrillation. Gibson and Murphy used hybrid peptide to prevent the insulin aggregation [61]. The hybrid peptide consisted of one recognition domain and one disrupting domain [61]. The recognition domain preferentially binds to insulin, and the disrupting domain inhibits the fibril formation. In order to prepare a recognition domain, they initially identified the short insulin fragments that preferentially bind to insulin. They produced a mixture of insulin fragments by limited proteolysis and incubated it with native insulin. The mixture was then separated by reversed-phase HPLC and analyzed by MALDI-TOF spectrometry. Among the different fragments of insulin, ALYLV, GSHLVEAL, and VEALYL selectively bind to insulin. Since the LVEALYLE domain is proposed to be associated with insulin misfolding, it was hypothesized that this domain could also be effective as recognition domain in hybrid peptides [9, 61]. However, none of these peptides was able to inhibit insulin fibrillation. Numerous studies showed the suppression of protein aggregation by arginine [63, 64]. Hence, they used hexameric R as a disrupting region. This hexameric R was then added at either the *N*- or at *C*-terminal side of those three insulin fragments. Nonetheless, only RRRRRR LVEALYLV, above a critical concentration of 2 mM, was able to alter insulin fibrillation. Other combinations were ineffective. Therefore, a precise recognition domain with a properly oriented disrupting domain will be effective as inhibitor (Fig. 46.3). They hypothesized that the inhibitory effect was may be due to micelle-like property of the hybrid peptide, which can decrease solvent surface tension above a critical concentration and thereby decrease the unwanted hydrophobic interactions. However, cetyltrimethylammonium chloride (CTAC), a cationic surfactant, was not able to prevent insulin fibrillation, indicating that the micelle theory may not have direct influence on the inhibitory effect of the hybrid peptide. The inhibitory effect could also be attributed to the specific binding of the LVEALYLV region, which is in close proximity to F25 and Y26 residues, which play a critical role in insulin fibrillation. Thus, the local concentration of the disrupting domain becomes very high at the active site of fibrillation and prevents the unwanted hydrophobic association.

Gibson and Murphy [65] also used a hybrid peptide to influence the Aβ aggregation. The recognition domain

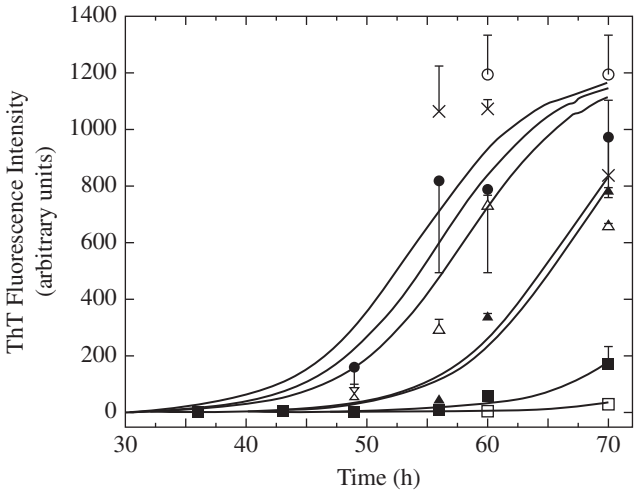

FIGURE 46.3 Kinetics of insulin fibrillogenesis in the presence of various peptides. Insulin was dissolved at 0.52 mM in 1 M acetic acid (pH 2.0), and mixed with indicated peptides at 2 mM. Samples were kept at 37°C during the duration of the experiment. ThT of insulin alone (3) or mixed with RRRRRR (s), ALYLVRRRRRR (d), GSHLVEALRRRRRR (m), RRRRRRGSHLVEAL (D), LVEALYLVRRRRRR (j), or RRRRRRLVE ALYLV (u) was measured over time. Lines represent fitting of the data to a two-step kinetic model. (Adapted from Gibson and Murphy 2006 [61], p. 1133. © The Protein Society; reproduced with permission.)

contains 15–25 amino acid residues of Aβ-peptide linked to oligolysine-disrupting element. However, the inhibitor did not alter the aggregation rate of the Aβ-peptide. The hybrid peptide attenuated the toxicity of the fibrillation process by reducing the appearance of early soluble oligomeric phases. Later other researchers modified the disrupting region by replacing the linear oligolysine with branched compounds [65]. The L-lysines were also replaced by their D analogs. The purpose of this replacement was a success. The rate of Aβ aggregation was reduced to a significant amount by the introduction of new hybrid peptides.

46.2.2.2 Naturally Occurring Peptides as Insulin Fibril Inhibitors. The main challenge in the development of potential inhibitors of fibrillation is to retain the functional activity of the target protein. Since most of the inhibitors developed so far bind to the active site of the proteins, their functional activity has been weighed down. Insulin is a natively occurring inhibitor of islet amyloid polypeptide (IAPP) [66]. IAPP and insulin are cosecreted from pancreatic β-cells together [67]. IAPP is a glucose regulatory protein that shares sequence homology with insulin. However, IAPP is susceptible to aggregation, and its aggregates are found in the pancreatic amyloid in type 2 diabetes [68]. Since IAPP strongly interacts with insulin, it was hypothesized that a nonamyloidogenic analog of IAPP may reduce the aggregation of insulin [66, 69]. Yan et al. developed a nontoxic and nonamyloidogenic conformationally constrained IAPP analog (IAPP-GI) that blocked the cytotoxic self assembly of IAPP (Fig. 46.4) [70]. Velkova et al. used this analogue to test its inhibitory effect on the insulin fibrillation [66]. Incubation of insulin with 5–10-fold molar excess of IAPP-GI under low-pH and high-temperature conditions showed suppression of insulin fibrillation. It is well known that in the course of fibrillation, insulin forms a series of soluble oligomeric species that are toxic in nature [10,71]. To address the question of whether IAPP-GI intervenes in the formation of soluble toxic oligomers of insulin, Velkova's team used nonreducing Nu-PAGE and Western Blot and monitored the fibrillation kinetics [66]. The data showed that the IAPP-GI completely blocked the formation of nonnative soluble oligomers and thus reduced the overall toxicity of the process [66]. Cell viability assay also supported the finding. Insulin-induced IR autophosphorylation assay was executed using cultured human breast cancer cells to determine whether insulin retains its activity on binding to the inhibitor. Insulin and the insulin IAPP-GI conjugate induced same amounts phosphorylated IRβ. Thus, insulin function remains unaffected on binding to IAPP conjugate. The proposed mechanism of interaction of insulin with IAPP-GI and nontoxic IAPP conformer is illustrated in Fig. 46.5. This

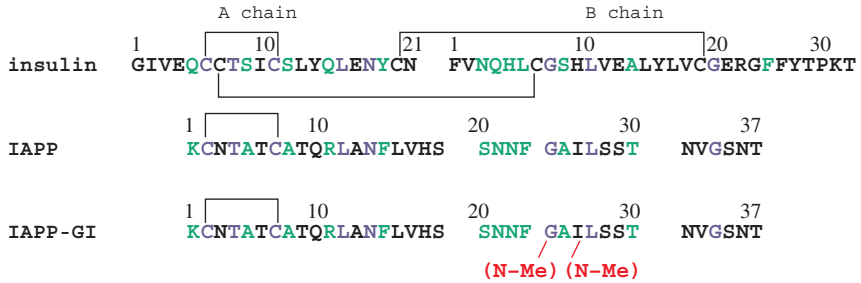

FIGURE 46.4 Primary structures of insulin, IAPP, and the IAPP mimic IAPP-GI. Residues common to all three sequences are shown in blue, and similar residues are shown in green. study was very important, not only for the strategy but also for the insightful message of cross-amyloid interaction. If this interaction existed in vivo, then there would be a molecular link between Alzheimer's disease and type 2 diabetes [66, 72, 73].

A more recent study showed that the proinsulin C-peptide is a natural inhibitor of insulin fibrillation [74]. Proinsulin C-peptide is a 31-residue peptide that is cleaved from the proinsulin by different peptidases to release insulin. Insulin and the C-peptide are then secreted into the bloodstream [75]. Although C-peptide is mostly unordered, it is required for the correct folding of the proinsulin [76, 77]. Early studies showed that the C-peptide alters the aggregation of IAPP [69, 78]. However, two reports showed that the C-peptide does not influence insulin aggregation at pH 2 and 7.3 [79, 80]. These reports are in contradiction with a more recently published article [74]. Insulin fibrillation kinetics depends on a critical concentration [39]. Beyond this concentration, there is not much change in the lag phase of the process. Huang et al. and Noormagi et al. both used very low insulin concentrations, which were lower than the critical concentration [79, 80]. However, another team used

a 1 mM concentration of insulin, which is well above the critical range [74]. This might be the cause of the differences in the results between these studies. The aggregation prevention was executed by the formation of stable insulin C-peptide complex. H/D exchange study of aggregates containing insulin and the C-peptide showed the presence of two populations: one with the completely fibrillated insulin and the other with lower backbone accessibility, which can be achieved by the formation of stable insulin C-peptide complex [74]. Thus, two naturally occurring peptide variants IAPP and C-peptide have the potential to be a supporting drug in insulin therapy of type 2 diabetes.

46.2.2.3 Hydrophobic Peptides as Inhibitors of Insulin Fibrillation. Insulin fibrillation was initiated with the partial opening of the charged *C*-terminal domain followed by unfolding of the *N*-terminal B-chain helix [22]. The residues F (B24), F (B25), and Y (B26) support the formation of an antiparallel β-sheet [81]. Thus, fibrillation is the interplay of electrostatic and hydrophobic interaction. Another team used Trp–Trp–Tau-based tripeptide conjugates containing both charged and hydrophobic residues to counteract the possible hydrophobic and hydrophilic interactions in the insulin fibrillation [81]. They explored the interaction of two designed peptides 1 and 3 and their dimeric forms 2 and 4 with insulin in fibrillating condition (Fig. 46.6). They found that all of the peptide conjugates inhibit the fibrillation process and the maximum inhibition observed for peptide 4. The secondary structure of both bovine and human insulin was retained even after the 20 h of incubation in presence of substoichiometric concentration of peptide 4. To ascertain whether peptide 4 interfered in the nucleation phase of the fibrillation process, it was added to the incubating solution of insulin at different times and the fibrillation kinetics was monitored by Thioflavin T fluorescence measurement. As the time of incubation increased, the inhibitory effect of peptide 4 declined. Beyond 6h incubation there was hardly any effect observed. Thus, peptide 4 interacted with the early conformers of insulin in fibril-forming condition. Since these early conformers elicit more toxic effects in the cellular environment compared to the matured fibrils, it was surmised that peptide 4 may actually reduce the overall toxicity of the process by interacting with those conformers. The molecular interaction was probed by the solution ^{1}H NMR that showed a downfield shift of amide (NH), indolic and aromatic proton of the 4, followed by an upfield shift with peak broadening of the aromatic protons of the insulin. This might be the cause of ring current shift due to the π–π interaction of the inhibitor and the insulin. As stated earlier, the F (B24), F (B25), and Y (B26) residues play a critical role in insulin fibrillation, and it was assumed that peptide 4 interacted with these residues to quench the process.

We also explored the interaction of different hydrophobic peptides with insulin in fibril-forming condition. We found that a nine-residue peptide, NK9 (NIVNVSLVK), which was adopted from the middle of SARS corona virus E-protein primary sequence, initially chosen serendipitously, delays the insulin fibrillation process [20]. The maximum inhibition was observed for 1:1 molar ratio of NK9 to insulin. Beyond this concentration, there was minimal change in the lag phase (Fig. 46.7a). However, the amount of fibril mass declined as the molar ratio of NK9 to insulin increased (Fig. 46.7a). To investigate whether NK9 intervenes in the nucleation phase, we added NK9 into an incubating solution of insulin at different times of incubation (Fig. 46.7b). The results were similar to what Mishra's team observed with the inhibitor peptide 4. Thus, NK9 also interfered in the nucleation phase of insulin fibrillation (Fig. 46.7b) [20,81]. Therefore, it could be surmised that NK9 prevents the appearance of soluble toxic oligomeric phases of insulin. NK9 prevented the

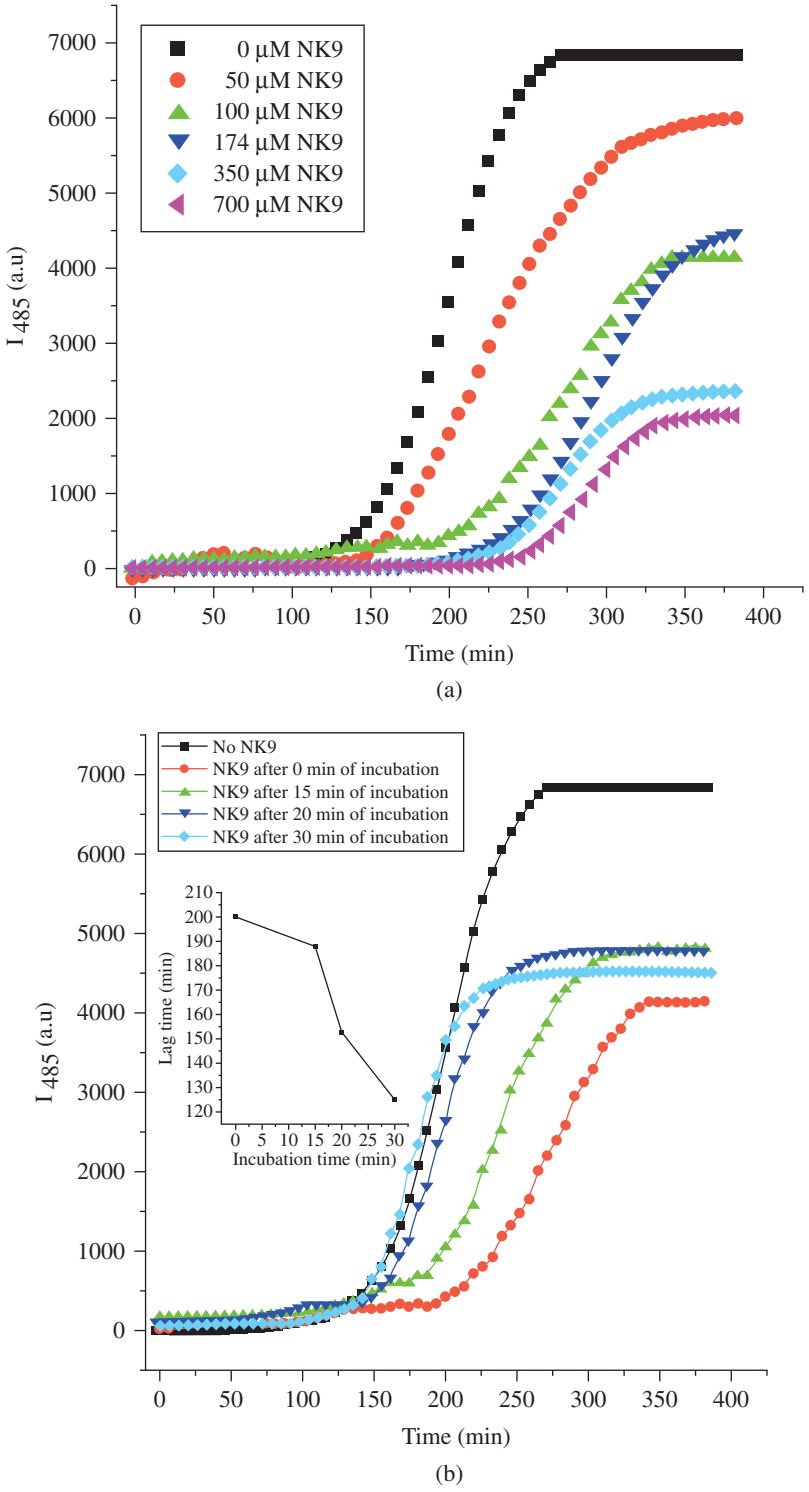

FIGURE 46.7 Timecourse of insulin fibrillation in the presence and absence of NK9, monitored using ThT fluorescence. (a) Temporal evolution of the ThT fluorescence intensity during incubation of insulin (350 μM) in fibrillation condition (pH 2.6, 62°C) in presence and absence of NK9 at different concentrations. ThT curves of insulin in respective NK9 concentrations are shown in the figure. (b) Effect of NK9 on fibrillation kinetics of insulin. NK9 (100 μM) was added to the buffer solutions (pH 2.6) of insulin (350 μM) at 62°C at 0, 15, 20, and 30 min of incubation. Molar ratio of NK9 to insulin is 0.28:1. Inset shows a plot of lagtime of insulin fibrillation in presence of 100 μM NK9 against incubation time. (Adapted from Banerjee et al. 2013 [20], p. e72318.)

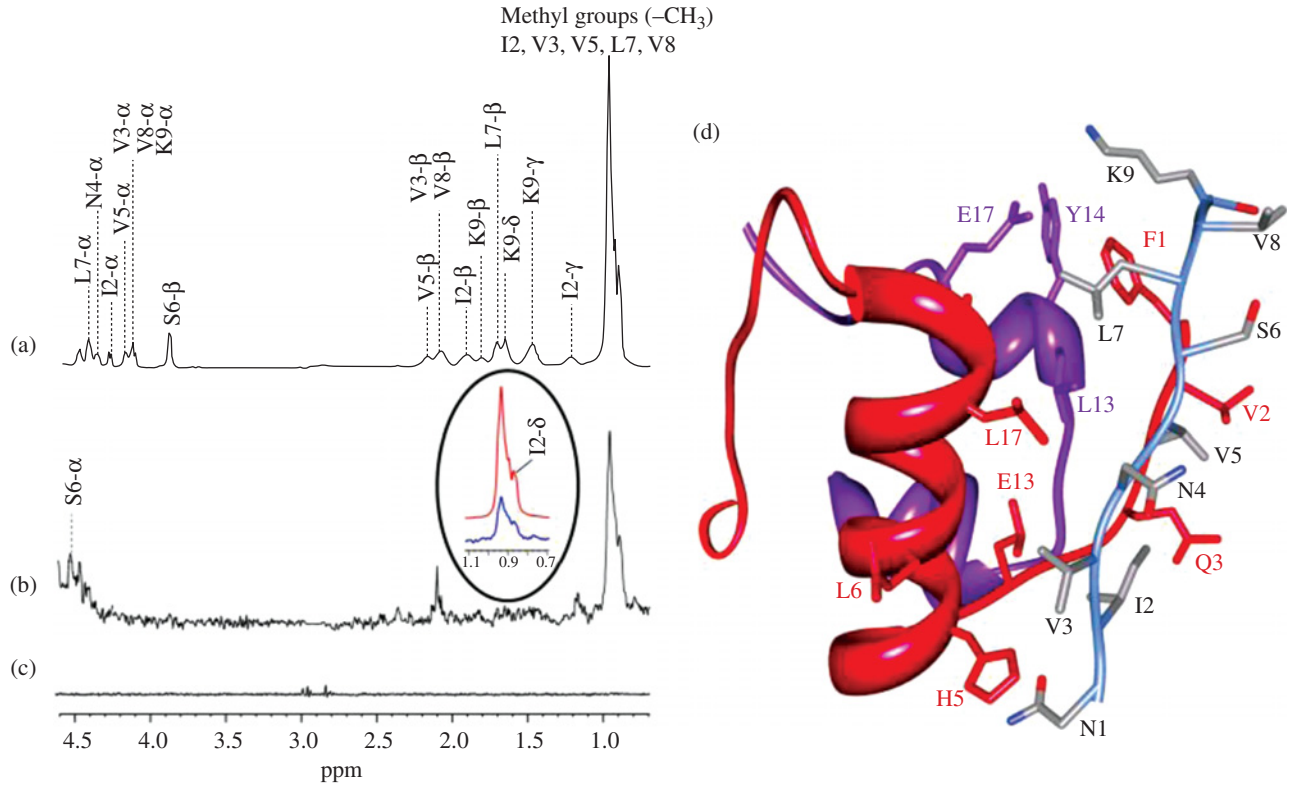

FIGURE 46.8 STD NMR spectra. (a) Reference spectrum of NK9 in presence of insulin at a molar ratio of insulin:NK9 = 1:100. (b) STD NMR spectrum of same sample showing the resonance transfer within the binding epitope of insulin. The experiments were performed at 298 K with 2 s of saturation time (on resonance = 7.3 ppm; off resonance = 40 ppm). (c) STD spectrum of NK9 alone (on resonance = 7.3 ppm; off resonance = 40 ppm). (d) The docking model of insulin-NK9 complex correlated of the STD NMR data. (Adapted from Banerjee et al. 2013 [20], p. e72318.)

dissociation of native insulin oligomer to its monomeric form with micromolar binding affinity. With the help of a docked model and ^{1}H-STD-NMR study, NK9 was found to be in close proximity with F (B1), V (B2), Q (B3), L (B6), H (B10), L (B17), L (A13), Y (A14), and E (A17) residues of insulin (Fig. 46.8). The result showed that unordered portion of the chain B also contributed to the nucleation phase of the fibrillation process.

Thus, NK9 and peptide 4 have different binding sites for insulin [20, 81]. Still, both of these peptides intervene in the nucleation phase of the process. Hence, it could be assumed that the unordered portion and the *N*-terminal helical portion of chain B mutually assist each other to form the fibril nucleus. Blockage of either site will slow down the nucleation phase and thus inhibit the fibrillation process.

46.2.3 Small Molecule Inhibitors of Insulin Fibrillation

Various class of small molecules have been used as inhibitors of the protein fibrillation. Aromatic compounds, fluoroalcohols, trehalose, amphiphilic surfactants, metal complexes, and nanoparticles attenuate the fibrillation propensity of insulin [10, 82–85].

46.2.3.1 Polycyclic Aromatic Compounds. Polycyclic aromatic compounds are well-known fibril inhibitors as both contain a recognition domain as well as a blocking domain [82]. Among these polycyclic compounds, phenolsulfonphthaleine, epigallocatechin gallate, and curcumin inhibit insulin fibrillation [82,86,87]. (–)-Epigallocatechin-3-gallate (EGCG) inhibits the insulin fibrillation under two different conditions [86]. However, the optimum concentration for EGCG to exert an inhibitory effect varies under these two conditions. At low pH and high temperature, the fibrils appear in the presence of EGCG to be shorter and thinner, whereas under physiological conditions, insulin forms globular aggregates in the presence of EGCG, which indicates that EGCG inhibits insulin fibrillation in two different pathways. Curcumin interacts with native, intermediate oligomeric forms and the final fibril forms of insulin and inhibits the process in a dose-dependent manner [87]. Curcumin has the ability to break β-sheets of the fibril form and thus reduce the amount of fibril formed [87]. A molecular docking study

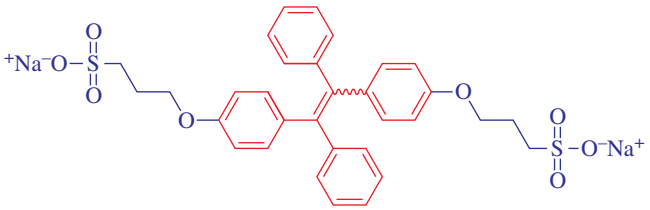

FIGURE 46.9 Structure of 1,2-bis[4-(3-sulfonatopropoxyl) phenyl]-1,2-diphenylethene sodium salt (BSPOTPE), which plays dual roles (ex situ monitor and in situ inhibitor) in the insulin fibrillogenesis process. (Adapted from Hong et al. 2011 [88], p. 1680. © American Chemical Society; reproduced with permission.)

proposed that chain B is the most likely region of interaction of insulin [87].

1,2-Bis[4-(3-sulfonatopropoxyl)phenyl]-1,2-diphenylethene sodium salt (BSPOTPE), a derivative of tetraphenylethene (TPE), is an efficient inhibitor of insulin fibrillation (Fig. 46.9) [88]. As low as 10 μM concentration of BSPOTPE extends the nucleation phase of insulin fibrillation to 2 h. The biocompatible inhibitor BSPOTPE binds to the partially unfolded conformers of insulin and inhibited the nucleation phase. The compound does not disintegrate the protofibrils of insulin and thus will be ineffective if added after the nucleation phase. Molecular docking studies proposed that the compound binds to the hydrophobic residues near the B-chain helix of 11–19. This helix portion partially unfolds in the nucleation phase and exposes the hydrophobic residues to the solvent. This persuades the binding of the BSPOTPE to these exposed residues and prevents unwanted hydrophobic interaction. Interestingly, this compound not only acts as in situ inhibitor of insulin fibrillation but also is an ex situ probe used to detect fibrils. The compound binds to the partially unfolded states and aggregated states of insulin, and thus the rotation of phenyl rings of the probe is physically restricted. This blocks the nonradiative relaxation channels and populates the radiative decays of the excitons. This renders the partially unfolded conformers and aggregates highly luminescent.

Interestingly, some monocyclic benzene derivatives also act as insulin fibril inhibitors [89]. Two monocyclic aromatic compounds, aspirin and nitrophenol, were found to inhibit A-β aggregation [90, 91]. However, aromatic monocyclic compounds such as insulin fibril inhibiter have also been reported [89]. That same study [89] showed that the substituent of the benzene ring signicantly influences the inhibitory effect. Stronger electron-withdrawing groups showed a pronounced effect on the rate of fibrillation. Those researchers [89] proposed that Y16 and the electron-deficient aromatic compound may act as a donor–acceptor pair and that inhibition is executed by this π–π stacking interaction. These aromatic compounds also stabilize the helical conformation of insulin and thereby prevent its conversion into cross-β structure formation.

46.2.3.2 Trifluoroethanol as Insulin Fibril Inhibitor. 2,2,2-Trifluoroethanol (TFE) stabilizes the α-helical structure in proteins and also induces α-helical structure in unordered proteins at high concentration [92, 93]. As stated earlier, insulin fibril consists of a parallel β-sheet structure. Hence, stabilization of the native α-helix may reduce the propensity of insulin to assume its fibrillar form. We have tested the role of TFE in the fibrillation pathway of insulin [10]. TFE promotes fibrillation of αA,αB-crystallin and peptide LYS (11–36) derived from the T4 lysozyme, whereas, in cases with prion and Aβ, TFE inhibits their fibrillation propensity. Therefore, TFE has a controversial role in the fibrillation process of proteins and is highly system-dependent [40, 94–96]. We monitored the kinetics of insulin fibrillation in presence and absence of TFE using ThT fluorescence intensity (Fig. 46.10). The sigmoidal curves were fitted into the equation [Eq. (46.1)] for determination of kinetic parameters. The kinetic parameters, such as lag phase and apparent rate of fibril growth, are presented in Table 46.2. The kinetic data clearly show that TFE dose dependently increases the lag phase of the process, indicating the possible occurrence of an interaction within the nucleation phase. Interestingly, the apparent rate constant for fibril growth has increased in the presence of TFE, showing a cooperative transition from fibril nucleus to matured fibrils (Table 46.2). TEM micrographs in Fig. 46.11 showed that in the presence of TFE, insulin fibrils are shorter in length and are discrete. Shorter fibrils have more edges compared to longer fibrils and thus, have more surfaces to act as seeds in the process. This will eventually increase the fibril growth rate. This may be the reason of high cooperativity in the elongation phase of fibrils in the presence of TFE. Monitoring the hydrodynamic radius of insulin during its fibrillation process by using dynamic light scattering showed that TFE inhibited the formation of early soluble oligomers that is reported to be the toxic element in the fibrillation pathway (Fig. 46.12a,b), thereby modulating the pathway of insulin fibrillation. Generally, it is assumed that TFE displaces the water molecules from the protein surface and strengthens the intramolecular H bonding. Thus, unwanted hydrophobic interactions are reduced, and so is the propensity of fibrillation. Another fluoroalcohol, HFIP, also modulates the structure of the protofibrils of a model protein Barster [97]. However, HFIP-induced

TABLE 46.2 Kinetic Parameters of Insulin Fibrillation

Solution	Lagtime (h)	Apparent rate constant of fibril growth (h^{-1})
Insulin	0.41 ± 0.01	3.2 ± 0.1
Insulin + 5% TFE	0.78 ± 0.01	6.2 ± 0.3
Insulin + 15% TFE	1.21 ± 0.01	9.5 ± 0.3
Insulin + 25% TFE	2.78 ± 0.003	9.8 ± 0.3

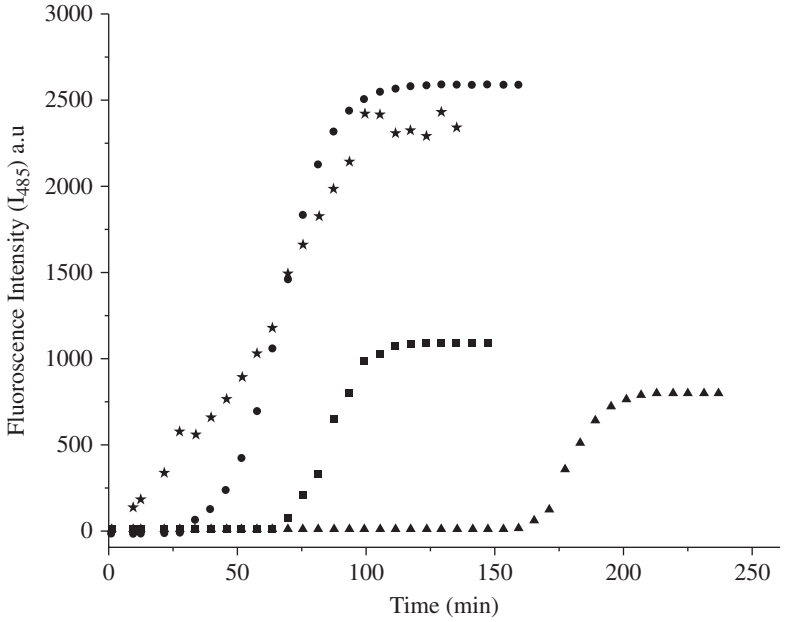

FIGURE 46.10 Aggregation kinetics of bovine insulin ($\lambda_{ex} = 450$ nm, $\lambda_{em} = 485$ nm) was monitored by ThT fluorescence after the addition of different concentrations of TFE to samples preincubated at 50 mM citrate phosphate buffer, 0.1 M NaCl, of pH 2.6 and at 62°C. The ThT fluorescence is shown as a function of incubation time at different TFE concentrations. Final concentrations of ThT and insulin in the solution are 20 μM and 17.44 μM, respectively. 0% (v/v) TFE (★), 5% (v/v) TFE (•), 15% (v/v) TFE (■), 25% (v/v) TFE (▲). FIGURE 46.11 Selected images of electron micrographs of an insulin fibril sample incubated for 12 h in 50 mM citrate phosphate buffer at pH 2.6 in presence of (a) 0% TFE, (b) 5% TFE, (c) 15% TFE. (d) 25% TFE. (Adapted from Banerjee and Das 2011 [10], p. 142. © Elsevier B.V.; reproduced with permission.)

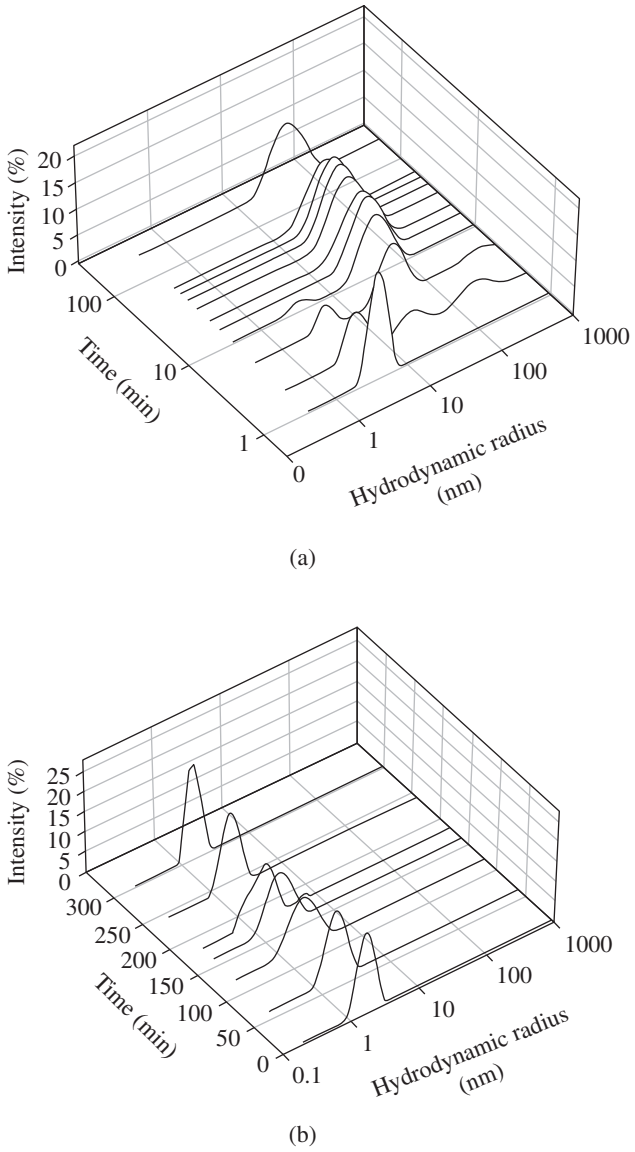

FIGURE 46.12 Intensity particle size distribution spectra of bovine insulin in 10(a) 0% (v/v) and (b) 25 % (v/v) concentrations of TFE at 25°C. Since insulin is monodispersed in this concentration and temperature range, particle size above 100 nm was excluded. (Adapted from Banerjee and Das 2011 [10], p. 142. © Elsevier B.V.; reproduced with permission.)

protofibrils are longer than the TFE-induced fibrils of Barster. Hence, these fluoroalcohols may not follow a similar mechanism of interaction with the fibrillating proteins.

46.3 SUMMARY AND CONCLUSION

Insulin is a relatively small α-helical protein, which can undergoes structural transition to produce insulin fibrils having a preponderance of cross-β-sheets. Fibrillation under physiological conditions is a slow process and often takes a very long time to evolve. However, fibrillation of insulin can pose a serious threat to its therapeutic uses against type 2 diabetes. Insulin exists in various multimeric forms under physiological conditions. The key step in the formation of insulin fibrils is its dissociation of the insulin oligomer into the monomer, which is the precursor for the nucleation phase of the fibrillation process. Small molecules, which can interfere with the insulin dissociation process, can delay the fibrillation process. On the basis of this principle, several small molecules and peptides have been developed that can slow down the fibrillation process. Of these, the designed hybrid peptides have been found to be quite promising. The role of hydrophobic peptide NK9 was studied in detail to understand the structural basis of the mechanism of delaying the fibrillation process. Among other small molecules, some aromatic polycyclic compounds and trifluoroethanol were found to be quite effective. These studies may constitute the basis for designing small molecules to control protein fibrillation in general.

INTERFACIAL WATER BETWEEN CHARGE-NEUTRALIZED POLYMER AND LIQUID WATER

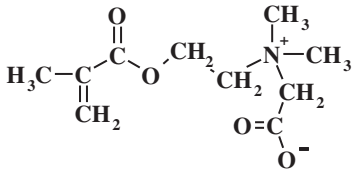
Hiromi Kitano and Makoto Gemmei-Ide

Department of Applied Chemistry, Graduate School of Science and Engineering, University of Toyama, Toyama, Japan

47.1 INTRODUCTION

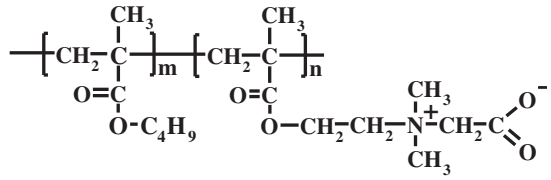
The structure of water at polymer material–liquid water interfaces reflects chemical and physical properties of the polymer. Therefore, the structure analysis of interfacial water gives us invaluable information about usability of polymer materials in biomedical fields.

Zwitterionic polymer is the general term for an ampholytic polymer containing identical numbers of cationic and anionic species, commonly on the same monomer units [1]. Zwitterionic polymers have been designed to mimic phosphatidylcholine (lecithin, PC), which is abundant in cell membranes [2, 3], and their applicability to biomedical fields has been extensively investigated. For example, polymer films composed of apolar monomers such as *n*-butyl methacrylate (BMA) and zwitterionic monomers such as 2-methacryloyloxyethyl phosphorylcholine (MPC, phosphobetaine), 3-sulfo-*N,N*-dimethyl-*N*-(3-methacrylamidopropyl)propanaminium hydroxide inner salt (SPB, sulfopropylbetaine), and 1-carboxy-*N*,*N*-dimethyl-*N*-(2-methacryloyloxyethyl)methanaminium hydroxide inner salt (CMB, caboxymethylbetaine; Scheme 47.1a) [4–8] were found to be highly biocompatible [4, 6–9]. The amount of proteins adsorbed and the number of platelets adhering to a film of a random copolymer of CMB and BMA were found to be much less than those onto a PolyBMA film [7, 8].



The sorbing processes of water to polymeric materials or distinction of the water sorbed to the polymers from that incorporated within the polymer matrix were examined with difference spectra obtained by attenuated total reflection (ATR) infrared spectroscopy [10, 11], and it was found that the structure of water incorporated in the matrix of polymer thin films composed of BMA and zwitterionic monomers such as MPC, SPB, and CMB was similar to that of bulk water [7, 8]. Raman spectroscopy also indicated that the hydrogen-bonded network structure of water in the vicinity of zwitterionic polymers and copolymers is not largely disturbed, in contrast to the electrostatically hydrated ordinary polyelectrolytes [12, 13]. However, the structure of "interfacial" water cannot directly be observed by these methods, and therefore, the *sum frequency generation* (SFG) method, which can detect molecules that lose centrosymmetry [14], was adopted to investigate the structure of water at various polymer–liquid water interfaces. The polymer materials examined were (1) a thin film of a zwitterionic copolymer, poly(CMB-*r*-BMA); (2) a brush of polyCMB; and (3) an amphoteric brush of poly(MA-*r*-DMAEMA)(1:1).

47.2 POLYMER FILM SYSTEMS



For the deposition of copolymer films, a flat face of fused-quartz semicylindrical prism was modified with octacdecyltrichlorosilane (ODS). Copolymers [poly(CMB-*r*-BMA), poly(MA-*r*-BMA), and poly(DMAEMA-*r*-BMA)] having ∼70 mol% of BMA residues were prepared in ethanol using 2,2′-azobisinsobutyronitrile (AIBN), and their thin films

Scheme 47.1 Chemical structures of (a) 1-carboxy-*N*,*N*-dimethyl-*N*-(2-methacryloyloxyethyl)-methanaminium hydroxide inner salt (CMB), (b) a copolymer of CMB and *n*-butyl methacrylate (BMA) [poly(CMB-*r*-BMA)], (c) a copolymer of methacrylic acid (MA) and BMA [poly(MA-*r*-BMA)], and (d) a copolymer of 2-(dimethylamino)ethyl methacrylate (DMAEMA) and BMA [poly(DMAEMA-*r*-BMA)].

were prepared by the cast method on a flat face of the prism [15].

The sum frequency generation (SFG) spectra of water at the polymer–water interfaces were obtained using the apparatus reported elsewhere [16, 17]. Namely, a picosecond Nd:YAG laser was employed to pump an (OPG/OPA/DFG) system, which generates tunable infrared radiation from 2.3 to 8.5 μm. The second-harmonic output (532 nm) from the laser was used as a visible light. The flat face of a quartz prism was in contact with various media, and infrared and visible beams were overlapped at the interfaces. The incident angles of the visible and IR beams were 70° and 50°, respectively. The polarization conditions in the present experiment were all *s*, *s*, and *p* for SFG, visible, and IR laser beams, respectively. This polarization combination (*ssp*) is sensitive only to the vibrational mode normal to the surface of isotropic media. The SFG light generated from the sample surface was detected by a monochromator and Photomultiplier Tube.

Figure 47.1a shows SFG spectra of various polymer-coated prisms in the region 2800–3800 cm^{-1} in contact with liquid water. Peaks corresponding to O–H stretching (>3000 cm^{-1}) were observed for interfaces between the prisms and liquid water. The intensity of O–H stretching was in the following order: poly(MA-*r*-BMA) > polyBMA > poly(CMB-*r*-BMA) > poly(DMAEMA-*r*-BMA). SFG spectra in the region of 2800–3800 cm^{-1} for prisms soaked in liquid water for 48 h are shown in Fig. 47.1b. The intensity of O–H stretching was in the following order: poly(MA-*r*-BMA) > polyBMA > poly(DMAEMA-*r*-BMA) > poly(CMB-*r*-BMA). The total peak area for the same wavenumber region is compiled in Table 47.1. A slight *increase* in the peak area corresponding to O–H stretching was observed for the prisms covered with polyBMA, poly(MA-*r*-BMA), and poly(DMAEMA-*r*-BMA) films. In contrast, that for the poly(CMB-*r*-BMA)-covered quartz prism *decreased* with time.

The contact angles of the air-in-water system for three kinds of copolymer films and a polyBMA film are shown in Fig. 47.2. The figure indicates that the surface of poly(CMB-*r*-BMA) was most promptly equilibrated on contact with liquid water, whereas the surfaces of poly(MA-*r*-BMA) and poly(DMAEMA-*r*-BMA) were equilibrated more slowly, and even 48 h after onset of the contact with liquid water, the copolymer surfaces were not completely equilibrated yet.

These results indicated prompt appearance of hydrophilic and zwitterionic CMB residues on the surface of the film and disappearance of BMA residues on contact with liquid water to minimize free energy of the surface. As a result, the SFG signal of hydrophobically hydrated water (clathrate-formed water) decreased and the CMB inert to the water molecules dominated the SFG spectra (drastic reduction of oriented water layer).

On the other hand, the MA residue in the poly(MA-*r*-BMA) film was not greatly deprotonated, and its hydrophilicity was much smaller than that of CMB. Therefore, the exposure of MA residues at the film surface might not be significant in comparison with that of CMB residues. A similar tendency existed in the film of poly(DMAEMA-*r*-BMA). MA and DMAEMA residues gradually appeared at the surface, resulting in electrostatically hydrated water, and the SFG signal of the O–H stretching region increased correspondingly.

The contact angles (air-in-water) for poly(MA-*r*-BMA) and poly(DMAEMA-*r*-BMA) films 48 h after onset of immersion in liquid water were around 125° and 140°, respectively, whereas that for poly(CMB-*r*-BMA) was around 150°. Therefore, the poly(CMB-*r*-BMA) film was more hydrophilic than the poly(MA-*r*-BMA) and poly(DMAEMA-*r*-BMA) films at the equilibrated state with water. However, the hydrophilicity does not significantly contribute to the biocompatibility of the materials concerned. For example, a self-assembled monolayer having a sulfonate or tertiary ammonium headgroup adsorbed both lysozyme

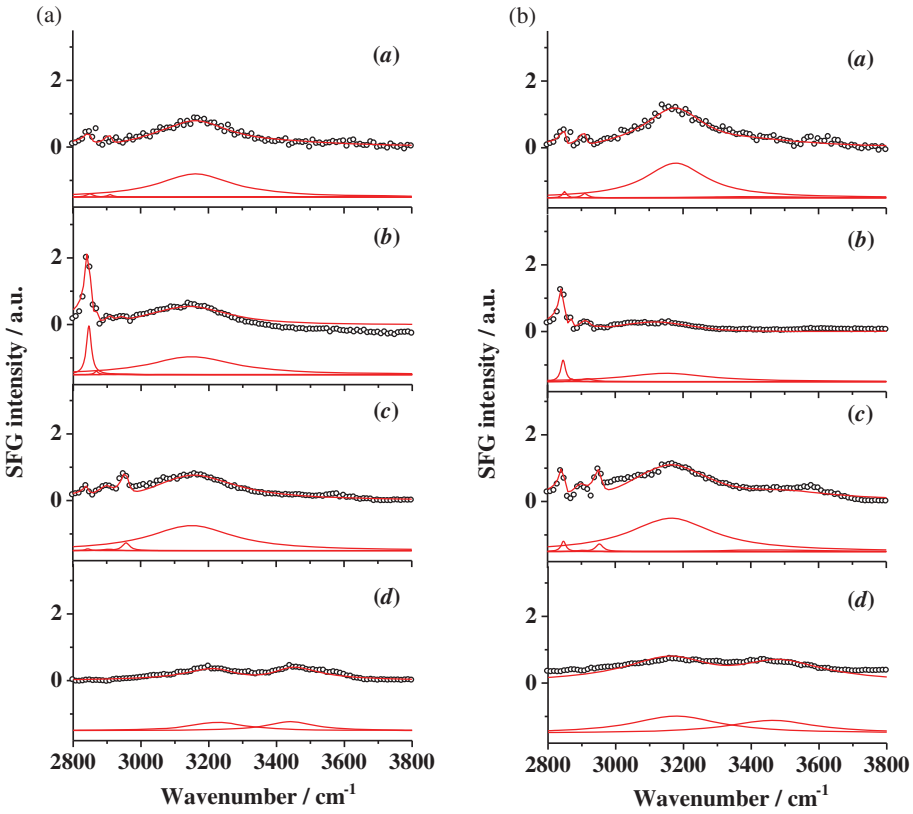

FIGURE 47.1 SFG spectra of O–H stretching region (>3000 cm^{-1}) and C–H stretching region (>3000 cm^{-1}) of various polymer films: (*a*) polyBMA; (*b*) poly(CMB-*r*-BMA) (CMB 29 mol%); (*c*) poly(MA-*r*-BMA) (MA 29 mol%); (*d*) poly(DMAEMA-*r*-BMA) (DMAEMA 28 mol%). (a) 0 h and (b) 48 h on immersion in water.

and fibrinogen to a large extent, whereas the zwitterionic group–carrying SAM showed significant suppression of protein adsorption [18]. The tendencies seen in Fig. 47.1b and Table 47.1 are in accordance with results of previous studies obtained by using Raman and infrared spectroscopies [12, 13].

As for the polyBMA system, the SFG signal was slightly increased 48 h after onset of the immersion in liquid water (Fig. 47.1b). The contact angle of polyBMA-modified quartz in the air-in-water system slightly decreased at the beginning, probably due to the gradual detachment of the film from the ODS-modified quartz in water.

TABLE 47.1 Intensity of SFG Signal for O–H Stretching Region at Interfaces of Water and Copolymer Films

	Total[a]	
Sample	0 h	48 h
PolyBMA	130.2 (0.58)	166.0 (0.74)
Poly(CMB-*r*-BMA)	108.4 (0.48)	50.4 (0.22)
Poly(MA-*r*-BMA)	151.4 (0.67)	225.1 (1.00)
Poly(DMAEMA-*r*-BMA)	72.6 (0.32)	158.4 (0.71)

[a]The values in parentheses are peak areas normalized by the peak area for a bare fused-quartz prism.

In SFG spectra for the interfaces of various prisms with liquid water, the O–H signal of strongly hydrogen-bonded water molecules appeared at around 3200 cm^{-1}, and that of weakly hydrogen-bonded ones appeared at around 3400 cm^{-1}. These peaks were very broad because of the strong coupling of neighboring water molecules and Fermi resonance with H–O–H deformation [17].

The electrostatic interaction between any compounds concerned and surrounding water molecules determines the orientation of the water molecules. Previously, the structure of water was investigated at the quartz–water interface in the presence of supported lipid bilayers (SLBs) by the SFG method [19]. The O–H oscillator strengths were most affected by the charged SLBs, rather than bilayers that did not contain a net charge [egg yolk phosphatidylcholine (PC)]. More recently, phase-sensitive SFG spectroscopy has revealed that water molecules at phospholipid–water interfaces are oriented preferentially by the electrostatic potential imposed by phospholipids [20]. Zwitterionic PC and phosphatidylethanolamine showed weaker water-orientating capability relative to negative phospholipids.

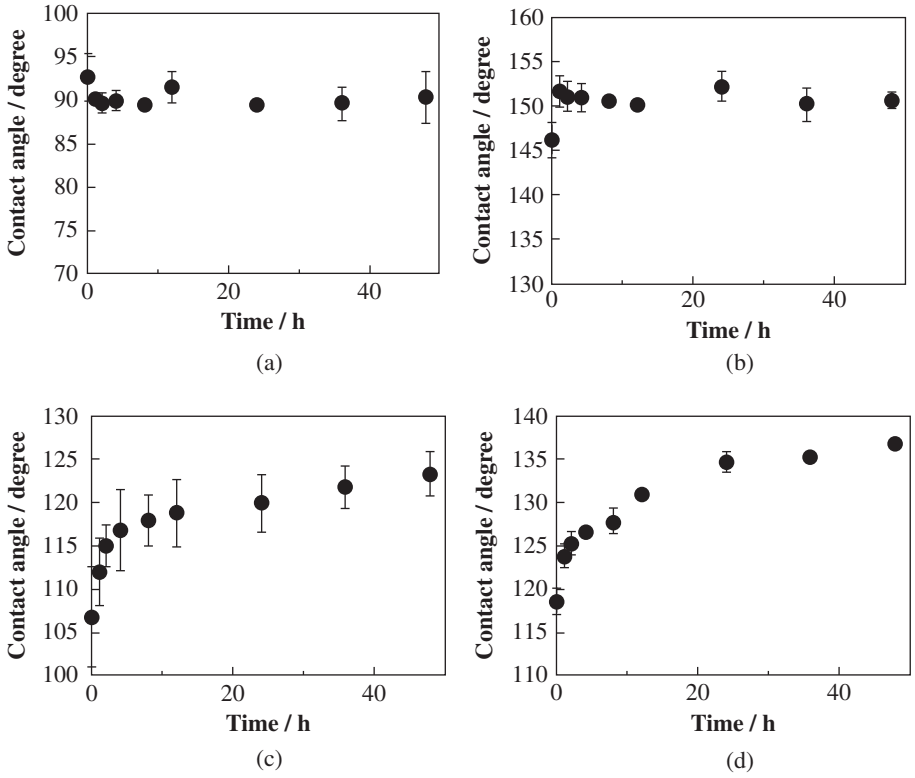

FIGURE 47.2 Time evolution of contact angles (air-in-water) of various surfaces: (a) polyBMA; (b) poly(CMB-*r*-BMA); (c) poly(MA-*r*-BMA); (d) poly(DMAEMA-*r*-BMA). Each θ value is the average value of five measurements, and the error bars denote standard deviation.

Using the same technique, the orientation of water at the PC–water interfaces was investigated in detail [21]. The water associated with the negatively charged phosphate is strongly H-bonded and has a net H-up orientation, whereas the water around the positively charged choline forms weaker H-bonds and has a net H-down orientation, and the water weakly interacting with the hydrophobic region of the lipid has a net H-up orientation.

The water molecules at the shortest distance from the phosphoryl choline groups might be affected by the ionic groups. The huge number of water molecules from the secondary hydration layer would be affected by both positively and negatively charged groups, resulting in orientation weaker than that of primary hydrating water. Phase-sensitive (heterodyne-detected) SFG can provide invaluable information about the "direction" of orientation (hydration), whereas conventional (homodyne-detected) SFG discussed in this chapter can give information about the "degree" of orientation. It should be mentioned here that the heterodyne-detected SFG method cannot easily be applied to liquid-solid interfaces in comparison with the homodyne-detected SFG method.

These results strongly suggested that the water molecules at the zwitterionic copolymer–water interfaces were not greatly oriented in comparison with the water molecules on the surfaces of polyBMA film-, poly(MA-*r*-BMA) film-, and poly(DMAEMA-*r*-BMA) film-modified quartz prisms. The order of the peak area of O–H stretching indicates that the zwitterionic polymer was the least perturbative to the structure of vicinal water (Table 47.1).

47.3 ZWITTERIONIC POLYMER BRUSH SYSTEM

A zwitterionic PCMB brush was prepared on a fused-quartz prism by the surface-initiated atom transfer radical polymerization (SI-ATRP) of CMB monomer [22]. The conformation of PCMB brush and the state of water at the surface of the brush were examined using the SFG technique. The C–H stretching band of the brush, indicating the *gauche* defect of the brush, was affected by the contact medium such as dry nitrogen, water vapor–saturated nitrogen, and liquid water. The water molecules at the PCMB–water interfaces were not largely oriented in comparison with the interfacial water of both bare and ATRP–initiator-modified quartz prisms. The electrical neutralization between neighboring positive and negative charges might diminish the electrostatic adsorption of water molecules to the vicinity of zwitterionic polymer brushes.

47.4 AMPHOTERIC POLYMER BRUSH SYSTEM

A polyampholyte brush was prepared on the surface of a quartz prism by surface-initiated reversible addition–fragmentation chain transfer (RAFT) polymerization of MA and DMAEMA at a monomer ratio of 1:1 [23]. The sum frequency generation method indicated that water molecules at the amphoteric polymer brush–water interfaces were not greatly oriented in comparison with those at the surfaces of bare quartz prisms, and negatively charged polyMA and positively charged polyDMAEMA brushes. The small perturbation effect of an amphoteric polymer brush on the structure of vicinal water was in accordance with the tendency of aqueous solution and thin films of amphoteric polymers observed by using Raman and infrared spectroscopies, respectively.

47.5 CONCLUSION

Water molecules at the surface of charge-neutralized polymer materials are not strongly oriented in comparison with those at the surfaces of nonpolar polymer film and positively or negatively charged polymer films and polymer brushes. Since zwitterionic polymer materials have excellent biocompatibilities in general [24, 25], it is highly probable that a small perturbation on the structure of vicinal water is a factor of biocompatibility of the materials concerned.

On contact of polymer materials with blood, for example, adsorption of proteins occurs, and, subsequently, cells adhere to the polymers via the adsorbed proteins. On contact of the proteins with the polymers, water molecules in the contacting region on the surface of the proteins and the polymers are repelled, and the partly dehydrated proteins are adsorbed to the polymers and denatured. Since the water molecules above zwitterionic polymers are not so strongly oriented, an increase in entropy on dehydration of the polymer surface at the collision of the protein molecule might not be as large as that in the case of a lopsidedly charged polymer surface and a hydrophobically hydrated polymer surface, providing the antibiofouling properties to zwitterionic polymers. Whether they are zwitterionic or amphoteric, charge-balanced polymer materials might satisfy these conditions.

LANGMUIR MONOLAYER INTERACTION OF PERFLUOROOCTYLATED LONG-CHAIN ALCOHOLS WITH BIOMEMBRANE CONSTITUENTS

Hiromichi Nakahara and Osamu Shibata

Department of Biophysical Chemistry, Graduate School of Pharmaceutical Sciences, Nagasaki International University, Sasebo, Nagasaki, Japan

48.1 INTRODUCTION

Fluorinated amphiphiles have attracted significant interest largely owing to their unique properties including their hydrophobicity and lipophobicity [1], high gas-dissolving capacity [1, 2], chemical and biological inertness, low surface tension, and high fluidity [1, 3]. The potential applications of these compounds in medicine, disease diagnosis, and therapy have promoted numerous investigations on materials substituted with fluorine [1,4–6]. Indeed, it has been reported that fluorinated amphiphiles are potentially applicable as blood substitutes [4, 7–10] and effective additives to lung surfactant preparations [11–14]. However, highly fluorinated compounds [especially perfluorooctanoic acid (PFOA)] tend to accumulate in the environment and in the human body [15–18]. The key to the accumulation of PFOA is its anionic type and the sorption of the anionic PFOA by soils and sediments is quite smaller compared to the undissociated PFOA. In another sense, perfluorooctyl bromide (PFOB) has been shown to have short organ retention times and to have a potential for use for oxygen delivery [1, 2]. Thus, it is important to gain a more in-depth understanding of the effect of fluorinated chemicals on the human body and of their interaction with biomembranes lipids.

Perfluorinated chains (*F*-chains) differ markedly from hydrogenated chains (*H*-chains) in terms of bulkiness, helical conformation, and stiffness [2]. The properties of *F*-chains are described well in the review articles [2–4, 6, 19]. Among numerous techniques used to investigate the properties of fluorinated amphiphiles, Langmuir monolayers at the air–water interface represent a considerably simple and optimal model in mimicry of biomembranes. The monolayer technique provides a clue to understanding the interfacial behavior of amphiphiles and the mutual interaction between them. With Brewster angle microscopy (BAM), fluorescence microscopy (FM) [20–22], and atomic force microscopy (AFM), such behavior and interaction can be visualized on the micro- and nanoscales.

This chapter describes more recent efforts devoted to understanding the interaction and miscibility of two-component monolayers of long-chain alcohols [$CF_3(CF_2)_7(CH_2)_mOH$, or *F*8*Hm*OH] and biomembrane constituents [in particular, dipalmitoylphosphatidylcholine (DPPC)]. The thermodynamical and morphological elucidation of the binary miscibility in the monolayer state has been performed by using isotherm data of surface pressure (π) and surface potential (ΔV) against molecular area (A), and topological images with BAM, FM, and AFM.

48.2 THERMAL PROPERTIES OF *F*8*Hm*OH

An effect of fluorination of a tail group of saturated long-chain carboxylic acids on their physicochemical property such as melting point (T_m) has been documented well in a review article [19]. The whole fluorination of the acids

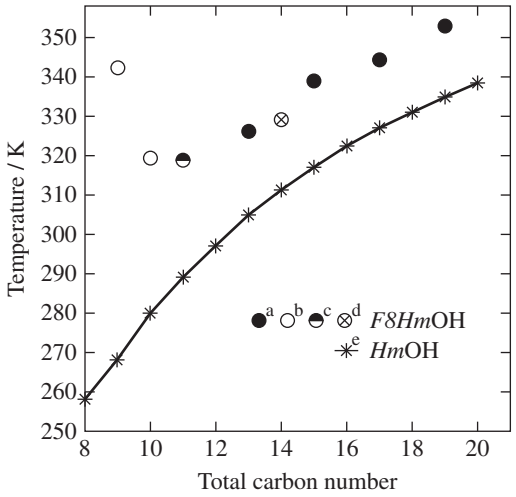

FIGURE 48.1 Change in melting point of *F*8*Hm*OH and *Hm*OH against carbon number. [Data (see symbols in diagram): (a) data from Nakahara et al. 2013 [23]; (b) from Tokyo Chemical Industry Co., Ltd.; (c) from Matrix Scientific; (d) from Apollo Scientific Ltd.; (e) from *CRC Handbook of Chemistry and Physics* 2010 [63].]

results in more than twice larger increments in a plot of melting-point slopes versus carbon number. This means that the high fluorination provides original compounds with thermal stability or resistance. In this regard, partially fluorinated amphiphiles are also expected to be endowed with such properties. The melting point of ω-(perfluorooctyl)alkanol (or *F*8*Hm*OH) and the corresponding hydrogenated alcohol (or *Hm*OH) is plotted against the total carbon number of the alcohols in Fig. 48.1. The relationship between the melting point of *F*8*Hm*OH and the carbon number ($11 \leq m \leq 19$) is almost linear. A slope of the line ($\partial T_m/\partial m$) is ~4.4 K. The melting point of *Hm*OH also increases with increasing carbon numbers, with a gradient of $\partial T_m/\partial m = 5.7$ K ($11 \leq m \leq 19$). The slopes for both the alcohols mean the contribution to an increase in melting point per methylene group ($-CH_2-$). Thus, it is found that perfluorooctylation in the terminal aliphatic chain of *Hm*OH generates thermal resistance (~1 K) for the elongation of a methylene group. Considering the larger T_m of *F*8*Hm*OH in Fig. 48.1, the behavior apparently seems to conflict with the weak van der Waals interactions between *F*-chains. However, we must reconsider the fact that the weak van der Waals interaction is closely related to molecular weight (MW). Here, focusing our attention on the melting points of *F*8*H*7OH (T_m = 338.8 K, MW = 534.25) and *H*20OH (T_m = 338.6 K, MW = 298.55), it is understandable that the larger molecular weight of *F*8*H*7OH reflects the weak van der Waals interaction between *F*8-chains. In the smaller carbon number region below $m = 10$ in Fig. 48.1, the melting points (especially *F*8*H*1OH) show irregular values. This is considered to be due to the low purity (>97%; Tokyo Chemical Industry Co., Ltd.) of the measured *F*8*H*1OH samples or the structural instability of *F*8*H*1OH. To our knowledge, several reagent companies generally supply *F*8*H*1OH (CAS 423-56-3) at the similar grade (purity = ~97%). On the other hand, *F*8*Hm*OH ($m \geq 5$) can be highly purified by repeated recrystallizations (purity > 99.5%) [23]. Furthermore, it is widely accepted that the fluorination in α-carbon of aliphatic alcohols includes difficulties in the synthetic process. Combinations of these observations may produce the irregular values, which needs to be investigated in more detail.

48.3 LANGMUIR MONOLAYER BEHAVIOR OF *F*8*Hm*OH

The surface pressure (π) molecular area (A) and the surface potential (ΔV)–A isotherms of *F*8*Hm*OH (m = 5,7,9,11) monolayers on 0.15 M NaCl are shown in Fig. 48.2. The other alcohols with $m \leq 4$ are, in common, difficult to form a insoluble (or stable) monolayer at the air–water interface because of their high solubility in water. The *F*8*H*5OH monolayer (curve 1) initially has a π-value of >1 mN m^{-1} at large molecular areas, where the monolayer is in a disordered phase corresponding to the liquid-expanded (LE) phase of typical hydrogenated lipid monolayers. The isotherm has a kink at ~5 mN m^{-1} (indicated by a dashed arrow), which means a phase transition of the disordered state to an ordered state corresponding to liquid-condensed (LC) phase of the lipid monolayers. The kink is

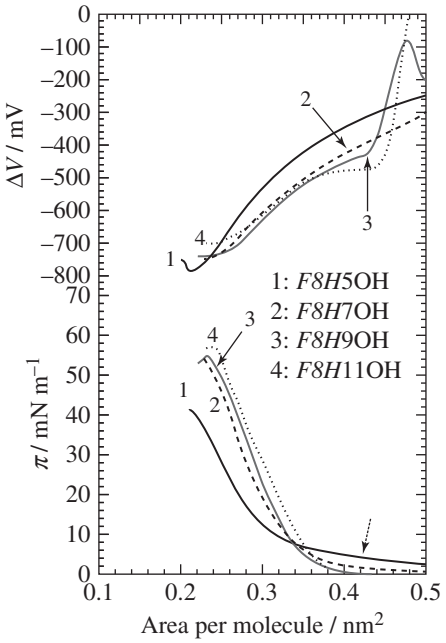

FIGURE 48.2 The π–A and ΔV–A isotherms of *F*8*Hm*OH [m = 5 (curve 1), 7 (curve 2), 9 (curve 3), 11 (curve 4)] monolayers on 0.15 M NaCl. The isotherms except for m = 5 (at 293.2 K) were measured at 298.2 K.

much more obscure in comparison to typical hydrogenated lipids such as myristic acid [24], dipalmitoylphosphatidylcholine (DPPC) [25–28], dipalmitoylphosphatidylglycerol (DPPG)[28–30], and dimyristoylphosphatidylethanolamine (DMPE) [31, 32]. Indeed, the fluorinated amphiphiles often undergo a phase transition, which is difficult to distinguish on π–A isotherms [26, 33]. However, the break has been confirmed by temperature dependence of the transition pressure (π^{eq}) [23]. The π^{eq} values of *F*8*H*5OH monolayers increase linearly with increasing temperatures. The π^{eq} inclination against temperature ($\partial\pi^{eq}/\partial T$) for *F*8*H*5OH monolayers is $\sim$0.4 mN m^{-1} K^{-1} [23]. On the other hand, the slope for the *Hm*OH monolayers ($11 \leq m \leq 14$) is reported to be $\sim$1.0 mN m^{-1} K^{-1} regardless of aliphatic chain lengths [34]. It is well known that the $\partial\pi^{eq}/\partial T$ value for the monolayers of fluorinated amphiphiles is smaller than that for hydrogenated ones, due to the thermal resistance of *F*-chains [9, 19, 35]. Actually, perfluorocarboxylic acid monolayers have the inclination of 0.2–0.3 mN m^{-1} K^{-1}, which means that perfluorination of hydrocarbon chains in monolayers generates three- to fivefold thermal resistance [19]. Herein, the slopes of *F*8*H*5OH monolayers are very similar to perfluorinated amphiphiles.; thus, it can be assumed that *F*8*H*5OH of partially fluorinated alcohol faithfully inherits the thermal resistance from perfluorinated *F*-chains.

The other *F*8*Hm*OH monolayers exhibit an isotherm of the typical ordered phase without the transition. The collapse pressure (π^{c}) at which the monolayer is transformed into a bilayer or other three-dimensional (3D) structures, increases slightly with increasing chain length. The limiting (or extrapolated) areas of *F*8*Hm*OH monolayers are concentrated in 0.33−0.35 nm^2 and are similar to the cross-sectional area of an *F*-chain ($\sim$0.30 nm^2) [1]. Considering the cross-sectional area of an *H*-chain ($\sim$0.20 nm^2), it is found that the *F*8 moiety in *F*8*Hm*OH molecules dominates over the monolayer ordering and orientation at the close-packed state for *F*8*Hm*OH monolayers.

The ΔV–A isotherms of *F*8*Hm*OH monolayers indicate changes in molecular orientation on lateral compression. It is widely accepted that the ΔV–A isotherm of lipid monolayers consisting of *H*-chains or *F*-chains exhibits positive or negative variation with decreasing A. The negative ΔV value of *F*-chains is attributed to the electronegativity of a fluorine, which has been discussed thoroughly [25, 33, 36–40]. The ΔV value decreases with decreasing molecular areas and finally approaches a minimum ΔV value (ΔV_{min}) at the close-packed state, where monolayers begin to collapse. The ΔV_{min} values reach around −750 mV independent of total chain lengths. This means that the orderings of *F*8*Hm*OH monolayers at the close-packed state are similar. The convergence of ΔV_{min} value and the negative ΔV variation on compression support the *F*8 moiety (or, more accurately, terminal CF_3 group) to be exposed to the air, similarly to typical lipid monolayers.

48.4 BINARY MONOLAYERS OF DPPC AND *F*8*Hm*OH

48.4.1 The π–A and ΔV–A Isotherms

The miscibility of binary monolayers can be assessed from the π–A and ΔV–A isotherms measured by varying the monolayer composition. The isotherms of binary monolayers often lie in compositional order between the isotherms of each pure monolayer. The binary monolayers, including both a hydrogenated amphiphile and a fluorinated amphiphile, indicate the distinct and large variation in ΔV–A isotherms due to their opposite ΔV signs [30, 40–42]. The criteria for miscibility of binary monolayers are based on a variation in π^{eq} as well as π^{c} with regard to composition [43]. Determination of the pressures (π^{eq} and π^{c}) can be precisely performed by considering the inflection point in the corresponding ΔV–A isotherm appears. The π–A isotherms for the binary DPPC/*F*8*Hm*OH monolayers are shown in Fig. 48.3. DPPC monolayers (curve 1) have a LE/LC phase transition at $\sim$11 mN m^{-1}, which has been discussed widely [25, 27, 28, 31]. In all the binary systems, the π^{eq} value is found to change with mole fraction of *F*8*Hm*OH (or X_{F8HmOH}), which suggests the miscibility of the two components. The slope of $\partial\pi^{eq}/\partial X_{F8HmOH}$ is the point to understand how the two components are miscible with each other. The positive and negative slopes are respectively indicative of fluidization and solidification of DPPC monolayers by the *F*8*Hm*OH addition. The binary DPPC/*F*8*Hm*OH monolayers exhibit a fluidizing ($m = 5$) or solidifying ($m = 7, 9, 11$) effect. It depends on a mismatch of the hydrophobic chain lengths of the two components. Thus, the influence of *F*8*Hm*OH addition on DPPC monolayers varies at the boundary of total carbon number of 15 in *F*8*Hm*OH, which agrees nearly with the chain length of DPPC. Detailed discussions on the effect will be made quantitatively in the latter section. At high surface pressures, the π^{c} value for all the systems also changes with X_{F8HmOH}, which provides further evidence of the binary miscibility within a monolayer. These variations of surface pressures (π^{eq} and π^{c}) against X_{F8HmOH} strongly suggest thermodynamical miscibility between DPPC and *F*8*Hm*OH irrespective of the number of methylene groups (m).

48.4.2 Excess Gibbs Free Energy

The lateral interactions between DPPC and *F*8*Hm*OH within a monolayer can be analyzed in terms of the excess Gibbs free energy of mixing (ΔG^{exc}_{mix}), which is calculated with the following equation [43]

$$\Delta G^{exc}_{mix} = \int_0^{\pi} (A_{12} - X_1 A_1 - X_2 A_2) \mathrm{d}\pi \qquad (48.1)$$

where A_i and X_i are the molecular area and mole fraction of component i, respectively, and A_{12} is the mean molecular area

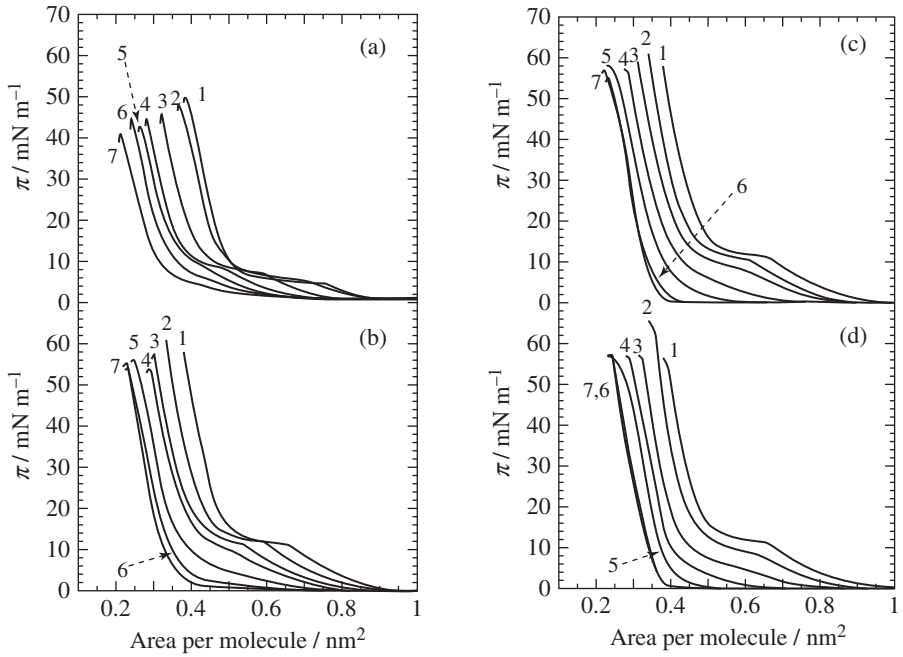

FIGURE 48.3 The π–A isotherms of the two-component DPPC/*F*8*Hm*OH monolayers on 0.15 M NaCl at $X_{F8HmOH} = 0$ (curve 1), 0.1 (curve 2), 0.3 (curve 3), 0.5 (curve 4), 0.7 (curve 5), 0.9 (curve 6), and 1 (curve 7): (a) $m = 5$, (b) $m = 7$, (c) $m = 9$, and (d) $m = 11$. The isotherms except for $m = 5$ (at 293.2 K) were measured at 298.2 K.

of the binary monolayer. For identical interactions between the two components, ΔG^{exc}_{mix} is zero. In this state, they are either ideally mixed in the monolayer or are not mixed completely, resulting in a patchlike packing state [44,45]. A negative ΔG^{exc}_{mix} value indicates that an attractive interaction exists between the two components. The $\Delta G^{exc}_{mix} - X_{F8HmOH}$ plot for DPPC/*F*8*Hm*OH at representative surface pressures is shown in Fig. 48.4. The ΔG^{exc}_{mix} value decreases with an increase in surface pressure greater than 15 mN m^{-1} for all the systems. At 5 mN m^{-1}, however, complicated behavior is observed especially for m = 5,7. This is attributed to the different phases of the monolayers (disordered and ordered), which

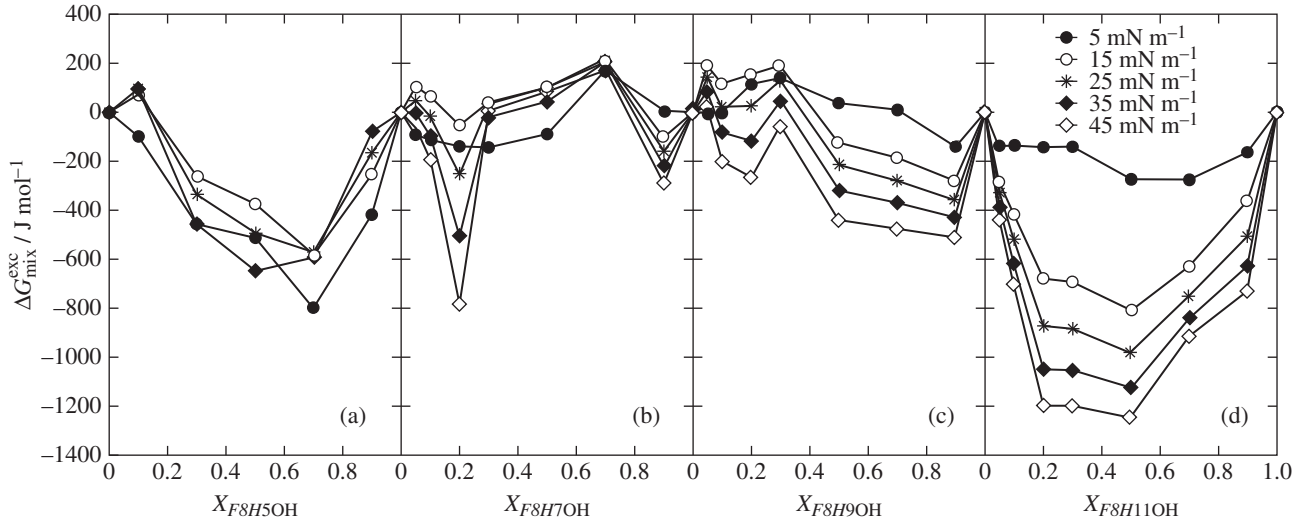

FIGURE 48.4 Excess Gibbs free energy of mixing (ΔG^{exc}_{mix}) of the binary DPPC/*F*8*Hm*OH monolayers as a function of X_{F8HmOH} at typical surface pressures on 0.15 M NaCl: (a) $m = 5$, (b) $m = 7$, (c) $m = 9$, and (d) $m = 11$. The isotherms except for $m = 5$ (at 293.2 K) were measured at 298.2 K.

are caused by the changes in π^{eq} with regard to X_{F8HmOH} (see Fig. 48.3). For example, the monolayers at 5 mN m^{-1} for $X_{F8H7OH} = 0.2$ and 0.9 are in the disordered phase and the ordered phase respectively. Thus, the ΔG^{exc}_{mix} analysis for surface pressures greater than 15 mN m^{-1} provides a better understanding of the mutual interactions between the components because the monolayers are entirely in the ordered phase irrespective of surface pressure and composition. All the systems show negative ΔG^{exc}_{mix} signs, which suggests the existence of attractive interactions between the two components. In particular, the plots for DPPC/*F*8*H*11OH indicate most significant variations (Fig. 48.4d). As the surface pressure increases, the ΔG^{exc}_{mix} value reaches the minimum (~ -1200 J mol^{-1}) at 45 mN m^{-1} for $0.2 \leq X_{F8H11OH} \leq 0.5$. This behavior suggests that the attractive force between the palmitoyl chains of DPPC and the hydrocarbon moieties of *F*8*H*11OH increases on compression and that the affinity between the two components is the highest for $0.2 \leq X_{F8H11OH} \leq 0.5$. In other words, the shorter methylene group ($m \leq 9$) in *F*8*Hm*OH does not indicate strong interactions with hydrophobic chains in DPPC.

48.4.3 Two-Dimensional Phase Diagram

Two-dimensional (2D) phase diagrams (π vs. X_{F8HmOH}) exhibit the phase distributions of disordered and ordered phases at low surface pressures, and monolayer (2D) and bulk (3D) phases at high surface pressures. These diagrams are constructed by plotting the π^{eq} and π^{c} values for the binary monolayers against composition at a fixed temperature (see Fig. 48.5). In the DPPC/*F*8*H*5OH system, the π^{eq} value increases with increasing X_{F8H5OH} smaller than 0.7. Then, it decreases to the π^{eq} value of pure *F*8*H*5OH ($\sim$5 mN m^{-1}). On the other hand, for the $m \geq 7$ systems, the reduction in π^{eq} is caused by an increase in X_{F8HmOH}. The magnitude of the reduction is improved as the total chain length of *F*8*Hm*OH increases. The slope of $\partial\pi^{eq}/\partial X_{F8HmOH}$ provides information on the degree of the solidification (negative) or fluidization (positive) [19, 35]. The π^{eq} values for the $m = 9,11$ systems vary linearly with respect to X_{F8HmOH}. The indices of $\partial\pi^{eq}/\partial X_{F8HmOH}$ for $m = 9$ ($0 \leq X_{F8H9OH} \leq 0.3$) and 11 ($0 \leq X_{F8H11OH} \leq 0.2$) are around -14 [42] and -33 mN m^{-1} [30], respectively; that is, the magnitude of the solidification for the DPPC/*F*8*H*11OH system is more than twice that for the *F*8*H*9OH system. On the other hand, the binary DPPC/*F*8*H*7OH system indicates negative but nonlinear variations in π^{eq} with respect to X_{F8H7OH} [41]. From the small X_{F8HmOH} region for the $m \geq 7$ systems, it is found that the solidification degree becomes larger for longer m: *F*8*H*7OH < *F*8*H*9OH < *F*8*H*11OH. On the contrary, *F*8*H*5OH exerts the fluidizing effect on DPPC monolayers. It is suggested that the extension of methylene group ($-CH_2-$) in a partially fluorinated chain significantly contributes to the solidifying effect. In this regard, all the systems described here indicate the miscibility with DPPC in

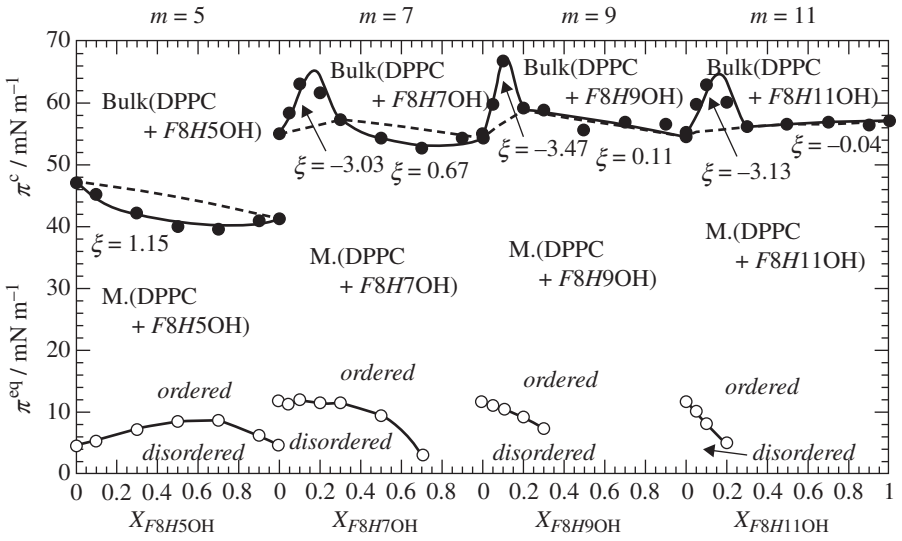

FIGURE 48.5 Two-dimensional phase diagrams based on the variation in transition pressure (π^{eq}: open circle) and collapse pressure (π^{c}: solid circle) on 0.15 M NaCl at 298.2 K (293.2 K for $m = 5$) as a function of X_{F8HmOH}. The dashed lines were calculated according to Eq. (48.2) for $\xi = 0$. The solid line at high surface pressures was obtained by curve fitting of experimental collapse pressures to Eq. (48.2). "M" indicates a mixed monolayer formed by DPPC and *F*8*Hm*OH species, whereas "Bulk" denotes a solid phase of DPPC and *F*8*Hm*OH ("bulk phase" may be called "solid phase" not in monolayer state).

the monolayer state, although there is considerable variation in the manner of miscibility (fluidization and solidification) among the systems.

The coexistence of the phase boundary of the 2D and 3D phases of the molecules spread on a surface can be theoretically simulated using the Joos equation [46, 47] under the assumption of a regular surface mixture:

$$1 = x_1^{\mathrm{s}} \exp\left\{\left(\pi_{\mathrm{m}}^{\mathrm{c}} - \pi_1^{\mathrm{c}}\right)\omega_1/kT\right\} \exp\left\{\xi\left(x_2^{\mathrm{s}}\right)^2\right\} + x_2^{\mathrm{s}} \exp\left\{\left(\pi_{\mathrm{m}}^{\mathrm{c}} - \pi_2^{\mathrm{c}}\right)\omega_2/kT\right\} \exp\left\{\xi\left(x_1^{\mathrm{s}}\right)^2\right\} \quad (48.2)$$

Here, x_1^{s} and x_2^{s} denote the respective molar fractions of components 1 and 2 in the two-component monolayers; π_1^{c} and π_2^{c}, the respective collapse pressures of components 1 and 2; $\pi_{\mathrm{m}}^{\mathrm{c}}$, the collapse pressure of the two-component monolayer at a given composition of x_1^{s} (or x_2^{s}); ω_1 and ω_2, the corresponding molecular areas at the collapse; and ξ, the interaction parameter. The solid curve at higher surface pressures was drawn by adjusting ξ in Eq. (48.2) to obtain the best fit for the experimental values of collapse pressures. The profiles of the phase diagrams of the DPPC/*F*8*Hm*OH systems are presented in Fig. 48.5. In the collapse pressure region, the $m \geq 7$ systems in the small X_{F8HmOH} region are of the positive azeotropic type, where the maximum in curves of the phase boundary corresponds to the 2D positive azeotropic point. On the other hand, the phase diagram for DPPC/*F*8*H*5OH is assigned to the negative azeotropic type.

The interaction energy can be calculated as the following equation

$$\Delta\varepsilon = \xi RT/z \quad (48.3)$$

where z is the number of nearest neighbors, equal to 6, in a close-packed monolayer, and the interaction energy is $\Delta\varepsilon = \varepsilon_{12} - (\varepsilon_{11} + \varepsilon_{22})/2$ [46]; ε_{ij} denotes the potential energy of interaction between components i and j. The calculated ξ and $\Delta\varepsilon$ are listed in Table 48.1. The ξ value for all the systems except for $m = 5$ is quite larger in magnitude in the small X_{F8HmOH} region. In contrast, in the large X_{F8HmOH} region, the two components nearly cause the ideal interaction (especially m = 9,11). As for the DPPC/*F*8*H*7OH system, the phase diagram in the large X_{F8H7OH} is of the negative azeotropic type. This behavior is similar to that for the DPPC/*F*8*H*5OH system, although the degree of ξ values is smaller. Thus, the mode of mutual interactions is different at the boundary between m = 5,7. Moreover, as mentioned above, the variation in π^{eq} against X_{F8HmOH} also supports the boundary; convex variations (fluidization) for $m = 5$ and linear or nonlinear negative ones (solidification) for $m \geq 7$. However, in comparison to the π^{eq} behavior, the magnitude of the effect is not found to be reflected in the ξ value. This may be due to the fact that the monolayer is in the closest packing (the lowest compressibility) at π^{c}. Thus, it is suggested that the mode of the binary interaction at low surface pressures is different from that at high surface pressures. In fact, such opposite mode of interactions was remarkably observed for the DPPC/*F*8*H*7OH system [41]. For $0 \leq X_{F8H7OH} \leq 0.3$, the two components do not favorably interact with each other at low surface pressures because of the almost constant π^{eq} value with respect to X_{F8H7OH}. However, the large negative ξ value ($\xi = -3.03$) is indicative of the strong interaction between them. On the other hand, the phase diagram for $0.3 \leq X_{F8H7OH} \leq 1$ exhibits the opposite behavior to the case of $0 \leq X_{F8H7OH} \leq 0.3$. Nevertheless, these results evidence the monolayer miscibility between DPPC and *F*8*Hm*OH.

TABLE 48.1 Interaction Parameters and Energies for the DPPC/*F*8*Hm*OH Systems on 0.15 M NaCl [30, 40–42]

m	T (K)	X_{F8HmOH}	ξ	$\Delta\varepsilon$ (kJ/mol)
5	293.2	$0 \leq X_{F8H5OH} \leq 1$	1.15	0.47
7	298.2	$0 \leq X_{F8H7OH} \leq 0.3$	−3.03	−1.26
		$0.3 \leq X_{F8H7OH} \leq 1$	0.67	0.28
9	298.2	$0 \leq X_{F8H9OH} \leq 0.2$	−3.47	−1.43
		$0.2 \leq X_{F8H9OH} \leq 1$	0.11	0.05
11	298.2	$0 \leq X_{F8H11OH} \leq 0.3$	−3.13	−1.29
		$0.3 \leq X_{F8H11OH} \leq 1$	−0.04	−0.02

48.4.4 Brewster Angle Microscopy (BAM)

Brewster angle microscopic observations at the air–water interface can directly provide morphological information on the phase behavior of monolayers at the air–water interface. In the BAM observation, the dark and bright contrasts are respectively assigned to LE (or disordered) and LC (or ordered) phases of lipid monolayers, which is based on the difference in refractive index of monolayer phases caused by a change in the molecular density or packing at the surface [48, 49]. As for DPPC monolayers (column 1 in Fig. 48.6a), the domain nucleation of LC phases is brought out at $\pi^{\mathrm{eq}} = \sim 5$ (at 293.2 K) and ~ 11 mN m^{-1} (at 298.2 K), and then the LC domains grow in size and number with increasing surface pressures. Further compression changes the LE/LC coexistence phases into homogeneous LC phases. A detailed analysis on the morphology of DPPC monolayers has already been reported elsewhere [14, 30]. On the other hand, *F*8*Hm*OH monolayers exhibit optically homogeneous images over the entire surface pressures [30,40–42]. The BAM images for the binary monolayer shown in Fig. 48.6 indicate morphologies different from those for DPPC alone. A small amount addition of *F*8*H*5OH ($X_{F8H5OH} = 0.1$) makes the LC domain of DPPC more branched, and thus it becomes elongated and forms a whirlpool (a so-called triskelion) that grows in a counterclockwise fashion. With the further addition ($X_{F8H5OH} = 0.3$), the domains with the whirled arms change into the round domains. On the other hand, a small addition

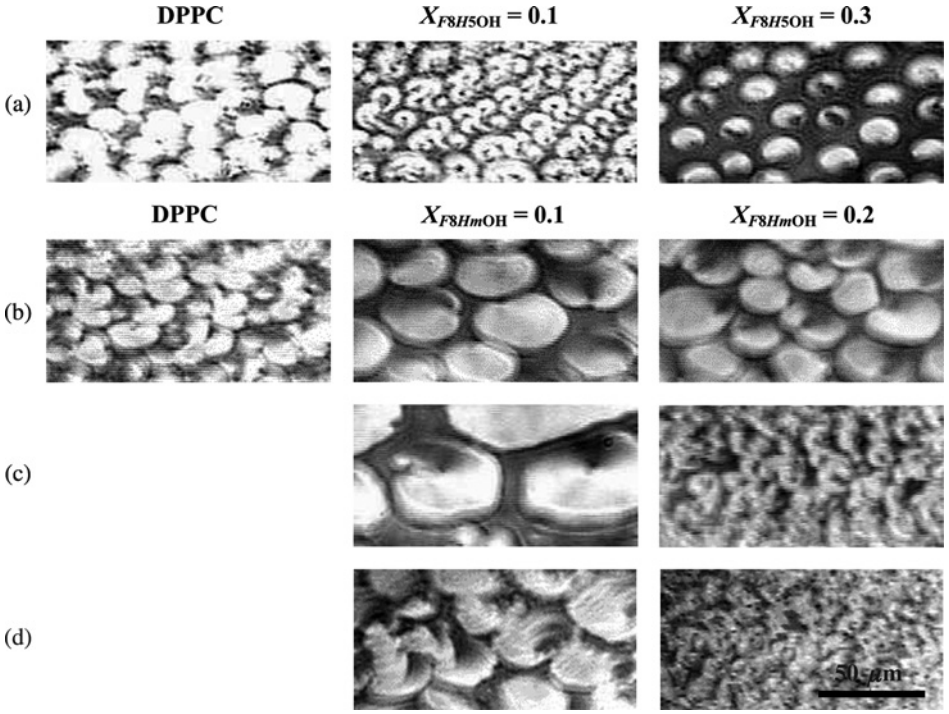

FIGURE 48.6 BAM images of the binary DPPC/*F*8*Hm*OH monolayers on 0.15 M NaCl at 298.2 K (293.2 K for $m = 5$): (a) $m = 5$ at 8 mN m^{-1}, (b) $m = 7$ at 15 mN m^{-1}, (c) $m = 9$ at 15 mN m^{-1}, and (d) $m = 11$ at 15 mN m^{-1}. The scale bar in the lower right represents 50 μm.

of *F*8*Hm*OH ($m \geq 7$) to DPPC monolayers ($X_{F8HmOH} = 0.1$) induces a size increment of the ordered domains, where the domain shape becomes round. At $X_{F8HmOH} = 0.2$, however, the domain size becomes much smaller and the domain shape changes to be branched similar to the LC domain of DPPC for $m = 9,11$. In the case of $m = 7$, the domain shape and size are kept almost constant despite the increment from $X_{F8H7OH} =$ 0.1–0.2. Above $X_{F8HmOH} = 0.2$, the BAM images are homogeneously dark over the entire surface pressures [30,41,42]. It is widely accepted that a domain formation is controlled by the balance of line tension at the phase boundary between the disordered and ordered domains and long-range dipole–dipole interactions between the ordered domains [50–53]. Therefore, the variations in domain shape and size describe the change of the composition at disordered/ordered phase boundary and the interaction between ordered domains for the two-component monolayers.

48.4.5 Fluorescence Microscopy (FM)

The phase behavior of monolayers is often observed with fluorescence microscopy (FM) as functions of composition and surface pressure. FM measurements require a fluorescent probe, which is incorporated into the monolayer. Contrast in the FM image is generated by the difference in solubility of fluorescent probes in the disordered (or LE) and ordered (or LC) monolayers [20–22]. This is based on the fact that the probe generally forms disordered monolayers at the interface as a result of its spatially bulky moiety (or fluorescent part). This induces strong affinity for the disordered phase of the monolayers. The FM observation provides powerful information on the phase growth and variation in higher resolution and magnification than the BAM observation. However, there is a possible risk that the probe (or dye) might affect the original phase behavior of monolayers. Thus, the validity of the resulting FM image should be checked in terms of whether the incorporation of FM probes has no influence on the original isotherm and the original domain shape in BAM images. It is widely accepted that the addition of <1 mol% FM probes produces few effects on the monolayer behavior [28, 54]. The FM micrographs of the binary DPPC/*F*8*Hm*OH monolayers (see Fig. 48.7) show the presence of different phase morphologies in the disordered/ordered coexistence region above π^{eq}. The phase morphologies (or domain shape and distribution) agree well with the corresponding BAM images (Fig. 48.6), which supports the validity of FM observations for the present systems. At $X_{F8HmOH} = 0.1$, the line tension at the phase boundary is dominated for $m \geq 7$, whereas the dipole–dipole repulsive force contributes more to the domain shape for $m = 5$. The further addition improves the contribution of the line tension to domain morphologies for DPPC/*F*8*H*5OH. As opposed to the system of $m = 5$, the domain sizes become smaller for the systems of $m = 9,11$ ($X_{F8HmOH} = 0.2$). This means that

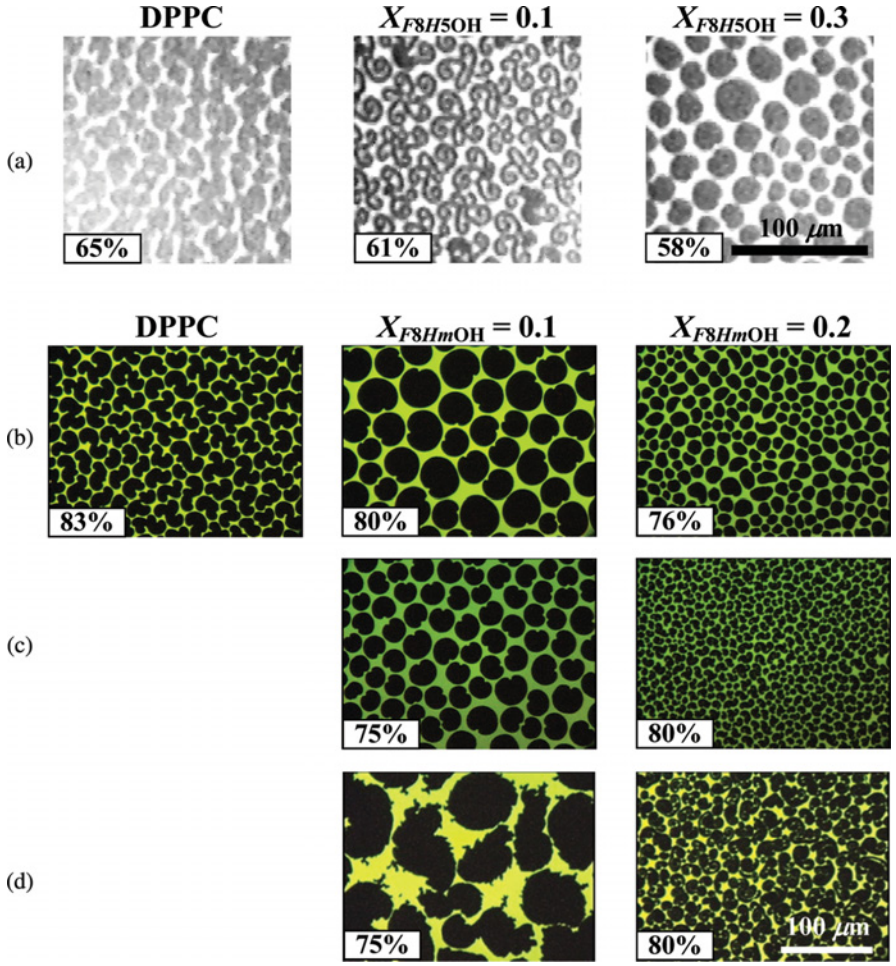

FIGURE 48.7 Fluorescent micrographs of the binary DPPC/*F*8*Hm*OH monolayers on 0.15 M NaCl at 15 mN m^{-1} at 298.2 K (293.2 K for $m = 5$) : (a) $m = 5$, (b) $m = 7$, (c) $m = 9$, and (d) $m = 11$. Percentages (%) refer to the ratio of ordered domains in the micrograph. The monolayers contain 1 mol% of fluorescent probe (R18 for $m = 5$ and NBD-PC for the others). The scale bar in the lower right represents 100 μm.

the contribution of the line tension decreases by the further addition. It is not yet understood how the composition of each domain is related to the balance of the line tension and dipole–dipole interaction. Nevertheless, a change in domain shape of the ordered domains is substantial evidence of the two-component miscibility.

48.4.6 Atomic Force microscopy (AFM)

The phase behavior and distribution of monolayers at the air–water interface can be visualized at the nanometer scale by AFM. Prior to the AFM observation, the monolayer located at the interface needs to be transferred onto a solid substrate using the Langmuir–Blodgett (LB) technique, where the monolayer is kept at the desired surface pressure. However, the LB technique includes a possibility of changes of the native monolayer structures by the electric charge between the samples and substrates, and by the physical factors during the deposition procedure. AFM images may therefore not provide completely accurate information on the phase behavior at the air–water interface but nevertheless allow us to understand phase morphologies that cannot be caught with in situ microscopic techniques (BAM and FM) due to the limited optical resolution and magnification of the microscopes. The AFM topographic images for the DPPC/*F*8*Hm*OH monolayers shown in Fig. 48.8 are apparently different from each other. The LB film of DPPC at high surface pressures indicates a homogeneous image [26]. In the DPPC/*F*8*H*5OH system (Fig. 48.8a), phase separation of the high (for DPPC) and low (for *F*8*H*5OH) domains is observed, which coincides with the positive ξ value (Fig. 48.5 and Table 48.1). Considering the BAM and FM images at micrometer scale, it is concluded that the two components are partially miscible within a monolayer. On the other hand,

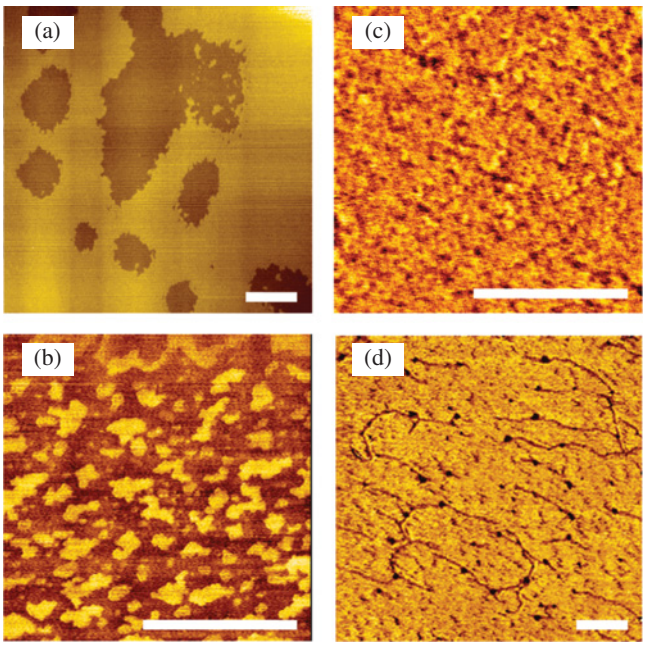

FIGURE 48.8 Typical AFM topographic images of the binary DPPC/*F*8*Hm*OH monolayers for $X_{F8HmOH} = 0.3$ at 35 mN m^{-1}: (a) $m = 5$, (b) $m = 7$, (c) $m = 9$, and (d) $m = 11$. The scale bar in the lower right represents 500 nm.

in the other systems, the domains are finely dispersed. In particular, for DPPC/*F*8*H*7OH (Fig. 48.8b), the dispersion or the fragmentation of DPPC monolayers is induced by the surface pressure [41]. In the DPPC/*F*8*H*9OH system (Fig. 48.8c), the dispersion is further enhanced and then the image becomes almost homogeneous in terms of height difference. The AFM image at $X_{F8H11OH} = 0.3$ show several dark "cracks" with low thickness (Fig. 48.8d). The cracks are formed predominantly by *F*8*H*11OH [30]. This means that the *F*8*H*11OH monolayers are less oriented because the hydrophobic chain of *F*8*H*11OH is longer than that of DPPC. The poor orientation is considered to be strongly affected by the further reclining *F*8 moieties at the linkage (CF_2–CH_2) in *F*8*Hm*OH. As a result, the dispersion of DPPC domains may be caused by combination of the poor orientation and the relatively weak van der Waals interaction or cohesive force between the *F*8 moieties.

The criteria for the monolayer miscibility is still disputable. The existence of the phase-separated domain in the micrographs does not necessarily imply the immiscibility between components, because the domain morphologies vary in shape and size with respect to monolayer composition as mentioned above. Assuming the completely immiscible monolayers, the domain shapes should be a circle form due to the minimization of surface free energy at the boundary among heterogeneous components; that is, if the circular and phase-separated domain is observed fully in BAM, FM, and AFM images, the components forming monolayers can be entirely immiscible at micro- as well as nanoscale [29, 32]. Therefore, herein, it is concluded that all the binary DPPC/*F*8*Hm*OH monolayers are (partially) miscible thermodynamically and morphologically.

48.5 MISCIBILITY OF *F*8*Hm*OH WITH LIPIDS

It is well known that *F*-chains and *H*-chains are immiscible with each other in both liquid and solid states, where they are dissolved in the aqueous medium. The immiscibility is attributed mainly to the weak van der Waals force of the *F*-chains. However, *F*-chains and *H*-chains can interact more in a monolayer state spread at the air-exposed surface than in a bulk solution [26, 55–57]. This is considered to be due to no hydrophobic interaction between hydrophobic chains in the air side. Indeed, the monolayers of perfluorinated long-chain carboxylic acids have a limited affinity for hydrocarbon-based lipids such as DPPC [26], DMPE [32], DPPG [29], and fatty acids [19]. In the case of partially fluorinated amphiphiles (here *F*8*Hm*OH), they indicate the miscibility with a variety of lipids composing biomembranes within a monolayer (see Table 48.2). In addition, *F*8*Hm*OH has the monolayer miscibility with other types of partially fluorinated amphiphiles such as *F*8*H*5PC and PBD. On the other hand, the corresponding fatty alcohols (*Hm*OH) are expectedly miscible well with the hydrocarbon-base lipids but are immiscible with a fluorinated alkane (*F*8*H*11) (see Table 48.3). This means that perfluorooctylation in lipids endows them with affinity for both *H*-chains and *F*-chains. Thus, the perfluorooctylated lipids in the monolayer state can exert the original physicochemical properties as well as the unique properties of *F*-chains mentioned in Section 48.1. Biological membranes (or biomembranes) comprise many kinds of lipids and proteins. Especially, double long-chain phospholipids such as phosphatidylcholines and phosphatidylethanolamine are their major components. In comparison to typical single-chain lipids, the molecular motion

and behavior of the phospholipids are much more complicated because of the intramolecular and intermolecular attractions between *H*-chains, which are usually restricted to spatially bulky hydrophilic groups. Even in the monolayer state, where the intermolecular interaction is simplified by the 2D treatment, the complex behavior generates unexpected influence on the monolayer properties such as ordering, packing, and phase transition. An in-depth deep understanding of phospholipid monolayers at the interface is quite important for elucidation of biomembrane functions as well as pulmonary surfactants, in particular. However, the available literature on the monolayer interaction between lipids and fluorinated amphiphiles is not yet sufficient. Further investigation on the interaction is successively necessary for use and application of materials substituted with fluorine.

48.6 CONCLUSIONS AND PERSPECTIVES

The two-component monolayers of partially fluorinated alcohols such as *F*8*Hm*OH and the lipids in biomembranes indicate lateral miscibility with each other. However, the miscibility behavior for the binary DPPC/*F*8*Hm*OH monolayers is significantly different in interaction parameter and energy. The system for $m = 5$ shows a positive interaction parameter (a negative azeotropic type), whereas the parameters for $m \geq 7$ are negative (a positive azeotropic type). In addition, it is found that *F*8*Hm*OH can be miscible with a wide range of lipid species, including fluorinated amphiphiles in the monolayer state. The accumulation effect of *F*8*Hm*OH on the human body and the environment is commonly smaller, compared to perfluorinated and highly fluorinated amphiphiles. Therefore, perfluorooctylated compounds have a potential for use and application in medical and pharmaceutical fields as well as in industrial and materials science. With the aim of such applications, partially (or hybrid-type) fluorinated compounds are currently under extensive investigation. It is hoped that a further understanding of interaction of fluorinated compounds breaks through the subject of intensive research on signal transfer via biomembranes (especially lipid rafts) and respiratory disease related to pulmonary surfactants.

AFFINITY LATEX

HARUMA KAWAGUCHI

Department of Chemistry, Faculty of Engineering, Kanagawa University, Yokohama, Japan

49.1 INTRODUCTION

49.1.1 Bioseparation

One of the most frequently used routine operations for biochemists and bioengineers is separation and purification of specific biomolecules from a mixture of various biomolecules. There are many bioseparation techniques, such as centrifugation, electrophoresis, filtration, and phase separation. Among them, chromatography is the most popular one. Chromatography is defined as a technique for separation of a specific molecule from a mixture by passing it through a material through which some parts of the mixture travel farther than others. It includes several systems, that is, adsorption chromatography, partition chromatography, gas–liquid chromatography, ion exchange chromatography, size exclusion chromatography, and affinity chromatography.

49.1.2 Affinity Chromatography

The principle of affinity chromatography is something different from those of other chromatographic methods. The general chromatography relies on differences in the physical properties of the molecules to be separated. However, affinity chromatography exploits the unique property of extremely specific biological interactions to accomplish separation.

The affinity chromatography system is constructed by the following process: (1) a ligand or probe is attached to gel beads, (2) the gel beads are packed into a column, (3) a mixture of biomolecules is forced into the column, and (4) affinity-dependent flowdown behavior enables the separation of target molecules.

Affinity chromatography has been used to identify ligand-binding proteins, nucleotides, nucleic membrane receptors, and so on. For example, a pair of investigators demonstrated the separation of a transcription factor by using a column in which sequence-specific DNA/agarose beads were packed [1].

Affinity chromatography seems to be an established technique. But it has a fatal fault due to the nature of gel beads. Efficiency of affinity chromatography needs to bind as many ligands as possible. Therefore, gel beads are chosen as a carrier of ligands because they have huge number of sites to bind ligands on the surface and in the interior. But the microenvironment in the interior network structure is not uniform. This means that the ligands are located at different microenvironments and thus their target-catching activities vary, resulting in inefficient purification of the target.

It was expected that a ligand carrier having neither micronor macropores would avoid this disadvantage. But the carrier particle of flat surface with no pores has a smaller surface area than do porous particles. In order to ensure a large surface area to the carrier particle, the size of particle should be decreased. One gram of agarose gel beads has a surface of about 6 m^2. One gram of particles with a flat surface should be 0.2 μm in diameter in order to possess the same surface area as gel beads. Because such particles of submicrometer size cannot be packed in a column, they are used in the dispersion. The dispersed particles carrying the ligand on their flat surface can meet their target molecules frequently and be expected to exhibit high efficiency in bioseparation.

Purification/separation of biomolecules by affinity latex can be done as follows: (1) adding the affinity latex to a protein mixture solution, (2) incubating them for a certain

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

time, (3) separating the latex particles that caught specific proteins from the solution, and (4) releasing the proteins from the latex particles by changing the medium. In the following section, the design of affinity latex is discussed.

49.2 IMMUNOLATEX

Before reporting affinity latex, a history of immunolatex is presented. An *immunolatex* is a latex on which an antigen or an antibody is bound. The first immunolatex appeared as a latex diagnostics for protein A in 1956 [2[. Antiprotein A antibody was immobilized on poly(vinyltoluene) particles, and the presence or absence of protein A in the patient's body was confirmed by observing the absence or presence of aggregates that resulted from the formation of antibody–antigen agglutination. In 1970, a team of researchers developed an immunolatex for cell labeling, that is, used it to find the location of its antigen on a cell surface [3, 4]. They used poly(acrolein-*co*-hydroxyethyl methacrylate) particles preferentially as a carrier of antibody due to their bioinertness [5]. Another investigator immobilized anticancer antibody on a magnetic microspheres, the size of which was comparable with that of the cells. The immune beads selectively caught cancer cells and collected by magnetic force [6]. These would be pioneer studies for affinity latex.

Other pioneer work was done using DNA-carrying microspheres. Another team developed oligothymidine (oligo[dT], degree of polymerization = 30)-carrying microspheres, which proved to be an efficient separator of mRNA from the mixture of all kinds of RNA and other substances [7]. This could be done because only mRNA has an adenine sequence at the chain ends. Single-stranded DNA-carrying microspheres were also used for solid-phase DNA sequencing [8].

49.3 MATERIALS COMPOSING AFFINITY LATEX

49.3.1 Latex Particle as a Ligand Carrier

Polymer particles are generally formed by particle-forming polymerization such as emulsion polymerization, suspension polymerization, and precipitation polymerization. Among these polymerizations, soap-free emulsion polymerization is preferred because it gives monodispersed and submicrometer-sized particles with a clean surface. The material for the polymer was carefully selected. The key criterion for the polymer particle material is its hydrophilicity–hydrophobicity balance. Latex particles with a hydrophobic surface are apt to adsorb proteins nonspecifically and, consequently, they are unsuitable for affinity latex. Several hydrophilic monomers are copolymeized with styrene in soap-free emulsion polymerization. Styrene contributes to the formation of monodisperse, spherical core particles and hydrophilic monomers do to the coating of the core with hydrophilic shell layer which keeps nonspecific proteins away in general.

TABLE 49.1 Requirements for Carrier Particles

- reject any nonspecific adsorption,
- have a site to bind a ligand,
- not disturb the specific interaction between ligand and target,
- Be easily collectable from the dispersion,

The comonomer finally chosen was glycidyl methacrylate (GMA) [9]. The polymerization was first carried out using styrene (St) with a small amount of GMA (5 wt% to St) and, at the final stage of the polymerization, additional GMA (10 wt% to St) was charged to the reaction vessel in order to form a shell layer on each particle. A part of GMA units was converted to glycelol methacrylate due to hydrolysis of glycidyl group of GMA during the polymerization.

The reason for choosing GMA as the comonomer was not only its moderate hydrophilicity to avoid nonspecific adsorption. As shown in Table 49.1, the particles have to have binding site for ligand, and GMA satisfied the requisite. Glycidyl groups in GMA units chemically bind amine groups of ligand. After binding ligands, the remaining glycidyl groups were hydrolyzed to convert them to diol groups. The P(St-*co*-GMA) core–PGMA shell particles with a diameter of ~0.2 μm thus obtained exhibited satisfactory performance in rejecting nonspecific adsorption of proteins.

49.3.2 Procedure for Binding Ligands to a Latex Particle Surface

The process to bind ligands is a crucial one for affinity latex preparation. If the ligand is bound badly to the particle, as shown in Fig. 49.1, domains *A* and *C*, the ligand has a poor ability to catch its target.

Direct binding of ligand to the particle surface sometimes gives no successful results. It was because the target molecule could not approach the ligand close to the particle surface due to steric hindrance. The example discussed below demonstrated this situation clearly.

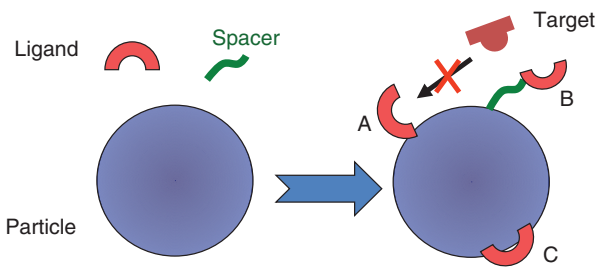

FIGURE 49.1 Mode of ligand attachment. Segments *A* and *C* are not good, but *B* is OK for catching the target.

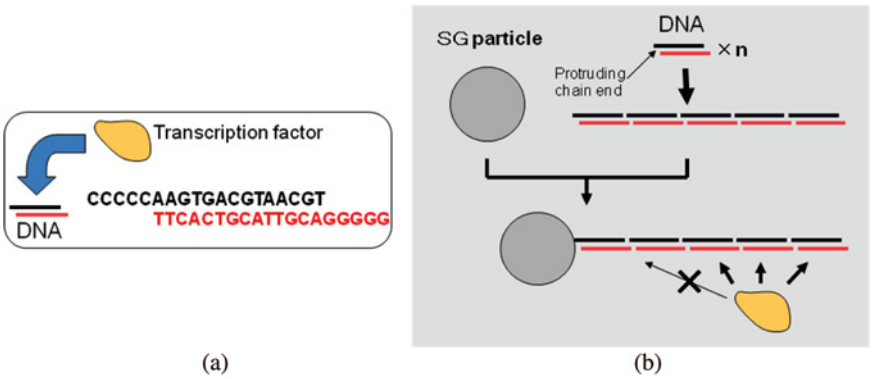

FIGURE 49.2 Preparation of sequence-specific DNA-carrying affinity particle for separation of transcription factor.

A transcription factor ATF/E4TF3 attaches specifically to a DNA with a specific base sequence (Fig. 49.2a), and the attachment switches the transcription on. Purification and concentration of the transcription factor was attempted using an affinity latex carrying the abovementioned fragment, taking advantage of the mechanism described above [9, 10]; however, it failed. The failure was attributed to steric hindrance near the ligand by a particle surface. Therefore, the DNA sequence was joined in tandem and attached to the particle surface as shown in Fig. 49.2b. This affinity latex resulted in the successful separation of pure and concentrated transcription factor from the serum. The result indicated that at least three sets of the DNA units from the surface of particles contributed as a spacer.

The recommendable spacers were oligoethyleneoxide, ethylene glycol diglycidyl ether, and glycil glysine for general targets.

49.3.3 Binding Site of Ligand Molecule

The choice of binding site of the ligand is another important consideration. The first event of some drugs injected into the body is to attach to their receptors on cell surfaces. This scheme is applicable for detection of the drug's receptor using drug-carrying affinity particles. The examined drug was naltrindole (NTI; Fig. 49.3, center) [11]. NTI was bound to a latex particle through three directions, *A*, *B*, and *C*. Use of affinity latices on which the drug was attached to the particles at *B* and *C* resulted in unsuccessful capture of target protein, but use of affinity latex carrying the drug at *A* brought about efficient capture of the target. These results imply that *B* and *C* domains in NTI are essential for pharmacologic activity.

Screening of biomolecules for a specific compound is one of the major purposes of affinity latex. Successful results were obtained and the mechanism and kinetics of their binding reaction [12, 13] For example, an affinity latex carrying a DNA-binding transcription factor caught eight polypeptides, which were found to be bound to the same DNA sequence and regarded as a family concerning to transcription.

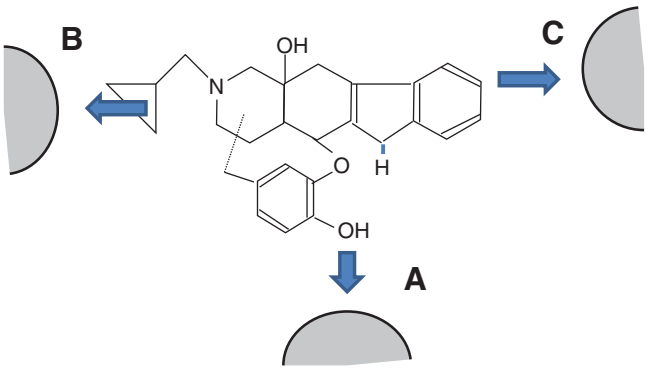

FIGURE 49.3 Choice of binding site of drug onto latex particle.

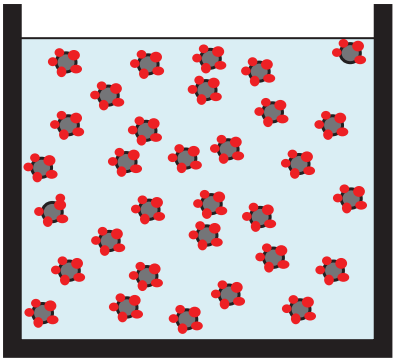
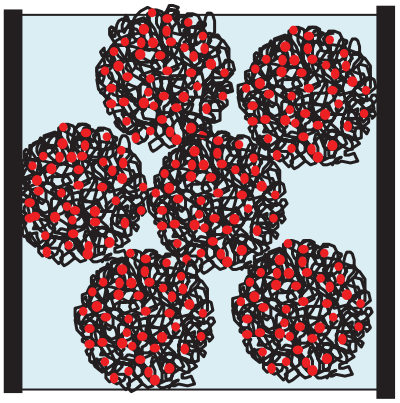
49.4 COMPARISON BETWEEN AFFINITY COLUMN CHROMATOGRAPHY AND AFFINITY LATEX

As presented in the previous section, affinity latex exhibited an excellent ability to separate its receptor protein from a mixture of proteins. Here, the ability of the affinity latex is compared with that of affinity column chromatography. Table 49.2 shows the differences of two systems in terms of the location of ligands, the chance of ligands to encounter the targets, recovery of separated targets, and so on.





Differences in the homogeneity of the microenvironment surrounding a ligand and the action of the ligand seem to indicate that the affinity latex method is more efficient than affinity column chromatography.

49.5 FEATURES OF AFFINITY LATEX

49.5.1 Specific Base Sequence ssDNA-Carrying Affinity Latex

A complementary DNA pair in its solution forms a double-stranded DNA spontaneously below its specific melting temperature. A pair of one-point mismatch DNA also forms a

TABLE 49.2 Comparison between Affinity Latex and Affinity Column Chromatography

	Affinity latex	Affinity column chromatography
		
Reaction site	particle surface	pores in gel particle
Homogeneity of the site	high	miscellaneous
Action of ligand	approaching to target	waiting for targets
Dead volume	small	large
Recovery of targets	release of them from gathered particles	collection of flow

moderate amount of double-stranded DNA under the same conditions if the DNA is composed of more than 20 bases. But this was not the case in the affinity latex system in one study [14]. The experiment was carried out using the following procedure [14]: (1) DNA-S was bound to a particle, (2) a dispersion of particle S was mixed with a solution of DNA-A or DNA-B, and (3) the amount of hybrid (A/S or B/S) was measured as a function of time.

In that study [14], 50% of A hybridized with particle S within 1 h whereas the amount of B/S hybrid was almost 0; this means that the hybridization efficiency was almost zero at room temperature (see Fig. 49.4).

Another experiment was done by mixing both solutions of DNA-A (labeled) and DNA-B simultaneously with the dispersion of particle L. In this competitive hybridization, the amount of A/L hybrid was measured by the label. It was confirmed that the coexistence of DNA-B with 300 times DNA-A did not disturb the hybridization of A with particle L.

Both experiments strongly indicated that the DNA bound on a particle surface had a strong affinity to capture its complement DNA and, on the other hand, strongly refuted

FIGURE 49.4 DNA used for determination of hybridization efficiency.

hybridization with mismatched DNA. This was attributed to the relative inflexibility of the DNA bound to the particle surface. Such DNA would not be efficient at fitting the conformation with mismatch DNA:

$$\left(\frac{\text{dsDNA of mismatch pair}}{\text{dsDNA of complementally pair}}\right)_{\text{in solution}} \gg \left(\frac{\text{dsDNA of mismatch pair}}{\text{dsDNA of complementally pair}}\right)_{\text{on latex}}$$

49.5.2 Speedy Recovery of Target-Capturing Affinity Particles

The first-generation affinity latex was recovered from the medium by centrifugation after hybridization. Because the particles were small (<1 μm), centrifugation at >12,000 × g for >30 min was necessary to sediment them out of the medium. However, such a severe condition could potentially damage the target molecules and reduce the efficiency of the separation process. To overcome this disadvantage, another method to recover the affinity particles was examined and magnetic force was chosen as an alternative option [15]. First, composite particles, including magnetic nanoparticles, were prepared. Various methods are used to entrap magnetic nanoparticles in polymer particles; these fall into two basic categories: (1) direct entrapment of nanoparticles and introduction of precursor and (2) introduction of precursor of magnetic nanoparticles followed by in situ nanoparticle formation. The suitable size of magnetic particles embedded in affinity latex particles was estimated to be around 20 nm.

49.6 NOVEL AFFINITY LATEX

49.6.1 Capture and Cutting Affinity Latex

An affinity latex with dual functions was developed. It is P(St-*co*-GMA) core/PGMA shell particle carrying mismatch binding protein (MutS) and an anthraquinone derivative (AQ). AQ is a light-activated agent that photocleaves dsDNA [16]. This novel affinity latex can catch and cleave mismatched DNA selectively and propose a new mismatch detection system. Use of the affinity latex made it possible to discriminate complementary and mismatched DNA and photocleave only mismatched DNA. The efficiency of photocleavage increased with UV irradiation time.

49.6.2 Affinity Latex for the Detection of Telomerase

Highly sensitive detection of telomerase enables us to detect many kinds of cancers in early stage, and also gives us much important information about cell biology. This was made possible by an affinity latex that detected G4-DNA generated from elongation of telomere by telomerase [17]. The measurement using SPR biosensor increased the sensitivity drastically.

49.7 CONCLUDING REMARKS AND FUTURE PROSPECTS

Since the first immunolatex was proposed as a latex diagnostics, submicrometer-sized particles have been used for biomedical applications. Affinity latices should be inert particles to nonspecific biomolecules but have high affinity with specific target molecules. Such an affinity latex could be obtained by careful binding of ligand molecules on well-designed polymer particles. Affinity latices are applied not only to various bioseparations but also to identification of drug receptors, to activation of cells, and so on.

The ability of biomolecules to bind to a particle surface but the feature that causes them to thereby become less flexible and increase the recognition ability might be applicable to the control of biomolecules functions.

LATEX DIAGNOSIS

HARUMA KAWAGUCHI
Department of Chemistry, Faculty of Engineering, Kanagawa University, Yokohama, Japan

50.1 INTRODUCTION

Early detection of disease is necessary to ensure high quality of life. Many diagnostic methodologies such as fluorescence-, radio-, enzyme-linked, and chemiluminescence immunoassays, enzyme-linked immunosorbent assay, Western blotting, and agglutination testing, were developed and their advantages have been increasingly evident. Among them, latex diagnostics cut a conspicuous figure because of its unique process in which latex particles carrying antigen or antibody, called *immunolatex*, are ingeniously used for a variety of assays [1]. There are three major types of immunolatex: an agglutination test caused by antigen–antibody interaction, particle-enhanced immunoassay, and multiplex assay.

50.2 MATERIALS COMPOSING IMMUNOLATEX

The basic event in latex diagnostics is enabled by cooperation between antigen, antibody, and latex particles, the features of which are introduced below.

50.2.1 Antigen and Antibody

An *antigen* is a substance that generates the respective antibody (e.g., the Y-shaped protein shown in Fig. 50.1) and binds to it specifically by means of its variable region interaction. Antigens are usually proteins and polysaccharides, less frequently also lipids, that originated from within the body or from the external environment. The latter, such as bacteria and viruses, are recognized as invaders and are attacked by the antibody. The binding reaction between antigen and antibody produces aggregates with high specificity and precision. Therefore, if the body fluid of a patient generates aggregates when mixed with a solution containing a tiny amount of antibody, we can recognize the existence of an antigen in that patient's body.

50.2.2 Latex Particle

A *latex* is the aqueous dispersion of polymer particles. Latices are generally prepared by procedures such as emulsion polymerization, soap-free emulsion polymerization, and miniemulsion polymerization. The reaction medium is water in most cases. These polymerizations produce mostly monodispersed, submicrometer-sized polymeric particles with huge specific surface areas. The stability of particles in dispersion should be controlled by considering the long-term storage and the quick assay. A moderate degree of stability is attained by achieving balance between electrostatic repulsive force and van der Waals attractive force.

The surface of particles can be modified, if necessary, to accept the binding or adsorption of immunocompounds.

50.3 DESIGN OF IMMNOLATEX

50.3.1 Hemagglutination

As mentioned above, antigen and antibody coagulate specifically and, in some cases, the size of aggregates reaches the one observable macroscopically. The diagnostics obtained via such observation is referred to as a *direct* (or *active*)

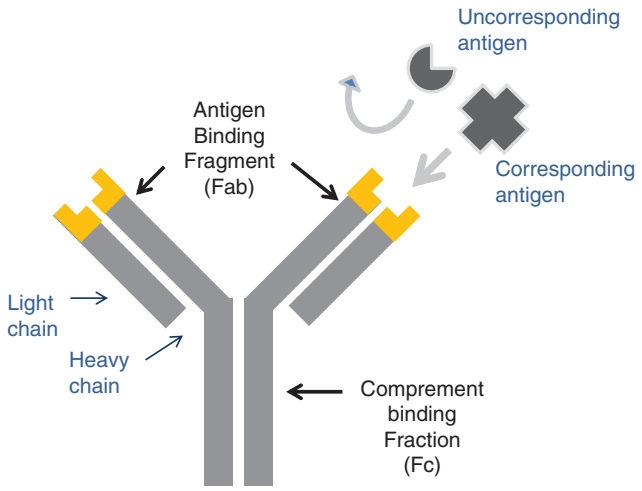

FIGURE 50.1 Structure of antibody.

agglutination test. But usually the products of agglutination are too small to confirm their presence or absence or to measure their size quantitatively. To detect the antigen–antibody agglutination more clearly, the antibody molecules were attached to a red cell in order to convert independent antibody molecules to multiple valence antibodies [2]. The multiple valence antibodies contributed to the formation of massive aggregates, as illustrated in Fig. 50.2. This diagnostic methodology using antibody-sensitized red cells is referred to as *reversed passive hemagglutination* (RPHA). The term *passive* indicates that the agglutination occurs with the aid of a carrier, in this case, a red cell, that is sensitized with immunocomponent. The system in which a red cell carries antigen is called simply a *passive hemagglutination system*, where *reversed* indicates that the particle (red cell) is sensitized with antibody but not antigen. If a red cell holds any antigen by nature, the system is classified as a direct agglutination system.

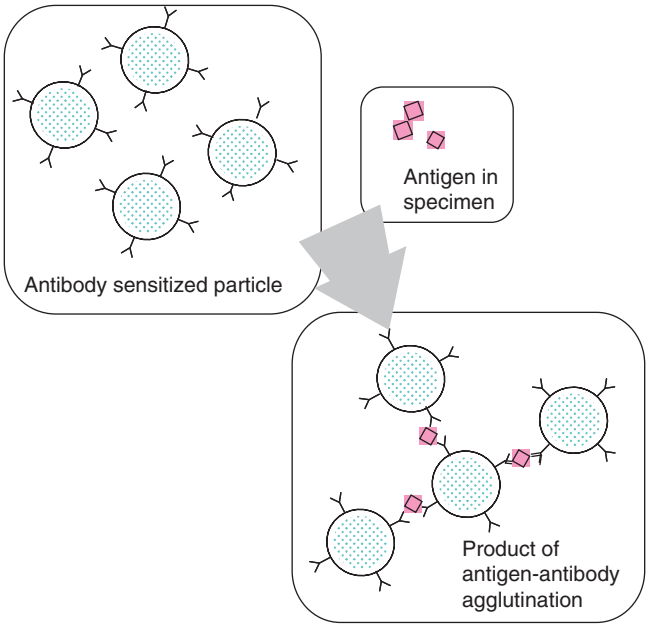

FIGURE 50.2 Typical agglutination using sensitized particle.

50.3.2 Use of Latex Particle as Carrier of Immunocomponents

A red cell is a suitable carrier for antigen or antibody, but it includes some drawbacks. For instance, a red cell itself is sometimes antigenic, with diameter size limited to around 7 μm. It is fragile and is not suited for long-term storage. In contrast to a red cell, a latex particle has the following merits: (1) no antigenicity, (2) high productivity, (3) controllable size and surface chemistry, and (4) high storage stability. Because of these advantages, latex particles are preferred to red cells as carriers of immunocomponents.

The first immunolatex was reported in the literature in 1956 [3]. It consisted of a dispersion of poly(vinyltoluene-*co*-styrene) microspheres carrying antirheumatoid antibody. Aggregates formed when the latex was mixed with the blood sample of a patient who was positive for the rheumatoid factor, due to antigen–antibody binding as shown in Fig. 50.2. Thus, the extent of aggregate formation is regarded as the measure of rheumatism.

Singer's immunolatex yielded successful results to some extent. But it had some disadvantages, namely, unavoidable nonspecific adsorption and low efficiency of aggregate formation.

50.3.3 Improvement of Immunolatex in Terms of Sensitization Mode

There are two strategies for the selection of particle material, that is, to use hydrophobic particles or hydrophilic particles.

50.3.3.1 Hydrophobic Particle as a Carrier. The surface of latex particle is generally hydrophobic. Such surface is favorable to adsorb an antigen or an antibody so that the hydrophobic particle surface can be sensitized easily by a simple adsorption process. Adsorption is generally done in a phosphate buffer saline at room temperature for 1–2 h.

The adsorption of proteins to a hydrophobic surface is not limited to that of targeted immunomolecules but also takes place for nonspecific molecules. Therefore, the surface must be converted to hydrophilic one after sensitization. Generally the surface modification can be done by covering the hydrophobic surface with albumin or poly(ethylene glycol) adsorbed spontaneously [1]. The particles thus obtained have a sterically stabilized surface. The extent of steric stabilization must be controlled properly because colloidal stability

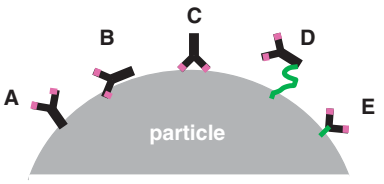

FIGURE 50.3 Style of immobilized antibody.

that is either too low or too high can reduce the sensitivity of latex diagnostics.

Biomolecules have their specific conformation. In particular, the conformation around the functional domain is important. Each antibody has a specific domain, a fragment of antigen binding site called *Fab*, that recognizes and binds its counterpart antigen at the edge of a Y-shaped molecule (Fig. 50.1). Fab fragment should be exposed to the medium (Fig. 50.3 pattern A) but B and C must be avoided. The pH at which an antibody molecule is attached is an important factor in controlling the orientation of antibody on the particle surface. Fc fragment was preferentially adsorbed to the surface at pH > 8 because the hydrophobic attractive force between Fc fragment and the particle surface overcame the electrorepulsive force between them, but this was not the case for less hydrophobic Fab [4]. As mentioned above, Fc does not directly contribute to antigen–antibody agglutination and even obstructs it in some cases. Therefore, $(Fab)_2$ is sometimes separated from Fc by pepsin and only V arms [$(Fab)_2$] can be bound to the particle surface (Fig. 50.3, pattern *E*) [5].

50.3.3.2 Hydrophilic Particle as a Carrier. Aiming to avoid nonspecific adsorption in the course of agglutination test, a particle with a hydrophilic surface can be used as a carrier of antigen or antibody, In this case, spontaneous adsorption of an antigen or an antibody to hydrophilic particles does not take place. Therefore, sensitization of hydrophilic particle can be done by chemical bonding of immunocompounds. In this case, carboxy, hydroxy, amino, epoxy, and aldehyde groups on the particle surfaces are commonly used for binding with amino groups in antibody molecules. Among binding reagents, carbodiimide is the most popular one. The carbodiimide method requires the inclusion of an activation process of carboxy groups of particles prior to reaction with amino groups of antibody. Undesirable side reactions caused by carbodiimide may result in denaturing and/or cross-linking. Glutalaldehyde is commonly used to bind the amino groups of the particle and antibody molecules. CNBr and sulfonyl chloride are used to activate glycol groups and hydroxy groups, respectively, on the particle to bind antibody at its amino group

50.3.3.3 Use of Spacer. To separate Fab from the particle surface and avoid the steric hindrance of antigen–antibody reaction, antibody is bound to the particle not directly but through a linker or spacer as shown in pattern *D* in Fig. 50.3. The linker would be hydrophilic chains of 6–10 atoms such as ethyleneglycol diglycidyl ether and glycil glycine.

50.4 MEASUREMENT OF AGGLUTINATION

50.4.1 Patterns of Agglutination Test

The extent of antigen–antibody agglutination is detected by several means, from qualitative to highly quantitative ones. The simplest one is observation of the products of agglutination on a petri dish, although it is only a qualitative check. Semiquantitative measurement is done using a titer in which samples with different dilutions are charged and the figure of agglutinated precipitates on the bottom of each well is observed. Carrier particles with large diameter and high density are used in order to shorten the time for aggregate formation.

The extent of agglutination is quantitatively detectable by spectroscopy as shown in Table 50.1.

Transmitted light through the sample presented the change in turbidity caused by antigen–antibody agglutination. This refers to as immunoturbidmetric test and the detectable concentration of antigen is 10^{-9}–10^{-4} mol/L. The turbidity of dispersion depends not only on the particle size but also on the wavelength of incident light. In a latex photometric immunoassay (LPIA), the initial rate of turbidity change at 940 nm on mixing a specimen with immunolatex of relatively small particle size, is measured to quantitatively determine the antigen or antibody (10^{-11}–10^{-7} mol/L) [6]. The near-nfrared wavelength was chosen for the determination because the turbidity at 940 nm highly depends on the size of aggregates.

The turbidity is a result of scattering. Therefore, the intensity of scattered light is another measure of the extent of agglutination. This is nephelometric immunoassay (NIA), in which the detectable concentration is 10^{-10}–10^{-5} mol/L. The size of particles used for these measurements ranges from 100 to 500 nm in general. The large particles present high sensitivity in agglutination test, but such particles lack the dispersion stability.

The principle of particle-counting immunoassay (PACIA) is different from those of the abovementioned methods. In

TABLE 50.1 Optical Measurements for Agglutination Testing

Method	Detected light
Turbimetric	Transmitted light
Nephelometric	Forwardscattered light

Particle counting	—

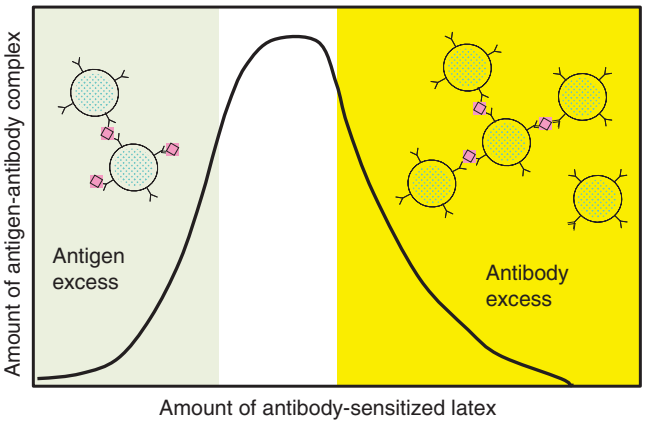

FIGURE 50.4 Dependence of agglutination on amount of titrant (antibody-sensitized latex).

PACIA the distribution of individual particles and two- and three-particle aggregates or the amount of unreacted individual particles can be measured. It counts the latex aggregates (P) and single latex particles (M) and the value of P/(P+M) is applied to a calibration curve to estimate the concentration of antigen [7].

The small increments in average diameter caused by weak agglutination can be measured by photon correlation spectroscopy (PCS), capillary hydrodynamic fractionation, laser photoacoustic spectroscopy, and similar methods. The latex particles used for these highly sensitive tests must be extremely monodisperse, and any aggregates must be eliminated in the original dispersion.

50.4.2 Antigen Excess Zone

The antibody or antigen excess zone is an important consideration. In the titration of antibody to a sample solution including antigen, the turbidity increases with increasing titrant (see Fig. 50.4) but then gradually levels off. Further addition of antibody results in a decrease in the turbidity. This is the antibody excess zone in which the aggregates, once formed, redissolves, due to the poor antigen–antibody balance.

A drawback of these latex systems is the narrow concentration range of detectable target compounds, antigen or antibody. To overcome this drawback, a latex composed of a wide distribution of size of particles is used.

50.5 LATEX DIAGNOSTICS INDEPENDENT FROM AGGLUTINATION

A particle capture enzyme-linked immunosorbent assay (PC-ELISA) is discussed here. It includes two methods: a "sandwich" method and a competitive method, which are illustrated in Fig. 50.5. The immunolatex is first captured on

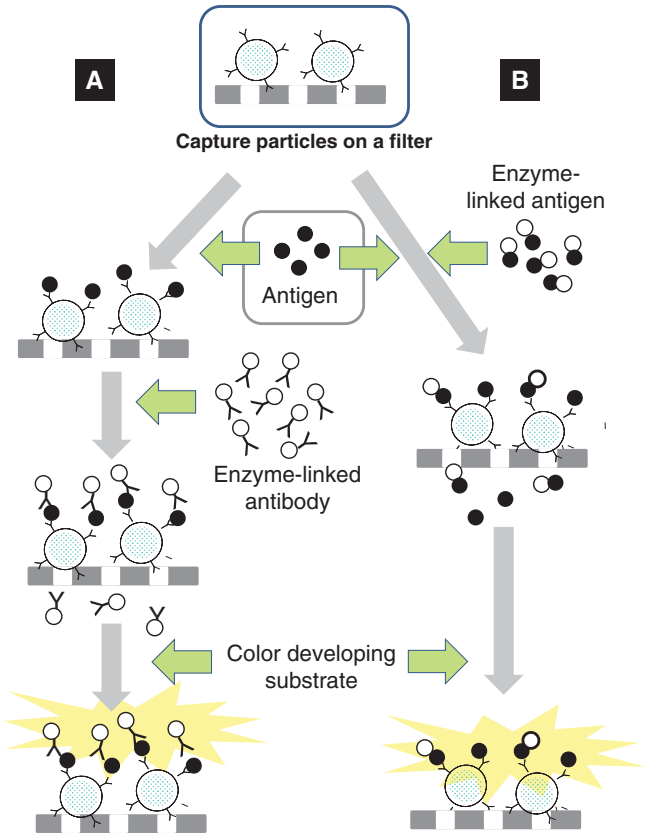

FIGURE 50.5 Particle capture enzyme-linked immunosorbent assays: (a) sandwich method; (b) competitive method.

a filter in both methods. A specimen is added on it. In the sandwich method, an antibody –antigen – antibody sandwich forms if the specimen includes antigen. In the competitive method, an enzyme-linked antigen is added simultaneously with the specimen and competitive adsorption takes place between antigen and enzyme-linked antigen to the antibody on the particle surface.

All of unbound antigen and enzyme-linked antigen are filtered out and the color intensity on the filter is measured to determine the antigen. The color-developing process can be omitted if enzyme is replaced with any colorant.

Another method is used to carry out ELISA with no particle trapping on a filter. In this method, antibody-carrying particles react with antigen molecules followed by sandwich formation with enzyme-linked antibody in the dispersion. Then the particles are recovered from the dispersion. The determination of the antigen is carried out in the same manner as that for ELISA. This method is referred to as *chemiluminescence enzyme immunoassay* (CLEIA). A similar assay using fluorescence instead of enzyme is becoming popular [chemiluminescence immunoassay (CLIA)]. Magnetic immunoparticles are used for these assay system because of enhancement of particle recovery.

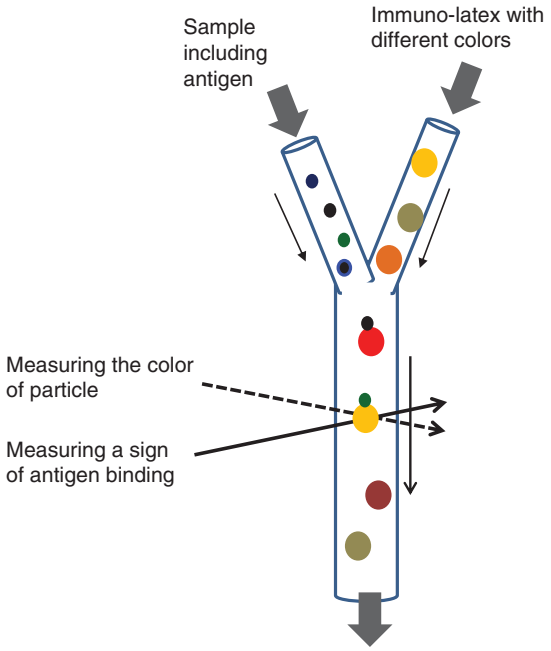

FIGURE 50.6 Multiplex assay using bead array.

50.6 MULTIPLEX ASSAY USING AFFINITY LATEX

Multiplex assay is defined as the assay for simultaneous detection of multiple targets by using multiple ligands. This assay needs only very small amount of samples and, therefore, patients suffer little pain. Speed is another merit of the multiplex assay. There are two types of multiplex assay systems: one that is composed of chips and another one that is composed of dispersing particles. In the former, each ligand is identified by the position on a chip. In contrast, in multiplex assay using affinity particles, called *suspension array* or *bead array*, each particle in the dispersion carries its own sign, or barcode, to indicate its identity as presented in Fig. 50.6 [8,9].

Color, size, density, electric charge, and other parameters have been used for the barcode. A series of multicolored particles were obtained by mixing multiple dyes or quantum dots (QD) with different mixing ratio [10]. For example, 100 kinds of microbe were prepared by combining different amounts of two kinds of fluorescent dyes with 10 concentrations per dye into the beads with a diameter of 5 μm. Such beads are identified in a flow cell by the specific fluorescence emitted from each dye embedded in the beads. In some QD-assisted multiplex assay systems, leakage of QD caused problems. To prevent leakage of QDs, silica nanoparticles were deposited on the polymer particles to form silica shell [11].

50.7 CONCLUDING REMARKS AND FUTURE PROSPECTS

Latex particles provide an excellent carrier for bioassays because of their bioinertness, uniformity, abundant lineup, controllable dispersion stability, and other factors. In addition, development of instruments participates in further progress of latex diagnostics to raise the sensitivity, reduce the amount of specimen, and shorten the measurement time.

LIGHT SCATTERING AND ELECTROPHORETIC LIGHT SCATTERING OF BIOPOLYMERS

ETSUO KOKUFUTA

Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan

51.1 INTRODUCTION

In general, the term *biopolymer* refers to proteins, polysaccharides, polynucleotides, and bacterial aliphatic polyesters. In 2012 the IUPAC recommended the use of the term *biomacromolecule* when molecular characteristics are considered [1]. The light-scattering methods, usually separated into static light scattering (SLS) and dynamic light scattering (DLS), are a useful experimental tool to explore characteristics of macromolecules in solutions, so most of the discussion focuses on the SLS and DLS of biomacromolecules. This is case for electrophoretic light scattering (ELS), by which the electrophoretic mobility of macromolecules bearing charges can be determined and if necessary, the mobility can be converted into zeta-potential.

51.2 STATIC LIGHT SCATTERING

Static light scattering (SLS) is founded on the principle of Rayleigh scattering, which is the scattering of light by particles and molecules that are much smaller than the wavelength of the light [2]. The scattered intensity is then characterized by the *Rayleigh ratio* $R(\theta)$, which is defined as $R(\theta) = (i_\theta r^2)/(IfV)$, where I is the intensity of the incident light, i_θ is the total intensity of scattered light observed at an angle θ and a distance r from the point of scattering, and V is the scattering volume. The factor f is dependent on the polarization of the incident light: $f = 1$ for vertically polarized light, $f = \cos^2\theta$ for horizontally polarized light, and $f = (1 + \cos^2\theta)/2$ for unpolarized light. In Rayleigh light scattering, it is well known that $R(\theta)$ is proportional to the product of molar mass (M) and weight concentration (c) of particles or molecules. The proportional constant is often regarded as an optical constant (K), and for vertically polarized light it can be given as $K = (4\pi^2 n_0^2/N_A\lambda^4)(\partial n/\partial c)^2$, where n_0 is the refractive index of the pure solvent, N_A is the Avogadro number, λ is the incident light wavelength, and $\partial n/\partial c$ denotes the refractive-index increment. Thus, $R(\theta)$ expressed by $R(\theta) = KMc$, but this is true for only very small rigid objects.

When the scattering objects are polymers, we must consider the effects of polymer–solvent interactions. Also, the effects arising from their shape anisotropy must be considered. The former can be treated by the virial expansion of the osmotic pressure, and the latter is accomplished by introduction of the particle-scattering function $P(\theta)$, which is often called the *particle form factor*. As a result, the fundamental equation for SLS, which is useful for determining the weight-average molecular weight M_w, the z-average radius of gyration $\langle R_g\rangle_z$ (hereafter simply denoted as R_g), and the second virial coefficient A_2, can be given as follows [3–5]:

$$\frac{Kc}{R_\theta} = \frac{1}{M_w P(\theta)} + 2A_2 c + \cdots = \tag{51.1a}$$

$$\frac{1}{M_w}\left(1 + \frac{16\pi^2}{3\lambda^2}R_g^2 \sin^2\left(\frac{\theta}{2}\right) + \cdots\right) + 2A_2 c + \cdots \tag{51.1b}$$

Note that $P(\theta)$ is defined as the ratio of the intensity of radiation scattered at an observation angle θ to the intensity of radiation scattered at an angle zero and can be related to R_g by $P(\theta) = 1 - (16\pi^2 R_g^2/3\lambda^2)\sin^2(\theta/2) + \cdots$. Also note that

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

this equation is combined with Eq. (51.1a) using the relation of $1/(1-x) \cong 1+x$.

In actual SLS measurements, the calibration of SLS instruments is required with standard pure liquids whose Rayleigh ratios are known [6–8]. For this, toluene is frequently used because the Rayleigh ratios of toluene are suitably high for precise measurements and are known over a range of wavelengths and temperatures. Now we consider the excess Rayleigh ratio $\Delta R_\theta (= R(\theta)_{solution} - R(\theta)_{solvent})$, although R_θ in Eq. (51.1a) should have been written as ΔR_θ in the strict sense. When calibration is performed with toluene as the reference with a known absolute scattering intensity, ΔR_θ can be given as

$$\Delta R_\theta = \left(\frac{\Delta I_\theta}{I_{tol}}\right)\left(\frac{n_0}{n_{tol}}\right)^2 R_{tol} \tag{51.2}$$

where $\Delta I_\theta (= I_{solution} - I_{solvent})$ is the excess light-scattering intensity (i.e., the difference between the scattering intensities at angle θ for a solution and for a pure solvent), I_{tol} is the scattering intensity of toluene at θ, n_0 is the refractive index of the solvent (used for sample preparation), n_{tol} is the refractive index of toluene, and R_{tol} is the Rayleigh ratio of toluene. In Eq. (51.2), the term $(n_0/n_{tol})^2$ is the factor used to correct the scattering volume [9, 10]. Combination of Eqs. (51.1b) and (51.2) gives

$$\frac{Kc}{\Delta R_\theta} \equiv \frac{1}{M_w}\left(1 + \frac{R_g^2 q^2}{3}\right) + 2A_2 c \tag{51.3}$$

In Eq. (51.3), the scattering vector q, defined as $q = 4\pi n \sin(\theta/2)/\lambda$ (where n is the refractive index of the solution), is used. Also, the contribution of terms higher than the third one, shown by dots in Eq. (51.1b), is neglected in common practice.

Equation (51.3) becomes $Kc/\Delta R_\theta = M_w^{-1} + 2A_2 c$ at $q = 0$ (or $\theta = 0$) and $Kc/\Delta R_\theta = M_w^{-1} + R_g^2 (3M_w)^{-1} q^2$ at $c = 0$. When the ΔR_θ values obtained at different concentrations and at different angles are plotted against $q^2 + kc$ (where k is an arbitrary constant used to adjust the scale), the extrapolation allows us to determine the $\lim_{q\to 0}(Kc/R_\theta)$ values at different c and the $\lim_{c\to 0}(Kc/R_\theta)$ values at different q (see Fig. 51.1). As a result, we can obtain (1) M_w from the intercept of the $\lim_{c\to 0}(Kc/R_\theta)$ versus $q^2 + kc$ curve and of the $\lim_{q\to 0}(Kc/R_\theta)$ versus $q^2 + kc$ curve, (2) R_g from the slope of the $\lim_{q\to 0}(Kc/\Delta R_\theta)$ versus $q^2 + kc$ curve, and (3) A_2 from the slope of the $\lim_{c\to 0}(Kc/\Delta R_\theta)$ versus $q^2 + kc$ curve.

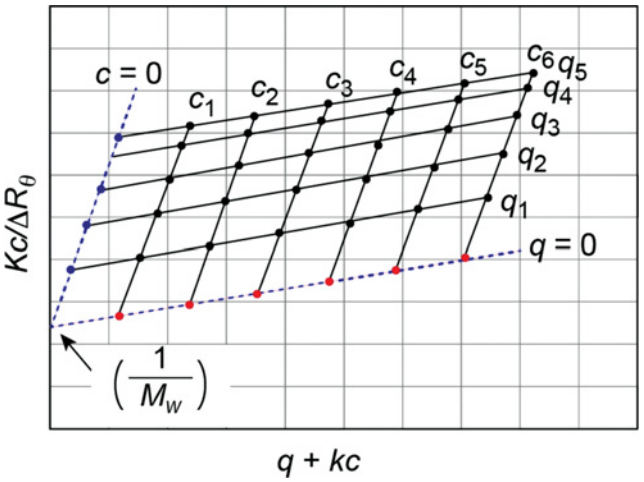

FIGURE 51.1 Schematic Zimm plot. See text on how to determine M_w, R_g, and A_2.

51.3 DYNAMIC LIGHT SCATTERING

While in SLS the time average of the scattering intensity (i.e., the absolute mean intensity) is measured, *dynamic light scattering* (DLS) analyzes the fluctuations of the scattering intensity caused by the Brownian motion of particles or molecules in solution. DLS is also known as *photon correlation spectroscopy* (PCS) or *quasielastic light scattering* (QELS). Methodologically, the DLS measurements performed in the 1950s and 1960s utilized optical *heterodyne* detection techniques [11, 12], which will be described later in this chapter. According to the author's literature survey, it seems that the principle of measuring the time-dependent fluctuation in the scattering intensity was established in the late 1960s [13]. The *homodyne* DLS measurements, which are now common, were likely to be started in the 1970s [14–18]. To understand the measuring principle, let us consider the case in which the particles in solution are illuminated by a coherent light source, typically a laser. The movement of the particles causes either constructive or destructive interference of the scattered light. The sum of these interferences generates a "speckle" pattern consisting of bright spots (due to constructive interference) and dark spots (due to destructive interference). Because the speckle pattern fluctuates in time, due to the mutual movements of the particles, the time-dependent change in the intensity of one speckle would provide their dynamic information.

As shown in Fig. 51.2, in DLS the time dependence of the scattering intensity is first measured. The time correlation of the intensity is then examined with the intensity $I(t)$ detected at a time t and the intensity $I(t+\tau)$ after a delay of τ. In practice, the second-order autocorrelation function $g_2(\tau)$ is obtained directly from the software of the correlator during the measurement.

$$g_2(\tau) = \frac{\langle I(t) \cdot I(t+\tau)\rangle}{\langle I(t)\rangle^2} \tag{51.4}$$

Here, the brackets denote an average over the duration of the intensity measurement. In some cases, $g_2(\tau)$ is referred

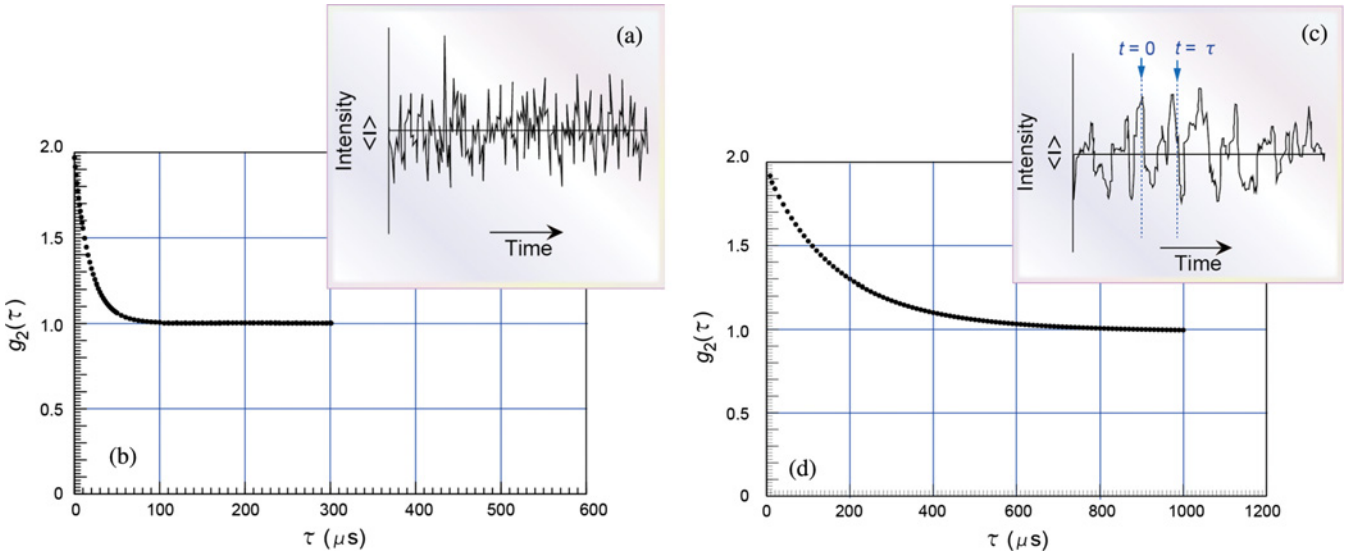

FIGURE 51.2 Typical examples of time dependence of scattering intensity (a,c) and for second-order autocorrelation function $g_2(\tau)$ (b,d). (a,b) Monodisperse gold particles with a diameter of 10 nm; (c,d) polystyrene latex particles with an average diameter of 100 nm. Note that parts (a) and (c) contain the illustration, whereas the $g_2(\tau)$ curves are raw data obtained from the correlator.

to as the *normalized intensity autocorrelation function* and written as $G(\tau)$, instead of $g_2(\tau)$. Because $g_2(\tau)$ or $G(\tau)$ is a function of the scattering vector q, expression $g_2(q, \tau)$ or $G(q, \tau)$ is also used. In addition, by considering the intensity $I(0)$ at a time $t = 0$ and the intensity $I(t)$ after a delay time of t, the second-order autocorrelation function in normalized form can also be written as $g_2(t)$ or $G(t)$ or $g_2(q, t)$ or $G(q, t) = \langle I(0) \cdot I(t) \rangle / \langle I \rangle^2$.

As can be seen from Fig. 51.2, $g_2(\tau)$ at short delay times is usually large, indicating a high correlation because of a few movements of particles from the initial state. However, $g_2(\tau)$ decays exponentially with an increase in τ, and becomes unity at the final state. This means that there is no correlation between the scattered intensity of the initial and final states after the elapse of long periods. Large particles diffuse more slowly than small particles, so that $g_2(\tau)$ decays at a slower rate (compare Fig. 51.2c,d). As a result, $g_2(\tau)$ in Eq. (51.4) provides the raw DLS data for analyzing the correlated movement of the particles, from which the size and size distribution of particles or molecules in solution can be calculated.

To analyze the DLS data, $g_2(\tau)$ is related to the first-order autocorrelation function $g_1(\tau)$, which is often referred to as the *electric field autocorrelation function*, using the Siegert relation [19]

$$g_2(\tau) = 1 + \beta |g_1(\tau)|^2 \tag{51.5}$$

where $\beta (\leq 1)$ is a constant, which depends an apparatus and measuring conditions, such as the number of coherence areas that generate the signal. In other words, β is an indication that we must factor in deviations from ideal correlation, so that we may perform DLS measurements under the most suitable conditions through examination of β. It should be noted that when $g_2(\tau)$ is not normalized, that is, when $g_2(\tau) = \langle I(t) \cdot I(t + \tau) \rangle / \langle I(t) \rangle^2$, the Siegert relation is given as $g_2(\tau) = B[1 + \beta |g_1(\tau)|^2]$, where B is the experimental baseline and should be equal to unity. However, in practice, a small amount of noise in the measurement can result in values that differ from unity by small ($\leq 10^{-4}$) amounts.

Once the $g_1(\tau)$ data have been obtained, different mathematical approaches can be employed to determine the size distribution profile of particles or molecules in solution. The simplest approach is to treat the center-of-mass diffusion of identical, monodisperse particles, because $g_1(\tau)$ can be given as

$$g_1(\tau) = \exp(-\Gamma\tau) \tag{51.6a}$$

$$\Gamma = q^2 D \tag{51.6b}$$

Here, Γ is the decay or relaxation rate, D is the diffusion coefficient of the particles, and q is as above. When using the Stokes–Einstein relation, we may calculate the hydrodynamic radius R_h from

$$R_h = \left(\frac{kT}{6\pi\eta} \cdot \frac{1}{D} \right) \tag{51.7}$$

where k is the Boltzmann constant, T is the absolute temperature, and η is the viscosity of the solvent. For identical particles, there is no angular dependence of D, so that R_h from Eq. (51.7) is of real value for a spherical particle in solution.

Indeed, the plot of $\ln[g_2(\tau) - 1]$ against τ from Fig. 51.2b can be fitted by a relation of $y = -0.0560x - 0.0356$ with the squared correlation coefficient (r^2) of 0.999, provided that $\Gamma = 2.80 \times 10^{-2}\ \mu s^{-1}$ and $\beta = 0.965$. Consequently, we obtain $R_h = 5.3_{(5)}$ nm by Eqs. (51.6b) and (51.7). However, in the case where the plot of Γ/q^2 against q^2 shows an angular dependence, particles are not spherical in shape. Thus, a high-quality DLS analysis must be performed at several angles, in particular for a polydisperse sample with an unknown particle size distribution.

For polydisperse systems, the correlation function $g_1(\tau)$ can be expressed as an integral of the exponential decays weighted over the distribution of relaxation rates $G(\Gamma)$

$$g_1(\tau) = \int_0^\infty G(\Gamma) \exp(-\Gamma\tau)\, d\Gamma \qquad (51.8)$$

The distribution $G(\Gamma)$ contains information about the diffusion characteristics of each particle in the population; therefore, it is of importance to extract $G(\Gamma)$ from $g_1(\tau)$ in Eq. (51.8). In principle, inversion of $g_1(\tau)$ is possible, but this is regarded as an ill-posed problem. Several numerical methods developed so far are devoted to the calculation of $G(\Gamma)$. One of the most common methods is a cumulant expansion [20] of $g_1(\tau)$ in Eq. (51.8), from which we obtain

$$g_1(\tau) = \exp\left(-\bar{\Gamma}\tau\right)\left(1 + \frac{\mu_2}{2!}\tau^2 - \frac{\mu_3}{3!}\tau^3 + \cdots\right) \qquad (51.9)$$

Here, $\bar{\Gamma}$ is the first cumulant (average decay rate) and μ_2 and μ_3 are the second and third cumulants. The relation of $\bar{\Gamma}$ and q is given by

$$\bar{\Gamma}/q^2 = D_{m,z}(1 + Cq^2R_g^2 + \cdots) \qquad (51.10)$$

where $D_{m,z}$ is the z-averaged mutual diffusion coefficient, and R_g is as above and becomes $L/(12)^{1/2}$ for a thin rod of length L. The coefficient C of the second term is the initial dependence of the first cumulant on q^2 and is found to increase with an increase in polydispersity, as well as in rotation for rods. We must remember that the cumulant method is valid for small τ and sufficiently narrow $G(\Gamma)$. An attempt to fit $g_2(\tau)$ in Fig. 51.2d with Eq. (51.9) provides a relation of $ln[g_2(\tau) - 1] = 2.67 \times 10^{-6}\tau^2 - 5.58 \times 10^{-3}\tau - 0.0357$ ($r^2 = 0.999$, within the second cumulant), from which we obtain $\bar{\Gamma} = 2.95 \times 10^{-3}\ \mu s^{-1}$, $\beta = 0.965$ and $\mu_2/\bar{\Gamma}^2$ (as the polydispersity index) = 0.189. Thus, the size of the particle in Fig. 51.2d is found to be almost 10 times larger than that in Fig. 51.2b.

An alternative method is used to analyze the autocorrelation function $g_1(\tau)$ for either heterodisperse or polydisperse, and multimodal distribution systems that cannot be resolved with the cumulant method; for example, note the bimodal $g_2(\tau)$ curve in Fig. 51.3a. This analytical method is a Laplace inversion program, which is called as CONTIN and was developed by Provencher [21]. A peak constrained analysis CONTIN allows us to provide a distribution function (spectrum) of Eq. (51.8), because we can modify Eq. (51.8) as

$$g_1(\tau) = \int_{-\infty}^{\infty} \Gamma G(\Gamma) \exp(-\Gamma\tau) d \log(\Gamma/q^2) \qquad (51.11)$$

so as to plot $\Gamma G(\Gamma)$ in an ordinate and $\log(\Gamma/q^2)$ in an abscissa (see Fig. 51.3b). The area under the each peak corresponds to the weight of each peak. Consequently, we may obtain the average decay rates $\langle\Gamma\rangle$ for each particle in solution. It should be noted that the R_h calculated from $\langle\Gamma\rangle$ with Eqs. (51.6b) and (51.7) is the averaged value for a hydrodynamically equivalent spherical particle or molecule.

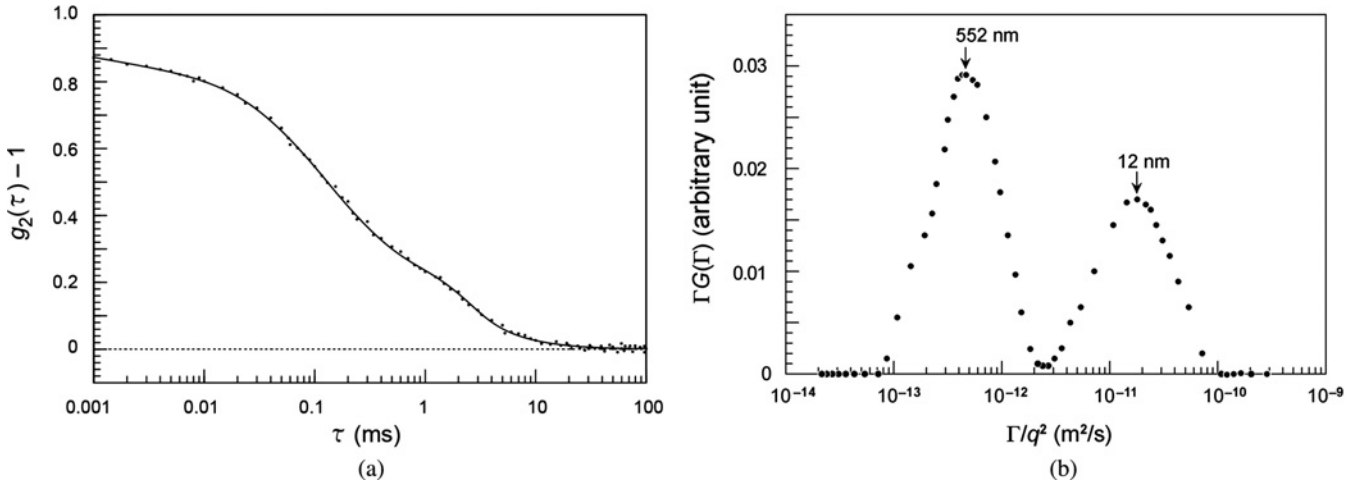

FIGURE 51.3 Typical example for a bimodal system in which protein molecules with an apparent R_h of 12 nm aggregate to form larger particles ($R_h \approx 552$ nm on average). (a) $g_2(\tau)$ curve; (b) result of CONTIN for the $g_2(\tau)$ in (a).

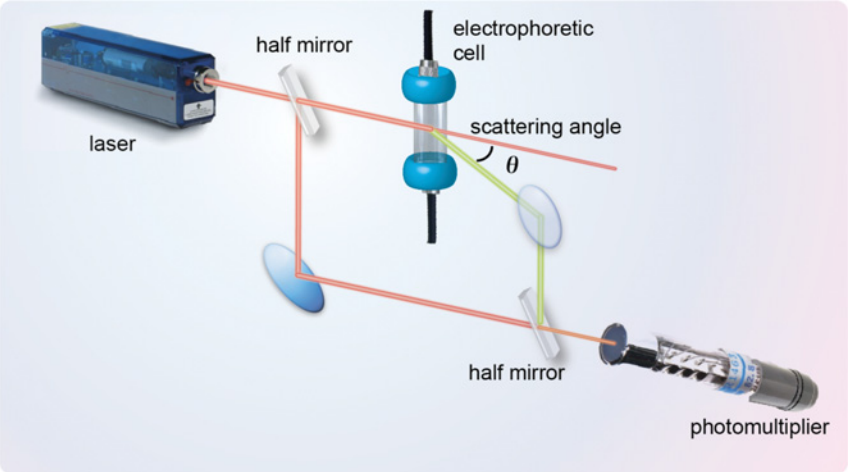

FIGURE 51.4 Simple heterodyne optical system for ELS. Note that the scattering light beam (dashed line) is mixed with the incident beam (solid line) via the half-mirror placed in the front of the photomultiplier.

51.4 ELECTROPHORETIC LIGHT SCATTERING

In *electrophoretic light scattering* (ELS) the motion of charged particles or molecules in solution is measured under an applied oscillating electric field. This is the main difference from DLS that relies on the Brownian motion as mentioned previously. Conventional DLS techniques employ *homodyne* scattering principles, in which all of the photons of light that reach a detector (photomultiplier) are scattered from the sample. In the case of ELS, however, the scattered light from the sample is mixed with unscattered reference light (usually the incident light) at the detector (see Fig. 51.4). This method is referred to as *heterodyne detection*, from which we can obtain a beat signal proportional to the Doppler shift or phase change in the scattered light (see Fig. 51.5a,b).

When the scattered light is mixed within a strong component of the incident radiation, we can obtain a spectrum that contains only the low-frequency beats between the incident frequency of the radiation and the frequency of scattered light. The resultant spectrum in the absence of the electric field is a Lorentzian curve centered at zero frequency, and the corresponding autocorrelation function is an exponential decay. In the presence of an electric field, the current spectrum is shifted from zero frequency by an amount equal to the original Doppler shift from the incident frequency, and the corresponding autocorrelation function is a damped cosine wave whose frequency is equal to the Doppler shift and whose decay constant is the same as that in the absence of the field. As a result, we may obtain the electrophoretic mobility of charged particles or molecules in solution. However, as shown in Fig. 51.5c, the heterodyne power spectrum

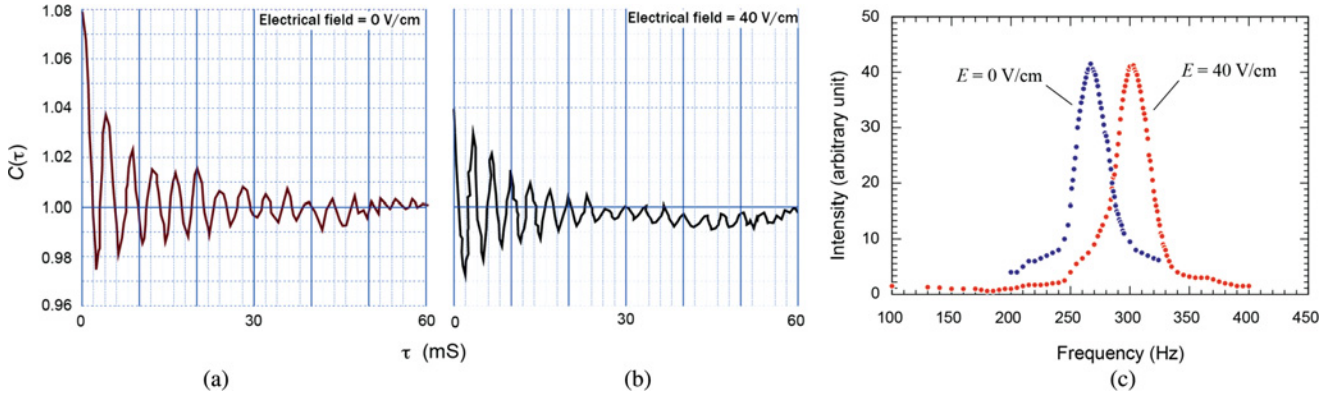

FIGURE 51.5 Determination of Doppler frequency shift due to motion of charged particles under an applied electric field. Graphs (a) and (b) show damping autocorrelation functions $C(\tau)$ with and without electric field. Graph (c) shows the power spectra obtained by fast Fourier transform of the correlation functions in graphs (a) and (b).

obtained by Fourier transform of the correlation function in the absence of the electric field (i.e., $E = 0$ V/cm) does not manifest a peak at zero frequency. This means that the heterodyne correlation functions include the contribution due to the Brownian motion of particles (see discussion below); thus a difference between the frequencies of spectra at $E = 0$ V/cm and 40 V/cm corresponds to the Doppler shift in this case. References 22–29 provide more details.

In practice, the first-order autocorrelation function $C(\tau)$, often referred to as the *photon-counting heterodyne correlation function*, for a solution with an electrophoretically monodisperse solute, can be written as [27]:

$$C(\tau) = \beta_0\delta(\tau) + \alpha_0 + \alpha_1 \exp(-2\Gamma\tau) + [\alpha_2 \exp(-2\Gamma\tau) \times \cos(\Delta\omega\tau)] \quad (51.12)$$

Here β_0, α_0, α_1, and α_2 are constants dependent on the optical system but independent of correlation time τ, and $\delta(\tau)$ is the delta function. The first two terms consist of the intensities of the reference light and the scattered light and are independent of the frequency. The next term includes the normalized electric field autocorrelation function because $\Gamma(= Dq^2)$ has the same definition as in DLS; see Eq. (51.6b). The fourth term in brackets, in which $\Delta\omega$ is a frequency shift of the heterodyne signal, as mentioned above, is due to simultaneous electrophoresis and diffusion. The Fourier transform of Eq. (51.12) with respect to time, as stipulated by the Weiner–Khinchine theorem [30], gives the power spectrum

$$S(\omega) = \beta_0 + \alpha\delta(\omega) + \frac{2(\alpha_1/\pi)\Gamma}{(\omega + \Delta\omega)^2 + \Gamma^2} + \frac{\alpha_2\Gamma}{2\pi}\left(\frac{1}{(\omega + \Delta\omega)^2 + \Gamma^2} + \frac{1}{(\omega - \Delta\omega)^2 + \Gamma^2}\right) \quad (51.13)$$

where α is a constant independent of the incident light frequency ω. In both Eqs. (51.12) and (51.13), $\Delta\omega$ is expressed as $\Delta\omega = |\omega_s - \omega_r| = |(\omega - \omega_D) - (\omega - \omega_M)|$, where ω_s is the angular frequency of the scattered light, ω_r is the angular frequency of the reference beam and is the same as that of the incident beam (i.e., $\omega_r = \omega$), ω_D is the Doppler frequency, and ω_M is the modulation frequency. Since the frequency of the incident beam is modulated in the scattered light by the amount of ω_D, $\Delta\omega$ is given as

$$\Delta\omega = \frac{2\pi n}{\lambda} EU \sin\theta \quad (51.14)$$

where E (V/cm) and U (μm/s)/(V/cm) are the applied electric field strength and electrophoretic mobility, respectively. Therefore, U can be directly evaluated from frequencies of the power spectrum.

In actual ELS measurements, $\Delta\omega$ varies depending on the position within the measuring cell, due mainly to the electroosmotic flow. Thus, the mobility obtained from Eq. (51.14) without considering electroosmotic effects is only an apparent value. Many efforts have been made to improve ELS instrument, mainly in optical system and cell geometry, as well as to develop computer software for analyzing the autocorrelation function and for displaying the power spectrum. As a result, it is possible to see how the mobility varies with the electroosmotic effect; for example, see Fig. 51.6, which illustrates the power spectra at different positions in a rectangular ELS cell. Now, highly precise measurements of electrophoretic mobility can be performed with ELS instruments commercially available from several manufacturers. Once the mobility is obtained, the zeta-potential (ζ) can be calculated by the Smoluchowski equation: $\zeta = 4\pi\eta u/\varepsilon$, where ε is the dielectric constant of the solvent. However, it should be noted that charged macromolecules (polyelectrolytes), which behave in sedimentation or diffusion as an impermeable coil, should behave in electrophoresis as if they were free draining. In such cases, the calculation of ζ from the mobility is scientifically meaningless. Also noted is the electrophoretic behavior of a particle composed of a hard core plus a shell of charged hairy surface-layer, the theory of which has been proposed by Ohshima [31]. A more recent publication [32] provides more detailed information about free draining or partially free-draining behavior in the electrophoresis.

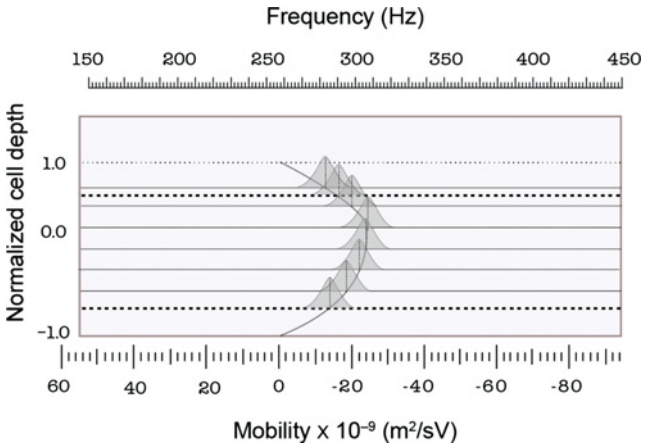

FIGURE 51.6 Electroosmotic flow profile obtained from ELS of bovine serum albumin (pH = 7.0; ionic strength = 0.015) using a rectangular cell (17 mm in length, 10 mm in width, and 2 mm in depth). Two broken lines show the positions of the stationary layer at which the electroosmotic flow is eliminated.

51.5 DISCUSSION AND CONCLUSION

Both SLS and DLS, as well as ELS, have been common tools in the characterization of a variety of colloid and polymer systems including biomacromolecules. Our recent interest is how to explore colloid–colloid and colloid–polymer interactions, as well as polymer–polymer interactions, in the absence or presence of additives via a "clever" combination of light-scattering techniques. As a simple example, let us

consider the aggregation of pure and monodisperse proteins with or without additives. Both M_w (absolute molar mass in this case) and R_g can be determined by SLS. A single exponential fit of the DLS data would provide an "apparent" R_h value. Also, examination of the plot of Γ/q^2 against q^2 at different scattering angles provides information about whether the protein is spherical in shape. In addition, the protein charges at given solution conditions become apparent from the ELS data. Even when the protein molecules aggregate, DLS and ELS can also be used because both techniques are applicable to the sample of known concentration. For example, a multimodal system consisting of the native protein and its aggregates may be examined by the CONTIN analysis of the DLS data. Also, ELS tells us the ionization states of protein particles leading to their aggregation. The problem is the use of SLS. In principle, the SLS measurement is impossible when the CONTIN analysis shows bimodal or more complex distributions. In addition, there is a restriction on the size of particles or molecules to be measured, called the *Rayleigh–Debye–Gans approximation* (RDGA).

To clarify particle size limits for SLS measurements, we have to go back to two theories of light scattering, which were proposed by Rayleigh and Mie. In Rayleigh scattering, the size of the particles is assumed to be much smaller than the wavelength of light, so that the particles act as point sources of scattered light. In practice, it is often estimated to be less than $\lambda/10$ (or $\lambda/20$), corresponding to ~60 (or 30) nm in diameter when He-Ne laser ($\lambda = 632.8$ nm) is a light source. If the particle sizes exceed this limit, we must consider Mie scattering [33], in which the particles are relatively large (diameter $\approx \lambda$), and the refractive index of the dispersed phase is significantly different from the dispersion medium. However, such simple discussions do not provide a clear answer as to how particle sizes and what geometries of particles are suitable for SLS, because in actual SLS measurements we have to consider various types of particles, such as multilayer spheres, clustering spheres, core–shell particles, and so on. Thus, a more real example [34] is shown below, in order to facilitate a discussion about how to combine SLS, DLS, and ELS to study the complex formation of protein with water-soluble polymers.

The complex formation of human serum albumin (HSA) with poly(*N*-isopropylacrylamide) (PNIPA) was studied in an aqueous acidic solution (pH 3) containing 0.01 M NaCl as a supporting salt [34]. Three PNIPA samples of different molar mass were used: PNIPA(L), $M_w = 1.72 \times 10^6$; PNIPA(M), $M_w = 4.82 \times 10^5$; and PNIPA(S), $M_w = 2.10 \times 10^4$. The HSA–PNIPA mixtures were prepared over a wide range of mixing ratio (r_m) given by $r_m = (C_{PNIPA}/C_{HSA})(M_{HSA}/M_{PNIPA})$, where C_{PNIPA} and C_{HSA} are the concentrations (in mg/mL) of PNIPA and HAS, respectively, and M_{HSA} is the molar mass (66,436 g/mol) of HAS and M_{PNIPA} is the M_w of each PNIPA. DLS and ELS were first performed to examine the complex formation. In DLS all of the $g_2(\tau)$ functions were analyzed by the CONTIN program.

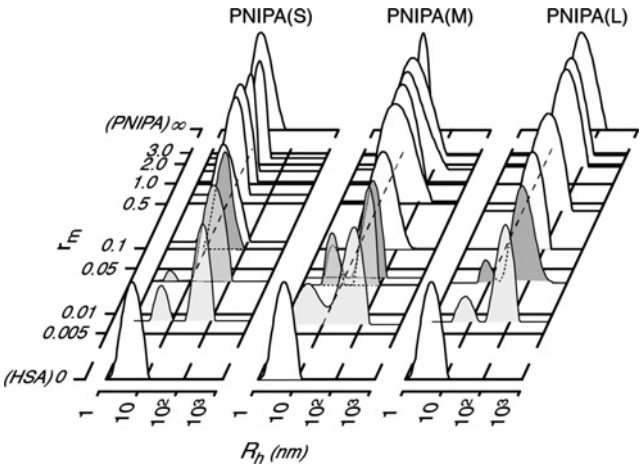

FIGURE 51.7 Results of DLS for HSA mixtures with three PNIPA samples as a function of r_m. Complexation was studied at 25°C, ionic strength = 0.01 (NaCl), pH = 3.0 and $C_{HSA} = 0.1$ mg/mL. Some distributions are distinguished in different shades of gray. Bimodal distributions due to the coexistence of the uncomplexed HAS and the HAS-PNIPA complex can be observed at $r_m < 0.1$ (protein-rich mixtures). (This drawing was reproduced from Ref. 34 with several modifications.)

It was found that DLS shows the presence of excess HSA in a low r_m range (see Fig. 51.7), whereas ELS detected excess PNIPA in a high r_m range (see Fig. 51.8). These results indicate the formation of water-soluble complexes in the HAS-PNIPA mixtures. However, unfortunately, the resulting complexes cannot be isolated from the mixture, due to weak protein–polymer interactions. Therefore, one may consider that SLS cannot be used in this case. Nevertheless, several modifications of Eq. (51.1b) allow us to use the SLS for examining the HAS-PNIPA mixtures containing water-soluble complexes. First, the concentration C_x and molar mass M_x of the complex were expressed as $C_x = C_{PNIPA}(1 + \beta)$ and $M_x = \alpha M_{PNIPA}(1 + \beta)$, according to mass balance requirements. Here, β represents the mass ratio of bound protein to the polymer and α is the number of polymer chains within one complex particle, that is, the number of aggregated *intrapolymer* complexes. Next, it was assumed that "unmeasurable" refractive-index increments $(dn/dc)_x$ of the complex can be expressed as $(dn/dc)_x = [1/(1 + \beta)](dn/dc)_{PNIPA} + [\beta/(1 + \beta)](dn/dc)_{HSA}$, where $(dn/dc)_{PNIPA}$ and $(dn/dc)_{HSA}$ are the "measurable" refractive index increments of PNIPA and HAS, respectively. Then, Eq. (51.1b) can be rewritten as

$$\frac{K'C_{PNIPA}}{R_\theta} = \frac{1}{\alpha M_{PNIPA}B^2}\left(1 + \frac{16\pi^2}{3\lambda^2}R_g^2 \sin^2\left(\frac{1}{\theta}\right)\right) + 2A_2C_{PNIPA}\left(\frac{1+\beta}{B}\right)^2 \quad (51.15)$$

where $K' = (4\pi^2 n_0^2/N_A\lambda^4)$ and $B = (dn/dc)_{PNIPA} + \beta(dn/dc)_{HSA}$.

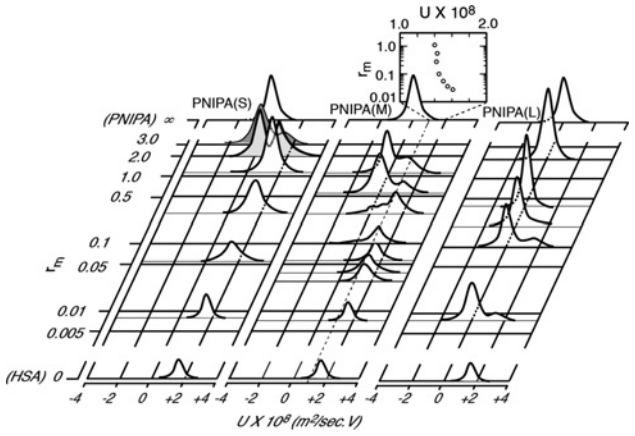

FIGURE 51.8 Results of ELS for HSA mixtures with three PNIPA samples as a function of r_m. Complexation was studied under the same conditions as mentioned in Fig. 51.7. Some distributions are distinguished in different shades of gray. From several PNIPA-rich mixtures ($r_m > 1.0$), a peak appears at mobility (U) = 0 m^2/sV, due to the presence of uncomplexed PNIPA, which is a neutral polymer. This trend is contingent on the M_w of PNIPA, because the scattering intensity strengthens with increasing M_w even when the polymer has no charge. (For more detail, see the original paper [34], from which this figure was reproduced with several modifications.)

Figure 51.9 shows typical examples of a "modified" Zimm plot for the HSA complexes with PNIPA(M) at $r_m = 1.10$ and with PNIPA(L) at $r_m = 0.00773$. For SLS measurements, C_{NIPA} was varied so as to remain constant r_m, because a marked r_m dependence of R_h was observed from Fig. 51.7 In addition, DLS was always performed over the range of 30° $\leq \theta \leq$ 140° before SLS to determine the best-suited power of the incident light at which the $g_2(\tau)$ gives a monomodal profile with the CONTIN program. As a result, the double extrapolations of $K'C_{PNIPA}/R_\theta$ versus $\sin^2(\theta/2) + kC_x$ plots to $\theta \to 0$ and $C_{PNIPA} \to 0$ gave two straight lines with correlation coefficients $r^2 > 0.99$, simultaneously intersecting the Y axis. However, M_x, A_2, and R_g cannot be estimated unless α is known. Thus, the second assumption was made, which is $\alpha \equiv 1$, meaning the formation of an intramolecular complex in the present case. This allows us to calculate β from an intersection on the Y axis of Fig. 51.9 Then, the following data are obtained: $M_x = 7.48 \times 10^5$ g/mol, $A_2 = -2.38 \times 10^{-5}$ $cm^3 \cdot mol/g$, and $R_g = 79$ nm for the HSA-PNIPA(M) complex; and $M_x = 2.40 \times 10^6$ g/mol, $A_2 = -1.38 \times 10^{-5}$ $cm^3 \cdot mol/g$ and $R_g = 203$ nm for the PNIPA(L) complex. Since the number (n) of the HAS molecules bound per chain of PNIPA can be given by $n = \beta(M_{PNIPA} + M_{HSA})$, we can obtain $n \approx 4$ for the complex at $r_m = 1.10$ and $n \approx 10$ for the complex at $r_m = 0.00773$. In the SLS analysis used here the two assumptions were made, so that the data must be confirmed by the other experimental method. For this, dialysis experiments were performed to estimate the β value, from which the n value was calculated. It was found that the n values obtained from SLS and dialysis experiments agree within ± 1, meaning that the analytical approach used here is proper.

Now let us go back to the discussion about particle size limits for SLS measurements. DLS provides $R_h = 35.9$ nm for PNIPA(L) with $M_w = 1.72 \times 10^6$ and $R_g = 63.4$ nm, both of which were determined by SLS. Because SLS was performed with the Ar–ion laser ($\lambda = 488$ nm), $\lambda/10$ becomes approximately 49 nm in diameter. Thus, it seems that SLS is not suitable for the characterization of PNIPA(L). In the case of polymer coils, however, the point sources of scattered light can be considered as "segments" of a polymer chain. According to Flory [35], the size limit for SLS measurements of polymers is within $0.1 < \sqrt{r^2}/\lambda < 1$, where $\sqrt{r^2}$ is the root-mean-square distance and is given by $\sqrt{r^2} = \sqrt{6} \times R_g$.

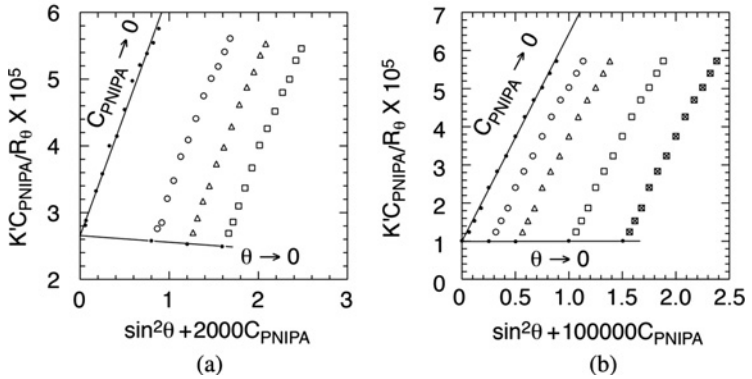

FIGURE 51.9 Modified Zimm plots for HSA mixtures with PNIPA(M) at $r_m = 1.10$ (a) and PNIPA(L) at $r_m = 0.00773$ (b). To retain constant r_m, both PNIPA and HAS concentrations (in g/mL) were varied: $C_{PNIPA} = 4 \times 10^{-4}$ and $C_{HSA} = 5 \times 10^{-5}$ (open circle), $C_{PNIPA} = 6 \times 10^{-4}$ and $C_{HSA} = 7.5 \times 10^{-5}$ (open triangle), $C_{PNIPA} = 8 \times 10^{-4}$ and $C_{HSA} = 10 \times 10^{-5}$ (open square) for PNIPA(M); $C_{PNIPA} = 2.5 \times 10^{-6}$ and $C_{HSA} = 1.25 \times 10^{-5}$ (open circle), $C_{PNIPA} = 5 \times 10^{-6}$ and $C_{HSA} = 2.5 \times 10^{-5}$ (open triangle), $C_{PNIPA} = 10 \times 10^{-6}$ and $C_{HSA} = 5 \times 10^{-5}$ (open square), $C_{PNIPA} = 15 \times 10^{-6}$ and $C_{HSA} = 7.5 \times 10^{-5}$ (open square with a cross) for PNIPA(L). (This illustration was reproduced from Ref. 34 with several modifications.)

For PNIPA(L), $\sqrt{r^2}/\lambda \approx 0.3$, suggesting that the SLS can be performed within the size limit. For the HAS–PNIPA(L) complex at $r_m = 0.00773$, $\sqrt{r^2}/\lambda \approx 1.02$, so that there remains the question of whether the SLS data are correct. However, as shown in Fig. 51.9, the Zimm plot is normal. Also, the negative A_2 is interpreted as a result of the attractive interaction between the complex particles. Far more important than these is the fact that there is a good agreement between the n values from the SLS and dialyzing experiments. On the other hand, the complex is considered to be a cluster of spheres, consisting of a PNIPA chain and the bound HAS particles. Consequently, the elements within the protein (as a hard particle) and the segments within the polymer chain act as scattering points, which cause the elastic scattering without loss of energy. A more detailed discussion of this issue can be found in a particular report [36] in which the complex formation between oppositely charged microgels ($R_h \approx 120$–160 nm) was studied by SLS and DLS.

Finally, we have to consider multiple scattering, because the light-scattering methods assume that each detected photon has been scattered by the sample exactly once. When examining various sorts of particles or molecules by the light-scattering techniques (mainly DLS and SLS, but also ELS), however, we will encounter multiple scattering, wherein photons are scattered multiple times by the sample before being detected. This is a very difficult issue, particularly for the reasons as mentioned above. In DLS experiments, a *cross-correlation* technique to suppress undesired contributions from multiple scattering has been reported [37–39]. This technique can be used to correct SLS data for multiple scattering contributions [40]. However, it is likely that such a light-scattering apparatus is not commercially available at the present, so that we need to be conscious of current needs and future trends in this field.

IMPACT OF LINE TENSION ON COLLOIDAL SYSTEMS

Hiroki Matsubara, Takanori Takiue, and Makoto Aratono
Department of Chemistry, Faculty of Sciences, Kyushu University, Fukuoka, Japan

52.1 INTRODUCTION

Line tension τ is the excess energy associated with the unit length of a contact line between either (1) two or (2) three coexisting interfaces. For case 1, the line tension is regarded as a natural analog of the surface tension between two bulk phases and therefore, in this case, the line tension takes only positive values. For case 2, with three coexisting interfaces, the line tension can be negative because of the interplay between these interfaces.

In both cases, theoretical estimates for the magnitude of the line tension lie in the range from 10^{-10} to 10^{-12} N, and therefore it has been considered that the effect of line tension is negligible compared to that of interfacial tension unless the system of interest has macroscopic size. However, it is also true that τ plays an increasingly important role in the stability of microscopic systems as the radius of contact line perimeter r decreases. In practice, the line tension becomes comparable to the interfacial tension when r is less than 10^{-6} m. Therefore, renewed interest in line tension has been generated recently by the advent of nanotechnology.

However, despite its technological importance, there is a still great scarcity of experimental information on line tension, primarily because line tension as measured by different researchers is still quite variable and controversial. In this review, we tried to choose reliable experiments of both types 1 and 2 line tension. Determination as to whether a literature presented good data is obtained line tension behavior can be explained reasonably by theory and/or by macroscopic observation such as domain deformation, budding of bilayer membrane, and spontaneous lens splitting. Hence, we focused on the theoretical interpretation of line tension data in this review as well as the methodology of line tension measurements.

This review is organized as follows. Section 52.2 describes the techniques used to determine type 1 line tension for condensed domains in Langmuir monolayers. How to control the domain line tension is explained in Section 52.3. The relation between the domain line tension and stability of vesicles is then discussed in Section 52.4. Type 2 line tension is the focus of Sections 52.5–52.7. The basic concept of this line tension is introduced in Section 52.5 in terms of wetting transition. Then, this is extended to understand the physicochemical behavior of other related systems, namely, fine particles at fluid–liquid interfaces (Section 52.6) and thin liquid films in foam systems (Section 52.7). Section 52.8 summarizes the main conclusions and proposes some interesting future topics.

52.2 DOMAINS IN LANGMUIR MONOLAYERS

Langmuir monolayers at the air–water interface often exhibit a first-order transition between a fluidlike lower-ensity phase (liquid-expanded state: LE) to a condensed phase (liquid-condensed state: LC) [1]. An essential feature of this transition is the existence of the gentle plateau region(s) in the surface pressure and area isotherm. In such systems, the line tension first produces an energy barrier for nucleation of the LC phase domain. However, once the coexistence of several LC domains is achieved, line tension promotes growth of the LC domains to reduce the total length of the phase boundary. In this second process, the electric repulsion between

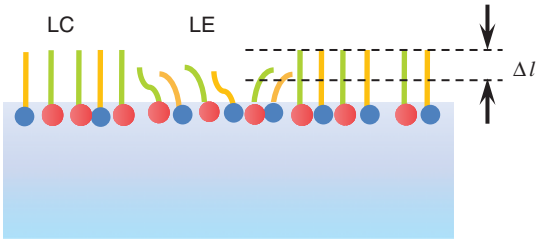

FIGURE 52.1 A schematic illustration of the generation of domain line tension between LE and LC phases.

hydrophilic groups of amphiphile molecules in each domain counteracts the domain growth.

In the simple expression, the line tension of the domain perimeter is given by [2]

$$\tau = \gamma \Delta l \tag{52.1}$$

where γ denotes the surface tension of the domain walls in the air and Δl is the difference in the height between the domain and surroundings (Fig. 52.1). One team of investigators considered the effect of electrostatic repulsion between molecules within an isolated condensed film domain and derived an expression for the edge energy E of a circular domain given by [3,4]

$$E = 2\pi R \left[\tau - \left(m^2/4\pi\varepsilon_0\epsilon\right) \ln(4R/e^2\delta)\right] \tag{52.2}$$

where R is the radius of domain, m (C m^{-1}) is the dipole moment density difference between the domain and the surrounding area, ε_0 (C^2 J^{-1} m^{-1}) is the permittivity of vacuum, ϵ is the dielectric constant of water, δ is a closest approach cutoff distance with an order of magnitude of an intermolecular distance. In Eq. (52.2), it is assumed that the condensed phase is isotropic and the molecular dipoles are perpendicular to the plane of monolayer (equivalent dipole model). From Eq. (52.2), one can realize that the optimal size of the 2D domains under consideration is determined by the competition between these two terms; the line tension term favors one large domain in order to minimize the energy penalty of the perimeter, whereas the electric repulsion favors coexistence of smaller domains. It is also revealed that elongated or striped domains can be observed in real experiments when strong electrostatic repulsion exists between hydrophilic groups [5,6].

Structuring in Langmuir monolayers has been a topic of longstanding interest [7–10]. In particular, from the perspective of domain line tension, the mixed monolayer of sphingolipid, phospholipid, and cholesterol has been studied widely because of its close relation to the raft formation in biomembranes [11, 12]. In such a ternary system, sphingolipid and cholesterol form a solidlike domain called *liquid-ordered phase* L_o, surrounded by phospholipid-rich fluid like phase (*liquid-disordered phase* L_d) because of tight molecular packing between them. It is believed that sphingolipid/cholesterol-rich domains, called *lipid raft*, have a strong affinity to certain proteins and are attributable for some important cell functions such as cell signaling [13]. Langmuir monolayers of these lipids are therefore useful model membrane to understand the structure–function relation of real biomembranes. The abovementioned McConnell theory was also based on the fluorescence microscopy studies on the domain formation in lipid Langmuir films.

A more recent development of the theoretical treatment of this issue was given by a team of researchers [2] who extended the standard thermodynamic theory of self-assembly of amphiphile molecules in 3D systems to the 2D domains in a lipid– cholesterol binary system. The free-energy balance between headgroup repulsion and hydrocarbon tail attraction in micellar systems was replaced by that between line tension and dipole repulsion, and the entropy of mixing in solid domains was also introduced to calculate the free energy as a function of domain aggregation number. From their model, it was revealed that lipid domains with finite size distribution can be allowed as thermodynamic equilibrium state under limited conditions.

In most cases, the line tension of domains in Langmuir films was determined indirectly by means of theoretical analysis of shape relaxation process of artificially deformed circular domains [14–16]. Both fluorescence microscopy and Brewster angle microscopy (BAM) are utilized to visualize lipid domains. The former method uses fluorescent phospholipid analysis, which preferentially partitions in the cholesterol-poor phase; therefore, the lipid condensed domains appear dark. On the contrary, in the latter case, the *p*-polarized light reflected from the air–water interface is detected at the Brewster angle of pure water. The condensed film domain reflects incident *p*-polarized light because of its large difference in dielectric constant from pure water; thus, in this case, the domain itself appears bright in obtained images.

One of the examples of such relaxation is shown in Fig. 52.2 The bola-shaped domain created by flow shear of water subphase shrinks toward the circular domain by line tension that is opposed by the viscous drag of the water subphase. In the low Reynolds number limit, the velocity of bola shrinking is given by [14]

$$V = 3\tau/8\eta R \tag{52.3}$$

where η is the viscosity of the subphase and R is the radius of a single bola. The line tension extracted from this relation was up to several hundreds pN. These values roughly coincided with theoretical estimation, but the error of measurements were no better than ±20%. Another team pointed out that the difficulty to measure perturbations that deform original circular domain and proposed original hydrodynamic model to describe domain relaxation [16].

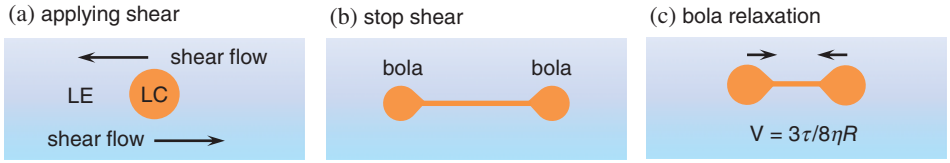

FIGURE 52.2 Principle of line tension measurement by the domain shape relaxation technique.

Figure 52.3 shows more direct method to obtain domain line tension in Langmuir films [17]. Here optical tweezers apply forces in the range of pN on the silica particle adsorbed at the edge of circular LC domain of methyl octadecanoate and the hydrodynamic flow of surrounding LE phase deformed domain edge into a wedgelike shape. For stationary state, a force balance the viscous drag F_η and effective line tension τ_{eff} at the wedge of angle θ is

$$F_\eta = -2\tau_{\text{eff}}\cos\theta/2 \tag{52.4}$$

In theory, the deformation of domain shape changes local molecular density in the domain and then τ_{eff} via the dipole repulsion term in Eq. (52.2). However, the authors claimed that the difference between the real and effective line tension is less than 10% and the optical tweezers method can give the line tension very close to its equilibrium value. They also took into account of the viscosity of surrounding LE phase η_s by the coefficient f and expressed F_η as

$$F_\eta = f\eta RV \tag{52.5}$$

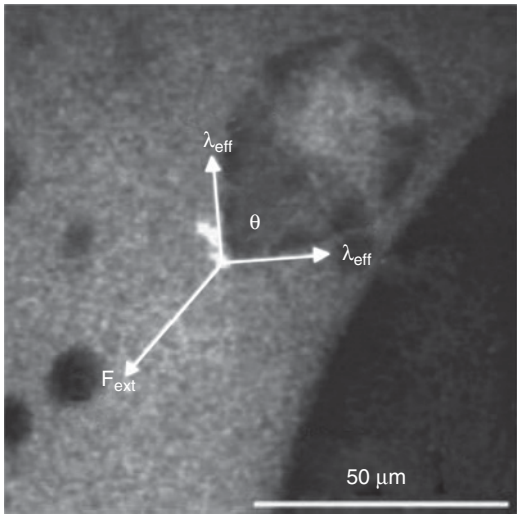

FIGURE 52.3 An LC domain captured by optical tweezers. A silica bead adsorbed at the domain boundary is held by the tweezers fixing the position of the domain and the flow deforming the domain. Here $F_{\text{ext}} = -F_\eta$ and $\lambda_{\text{eff}} = \tau_{\text{eff}}$. (Adapted from Wurlitzer et al. 2000 [17], pp. 3822–3828, Fig. 2. © AIP Publishing LLC; reproduced with permission.)

The coefficient f depends on the dimensionless Boussinesq number $B = \eta_s/\eta R$ and is

$$f = \frac{4\pi B}{\ln(2B) - 0.577 + 4/\pi B - \ln(2B)/2B^2} \tag{52.6}$$

when $B > 2$. The limitation assumed in Eq. (52.3) corresponds to $B \ll 1$, indicating that hydrodynamics is dominated by drag from the water. Considering that there are no well-established direct measurements of domain line tension, this report is deemed to be important for future line tension study. One of the unsolved problems of domain line tension measurement is how to determine line tension if the domain has elongated or striped shapes. To solve this issue, the theoretical fitting of domain shapes will be a powerful tool again.

52.3 MODIFICATION OF DOMAIN LINE TENSION

There are only a few studies that intentionally target the modification of line tension of the system. This is probably because the researchers had to spend their efforts for the measurement of the pN-order force in order to achieve satisfactory accuracy. However, just as surfactants can reduce surface tension and stabilize dispersed phases in 3D systems, one may expect that some sort of molecules act as line-active agents (or linactants) and stabilize 2D domains. Another group of researchers showed in a mixed Langmuir monolayer of pentadecanoic acid (PDA) and perfluoroundecanoic acid (PFUDA) that partially fluorinated phosphonic acid (linactant) partitioned at the phase boundaries between hydrocarbon-rich and fluorocarbon-rich phases and reduced line tension as the concentration of linactant increased [18, 19]. They abbreviated their linactants, namely, $CF_3(CF_2)_{n-1}(CH_2)_mPO_3H$, as $F_nH_mPO_3$ and ranked their linactant efficiency in the order $F_8H_8PO_3 < F_{10}H_6PO_3 < F_8H_{11}PO_3 < F_{10}H_9PO_3$ from the data shown in Fig. 52.4 The most efficient linactant reduced the line tension by more than 20% at a mole fraction of only 0.8%. They also showed that these linactants drive modification of preformed amphiphile domains [18]. The most remarkable shape deformation was observed in the $F_8H_{11}PO_3$ system, where the peanut-shaped domain was induced in the mixed monolayer of PDA (96.5%) and PFUDA (3.5%) if the linactant concentration was successively increased up to 0.08%.

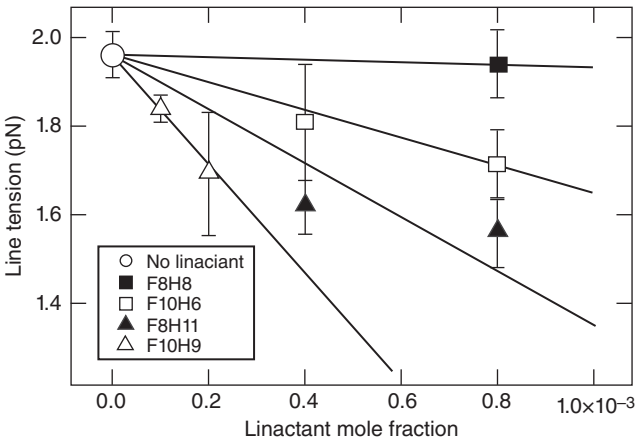

FIGURE 52.4 Line tension as a function of linactant concentration for a monolayer composed of PDA (96.5%) and PFUDA (3.5%). The origin of line tension measurement is set for the PDA-PFUDA monolayer without linactant at surface pressure of 6 mN m^{-1}. (Adapted from Trabelsi et al. 2009 [19], pp. 8056–8061. © American Chemical Society; reproduced with permission.)

Another pair of researchers suggested from MD simulation results that hybrid saturated–unsaturated chain lipids can bind to the liquid-ordered L_o domain composed of saturated lipid and cholesterol and reduce line tension of the domain against unsaturated lipid surroundings [20]. They insisted that these molecules are potential candidates of natural linactants for biomembranes. Another team examined the influence of nonlipid amphiphiles, vitamin E, Triton-X 100, and benzyl alcohol, on the phase separation of binary and ternary lipid mixtures by combination of MD simulation and microscope observation of corresponding giant unilamellar vesicles (GUVs) [21]. Their MD simulations suggested that vitamin E was preferentially partitioned boundaries between L_d and L_o phases and decreased tendency to form domains in GUV systems. On the other hand, it was expected for benzyl alcohol that they were partitioned to L_d phase then decreased lipid order there. This behavior may increase chain length mismatch Δl at domain boundary and explain why benzyl alcohol induced phase separation in GUV systems. Triton-X 100 was almost equally partitioned to both phases but promoted ordering in L_o phase. This also increased Δl and the phase separation again observed. These results indicate that nonlipid amphiphiles can be influential to domain line tension through their preferential partitioning into the one of coexisting phases. A similar argument can be found in our more recent paper concerning the condensed film formation of cationic surfactant at the air–water interface in the presence of long-chain alkanes [6], where the mixing of shorter chain alkanes in the condensed domain leads to smaller Δl then induces elongated or striped shape domains by increasing electric repulsion between surfactant ions relatively. We will explain how to realize the

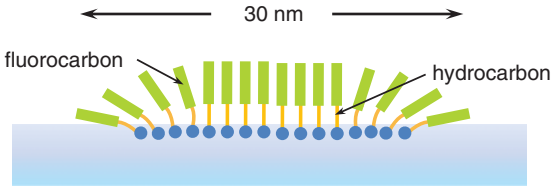

FIGURE 52.5 An expected structure of 2D micelle of $F_nH_mPO_3$.

condensed film of cationic surfactant later in Section 52.5 of this review.

Another team also showed that $F_nH_mPO_3$ formed 2D micelles of as their concentration increased in a neat one-component monolayer. When the concentration of linactant is further increased, these micelles were hexagonally packed analogous to a lyotropic liquid crystal phase in 3D system. The diameter of 2D micelle, $d \sim 30$ nm, is much larger than the extended chain length of $F_nH_mPO_3$, which is up to 3 nm. To understand the driving force for the 2D micelle formation, the earlier studies performed by Krafft et al. were informative [22, 23]. They applied X-ray reflectometry (XR) to the 2D micelle of semifluorinated alkaneF_8H_{16} at the air–water interface that also showed hexagonal packing structure in the high-surface-pressure region. The XR data suggested that the structure of 2D micelle is a bilayer in which the fluorinated segments outward to the air and hydrocarbon segments occupy inside of contacts with water phase. The difference in cross-sectional area between fluorocarbon (0.28 nm^2) and hydrocarbon (0.18 nm^2) bends the bilayer structure to optimize chain packing in the hydrocarbon segments and, as a result, the 2D micelle has a hemispherical shape as shown in Fig. 52.5 The diameter of 2D micelle is therefore determined by the balance of length (i.e., volume) of hydrocarbon and fluorocarbon segments.

There are various kinds of colloidal assemblies in 3D systems such as micelles, vesicles, bilayers, and lyotropic liquid crystals [24]; however, only the micelles and their hexagonally arranged structure were observed experimentally in 2D systems. In 3D systems, the optimal shape of surfactant aggregates changes not only by the interaction between surfactants in each aggregate but also by the interaction between aggregates. Therefore, to realize more complex pattern formation in 2D systems, the structural design of linactant molecules should be reconsidered to have a proper interaction between 2D aggregates.

52.4 VESICLES

GUVs are closed form of bilayer membrane and those composed of ternary mixtures of sphingolipid, phospholipid, and cholesterol, have been widely used as a model of biological cells. Another team first considered hypothetically what would happen if phase separation were to occur in such

a bilayer membrane [25, 26]. The starting point of their thoughts is that the edge energy of the domain is linearly increased with the length of the phase boundary. This condition gives rise to an outward bending of the domain when its radius reaches a finite critical value. They call this process the "domain-induced budding of vesicles," which is balanced by the bending energy of the bud determined by the bending rigidity of the film. The total energy of vesicle separated into phase α and β is therefore given by

$$E = E_b^{(\alpha)} + E_b^{(\beta)} + E_l^{(\alpha\beta)} \tag{52.7}$$

The bending energies are taken to be [27]

$$E_b^{(i)} = \int dA^{(i)} \frac{\kappa^{(i)}}{2} \left(C_1 + C_2 - 2C_{sp}^{(i)} \right)^2 \tag{52.8}$$

where $\kappa^{(i)}$ is the bending rigidity and $C_{sp}^{(i)}$ is the spontaneous curvature of α and β phases. C_1 and C_2 denote the principal curvature of the membrane surface. The edge energy is given by the line integral

$$E_l^{(\alpha\beta)} = \oint dl\tau \tag{52.9}$$

along the phase boundary. The total energy is minimized for a given set of the domain area A^α and A^β, the pressure difference P between the inside and outside of vesicle, the enclosed volume V, and the line tension τ. If the bending rigidity $\kappa^{(\beta)}$ of the growing domain is smaller than $\kappa^{(\alpha)}$, or the spontaneous curvature $C_{sp}^{(\beta)}$ is larger than $C_{sp}^{(\alpha)}$, the budding occurs for smaller values of domain area ratio $x = A^\beta/(A^\alpha + A^\beta)$ and thus leads to transition for smaller buds of phase β. For sufficiently large τ and x, the bud can have a neck with a finite diameter such as that shown in Fig. 52.6 This neck formation finally leads to breakup of the original vesicle into two vesicles consisting of components α and β.

An experimental verification of the abovementioned theory was demonstrated by Baumgart and coworkers for GUVs composed of sphingomyelin, dioleoylphosphatidylcholine (DOPC), and cholesterol [28]. Figure 52.7 shows images of equatorial sections of GUVs obtained using two-photon microscopy. The phase coexistence of the sphingomyelin and cholesterol enrich L_o phase (blue) and DOPC enrich L_d phase (red) are exhibited for various film compositions. The panels c, g, and h correspond to complete buds with necks and others show incomplete buds. They applied a refined Lipowsky theory [29] and obtained mechanical parameters for these vesicles. For example, for the vesicle in the panel a, $\tau \approx 9 \pm 0.3 \times 10^{-13}$N was obtained. However, the obtained line tension is one order of magnitude smaller than the estimation from Eq. (52.1) which is simply based on the energy penalty arose from height mismatch at domain boundary. Akimov et al. suggested an mechanical model that minimizes the height mismatch by the elastic deformation of

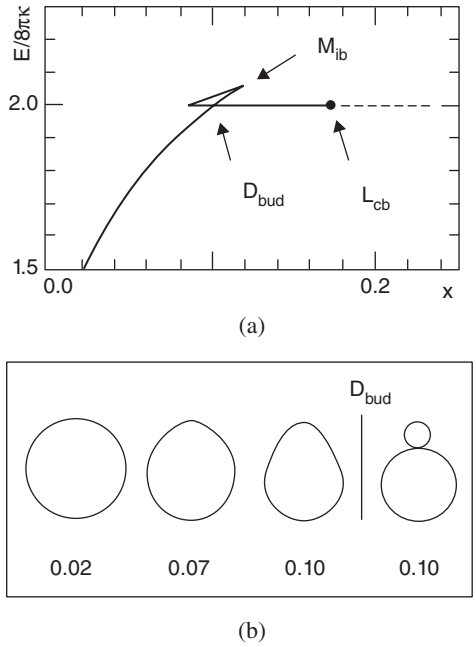

FIGURE 52.6 (a) Energy of the vesicle as a function of the relative domain area x for reduced line tension $\lambda \equiv \tau R_0/\kappa^{(\beta)} = 7$, and (b) some of the corresponding vesicle shapes. R_0 stands for the radius of the original vesicle. The incomplete bud is stable up to D_{bud} at $x = 0.10$, is metastable beyond it, and becomes unstable at M_{ib}. The vesicle separates into two smaller ones from the neck at L_{cb}. (Adapted from Jülicher and Lipowski 1993 [26], pp. 2964–2967. © American Physical Society; reproduced with permission.)

hydrophobic chains near the domain boundary [30]. They claimed that the line tension can be reduced to ∼1 pN if the height mismatch is reduced to ∼3 Å by tilting and stretching of lipid chains.

The Lipowsky theory also suggests the existence of critical domain radius for the initiation of budding, therefore, the components which stabilize small size domains, typically linactants, are disadvantageous to induce budding. García-Sáez et al. modified the height mismatch between L_o and L_d phases by controlling the thickness of the L_d phase using phosphatidylcholines with different chain length [31]. Their experiments showed that the phase separation temperature and the budding tendency of GUV increases as a function of chain length of lipids. The calculated line tension based on the elastic deformation model is in the range of 0.06-6 pN depending on the height mismatch. Furthermore, Staneva et al. found that budding can be induced also by the addition of nonlipid amphiphiles such as Triton-X 100 [32]. This is coincided with the finding mentioned in the previous section: Triton X-100 increases height mismatch by the promotion of ordering in the L_o phase [21]. These results confirmed that the line tension strongly influenced on physicochemical properties of lipid domains.

Some researchers found that the line tension also plays crucial role in pore-closing dynamics of GUVs [33–35].

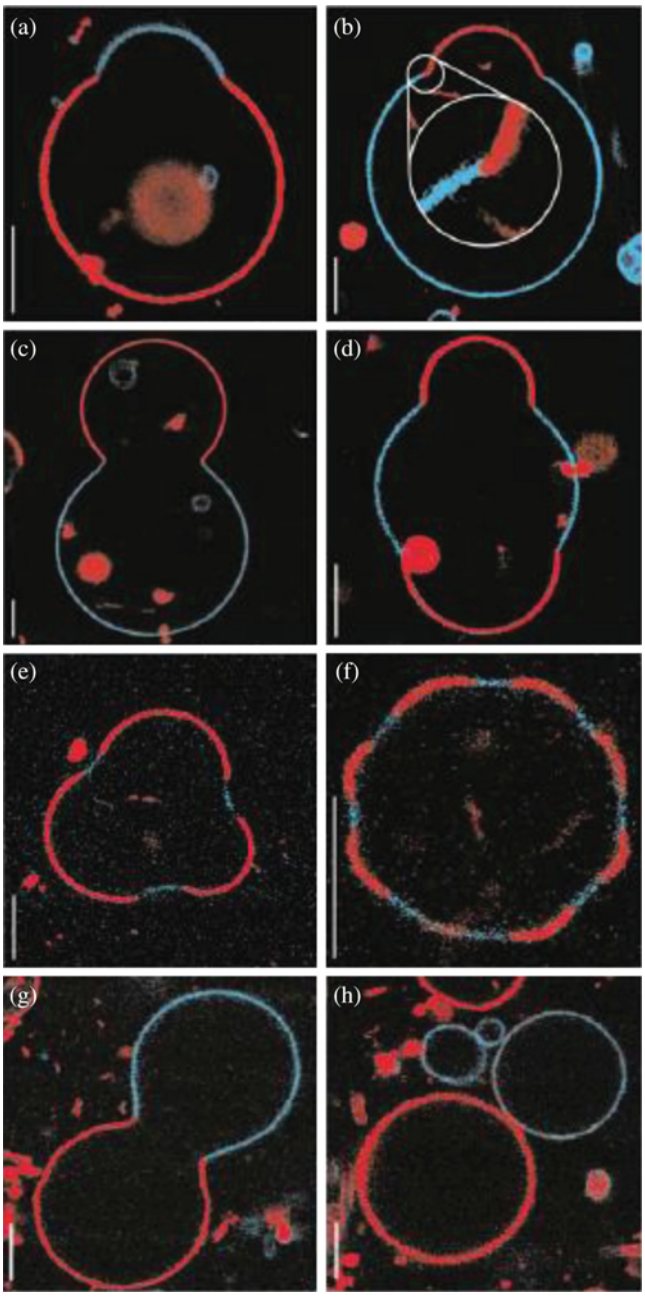

FIGURE 52.7 Two-photon microscopy images showing equatorial sections of GUVs with L_0 (blue)–L_d (red) phase coexistence. Scale bar shows 5 mm. (Adapted from Baumgart et al. 2003 [28], pp. 821–824, Fig. 1. © Nature Publishing Group; reproduced with permission.)

In their studies, UV irradiation and laser ablation were employed to generate transient pores on GUVs. Assuming that the rate of pore-closing is determined by the competition between line tension and surface tension γ at the membrane surface, one has [33, 34]

$$\frac{dr(t)}{dt} = \frac{r(t)}{2\eta}\left[\gamma(t) - \frac{\tau}{r(t)}\right] \tag{52.10}$$

where η is the viscosity of the medium and $r(t)$ is the radius of the transient pore. This experiment is performed to keep vesicle radius R constant during pore-opening and -closing processes. In such situation, the surface tension becomes constant and Eq. (52.10) is reduced to

$$R^2 \ln r(t) \approx -\frac{2\tau}{3\pi\eta}t \tag{52.11}$$

therefore, the line tension working at the edge of membrane pores can be obtained by determining $r(t)$. Srividya et al applied laser ablation method to GUVs formed by saturated lipids with 12, 14, 16, and 18 carbon acyl chains, and found that their line tension ranges from 1-12 pN, exhibiting an increase with acyl chain length. They also found that the natural lipid Egg-PC, which is a mixture of saturated and unsaturated lipids, increased the line tension of GUV up to 32 pN [35]. It was also discussed by Brochard-Wyart et al. [33] that the line tension increased with increasing the amounts of cholesterol in the bilayer.

52.5 LINE TENSION AT WETTING TRANSITIONS

From section 5, we will consider the line tension generated by three coexisting interfaces. When a liquid droplet is placed on a substrate, there are three possible outcomes which are called partial wetting, pseudo-partial wetting and complete wetting [36]. In the partial wetting state, the liquid does not spread on the substrate but instead remains in the form of a macroscopic lens. In contrast to this behavior, for complete wetting, the liquid spreads out to form a uniform film on the substrate. The pseudo-partial wetting state is an intermediate state between partial and complete wetting where a film of molecular thickness is in equilibrium with a macroscopic liquid lens. The microscopic structure of the three-phase contact line is also changed drastically when the transition between these three wetting states occurs. Therefore, the wetting transition is in principal accompanied with aprupt change in the line tension at the three-phase contact.

The theoretical connection between line tension and wetting transition was first proposed by Indekeu et al [37, 38]. According to his theory, the force acting through the thin film connected to the lens displaces the lens profile near the three-phase contact line from the idealized one that obeys the Young–Laplace equation, as schematically shown in Fig. 52.8 The excess free energy required for this deformation is the line tension. Thus, the line tension is considered to be the following functional:

$$\tau = \int_{-\infty}^{\infty}\left[\frac{\gamma}{2}\left(\frac{dl}{dx}\right)^2 + V(l) + \text{const.}\right]dx \tag{52.12}$$

where γ is the surface tension, l the interface displacement which is a function of x, and $V(l)$ the interface potential. The

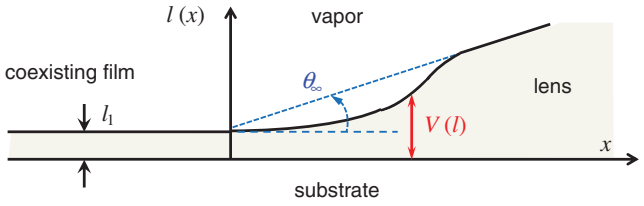

FIGURE 52.8 Interface displacement model for a droplet on solid substrate. θ_∞ indicates the ideal contact angle derived from the Young equation. The real contact angle θ becomes smaller than θ_∞ by the attractive surface force $V(l)$.

first term in the integrand of Eq. (52.12) is attributable to the increase in the interfacial area, while the second term is attributable to the free energy per unit area when a uniform film of thickness l is present. By minimizing Eq. (52.12) and taking the potential at $l \to \infty$ as a reference state, the following equation for the line tension can be derived:

$$\tau = (2\gamma)^{1/2}\,\xi \int_{l_1}^{\infty} \left[V(l)^{1/2} - S^{1/2}\right] dl \qquad (52.13)$$

where ξ is the bulk correlation length, l_1 the film thickness in equilibrium with the lens, and S the spreading coefficient. This equation suggests that the equilibrium line tension is calculated by estimating the interface potential $V(l)$ and integrating Eq. (52.13) from the thickness l_1 to infinity.

For a first-order wetting transition to complete wetting, two minima should exist at a finite and an infinite film thickness on the interfacial potential as shown in Fig. 52.9a. Before the wetting transition, the negative contribution J_1 in the integral of Eq. (52.13) exceeds the positive contribution J_2. However, the magnitude of J_1 reduces as the transition point is approached, and finally, only the positive contribution remains in the integral. Hence, the line tension should be positive at the complete-wetting transition. On the other hand, when the wetting transition occurs between two microscopic films of different thicknesses, the line tension changes sign from positive to negative, as expected from Fig. 52.9b. For a second-order transition from a film of finite thickness to a thick film, the line tension is negative and approaches zero at the wetting transition.

Experimentally, the line tension in three-phase systems can be estimated from the dependence of the contact angle on the contact line perimeter, i.e. on the lens radius. There are two methods available for determining contact angles and/or profiles of microscopic lenses. One method is based upon high-resolution scanning force microscopy (SFM) imaging in tapping mode which is applicable for liquid-vapor interfaces of stable lenses on solid substrates [39–41]. The measured interfacial profile is fitted with appropriate surface energies and then the line tension is theoretically calculated from the data.

For droplets on liquid surfaces lenses readily migrate across the surface, hence, the optical interference method [42–45] is more convenient to use for this situation. In this method, droplet lenses are illuminated by a monochromatic light source from above and the resultant interference fringes

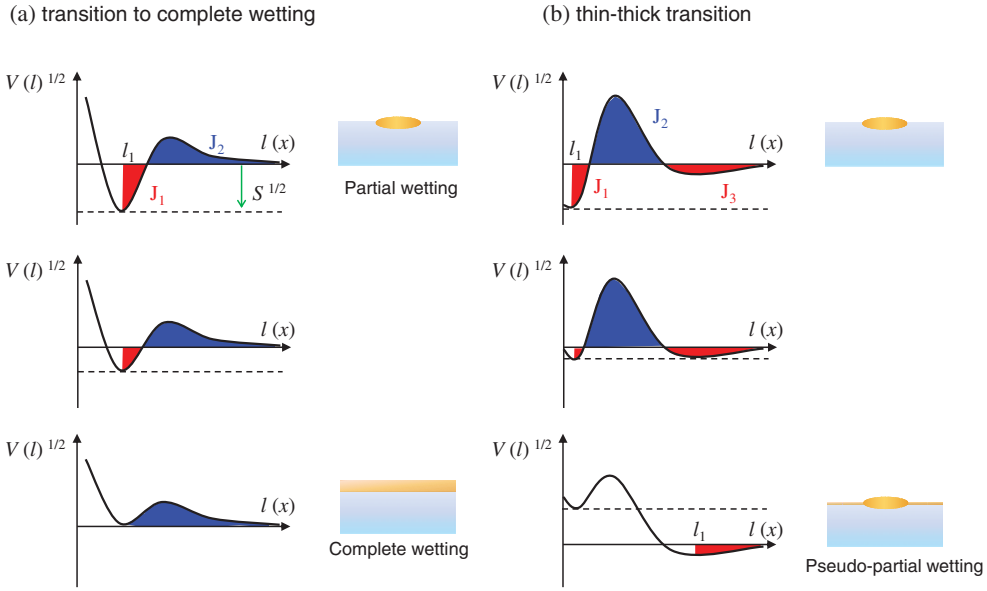

FIGURE 52.9 (a) A schematic interface potential for the first-order transition to the complete wetting and (b) that between wetting films with different thickness. l_1 represents the equilibrium thickness of the wetting film where the integral of Eq. (52.13) starts. If the thinner film in case (b) is considered as nonwetting state, the same conclusion can be obtained for the transition between partial wetting and pseudo–partial wetting.

are recorded on a CCD camera and converted to the lens contact angle, θ. The lens radius is also obtained from the CCD image. From the mechanical balance between the interfacial tensions and the line tension at the three-phase contact line, one can show that [43]

$$\gamma^{AO}\cos\left(\frac{\gamma^{OW}\theta}{\gamma^{AO}+\gamma^{OW}}\right)+\gamma^{AO}\cos\left(\frac{\gamma^{AO}\theta}{\gamma^{AO}+\gamma^{OW}}\right)=\gamma^{AW}-\frac{\tau}{r} \tag{52.14}$$

Here γ^{AW}, γ^{AO}, and γ^{OW} are the interfacial tensions between air-water, air-oil, and oil-water interfaces, respectively, and r is the radius of the lens. Hence, the slope of a straight line drawn from a plot of the left-hand side of Eq. (52.14) against r^{-1} yields the line tension at given experimental condition. This method is restricted to small θ where Eq. (52.14) is valid.

Law and co-workers measured the contact angle of octane and octene droplets on a silicon wafer as a function of temperature [40, 46]. The silicon wafer was coated with hexadecyltrichlorosilane to control the wettability of the surface. They demonstrated that the line tension changes sign from negative to positive with a diverging slope near the first-order wetting transition. If the long-range surface force decays slowly as a function of the thickness, the line tension would be allowed to diverge at the transition point. Pompe measured the line tension of hexaethylene glycol on a silicon wafer and obtained positive values below a contact angle of 6° and negative values above [47]. The measured interfacial profile was fitted with a nonretarded van der Waals and exponentially decaying interactions.

There are a few experimental verifications of the interfacial displacement model for wetting transitions on liquid surfaces. However, we have recently confirmed the reversal of the line tension sign associated with the wetting transition for a hexadecane lens on aqueous solutions of cationic surfactant with various chain length [48–50]. The surfactant molecules adsorbed at the air-water interface decreases required enthalpy for transferring oil molecules from oil lens to the film by lateral van der Waals dispersion interaction and simultaneously increases mixing entropy in the film. As a result, hexadecane, which is not spread on pure water by itself, undergoes wetting transition to a mixed monolayer of surfactant and oil at a certain surfactant concentration. From the formalism mentioned above, this is a wetting transition between partial wetting to pseudo-partial wetting and qualitatively its interface potential obeys the scenario for thin-thick transition shown in Fig. 52.9b. The detailed treatment of interface potential in this system can be found in the literature [49–51]. The reversal of line tension sign was also confirmed by splitting and merging behavior of hexadecane lenses in each wetting regimes (Fig. 52.10). Small lenses formed by stirring merge spontaneously into a large lens as the equilibrium is approached, however, after the wetting transition, large lenses break into small lenses

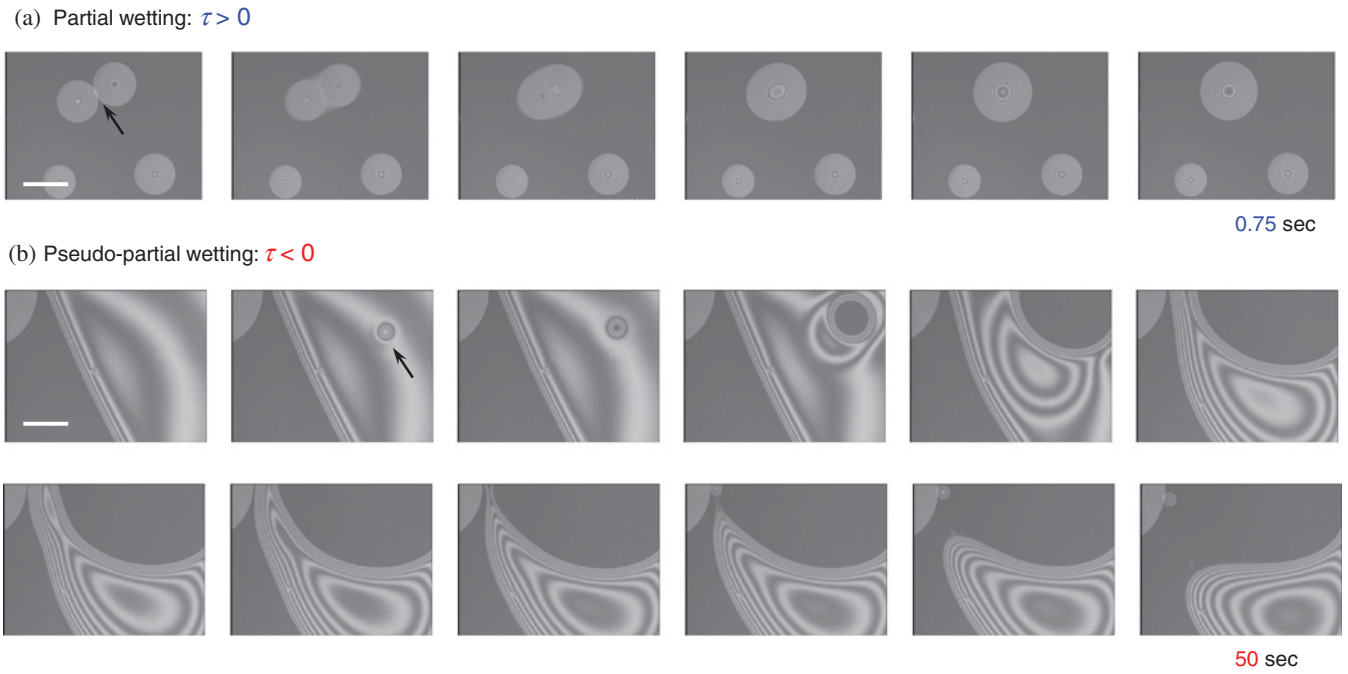

FIGURE 52.10 Microscopic images of alkane lenses on cationic surfactant solutions; (a) the coalescence of lenses in partial wetting state and (b) the spitting process in pseudo–partial wetting. Yellow arrows show places where the merging and splitting start. Scale bar shows 50 μm.

without stirring to increase the total length of three-phase contact.

Interestingly, in the mixed monolayer, cationic surfactants can form condensed film since the penetrated oil molecules into the surfactant adsorbed film enhanced lateral hydrophobic interaction between chains without increasing electric repulsion between hydrophilic groups [52]. Furthermore, it was also revealed that the freezing film can take a bilayer form depending on the combination of surfactant and oil [53]. We also utilized these freezing transitions to control line tension sign of coexisting oil lenses. At present, it was found that cooling of pseudo-partial wetting film leads to a reversal of line tension sign from negative to positive at both freezing transitions [54, 55]. The relation between line tension sign and physical states of the air-water interface was recently summarized in [55].

When small gas bubbles or liquid droplets are nucleated on a solid surface, there also exists three-phase contact lines. If positive line tension was expected for a bubble or droplet at the interface in question, this nucleation requires energy that exceeds potential barrier generated by the line tension as well as the interfacial energies between nucleated phase and its surroundings. Therefore, in the similar manner discussed in this section, the effect of line tension on heterogeneous nucleation has been studied. One of recent researches on this issue can be found in [56] for bubbles and in [57] for liquid droplets.

52.6 PARTICLES AT LIQUID SURFACES

Fine particles tend to be strongly trapped on fluid-liquid interfaces because of the reduction in the interfacial energy due to adsorption [58–60]. The structure of the particle monolayers depends on the particle contact angle [61, 62]. Hydrophobic particles with large contact angles provide well-ordered monolayers at interparticle distances of a few particle diameters by the long-range dipole repulsion between particles in the water phase whereas the monolayers of less-hydrophobic particles are totally disordered and aggregated. The difference between the monolayer structures also leads to different stabilization mechanisms for the Pickering emulsions; the steric-barrier mechanism for the oil in water emulsion and the bridging-particle-monolayer mechanism for the water in oil emulsion [63].

The sign of line tension of fine particles at fluid-liquid interface determines if the contact angle θ decreases or increases with increasing particle size. To determine contact angle of particle at fluid-liquid interface, the gel-trapping technique is one of the useful techniques [64]. In this technique, a hydrocolloid polymer is poured to gel the aqueous phase after the particle adsorption is equilibrated. Then the top phase is replaced with a poly (dimethylsiloxane) (PDMS) which allows us to peel particle layer off the aqueous phase after it is cured. The contact angle of particles is finally measured by using scanning electron microscope (SEM).

McBride et al. determined the line tension of dodecyltrichlorosilane coated silica spheres at the liquid PS-air interface by similar methodology [65]. They adsorbed particle at the interface well above the glass transition temperature of PS then cool the system below it to immobilize particles. Atomic force microscopy (AFM) was then used to image particles. They used silica particles with wide range of radius to show the presence of the minimum radius of silica particle, r_m, and minimum contact angle, θ_m, below which single particles are unstable at the liquid-vapor interface and submerged into the bulk liquid. The connection between these parameters was given by

$$r_m = \frac{\tau}{\gamma \sin\theta_m \left(1 - \frac{\cos\theta_\infty}{\cos\theta_m}\right)} \tag{52.15}$$

with

$$\cos\theta_m = \left[\cos\theta_\infty\right]^{1/3} \tag{52.16}$$

This equation was obtained by comparing the energy of single particle at the interface

$$E_s = \gamma_{SV} A_1 + \gamma_{SL} A_2 + 2\pi b\tau \tag{52.17}$$

and that of completely submerged one

$$E_b = \gamma_{SL}(A_1 + A_2) + \pi b^2 \gamma \tag{52.18}$$

where γ_{SV} and γ_{SL} denote the interfacial tension at the solid-vapor and solid-liquid interfaces and A_1 and A_2 are the upper and lower spherical cap area of the adsorbed particle. They averaged the experimental results for 147 individual spheres with radius ranging from 88 to 498 nm and yielded $\tau = 0.93 \pm 0.01$ nN from the modified Young-equation [66]

$$\cos\theta = \frac{\cos\theta_\infty}{1 - \frac{\tau}{\gamma b}} \tag{52.19}$$

Here θ_∞ express the contact angle of flat surface, γ is the surface tension of the air-water interface, b is the radius of contact line which calculated by particle radius r as $b = r\sin\theta$ for particles with ideally smooth surface. The horizontal and vertical dashed lines in Fig. 52.11 represent $\theta_m \sim 40.4^{\circ}$ and $r_m \sim 78$ nm, respectively, deduced from the theory. The excellent agreement between experimental θ_m and r_m data and the theory suggests the adsorption behavior of fine particles in reality changes $r < r_m$, by the effect arises from the line tension.

Lewandowski et al. proposed an strategic usage of line tension to control the orientation of a cylindrical particles at the aqueous-gas interface [67]. They calculated the phase diagram of cylindrical particles at air–water and oil–water

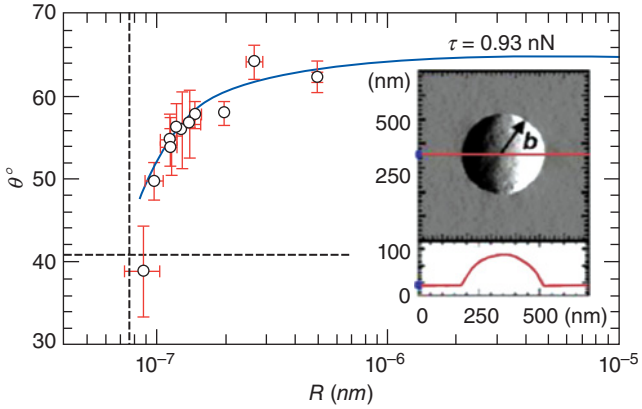

FIGURE 52.11 Contact angle θ versus particle radius R plots. Solid line indicates the estimation from Eq. (52.19) with $\tau = 0.93 \pm 0.01$ nN, and the vertical and horizontal dotted lines are those from Eqs. (52.15) and (52.16). The inset shows the AFM image of Stöber silica sphere of $R \sim 184$ nm. (Adapted from McBride and Law 2012 [66], p. 196101. (© American Physical Society; reprinted with permission.)

interfaces which included the side-on, end-on, and submerged states as a function of the scaled aspect ratio $x = 2L/\pi r$ and contact angle θ_∞, where L and r denoted the cylinder length and radius, respectively. Line tension can also influence the orientations by changing the equilibrium contact angle θ and by increasing the energetic cost of the contact line. They found that cylindrical particle can be driven from side-on to end-on orientations with increasing line tension over some range of x and θ_∞. This transition terminates for high enough τ where the energy of submerged particle overwhelms other two orientations similar to that noted for spherical particles. They confirmed the theory by using disk-shaped nanowires with $x = 0.28$ and longer nanowires with $x = 3.0$. The former always takes end-on orientation whereas the latter takes side-on orientation in SEM images taken for nanowires embedded in PDMS replicas of the air-aqueous solution interfaces.

There is only a few studies concerning with negative line tension or change in line tension sign for fine particles at fluid-liquid interfaces. Maestro et al. found that contact angle of polystyrene (PS) particle at the air-water interface decreases with increasing the particle diameter [68]. They obtained $\tau \sim 0.5$ nN when methanol was used as spreading solvent. From the fact that the τ increased to 5 nN if the spreading solvent was changed to 2-propanol, they considered that the spreading solvent adsorbed on particle surface due to its roughness and change its surface property. The rough surface magnifies the line tension effect so this hypothesis also explains high τ values obtained in this study. If the surface of PS was covered with 2-propanol, the particle becomes more hydrophobic and the excess line energy may increase. They also found that contact angle increases with particle diameter at the octane-water interface for PS particles spread by methanol, indicating the line tension becomes negative if the upper bulk phase changes from air to octane. They could not propose clear explanation for this observation, however, they implied that the preferential adsorption of spreading solvent on particle surface is probably also crucial for the occurrence of negative line tension because the contact angle of PS at the octane-water interface is independent on particle diameter when they spread from 2-propanol.

52.7 FOAM FILMS

The plateau border is the liquid junction connecting thin aqueous films which separates bubbles in a foam. In such a system, the presence of pressure difference between the inside and the outside of the plateau border drives film thinning. Therefore, to prevent the foam film from rapture, there are some proper repulsions between the interfaces on both sides of the film. The forces acting in foam film is called the disjoining pressure, π, which is considered as the sum of three interfacial forces [69];

$$\pi = \pi_{el} + \pi_{vdw} + \pi_{st} \tag{52.20}$$

In most cases, surfactant molecules adsorbed at the air-water interfaces generates the electric repulsion, π_{el}, between interfaces. The π_{vdw} is the van der Waals interaction between gas phases and is always attractive. Fig. 52.12 is a schematic

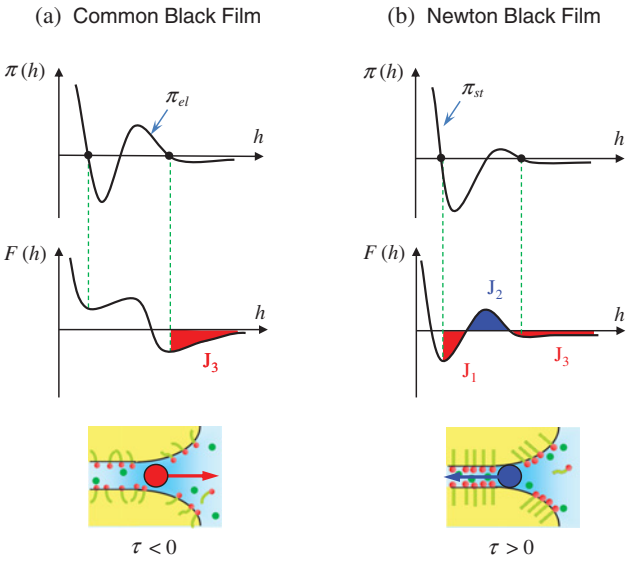

FIGURE 52.12 A schematic diagram of the disjoining pressure curve and free-energy of foam film of (a) common black film and (b) Newton black film. The sign of line tension at the boundary of foam film is determined by the sum of J_1, J_2, and J_3. If J_2 is large enough in panel (b), the line tension of NBF film could be positive whereas that of CBF is principally negative.

diagram of the disjoining pressure curve and free-energy of foam film obtained by integrating π against the film thickness h. The right panel shows the case that a strong π_{el} kinetically stabilizes the system at the secondary minimum of the free energy curve. The thickness of this minimum is less than the wavelength of visible lights (normally around several tens of nanometers), hence, the film stabilized by the electrostatic repulsion is called common black film (CBF). It is well known that the electric repulsion can be reduced easily by increasing electrolyte concentration. In foam film systems, this leads to the reduction of potential barrier between the primary and secondary minima and the occurrence of the thin-thick transition as shown in the left panel. In molecular dimension, the overlapping of hydration shell of hydrophilic groups, π_{st}, becomes dominant. The Newton black film (NBF) is the film stabilized by this steric repulsion and its thickness is normally less than 5 nm.

The line tension works in the transition zone where the foam film is connected to bulk aqueous phase in the liquid junction. Platikanov et al. developed the "diminishing bubble method" to determine the line tension of foam film systems [70, 71]. In this method, a small gas bubble is placed on the solution surface to form a circular NBF on its top. The bubble grows smaller due to the gas diffusion through the film as time passes. The experimentally measurable quantities are the radii of the bubble, R, and that of the film, r. They are related to the line tension as

$$\frac{1}{\cos\theta} = \frac{2\gamma}{\Delta} - \frac{\tau}{\Delta r} \tag{52.13}$$

where γ is the surface tension of the solution and $\Delta = 2\gamma\cos\theta_\infty$. The θ_∞ is the contact angle of the large black film ($r \to \infty$). They applied this method to 0.05 % sodium dodecyl sulfate (SDS) solution by varying the concentration of NaCl. The most important finding of these experiments is that line tension changes sign from positive to negative as NaCl concentration increases. For 0.32 M NaCl aqueous solution, the contact angle decreases with decreasing r, suggesting positive τ. The contact angle becomes almost independent on r at 0.36 M and increases with decreasing r at 0.45 M.

The line tension of CBF reported as well for 0.05 % SDS + 0.1 M NaCl aqueous solution [72]. Kolarov et al. found that the contact angle of the foam film in the porous plate cell increases with decreasing film radius by using the interference pattern in reflected light. This indicates the line tension is negative for the CBF.

The relation between line tension and interaction free-energy in the film was first derived by de Feijter et al. [73] and then applied to the experimental observations by Princen [74]. The final conclusion was quantitatively the same as discussed for the wetting films by using Eq. (52.13); the line tension τ is proportional to the integral of the free-energy curve from the thickness of the existing film, CBF or NBF in the present case, to infinity. For example, the line tension of CBF should take a finite negative value because the line tension was solely determined by the contribution J_3 that comes from the long-range van der Waals attraction. On the other hand, the line tension of NBF films can change its sign depending on the relative relation between $J_1 + J_3$ and J_2. The addition of electrolyte reduce the height of the potential barrier J_2 and leads to the reversal of line tension sign from positive to negative as observed in accordance with the experimental observation.

Figure 52.13 shows a comparison of equilibration processes of CBF and NBF stabilized by cationic surfactant–alkane mixed adsorbed film with different concentrations of

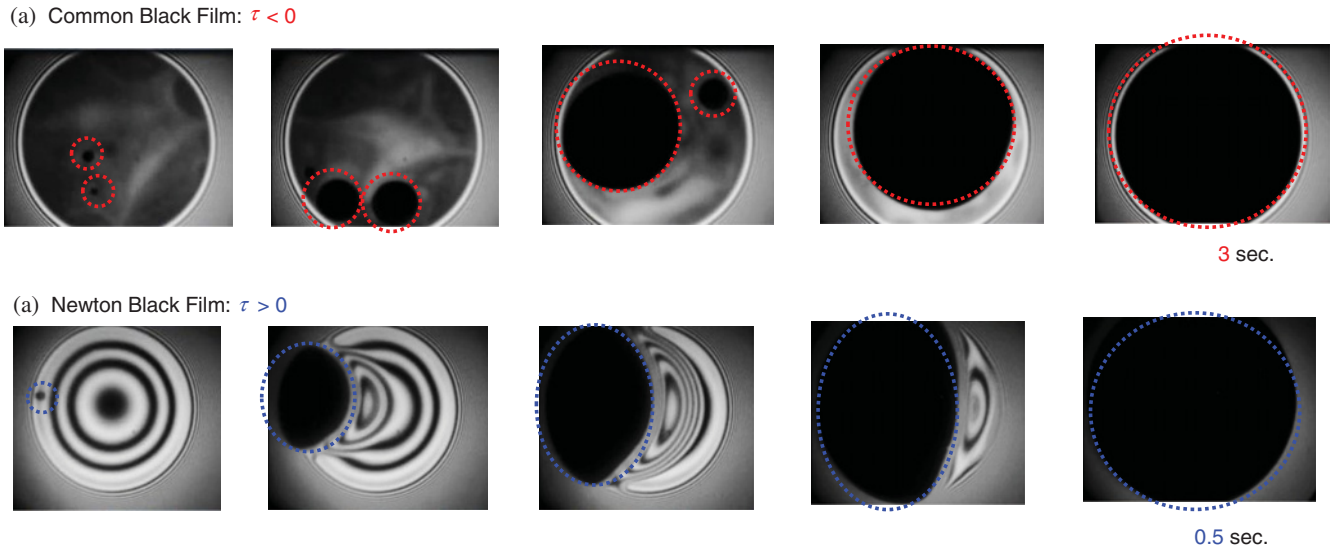

FIGURE 52.13 Equilibrium processes of (a) CBF and (b) NBF films in the porous plate cell.

NaCl [75]. The dotted regions are the black films nucleated from the surrounding thicker aqueous film. The nucleation of CBF occurs in different places at the same time, indicating that the creation of the contact line is energetically favourable due to the negative line tension. On the other hand, for NBF, the first nucleation takes longer time compared to CBF nucleation and the NBF film expands rapidly to cover the whole area of the film once its nucleation is happened. This behavior is corresponding to the fact that the nucleation of NBF is prevented by the energy barrier due to positive line tension.

De Feijter et al. [73] and Churaev et al. [76] also discussed the line tension between bulk liquid and its thin film from the shape of the transition zone. See original papers for details.

52.8 SUMMARY

In this review, we summarized line tension studies provided in recent publications. Because of the difficulties in measuring tiny forces in micron scale objects, the discrepancies of line tension data between researchers has yet to be resolved. However, as we have seen in this review, some of line tension data are supported by macroscopic observations and, we believe, worth to be trusted.

Among them, the domain line tension in Langmuir monolayers has been studied widely due to its technological importance (ex. structuring of 2D system) and experimental accessibility of the air-water interface. Therefore, the methods for measuring domain line tension were well-established compared to the other systems. Now the interest of researchers in this field is being shifted to the discovery of linactants. Most succeeded example of linactants is partially fluorinated compounds $F_nH_mPO_3$, which reduce the domain line tension of the condensed domain in the PDA - PFUDA mixed monolayers. In these cases, the bulkiness and lower surface energy of fluorocarbon moiety granted a head-group character to linactant molecules. However, this molecular design is exactly the same as that of surfactant from the view point that there is two chemical groups favoring different bulk phases, as a result, these linactants only form hemispheres in quasi-2D space when they are solely added at the air-water interface. Therefore, introducing a functional group which generates lateral interactions between linactant aggregates is one of the future candidate of linactant design.

The budding and breaking up of GUVs are one of the high-lights of domain line tension studies. These processes require high enough line tension value, hence, the additives influential to GUV budding had a character to dissolve preferentially to L_d or L_o phases and consequently enhance the Δl. Some researchers suggested other driving forces for GUV budding. For example, the calcium ions are considered to induce budding through the change in osmotic pressure [77]. The relation between a pore forming peptide and budding was also found in [78]. More experimental and theoretical efforts are probably necessary to obtain a collective view of domain budding mechanism. Schwartz et al. recently wrote a good review on the domain line tension which included the recent developments of their linactant studies [79].

The type (b) line tension can be understood by interaction free-energy between interfaces in three-phase contact zone. This theory has been verified extensively for line tension behavior at wetting transitions. The surfactant induced wetting transition is unique approach which is only available method to switch line tension sign by external thermodynamic variables such as surfactant concentration and temperature. The line tension also changes the phase diagram of fine particle adsorbed at fluid-liquid interfaces and, in principal, leads to the transition between side-on and end-on orientations for cylindrical particles. The self-assembly of particles is promising research field in bottom-up nanotechnology. However, there is only a few study on how chemical property of particle surface influences the line tension. Therefore, for practical use, the relation between particle wettability and line tension values should be established more in detail. The line tension effect on foam film stability was studied only qualitatively and therefore have a possibility to open new research field in the future.

LIQUID STRUCTURES AND PROPERTIES OF LIPIDS

Makio Iwahashi

Department of Chemistry, School of Science, Kitasato University, Sagamihara, Kanagawa-ken, Japan

53.1 INTRODUCTION

Lipids include hydrocarbons, alcohols, fatty acids, fatty-acid esters, steroids, soaps, detergents, and more complex molecules such as triacylglycerols, phospholipids, gangliosides, and lipopolysaccharides. These lipids are essential for human life as foods, pharmaceuticals, cosmetics, biodiesel for automobile engines and boilers, and dielectric insulating oil for transformers. The physicochemical properties of lipids have been introduced widely and in detail [1–3]. In general, lipids melt from their highest melting form (the most stable form) to an apparently isotropic liquid state. However, some short-range order is conceivably maintained even in the liquid state because only a small change (∼10%) in the volume occurs when the materials go from crystal to liquid. The short range order (microstructure) in liquid most probably affects the properties of lipids, especially in the liquid state and ultimately in the solid state; it would play important roles in the overall functions of lipids. However, the liquid structure of lipids, as opposed to crystal structure, has been scarcely investigated since the experimental determination of the liquid structure of lipids is very difficult. The experiments needed to clarify the liquid structure require a large amount of highly pure samples and a combination of different investigation methods. Namely, the true feature of the liquid structure does not rise to the surface with only one method.

Today, highly purified samples of several kinds of lipids have been sufficiently supplied and their structures and physical properties in the liquid state are being clarified by combining various experiment methods. In this chapter the liquid structures and properties of lipids such as alkanes, alcohols, fatty acids, and fatty-acid esters, inclusive mono-, di-, and triacyglycerols, are introduced as follows:

(1) comparison of alcohols with their corresponding fatty acids in their aggregated structures and property (the aggregation number of alcohols and the stability of fatty acid dimer); (2) inter- or intramolecular movements of alkanes, alcohols, fatty acids, and fatty-acid esters (segmental and translational movements of molecules); (3) structure of cluster composed of fatty-acid dimers in the pure liquid state and in CCl_4 solution; (4) effect of cluster structures of fatty acids on their properties such as density, viscosity, and self-diffusion coefficient; (5) effect of additivities on the cluster structure and the liquid properties of oleic acid; (6) aggregated structures and properties of acylglycerols; and (7) application of fatty-acid esters as an insulating oil and a medical agent for a hepatoma operation using microcatheters.

53.2 COMPARISON OF ALCOHOLS WITH THEIR CORRESPONDING FATTY ACIDS IN THEIR AGGREGATED STRUCTURES AND PROPERTIES

53.2.1 Density and Molar Volume

Figure 53.1 shows the density ρ of normal fatty acid (open circle) and normal alcohol (solid circle) possessing one to nine carbon atoms at 20°C as an example [1]. The density of fatty acid is evidently larger than that of the corresponding alcohol. Then let us calculate the molar volumes V for fatty acid and alcohol, using their ρ values and the following equation:

$$V = \frac{M}{\rho} \tag{53.1}$$

where M is the molar weight of fatty acid or alcohol.

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

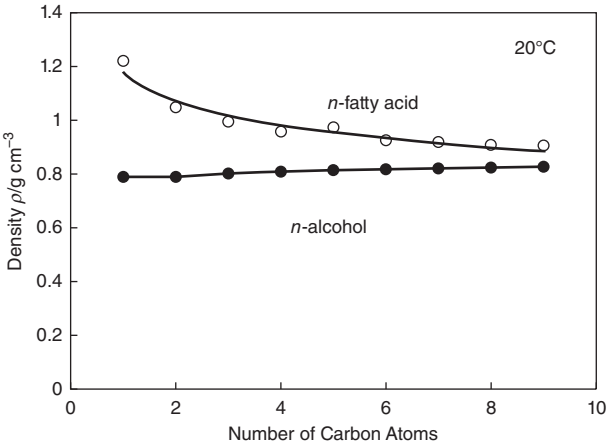

FIGURE 53.1 The relationship between density ρ and number of carbon atoms for normal fatty acid (○) and alcohol (●) at 20°C (293 K). (Original data are from Ref. 1.)

As shown in Fig. 53.2, the molar volume of fatty acid (open circle) except formic acid is almost equal to that of the corresponding alcohol (solid circle). Fatty-acid and alcohol molecules, which have a same number of carbon atoms, occupy almost an equivalent space in the liquid state.

53.2.2 Viscosity of Fatty Acids and Alcohols

Most readers would expect that fatty acid has a higher viscosity than the corresponding alcohol since the hydrogen bonding of carboxyl group of fatty acid is stronger than that of the OH group of alcohol. Figure 53.3 shows the temperature dependence of viscosity η of formic acid and methanol and also that of acetic acid and ethanol, respectively. Formic acid has higher viscosity than methanol at the same temperatures; acetic acid also has slightly higher viscosity than ethanol [1].

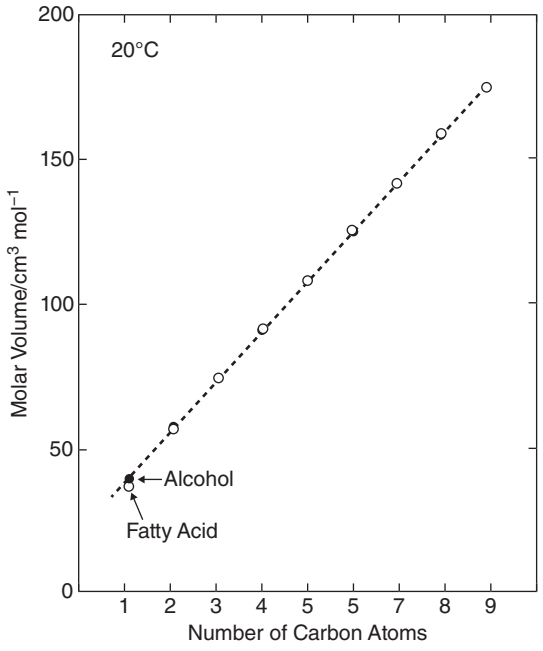

FIGURE 53.2 Relationship between molar volume and number of carbon atoms for normal fatty acid (○) and alcohol (●) at 20°C (293 K).

Interestingly, the viscosity of formic acid is higher than that of acetic acid in spite of its smaller molecular size. X-ray diffraction measurements indicated that formic acid in its crystalline phase forms large polymers through its strong hydrogen bonding. The proton, which is directly attached to C1-carbon atom of formic acid, would contribute to the formation of hydrogen bonding among the formic acid molecules [4].

The viscosity of propanoic or butanoic acid is, however, lower than that of the corresponding alcohol as shown in Fig. 53.4 This suggests that, in spite of relatively low hydrogen-bonding ability of alcohol compared to that of fatty acid, the alcohol molecules in the liquid phase easily aggregate to form larger polymers than fatty acid molecules owing to the appropriate direction of hydrogen bonding among alcohol molecules. On the contrary, the carboxylic acids form only cyclic, hydrogen-bonded dimers by the strong hydrogen bonding between the two fatty-acid molecules. Consequently, the viscosity of alcohol having three or four carbon atoms in its hydrocarbon chain is larger than that of the corresponding fatty acid.

The viscosity profiles for octanoic acid and octan-1-ol (Fig. 53.5) are different from those for propanoic acid and propanol or those for butanoic acid and butan-1-ol (Fig. 53.4). Namely, the viscosity of octan-1-ol decreases steeply as temperature increases, while that of octanoic acid decreases gradually; above 330 K (57°C) the viscosity of octan-1-ol becomes lower than that of octanoic acid [1,5]. This suggests that at high temperature the hydrogen bonding among the OH groups of octan-1-ol becomes weak and that the polymers of octan-1-ol become small in size and decrease in their number, while octanoic acid still maintains its dimer structure even at high temperature.

In the case of *cis*-9-octadecenoic acid (oleic acid) and *cis*-9-octadecen-1-ol (oleyl alcohol), the viscosity of oleic acid is always larger than that of oleyl alcohol as shown in Fig. 53.6 [6]. This suggests that the polymer of oleyl alcohol is small in its size and few in its number even at room temperature. Consequently, it is concluded that the long hydrocarbon part in an alcohol molecule plays as a solvent and dilutes the concentration of OH group. The longer hydrocarbon chain would decrease the association number of alcohol and the number of the aggregates since the hydrogen bonding among OH groups of alcohols is not so strong. On the contrary, owing to the strong hydrogen bonding, fatty acids, except formic and acetic acids, are thought to exist always as cyclic dimers regardless of the hydrocarbon chain length

even at high temperature, as to be described in the following section.

53.3 AGGREGATION NUMBER OF ALCOHOL AND STABILITY OF FATTY ACID DIMER

53.3.1 Effect of Molecular Structure on Aggregation Number of Alcohol in CCl_4 and in Its Pure Liquid

The effect of molecular structure on the self-association of alcohol in its pure liquid state and in carbon tetrachloride was quantitatively investigated through the near-infrared spectroscopic (NIR) observation for butan-1-ol, butan-2-ol, and 2-methylpropan-2-ol (*tert*-butanol), which are structural isomers to each other [7]. A successive association process was assumed for the aggregation of alcohol molecules; the analysis based on this process was applied to the sharp band around 1410 nm (the first-overtone band of the OH stretching vibration mode attributed to free OH monomer and partly to OH polymer).

Figure 53.7a shows, as a typical example, the degree of association (the size of the multimer in monomeric units), <*N*>, for the aggregate of butan-1-ol at various constant temperatures. The <*N*> value increases with increasing concentration and decreases with increasing temperature [7]. Figure 53.7b shows a comparison of the concentration

(a) (b)

FIGURE 53.7 (a) Effect of concentration on the aggregation number <*N*> for butan-1-ol at temperatures ranging from 278.2 K (25.1°C) (◆) to 338.1 K (65°C) (×) at 5 K intervals. Inserted small graph also indicates the <*N*> versus concentration relationship below 1.0 mol dm^{-3}. (b) Comparison of <*N*> for three kinds of butanols at 298.1 K (25°C): □ denotes butan-1-ol; ○, butan-2-ol; ▲, 2-methylpropan-2-ol (*tert*-butanol). FIGURE 53.9 Concentration dependence of dissociation α_0 of oleic acid dimer in CCl_4 at 35°C (●), 40°C (○), 45°C (□), and 50°C (Δ). (Adapted from Iwahashi et al. 1995 [10], pp. 697–701. © Royal Society of Chemistry; reproduced with permission.)

dependence of <*N*> for the above three kinds of butanols at 298.1 K (25°C), the association ability is in the following order: butan-1-ol > butan-2-ol > *tert*-butanol.

The <*N*> value for octan-1-ol in the temperature range 298.1-348.1 K (25-65°C) was *ca*. four both in the pure liquid state and in decane [5]. That for *cis*-9-octadecen-1-ol (oleyl alcohol), which has a longer hydrocarbon chain, was 2.37-3.78 (average 2.95) both in the pure liquid state and in decane in the temperature range 298.1–348.1 K [6]; the <*N*> value had also a tendency to decrease with an increase in temperature. The apparent association constant K for oleyl alcohol was relatively low and also decreased with an increase in temperature. The low K value, which means small portions of polymerized molecules in the liquid state, is most likely responsible for the lower viscosity (Fig. 53.6) and the higher self-diffusion coefficient (Fig. 53.8) of oleyl alcohol than those of oleic acid, which exists almost entirely as cyclic dimers.

53.3.2 Stability of Fatty-Acid Dimers in CCl_4 and in the Pure Liquid State (Melt)

The IR spectra of octanoic acid in the liquid state in the temperature range 296–346 K (23–73°C) indicated that the acid molecules are always self-associated to form dimers by the hydrogen bond between the two carboxyl groups [8]. Namely, the strong absorption band at 1710 cm^{-1} due to the C=O stretching vibration and the relatively broad band at 920 cm^{-1} due to the OH out-of-plane bending vibration of the carboxyl group (assigned to the cyclic hydrogen-bonded dimer) were completely unaltered throughout the temperature range. Another researcher [9] designated, from the magnitude of the mutual diffusion coefficient and its concentration dependence, that the carboxylic acids in CCl_4 at 298 K were present almost entirely as dimers and gave no indication of further association.

To determine more quantitatively the degree of dissociation, α_0, of dimer of oleic acid into its free molecules in CCl_4 at its low concentration region, vapor pressure osmosis measurements were carried out [10].

Figure 53.9 shows the concentration dependence of α_0 at various constant temperatures. The α_0 value increases slightly with decreasing its concentration and increasing temperature: In its concentration from 5×10^{-3} to 2.6×10^{-2} mol dm^{-3} at 50°C, α_0 ranges from 0.35 to 0.22 molar fraction of dimer concentration. Thus, even in the dilute solutions the dissociation of the acid dimers into the monomeric species is not significant: Most fatty acid molecules exist as dimers in a non-polar solvent such as CCl_4 [10].

The degree of dissociation α of oleic acid dimers into monomers in the pure liquid state was also quantitatively determined through the NIR spectroscopic observations [10, 11], in which the temperature dependence of the absorbance intensity of the 1445-nm band assigned to the first overtone of the stretching mode of the free OH of the carboxyl group of oleic acid was observed. To evaluate α, the molar absorption coefficient, ε_{OH}, of the 1445-nm OH band for fatty acid is absolutely essential. However, the Lambert–Beer law was not applicable even to the extremely low concentrated samples of oleic acid in CCl_4. This is because the hydrogen bonding between the two carboxyl groups is too strong. To obtain the ε_{OH} value, the reciprocal apparent molar absorption coefficient for the 1445-nm OH band was extrapolated

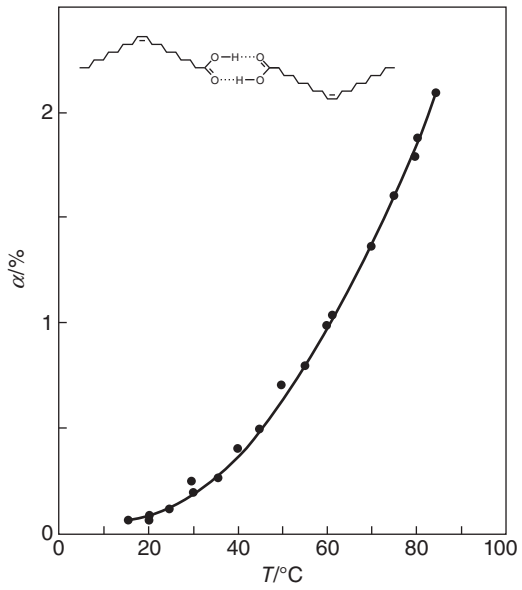

FIGURE 53.10 Temperature dependence of dissociation (α) of oleic acid dimer into its monomers in the melt. A schematic drawing of oleic acid dimer is inserted. (Adapted from Iwahashi et al. 1995 [10], pp. 697–701. © Royal Society of Chemistry; reproduced with permission.)

to that at zero concentration [11]. The obtained ε_{OH} value, however, gave a ten times larger degree of dissociation than its reliable value for oleic acid [9]: This is a typical failed case in the analysis of spectra of the samples having strong self-association ability.

Combination of NIR absorbance for a sample of oleic acid in CCl_4 and degree of dissociation, α_0, obtained through the vapor-pressure osmosis measurements gave a reliable ε_{OH} value for the 1445-nm band of oleic acid. Using this ε_{OH} value, reliable α values in the pure liquid state were determined as a function of T [10] as shown in Fig. 53.10

The dissociation of oleic acid dimer is not so large, although it slightly increases with increasing temperature: α is almost zero at room temperature and ~2% even at 80°C [10]. Other normal fatty acids (C8–C18) gave also similar results [12]. Thus, it is concluded that the fatty-acid dimers are the units in the molecular transfer and segmental movements in the pure liquids and even in nonpolar solvent within these temperature and concentration regions.

53.4 INTRA- OR INTERMOLECULAR MOVEMENTS OF LIPIDS

53.4.1 Segmental Movements (Intramolecular Movements)

^{13}C-NMR spin–lattice relaxation time T_1 for the different carbon atoms along the hydrocarbon chain of lipids is related to the segmental motion (specially, rotational tumbling motion) in the lipid molecules [13, 14]. In addition, as the ^{13}C-NMR spin–lattice relaxation of a protonated carbon is overwhelmingly dominated by dipole–dipole interactions with the attached protons, T_1 for the carbon atom in a segment is related to the number of directly bonded hydrogens N and the effective correlation time τ_c for the rotational movement of the segments in the sample molecule [13, 14]. T_1 is given in terms of N and $1/\tau_c$ as follows:

$$T_1 = \frac{r_{CH}^6}{N\left(\frac{h}{2\pi}\right)^2 \gamma_c^2 \gamma_H^2}\left(\frac{1}{\tau_c}\right) \tag{53.2}$$

where h is Planck's constant, and γ_C and γ_H are the gyromagnetic ratios of ^{13}C and ^{1}H, respectively. r_{CH} is the C–H distance usually about 0.109 nm. Specfically, the reciprocal of τ_c represents the net magnitude of the segmental motion of the carbon.

For alkanes it was reported that the $1/\tau_c$ value for each carbon atom increases with an increase in temperature [13, 14]. At a constant temperature, the movement of the carbon atom at each methyl end of alkane is large, while that at the gravitational center of the molecule is small. The $1/\tau_c$ value for the carbon atom located at the same position, counted from the methyl group for the alkanes at each constant temperature, decreases with an increase in the molecular length of alkane. For alcohols that form polymer through the hydrogen bonding among OH groups, the movement of the carbon atom at methyl end is also large and that adjacent to the hydrogen bonded atom is small [14]. For fatty acids, which exist as dimers, the movement of the carbon atom at the methyl end is large, while that of the carbon atom neighboring the carboxylic group is small [12,14,15].

For example, Fig. 53.11 shows the relationships between $1/\tau_c$ and the position of carbon atoms for octanoic acid (C8), dodecanoic acid (C12), and hexadecanoic acid (C16) at 80°C (353 K). The segmental movements of the methyl groups at the ends of fatty acids are large and almost equal to each other regardless of their hydrocarbon chain length, while the movements of the other same-positioned carbon atoms counted from the methyl end slightly decrease with an increase in the hydrocarbon chain length.

Figure 53.12 shows the relationship between $1/\tau_c$ and the position of carbon atoms for *cis*-9-octadecenoic acid (oleic acid) having a double bond in its molecule at various temperatures. The $1/\tau_c$ value for each carbon atom increases with increasing temperature. Interestingly, the segmental movements of the carbon atoms at the double-bond position are small; the movements of the carbon atoms neighboring the double bond are larger than those of the carbon atoms at the double bond position. Similar results were obtained for *cis*-6-octadecenoic acid (*cis*-6) and *cis*-11-octadecenoic acid

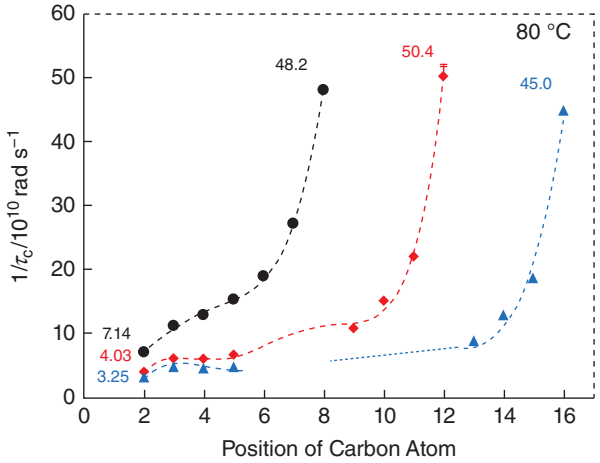

FIGURE 53.11 Relationship between $1/\tau_c$ (indicator of segmental movement) versus position of carbon atoms for octanoic acid (●), dodecanoic acid (◆) and hexadodecanoic acid (▲) at 80°C.

(*cis*-11) [15]. The segmental movements of the carbon atoms of *trans*-9-octadecenoic acid (elaidic acid: *trans*-9) neighboring its double bond are smaller than those of *cis*-type unsaturated fatty acids. Stearic acid, as a whole, exhibited movements similar to those of *trans*-9. Thus, the segmental movements of the fatty-acid dimer would resemble a dumbbell. These fatty-acid dimers gather together and construct their liquids.

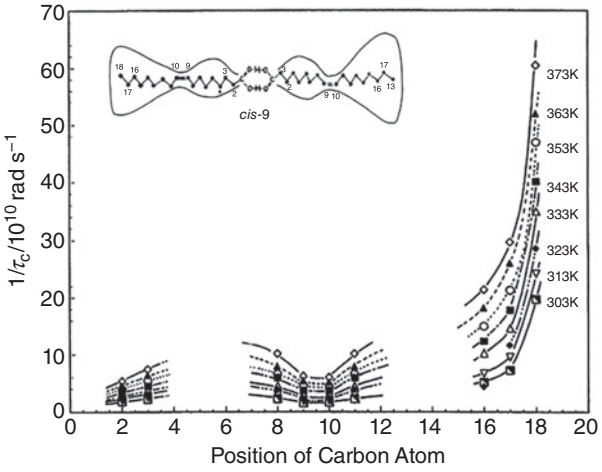

FIGURE 53.12 Relationship between $1/\tau_c$ (indicator of segmental movement) versus position of carbon atom for *cis*-9-ocatdecenoic acid at various constant temperatures: 303 (□), 313 (▽), 323 (◆), 333 (△), 343 (■), 353 (○), 363 (▲), and 373 K (◇). Inserted is a schematic drawing of the segmental movement of oleic acid dimer. The segmental movements of the fatty-acid dimer resemble a dumber. (Adapted from Iwahashi et al. 2000 [15], pp. 6186–6194. © American Chemical Society; reproduced with permission.)

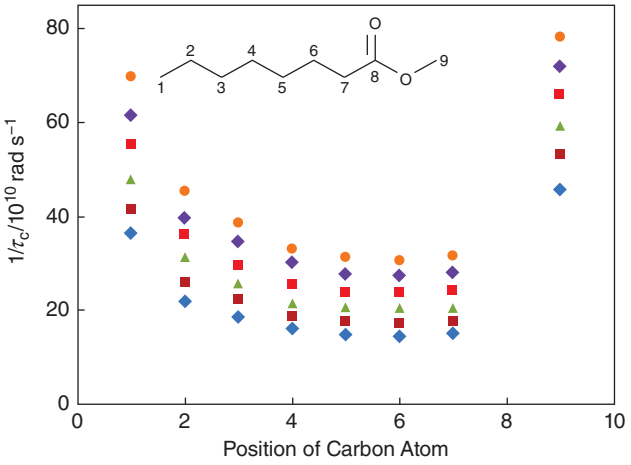

FIGURE 53.13 Relationship between $1/\tau_c$ versus position of carbon atom of methyloctanoate at various constant temperatures: 303 (◆), 313 (■), 323 (△), 333 (■), 343 (◆), and 353 K (●). Position of each carbon atom is counted from the methyl group of main acyl group as shown in the inserted model.

Figure 53.13 and 53.14 show the relationships between $1/\tau_c$ versus position of carbon atoms of methyloctanoate and 2-ethtylhexyloctanoate molecules at various temperatures, respectively. As a whole, the segmental movements increase also with increasing temperature. The movement of methyl group positioned at each end of ester molecules is large, while the movements of the carbon atom near the gravitational center and at the branched position are extremely small compared to that of the carbon atom at other positions [16]. This implies that the fatty acid esters do not form self-associated aggregates in the liquid state.

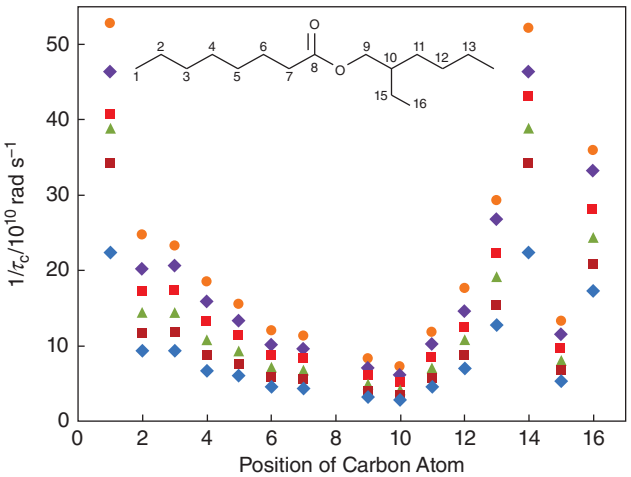

FIGURE 53.14 Relationship between $1/\tau_c$ versus position of carbon atom of 2-ethylhexyoctanoate at various constant temperatures: 303 (◆), 313 (■), 323 (▲), 333 (■), 343 (◆), 353 K (●). Position of each carbon atom is counted from the methyl group of main acyl group as shown in the inserted model.

53.4.2 Intermolecular (Transfer) Movements and Apparent Hydrodynamic Radius for Alkane, Alcohol, Fatty Acid, and Fatty-Acid Ester

As derived by Stokes, the ordinary frictional coefficient (f_0) for the spherical object contacting with fluid layer is given by $f_0 = 6\pi\eta a$, where a is radius of a spherical object moving in a fluid continuum, π the ratio of the circular constants, and η the viscosity of the solvent. The movement of the object is impelled by a force due to the pressure built up in front of it ($= 4\pi\eta a$) and a frictional force parallel to its surface ($= 2\pi\eta a$); these two forces add up to the value given for the above ordinary frictional coefficient. Even through the fluid does not stick to the surface of the spherical object (the slip boundary condition), some fluid in front of the object has to be displaced when the object moves [17]. On the other hand, the side surface of the object does not displace any fluid since the frictional force parallel to the surface of the spherical object is very small. Thus, the overall frictional force (f) becomes $4\pi\eta a$. Thus, for a moving spherical particle almost equal in size to surrounding solvent molecules under slip boundary condition, the Stokes' equation for frictional coefficient f is given by [18–20].

$$f = 4\pi\eta a \tag{53.3}$$

On the other hand, from the Einstein's equation for diffusion, the frictional coefficient is expressed by

$$f = kT/D \tag{53.4}$$

where k is the Boltzmann constant, T the absolute temperature, and D the diffusion coefficient. By combining Eqs. (53.3) and (53.4), the apparent hydrodynamic radius (Stokes–Einstein radius) a is given by

$$a = \frac{kT}{4\pi\eta D} \tag{53.5}$$

This is the Stokes–Einstein formula under the slip boundary condition [17–23]. Using this Stokes–Einstein formula, the dynamic conformation of a normal alkane molecule (C5–C14) in the pure liquid state was estimated [8].

In Figure 53.15 the apparent hydrodynamic radii a at 298.1 K for the normal alkanes (C5–C14) (open circles) are plotted against the number of carbon atoms. The a value seems to increase slightly with an increase in the number of carbon atoms. However, as a whole, these a values for alkanes are almost constant (*ca.* 2.5×10^{-10} m on average), which is comparable to van der Waals radius of the cross section of the hydrocarbon chain (2.4×10^{-10} m). The almost constant hydrodynamic radius suggests that alkane molecules in the pure liquid state take a flexible rodlike conformation, randomly orientate, and entangle with one another; the free rotational (end-over-end) motion as well as transverse

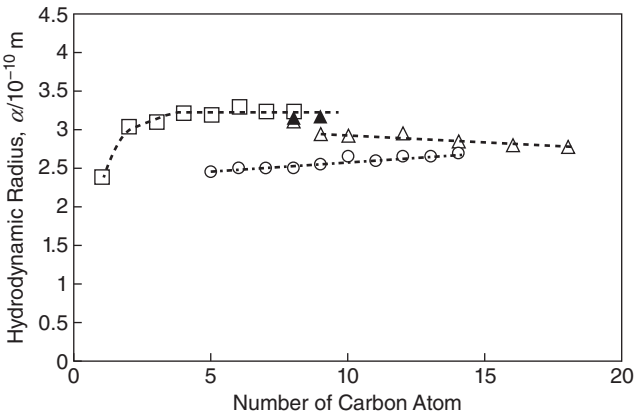

FIGURE 53.15 Apparent hydrodynamic radius a for alkanes (C5–C14), alcohols (C1–C8) and *n*-fatty acids (C8 and C9) at 298.1 K: ○ denotes alkanes; □, alcohols; ▲, fatty acids. In addition, △ denotes fatty acids (C8–C18) at 343 K. (The figure for alkane and alcohol are adapted from Iwahashi et al. 1990 [8], pp. 2154–2158; the figure for fatty acid is from Iwahashi et al. 2002 [12], pp. 157–164. © Chemical Society of Japan; reproduced with permission.)

motion of the alkane molecule would be severely restricted owing to the lack of enough space; the alkanes would translate only longitudinally along the axes of the flexible rod-like molecules. Specifically, the apparent hydrodynamic radius a obtained for alkanes reflects the radius of the cross section of the methyl parts at the terminal positions of alkane molecule and scarcely relates to its molecular length.

In the same graph, a value for normal alcohol (open square) at 25°C (298.1 K) is plotted against the number of carbon atoms in the hydrocarbon chain. The a value increases up to 1-propanol and saturates at 1-butanol to be constant ($\sim 3.2 \times 10^{-10}$ m). This also indicates that the alcohol molecule longer than 1-butanol molecule also takes a rodlike conformation with a constant cross section [24]. This would be supported by the results for octanoic and nonanoic acids.

The a value of octanoic or nonanoic acid at 25.0°C (298.1 K) (solid triangle) is approximately 3.1×10^{-10} m, which is close to that of normal alcohol. Of course, fatty acid exists as dimers, while alcohol usually exists as polymers. Thus it is presumed that alcohol molecules move not as large polymers but as linearly self-associated dimers as well as fatty-acid molecules at least in the translational motion because of their relatively low hydrogen-bonding ability [8]. As an additional example, the a values for fatty acids (C8–C18) (open triangle) at 70°C (343 K) are plotted against the number of carbon atoms in the same graph. Although the a value decreases slightly with increasing number of carbon atoms, as a whole, it is almost constant.

In general, the Stokes–Einstein formula under a slip boundary condition is applicable only for a spherically shaped molecule having a similar size to that for the surrounding solvent molecules [25]. However, the results for

the normal alkanes, alcohols, and fatty acids indicate that the formula is sufficiently applicable even to rodlike molecules having a relatively long hydrocarbon chain.

In the case of a rodlike molecule in its pure liquid, the free rotational (end-over-end), as well as transverse motion of the rodlike molecule, is severely restricted [26] even with slip between the molecules since the object molecule has to displace many other molecules in its transversal motion or end-over-end rotation. This is because the liquid has very little space for motion, as assumed by the fact that only ~10% increases in volume at a solid-melt transition for a long-chained fatty acid [4]. Thus, only a longitudinal translation is allowed. In the longitudinal motion of a flexible rodlike molecule, as the object molecule should displace some other molecules only in front of its molecules surrounding the object molecule, the resistance force comes to be only $4\pi\eta a$.

Other authors [27] also suggested that the elementary diffusion process for normal alkanes, alcohols and fatty acids involves the translation of extended molecule parallel to its chain axis, based on the fact that the activation energies of self-diffusion increase with increasing molecular weight of the alkanes.

In Fig. 53.16, a values for methylesters of fatty acid (C8–C16), butyldodecanoate, isobutyldodecanoate, 2-ethylhexylesters of fatty acid (C8–C16) at 353 K (80°C) are plotted as a function of the number of carbon atoms in their main acyl groups [16]. Obviously the a values of esters of the same kind are almost equal to each other regardless of the chain length of the acyl group in the ester molecule. The a values for fatty acid esters are larger than those for the corresponding normal fatty acids (open circles). By comparison of the a values for the various fatty acid esters having 12 carbon atoms in their main acyl groups, it has become apparent that the fatty-acid ester possessing the larger sidechain has the larger a value. Namely, the sidechain in the fatty-acid ester presumably determines the overall apparent hydrodynamic radius in the longitudinal translation of the fatty-acid ester.

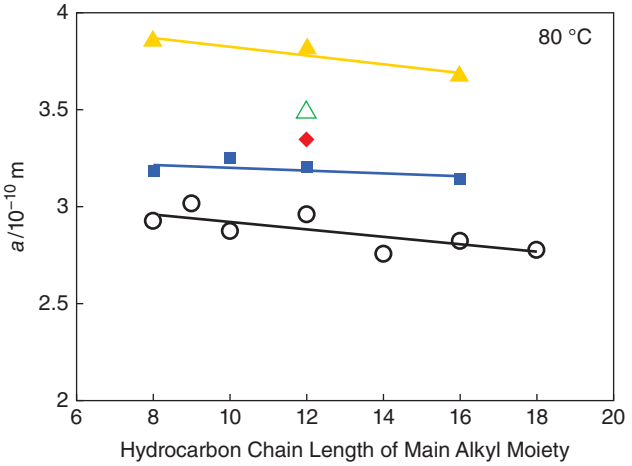

FIGURE 53.16 Apparent hydrodynamic radius a for various fatty-acid esters at 80°C (353.1 K): ▲ denotes 2-ethylhexyl esters (C8–C16); △, isobutyl ester (C12); ◆, butyl ester (C12); ■, methyl esters (C8–C16). As reference standard, a for fatty acid (C8–C18) at 80°C (open circle) is also plotted.

53.5 LIQUID STRUCTURES OF FATTY ACIDS

53.5.1 Fatty Acid Having a Longer Hydrocarbon Chain

The self-organization of fatty acids in the liquid state has been thoroughly studied by using near-infrared spectroscopy and vapor pressure osmosis on various fatty acids [2]. Fatty acids exist mostly as dimers, even at high temperature, where the dimers are the units in their intra- and intermolecular movements. These were found to aggregate to form clusters possessing the structure of a quasismectic liquid crystal, where the long-chained fatty acid dimers arrange longitudinally and alternately to form an interdigitated structure in the clusters. This has been determined based on measurements of viscosity, density, and NMR and X-ray diffraction [2]. The clusters most likely determine the liquid property of the fatty acid. [12,15,28–30].

As a typical example, Fig. 53.17 shows the temperature dependence of density for five kinds of fatty acids [*cis*-6-, *cis*-9- (oleic), *cis*-11-, *trans*-9-ocatdecenoic (elaidic) and octadecanoic (stearic) acids] in the pure liquid state [15]. From this graph, two questions are raised:

1. Why are the densities of three kinds of *cis*-type unsaturated fatty acids almost equal to each other?
2. Why does stearic acid possess the lowest density?

The lowest density of stearic acid is contract to our expectance based on chemical conformations, melting temperatures, and heats of fusion. The stearic acid molecules having fewer *gauche* structures should easily aggregate with each other and orient more tightly than the molecules of the unsaturated fatty acids.

X-Ray diffraction measurements for the liquid samples of the five kinds of fatty acids have solved the above questions and riddles.

In Table 53.1, the short and long spacings for the five kinds of fatty acids are listed. The short and long spacings are $\sim 4.6 \times 10^{-10}$ m and *ca.* 24-26 $\times 10^{-10}$ m, respectively. The long spacing seems to be too small, because two fatty acid molecules always form a dimer, which is $\sim 50 \times 10^{-10}$ m in length.

The incomprehensive value for the long spacing can be explained by assuming the existence of clusters possessing a unique arrangement of the dimerized molecules in the liquid of fatty acid.

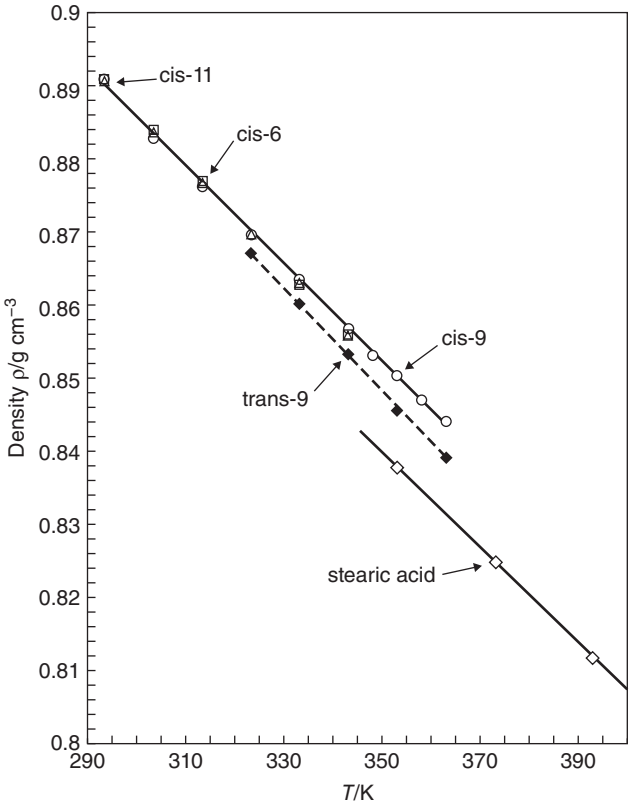

FIGURE 53.17 Temperature dependence of density ρ for various fatty acids: □ denotes *cis*-6; ○, *cis*-9; △, *cis*-11; ◆, *trans*-9; ◇, stearic acid. (Adapted from Iwahashi M., Kasahara Y. (2011). Dynamic molecular movements and aggregation structures of lipids in a liquid state. *Curr. Opin. Colloid Interface Sci.* **16**, 359–366. ©: Elsevier Ltd.; reproduced with permission.)

As represented in the schematic drawings for *cis*-9 and *cis*-11 in Fig. 53.18, the dimerized acid molecules arrange longitudinally and alternately to make an interdigitated structure. The dimerized carboxyl groups in one dimer and the methyl groups at the terminal of the neighboring dimers are aligned alternately in the same lateral plane. If the dimerized acid molecules take this intergitated structure, the methyl and methylene groups near the terminal positions of the acid molecules are able to move largely, because the movements of the carbonyl groups in the neighboring dimers are restricted. This structure allows the most compact packing for the dimerized molecules of the fatty acids. *cis*-6 would have almost a same cluster structure and a liquid structure as *cis*-9 and *cis*-11 [15]. This is the reason why the three kinds of *cis*-type unsaturated acids have a similar density *vs*. temperature profile to each other as shown in Fig. 53.17.

TABLE 53.1 Short and Long Spacings for *cis*-6, *cis*-9, *cis*-11, *trans*-9, and Stearic Acid Having 18 Carbon Atoms Near Their Melting Points

	T (K)	Short Spacing (10^{-10}m)	Long Spacing ($^{-10}$m)
cis-6	304	4.58	24.2
cis-9	298	4.57	23.8
cis-11	298	4.57	24.1
trans-9	319	4.59	25.0
Stearic acid	343	4.66	25.7

"Short spacing" means the distance among the neighboring fatty-acid molecules.

Source: Adapted from Iwahashi et al. 2000 [15], pp. 6186–6194. © American Chemical Society; reproduced with permission.

The long spacings for stearic acid and elaidic acid are larger than those for the *cis*-type unsaturated fatty acids, as listed in Table I. Additional X-ray diffraction experiments at various temperatures also revealed that the long spacing for stearic acid exceeds those for *cis*-type acids, while the short spacing for stearic acid was less than those for the *cis*-type acids [15]. Namely, stearic acid molecules are more extended and have a shorter lateral distance than the *cis*-type acid molecules. This indicates that stearic acid molecules also have an interdigitated lamellar structure in the liquid state and that the straight, rod-like molecules of stearic acid aggregate tightly with each other to form rigid clusters.

The rigid clusters aggregate randomly to produce many spaces among the clusters as shown in Fig. 53.19. The liquid structure may resemble the "house of cards" structure often found in bulky clay [31]. The spaces produce low density for the liquid of stearic acid. However, the real distance between the interacting molecules in the cluster of stearic acid is so small that the molecules in the cluster cannot move easily because of the large attractive forces (i.e., mainly by van der Waals forces) among the molecules. This causes the low self-diffusion coefficient of stearic acid compared to those of *cis*-type unsaturated fatty acids [15]. On the other hand, the flexible molecules of the *cis*-type unsaturated fatty acid make similar clusters, which seem to be soft, aggregate randomly with each other to construct a liquid. The softness of the clusters prevents the formation of the spaces among them. Thus, as a whole, the *cis*-type unsaturated fatty acids seemingly have higher density than stearic acid. As the interaction among the molecules in the cluster of the *cis*-type acid is not strong, the molecules of the *cis*-type acid can move more easily than those of stearic acid [15].

53.5.2 Fatty Acid Having a Medium Hydrocarbon Chain

In Fig. 53.20 the density of normal fatty acid (C2–C18) at 80°C (353K) is plotted against the number of carbon atoms (Cn). Extremely high density of formic acid (C1-acid) would result from the formation of polymer even in the liquid state. The density of fatty acid, except formic acid, decreases gradually with increasing chain length (Cn) of fatty acid. Interestingly, however, the inclination of the density curve apparently changes at C12. This relatively steep change in

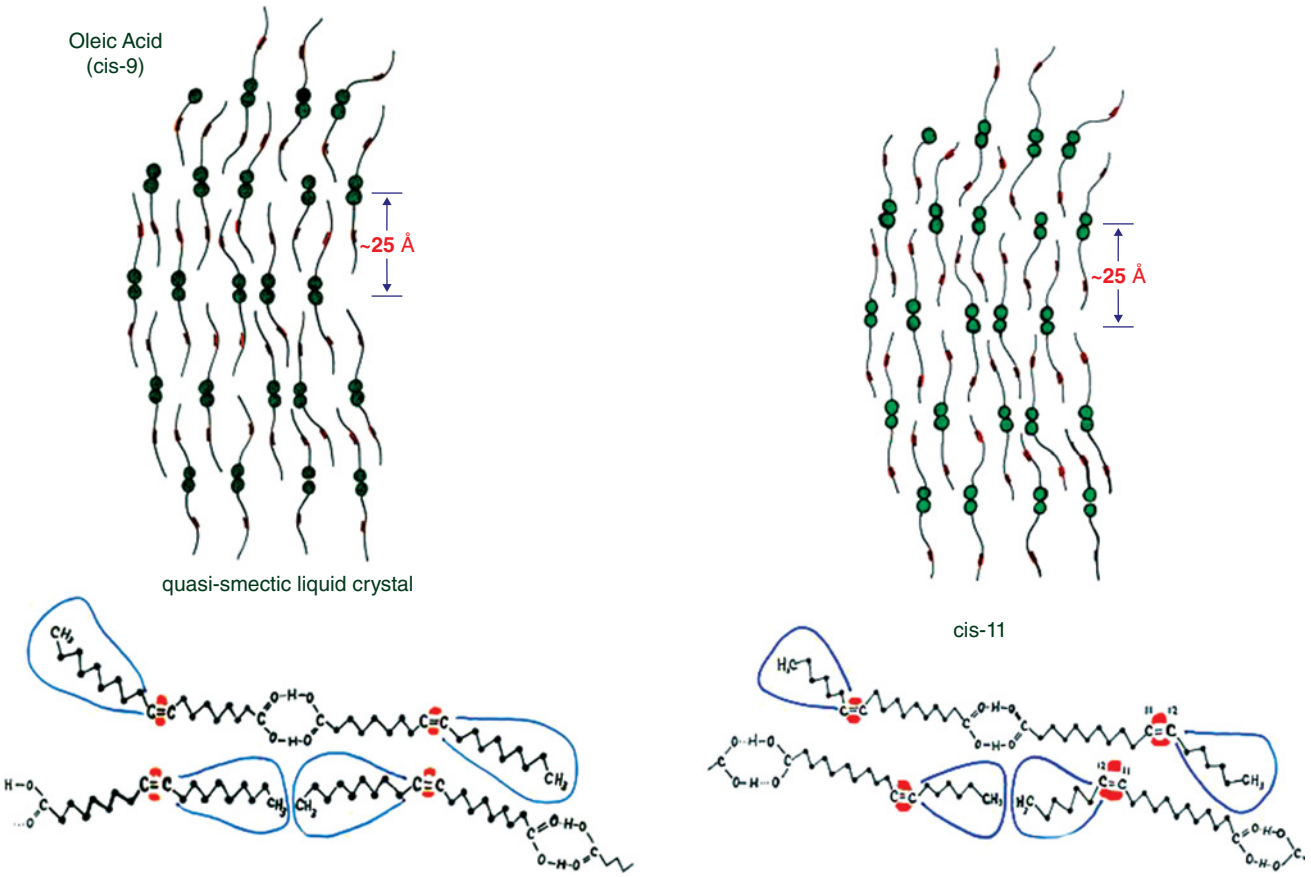

FIGURE 53.18 Cluster models, proposed for the dimers of *cis*-9 or *cis*-11 having 18 carbon atoms, in the liquid state. The clusters take the structure of a quasismectic liquid crystal. This structure allows the most compact packing for the dimer molecules of fatty acids. Below drawings are arrangements proposed for the dimers of *cis*-9 or *cis*-11 molecules in the cluster, respectively; *cis*-6 would take a similar cluster structure. (Adapted from Iwahashi 2000; 104:6186–6194, © American Chemical Society; reproduced with permission.)

inclination suggests that the microliquid structure (cluster structure) of the normal fatty acid is different below and above C12. Above C12 the long-chained fatty acid dimers would arrange longitudinally and alternately to make an interdigitated structure in the clusters, as being described for the fatty acids having 18 carbon atoms. Then what structure does the fatty acid having a medium length hydrocarbon chain take?

X-Ray diffraction, self-diffusion coefficient, ^{13}C-NMR spin–lattice relaxation time, near-infrared (NIR) spectroscopy, and ^{1}H-NMR chemical shift measurements for the samples of octanoic acid in its melt and in its CCl_4 solution were carried out; it became clear that the dimers of fatty acid having a moderate-length hydrocarbon chain construct also the clusters having a smectic liquid crystal-like structure in the melt and also in a non-polar solvent [32].

For example, Fig. 53.21 shows the temperature dependence of the long spacing for the neat sample of octanoic, oleic, or stearic acid. The long spacing for octanoic acid being longer than its molecular length increases gradually up to 350 K and then steeply with increasing temperature, while those for stearic and oleic acids maintain almost constant value regardless of temperature.

Figure 53.22 represents the schematic drawings of the clusters for octanoic acid (a) and stearic acid (b), respectively. The dimers of stearic acid are completely interdiginated in the cluster, while the dimers of octanoic acid are half-interdiginated. Thus the cluster of octanoic acid is thought to be not so stable compared to that of longer chained fatty acid such as oleic acid or stearic acid [32].

53.6 EFFECT OF CHOLESTEROL AND OTHER ADDITIVES ON THE CLUSTER STRUCTURE AND PROPERTIES OF OLEIC ACID

It is known empirically that cholesterol, one of lipids, increases the viscosity of oleic acid. The effect of cholesterol

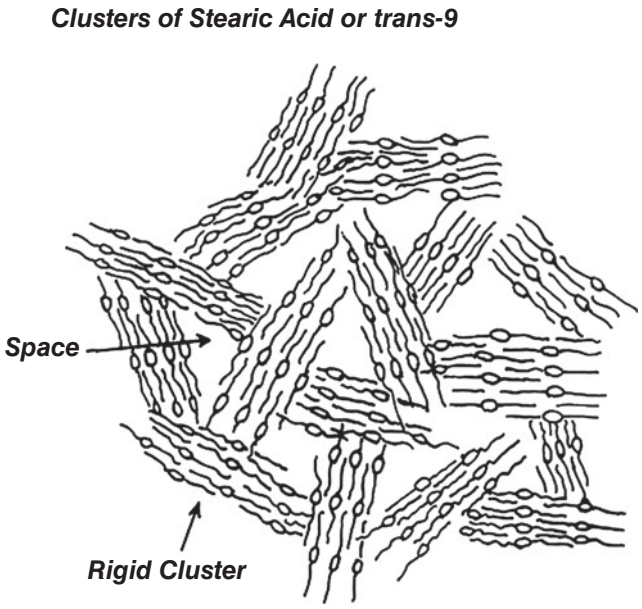

FIGURE 53.19 Schematic drawing of the clusters composed of stearic acid dimers. The straight, rodlike molecules of stearic acid aggregate tightly to form rigid clusters. These rigid clusters aggregate randomly to form a liquid having many spaces. The spaces produce low density and, consequently, a large apparent volume for the liquid of stearic acid.

and other additives on viscosity, self-diffusion coefficient, and intramolecular movements of oleic acid was investigated to clarify the mechanism of the effect of cholesterol on the intermolecular and intramolecular (segmental) movements of oleic acid in the liquid state [30].

Figures 53.23 and 53.24 show the effects of additives on the viscosity and self-diffusion coefficient of oleic acid,

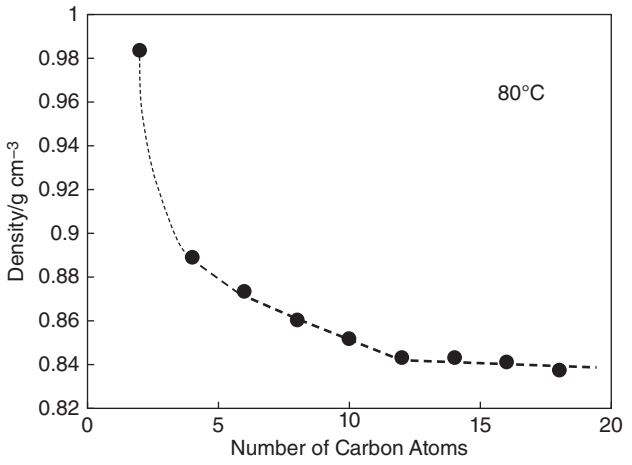

FIGURE 53.20 Density versus number of carbon atoms of normal fatty acids (C2–C18) at 80°C. (Original data are from Ref. 1.) Formic acid is an exception because it is thought to form polymer even in the liquid state.

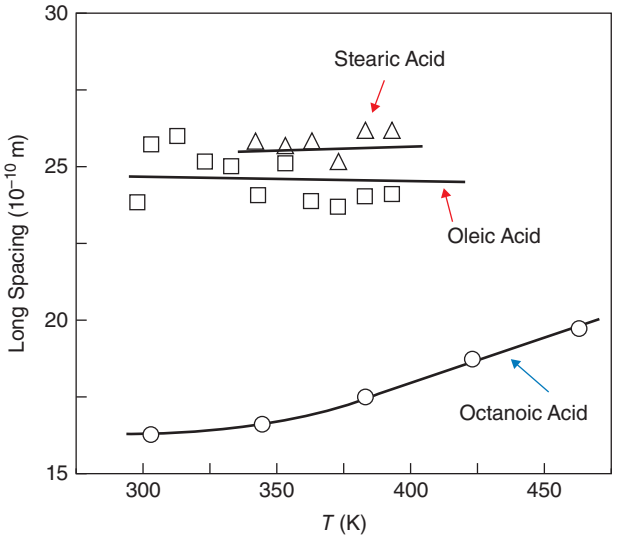

FIGURE 53.21 Temperature dependences of long spacing for octanoic acid (○), oleic acid (□), and stearic acid (Δ). (Adapted from Matsuzawa et al. 2013 [32], pp. 25–32. © Scientific Research Publishing, Inc.; reproduced with permission.)

respectively. The additives containing a steroid ring increase the viscosity of oleic acid, while the small additives such as ethanol and benzene decrease it; the former additives also decrease the self-diffusion coefficient, while the latter additives increase it. In particular, cholesterol significantly increases the viscosity and reduces the self-diffusion coefficient, while ethanol decreases the viscosity and increases the self-diffusion and intramolecular movements of oleic acid.

Here, two experimental findings exist for cholesterol and ethanol: (1) both cholesterol and ethanol possessing one OH

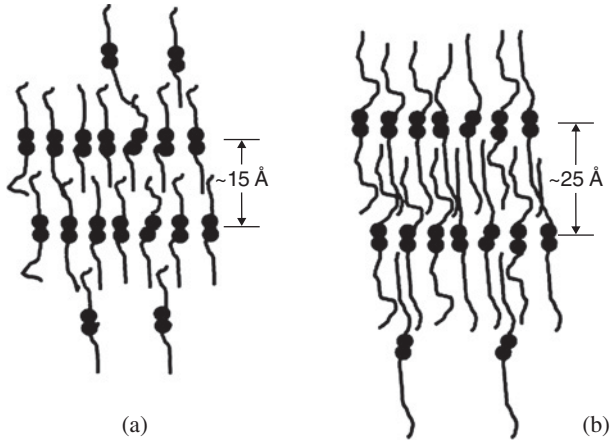

FIGURE 53.22 Cluster models for (a) octanoic acid and (b) stearic acid. Dimers in the cluster of stearic acid are completely interdiginated, while the dimers of octanoic acid are half-interdiginated. FIGURE 53.23 Effect of various additives on viscosity of oleic acid at 40°C (313 K): ○ denotes cholesterol; ●, cholestane; ◆, ethanol; □, benzene. (Adapted from Iwahashi et al. 2007 [30], pp. 740–747. © American Chemical Society; reproduced with permission.)

group promote similarly the upfield shift of the ^{1}H-NMR signal of the carboxyl group of oleic acid [30] and (2) the difference spectra obtained for the samples of oleic acid–cholesterol mixtures really resemble those for oleic acid–ethanol mixtures. The IR difference spectra were obtained by subtracting the spectrum relatively corrected for each pure component (oleic acid, cholesterol or ethanol) from the spectrum for the mixture (composed of oleic acid/cholesterol or oleic acid/ethanol). The IR difference spectra obtained indicate only the situation of hydrogen bonding [30].

The above two observations indicate that oleic acid makes a complex with cholesterol as well as with ethanol [30].

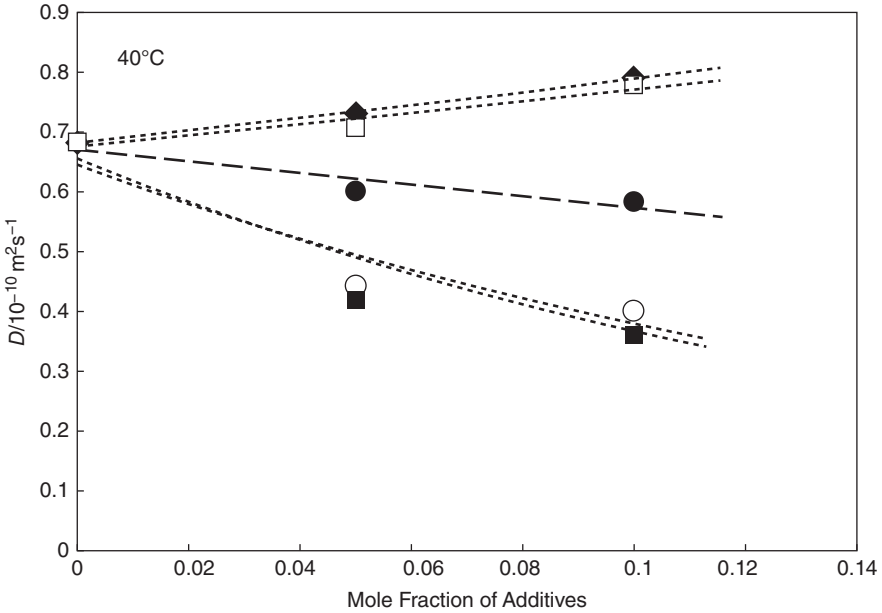

FIGURE 53.24 Effect of various additives on self-diffusion coefficient D of oleic acid at 40°C (313 K): ○ denotes cholesterol; ■, cholestanol; ●, cholestane; ◆, ethanol; □, benzene. (Adapted from Iwahashi et al. 2007 [30], pp. 740–747. © American Chemical Society; reproduced with permission.)

Then, why does cholesterol, as opposed to ethanol, decrease the inter- and intramolecular movements of oleic acid? This question can be addressed as follows.

The complex formed from cholesterol and oleic acid, whose structure may resemble cholesteryl oleate, most likely penetrates into clusters composed of oleic acid dimers. Such complexes improve the packing of dimers inside the clusters by attraction between their hydrophobic moieties of cholesterol and oleic acid molecules. The improvement of packing would increase the viscosity and decrease the self-diffusion coefficient and the intramolecular movements of oleic acid; the formation of the oleic acid–cholesterol complex would be the origin of the lowering of the molecular movements of oleic acid. On the other hand, the complex composed of oleic acid and ethanol also penetrates into the cluster consisting of oleic acid dimers. However, it does not condense the arrangement of the oleic acid dimers in the cluster; instead, it disturbs the arrangement because the hydrophobic moiety of ethanol is too small, even if the position of the oleic acid/ethanol complex in the cluster is same as that of the oleic acid/cholesterol complex [30].

53.7 AGGREGATED STRUCTURES AND PROPERTIES OF ACYLGLYCEROLS

53.7.1 Triacylglycerols

To date, three models for liquid-state ordering in triacylglycerols (TGs) have been proposed. By X-ray diffraction, one investigator [33, 34] proposed that TGs were present as domains approximately 20 nm in diameter and maintained a structure similar to that in the crystalline state, except that the chains were melted. Specifically, the structure for liquid TGs is small pseudolamellar domains (smectic liquid crystal); the lamellar domain remains 20–40°C above the melting point of TG and the domains decrease in size with an increase in temperature. In the domain TG molecules have a chairlike conformation (h-conformation).

By neutron diffraction, another author [35] proposed a nematic liquid crystal model for the TG melt. In this model, TG molecules have also a chair-like conformation (h-conformers) whose three hard aliphatic chains are orientated to form domains having a nematic liquid crystal structure. Another investigator [36] proposed that TG molecules have splayed, disordered chains in the liquid state. Namely, the TG molecules take a Y-shaped conformation (Y-conformers), in which the three soft hydrocarbon chains have an angle of 120°between them; the Y-conformer disks loosely attach to each other and stack into flexible, short cylindrical rods. They also suggested that the h-conformers exist at low temperature, and Y-conformers exist at high temperature. The Y-conformer model was supported by using molecular dynamics simulation [37]. In conclusion, the true liquid structure or the aggregation structure of TGs in the melt needs still further investigation.

53.7.2 Diacylglycerols

Regrettably, the liquid structure for diacylglycerols has not yet been clarified.

In general binary mixture (*RS*-form) of enantiopure compounds (*R*- and *S*-form) in the solid state can be classified, in terms of the interaction of *R*- and *S*-form molecules in the crystal, into three types of modification: a racemic compound, a solid solution, or a eutectic mixture of *R*- and *S*-crystallites. The three types of modification depend on the strength of interaction between *R*- and *S*-form molecules [38].

The phase diagram of binary mixture of enantiopure and racemic 1,2-diacylglycerol (1,2-DAG) containing palmitic or stearic acid was reported [39]. Racemic mixtures of 1,2-diacylglycerol formed a eutectic mixture (conglomerate) in the highest melting form (β') and a solid solution in the metastable (α) form [3,40]. Transformation from metastable α to highest melting form (β') of racemic 1,2-DAG is extremely slow compared to that of enantiopure even through the liquid state. This is because the racemic β'-form crystal is a mixture of *R*-form and *S*-form crystallites; on the other hand, metastable α-form crystal is a solid solution composed of *R*- and *S*-molecules, which freely mix to each other. Consequently, it is very difficult for *R*- or *S*-molecules in the solid solution to transfer separately and then aggregate to make β'-form crystals composed of only *S*- or *R*-species.

53.7.3 Monoacylglycerol

1-Monoacylglycerols have been used in many fields as harmless detergents. *RS*-1-monoacylglycerols containing even carbon-chain lengths from C12 to C18 are expected to be racemic compounds, as they appear at higher melting temperatures than their optically active *S*-forms do [38]. To confirm this presumption, the thermodynamic and spectrographic properties such as melting temperature, latent heat of fusion, solubility, heat of solution, and infrared and NMR spectra were investigated for the stable β-forms of the optically active *S*- and the corresponding racemic *RS*-1-monostearol in the solid state [41]. The phase diagram for the binary mixture and the IR spectra of *S*- and *RS*-crystals indicated that the *RS*-form is racemic molecular compound consisting of *R*- and *S*-1-monostearol molecules. The latent heats of fusion for *S*- and *RS*-1-monostearol crystals were 82.4 and 75.4 kJ mol^{-1}, respectively. On the other hand, the heats of solution in benzene for *S*- and *RS*-crystals were 86.3 and 99.9 kJ mol^{-1}, respectively. The difference in the heat of solution between the *S*- and *RS*-crystals, 13.6 kJ mol^{-1}, is thought to be attributable to the difference in the extent of hydrogen bonding. This indicates that *R*- and *S*- molecules

in the *RS*-form strongly interact to form a racemic pair not only in the solid state but also in the molten state. Such a racemic pair would dissociate into the free molecules when they are dissolved in a nonpolar solvent. This was supported by comparisons in IR and NMR spectra for both *S*- and *RS*-1-monoacylglycerols in dissolved states and melt.

53.8 NEW APPLICATION OF FATTY-ACID ESTERS

53.8.1 Application of Fatty-Acid Ester as Insulating Oil in Transformers

Ever since the prohibition of the use of polychlorinated biphenyl (PCB), mineral oils have been commonly used again as electrical insulating oil in transformers because of its relatively high electrical insulating ability and fluidity: Fluidity of insulating oil is essential for the exclusion of generated heat. Considering the depletion of resources and environmental problems, natural oils produced by plants are expected to be good electrical insulators in terms of a high dielectric breakdown voltage and environmental safety [42–44]. However, natural plant oils have higher viscosity than do the generally used mineral oils. Now then, fatty-acid esters synthesized from natural plant oils are attracting attention as an environmentally friendly insulating oil having low viscosity. Fatty-acid esters such as methyl octanoate (C8-Me), methyl dodecanoate (C12-Me), 2-ethylhexyl octanoate, and 2-ethylhexyl dodecanoate having high fluidity show excellent moisture tolerance against dielectric breakdown compared to mineral oil [45].

As shown in Fig. 53.25, the electrical breakdown for mineral oil (solid diamonds) occurs below 50 ppm of moisture content, while that for these fatty-acid esters occurs at higher moisture content. In particular, C8-Me (solid square) has the highest protective ability against the electrical breakdown.

To clarify the mechanism for the superior moisture tolerance of fatty-acid esters, the status of dissolved water in the esters was investigated with IR spectroscopic measurements and the computer calculation using the density functional theory (DFT) [45] for the normal vibration frequencies of water existing in fatty-acid ester. The IR spectroscopy and the calculation revealed that water molecules in fatty-acid ester are fairly trapped as a solitary molecule by the ester moiety of fatty acid ester. On the other hand, water molecules in mineral oil may exist as clusters [46], which are assumed to be a trigger in the electrical breakdown of insulating oil [45]. Consequently, fatty-acid esters have a higher tolerance against electrical breakdown than mineral oil. As shown in Fig. 53.26, however, when the moisture content in fatty-acid esters increases and reaches to the ratio of 200/1 (the ratio of the number of ester molecules to one water molecule), the breakdown voltage steeply decreases. This indicates that at the ratio of 200/1, water molecules probably start to aggregate and create the clusters composed of water molecules even in the fatty-acid esters.

53.8.2 An Application of Fatty-Acid Ester for Hepatoma Operation Using a Microcatheter

Hepatoma cells grow and multiply by obtaining nourishment and oxygen from arteries, while ordinary hepatocells,

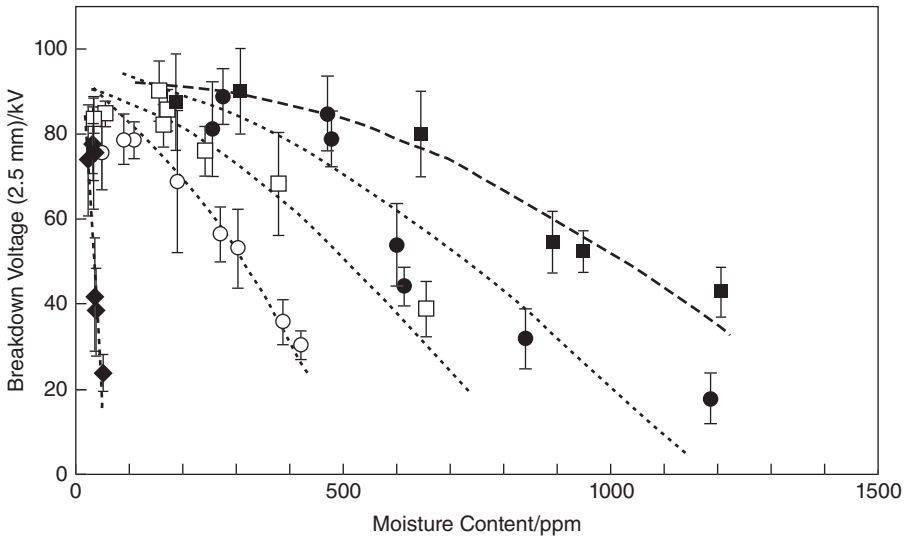

FIGURE 53.25 Breakdown voltage at 2.5-mm gap versus moisture content in mineral oil (◆) and in various fatty acid esters at room temperature (~25°C): ■ denotes C8-Me; ●, C12-Me; □, C8-2EH; ○, C12-2EH. (Adapted from Kasahara et al. 2013 [45], pp. 1223–1229. © American Oil Chemical Society; reproduced with permission.)

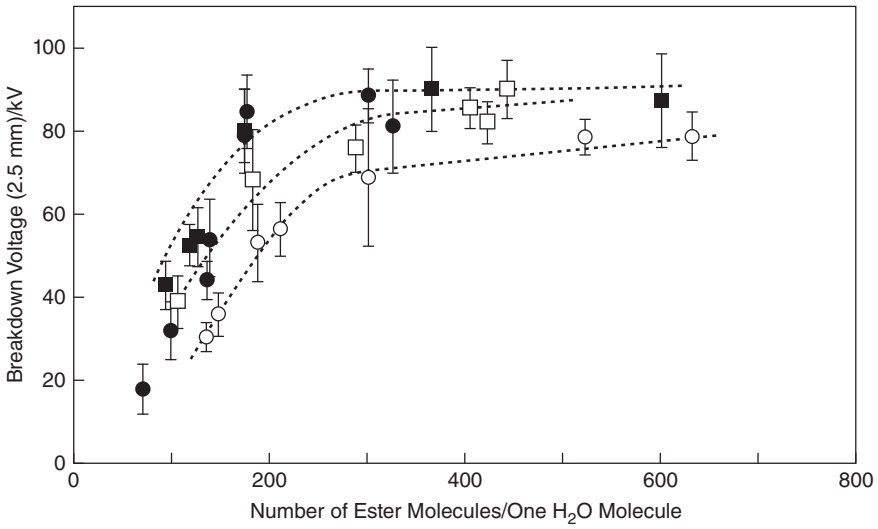

FIGURE 53.26 Relationship between breakdown voltage at 2.5-mm gap for various fatty acid esters including water and the number of fatty-acid ester molecules per one H_2O molecule: ■ denotes C8-Me; ●, C12-Me; □, C8-2EH; ○, C12-2EH. The breakdown voltage for each fatty-acid ester gradually decreases as the number of ester molecules per one H_2O molecule decreases, and then decreases sharply below ~200 ester molecules per one H_2O molecule. (Adapted from Kasahara et al. 2013 [45], pp. 1223–1229. © American Oil Chemical Society; reproduced with permission.)

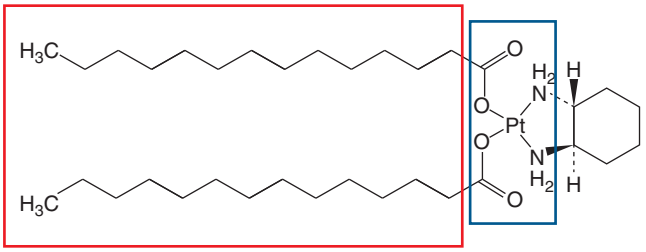
which receive nourishment and oxygen not only from arteries but also from portal veins (i.e., 25% from arteries and 75% from portal veins). Based on this character of the hepatoma cells, transcatheter arterial chemoembolization (TACE) is an effective treatment for patients with advanced hepatocellular carcinoma (HCC) [47, 48]. In TACE, the final chemoembolization is usually carried out with a piece of gelatin that would disappear within 2 weeks. For TACE, a joint use of a dispersion liquid of anticancer agent in ethylester of iodized fatty acid obtained from poppy seed oil [trivial name *lipiodol* (LPD)] is also recommended to enhance its anticancer effect: LPD has a tendency to gather to hepatoma cells and maintain its position. The fatty acid obtained from poppy seed oil consists mainly of linoleic acid. The iodized ethyl ester of the fatty acid plays as not only a solvent for the lipophilic anticancer agent but also as a liquid contrast medium for X-ray photographic imaging because iodine atom has many electrons.

As one of the anticancer agents, [(1*R*,2*R*)-cyclohexane-1, 2-diamine-*N*,*N*′]bis (tetradecanoate-*O*) platinum [trivial name *miriplatin* (MPT)] has been designed as a lipophic platinum complex that can be easily suspended in LPD [49–51].

Figure 53.27 shows the chemical structure of MPT. In vitro studies have shown that platinum compounds gradually released from MPT suspending in LPD were incorporated into rat hepatoma cells and bound to nuclear DNA to form platinum DNA adducts [52,53]. In several animal models, MPT/LPD suspension had sufficient antitumor effects on hepatic after intrahepatic arterial administration [54,56].



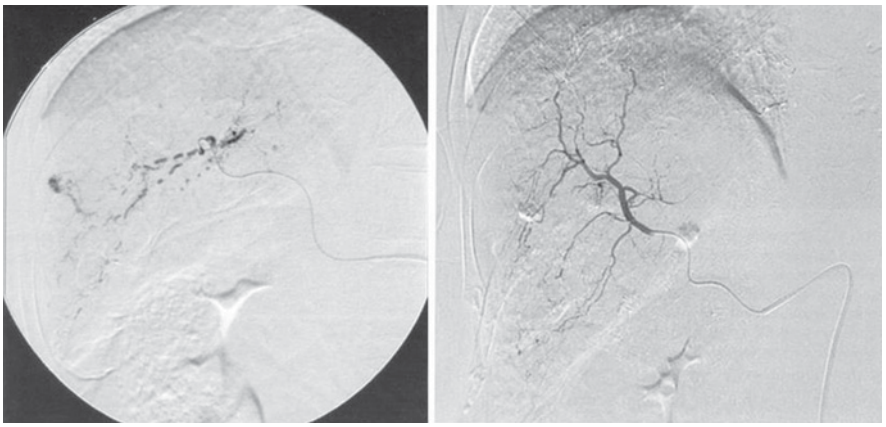


FIGURE 53.27 Structural formula of [(1*R*,2*R*)-cyclohexane-1,2-diamine-*N*,*N*′]bis (tetradecanoate-*O*)platinum. Its trivial name is miriplatin (MPT), which is used as one of the anticancer agents that can be suspended in iodized ethyl ester of fatty acid obtained from poppy seed oil [trivial name lipiodol (LPD)]. Note that the structure of MPT resembles a surfactant having two hydrophobic chains. Two alkyl groups surrounded by a thin square are hydrophobic, and the part surrounded by a thick square is hydrophilic. (Adapted from Tanaka et al. 2011 [50], pp. 39–48. © Dainippon Sumitomo Pharma Co., Ltd.; reproduced with permission.)

The TACE using MPT/LPD suspension is expected to have enhanced therapeutic effect on human HCC. However, in actual clinical practice, the injection of MPT/LPD suspension through a catherter requires high pressure owing to the high viscosity of the suspension. In addition, this high viscosity of MPT/LPD suspension was thought to lead to uneven distribution within HCC, as shown in Fig. 53.28a, which eventually hampers its therapeutic effect. Another team [56] proposed a warming method to reduce the viscosity of MPT/LPD suspension and to improve antitumor effect of

(a) (b)

FIGURE 53.28 The appearance of MPD/LPD suspension within the arteries immediately after its injection in patients who underwent TACE: (a) with MPD/LPD at room temperature and (b) with warmed MPD/LPD. In photo (a), globular or beaded appearance exists; in photo (b), smooth and continuous appearance exists. (Images from Kora et al. 2013 [56], pp. 1023–1029. © Springer; reproduced with permission.)

TACE. By an vitro study, it became clear that warming actually reduced the viscosity and also the injection pressure of MPT/LPD suspension through microcatheters. For example, warming the MPT/LPD suspension up to 40°C significantly reduced its viscosity to almost half that at room temperature (25°C) and injection pressure through microcatheters. Furthermore, the warmed MPT/LPD suspension exhibited a more smooth and continuous appearance within the vascular lumen (Fig. 53.28b) compared to that at room temperature (Fig. 53.28a).

Thus, the warming MPT/LPD suspension method is thought to be superior on its injection and improving antitumor effect. However, the mechanism of reducing pressure on injecting MPT/LPD suspension through a microcatherter and the reason for its continuous flow appearance have not been fully elucidated.

However, on the base of the surface and interfacial chemistry, the reducing pressure and the continuous distribution of the warmed MPT/LPD suspension within vascular lumen are explicable as follows:

LPD is oil (ethylester of iodized fatty acid), while blood is water, although it includes many substances; MPD is a kind of surfactant having two long hydrophobic hydrocarbon chains as shown in Fig. 53.27 As the solubility of MPD in LPD is very low, MPD in LPD usually exists as a dispersion of small, solvated solids.

On injection of MPT/LPD suspension (oil) into blood (water) at room temperature, oil–water interface is newly created. At this moment, MPD molecules (a kind of surfactant) adsorbing at the interface are extremely few because of the extremely low solubility of MPT in LPD (i.e., the low concentration of free MPT molecules in LPD) and their hard translations to the interface because of the high viscosity of MPT/LPD suspension at room temperature. Thus, on injection of MPT/LPD suspension into blood, a large droplet of MPT/LPD suspension (oil), which has a high interface tension, is formed at the end of a microcatherter. The high interface tension produces a high resistance against the injection of MPT/LPD suspension.

On the other hand, on injecting MPT/LPD suspension at a high temperature, the MPT molecules would easily absorb to the newly formed interface since the concentration of the free MPT molecules in LPD is large and the viscosity of the MPT/LPD suspension is low. Thus, on injection of MPT/LPD suspension at a high temperature, the absorption of the free MPT molecules onto the interface newly formed would easily and largely occur. Consequently, the interface tension becomes lower and the resistance against the injection would reduce. Furthermore, owing to the low interface tension the droplet easily becomes small droplets (small emulsions), which appear to be continuous. The small droplets can reach even to thin blood vessels.

In this chapter, the liquid structures of alkanes, alcohols, fatty acids, and fatty-acid esters including TGs are introduced. In practice, in the food industry, cosmetics, and other fields, the liquid contains various acylglycerols and fatty acids simultaneously and has special structures and functions. Therefore, study of the mixed liquid of lipids should be the main objective in future research.

BIREFRINGENCE IN LIPID BILAYER MEMBRANES

KIYOSHI MISHIMA

Yorozu Kohboh, Dome, 2-2804-1 Makuhari Hanumigawa-ku, Chiba-shi, Chiba 262-0032, Japan

54.1 INTRODUCTION

Much of the current knowledge about the structural and dynamic properties of lipid bilayers and biological membranes was gained by many techniques such as X-ray diffraction, differential scanning calorimetry (DSC), NMR, and electron microscopy [1–7]. However, recent findings suggest that our knowledge about the membrane structure and dynamics is still superficial in many respects [8]. For instance, bilayers vary considerably in thickness and orientation of molecules in the bilayer is not as simple as previously expected. Hydrophobic helices with hydrophilic endings are not necessarily arranged perpendicular to the membrane plane [9], and dynamic rearrangement of geometrical distribution is believed to be of even higher importance [10, 11]. Although structural biophysical techniques, such as X-ray and neutron scattering techniques, have been used to investigate structure of lipid bilayers, many of them provide information about the steady-state condition of the structure, rather than the dynamic information. To gain better understanding about the function of biological membranes, more specific information is required regarding the structure and dynamics of bilayer membranes.

Recent developments in optical technology and spectroscopy have raised hopes of addressing such issues [12]. Lipid bilayers are optically anisotropic materials because of the orientational assembly with rodlike polar molecules in the bilayer. The optical properties parallel are very different from those perpendicular to the bilayer plane, which leads to birefringence (double refraction). The birefringence is highly sensitive to the orientational order of lipid molecules in bilayer membranes. Thus, it is possible to detect changes in the orientational order by measuring birefringence. Several experimental techniques to reveal such optically anisotropic structure have been recently developed. These birefringence techniques are simple and powerful tools for investigating the structural and dynamic properties of lipid bilayers without any kind of labeling. The techniques are extended to a time-resolved technique where changes in the bilayer structure and dynamics can be observed in real time [13, 14]. In this chapter, we first give a general explanation for refractive indices in optically anisotropic materials. Then, we describe theoretical expressions of refractive indices in lipid bilayer membranes, and of interference resulting from birefringence in the bilayer membranes. Finally, we introduce some birefringence techniques that recently have been developed, and provide some experimental results obtained by these techniques.

54.2 BIREFRINGENCE IN UNIAXIAL CRYSTALS

First we describe basic properties of electromagnetic wave propagation in optically anisotropic materials [15, 16]. We consider materials whose electrical excitations depend on the direction of the electric field. In contrast to defining a single dielectric constant for an isotropic medium, the dielectric constant of an anisotropic medium depends on the direction of the electric field. The electric displacement vector $\mathbf{D}$ will then no longer be parallel to the electric field $\mathbf{E}$. The two vectors are related with a dielectric tensor $\boldsymbol{\varepsilon}$ as $\mathbf{D} = \boldsymbol{\varepsilon} \cdot \mathbf{E}$. If an electric field $\mathbf{E} = (E_1, E_2, E_3)$ is applied to the material, each component of the resultant displacement vector $\mathbf{D} = (D_1, D_2, D_3)$ is linearly related to the components of $\mathbf{E}$

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.

as $D_i = \varepsilon_{i1}E_1 + \varepsilon_{i2}E_2 + \varepsilon_{i3}E_3$ $(i = 1, 2, 3)$. Since the tensor is symmetric $(\varepsilon_{ij} = \varepsilon_{ji})$ in transparent dielectric materials, the number of independent components in the tensor is six instead of nine components. There exists a coordinate system fixed in the material such that the expression of the tensor take the diagonal form:

$$\boldsymbol{\varepsilon} = \begin{pmatrix} \varepsilon_x & 0 & 0 \\ 0 & \varepsilon_y & 0 \\ 0 & 0 & \varepsilon_z \end{pmatrix} \tag{54.1}$$

Where ε_x, ε_y and ε_z are called the *principal dielectric constants*. In this system of principal dielectric axes the relation between two vectors **D** and **E** takes the simple form: $D_i = \varepsilon_i E_i$ $(i = x, y, z)$. For some materials, two of the principal dielectric constants are equal. Such materials are said to be optically uniaxial. If $\varepsilon_x = \varepsilon_y \neq \varepsilon_z$, the z axis is called the *optical axis of the uniaxial material*.

When a plane light wave falls on to a boundary between two homogeneous media of different optical properties, it is partially refracted and partially reflected. The phenomenon is ruled by the continuous boundary conditions imposed by Maxwell's equations at the interface. The refracted wave proceeds into the second medium with a different direction because of the change in the wave velocity. Relation between the angle of incidence θ_i and angle of refraction θ_r is described by the law of refraction:

$$\frac{\sin\theta_i}{\sin\theta_r} = \frac{v_1}{v_2} = n_{12} \tag{54.2}$$

where v_1 and v_2 are the phase velocities of propagation in media 1 and 2, respectively, and n_{12} the relative index of refraction from the first into the second medium (Fig. 54.1).

An absolute refractive index of a medium is defined as the refractive index for refraction from vacuum into that medium. If n_1 and n_2 are the absolute refractive indices of two media, the relative index of refraction n_{12} is equal to the ratio n_2/n_1.

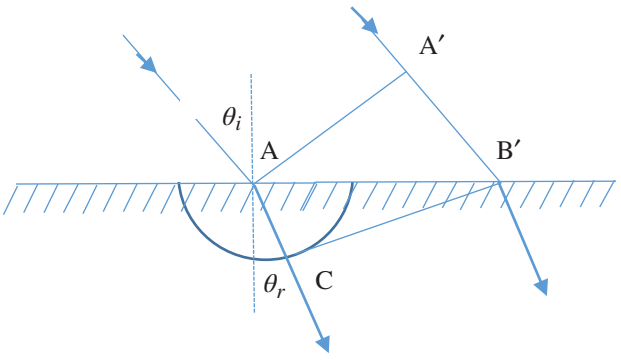

FIGURE 54.1 Refraction of a plane wave in homogeneous media $A'B'/AC = v_1/v_2$.

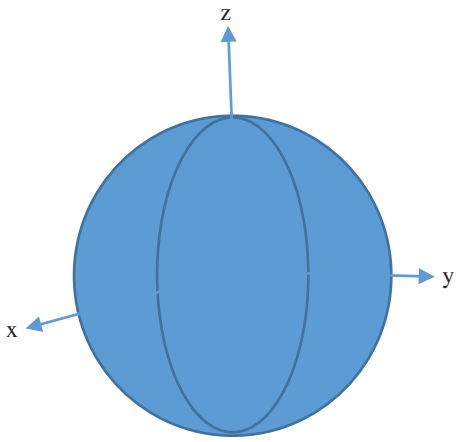

FIGURE 54.2 Phase velocities of ordinary wave (sphere) and extraordinary wave (ellipsoid) in a uniaxial medium. The z axis is the optical axis of the medium.

The absolute refractive index relates to the square root of the dielectric constant (Maxwell's formula). For a medium that does not adsorb light energy, the index equals to the square root of the dielectric constant. Since the dielectric constant of uniaxial materials differs in the direction, the refractive index also differs in the direction. So that the phase velocity is affected by the polarization and propagation direction of the light wave. In general two waves with different velocity travel in the uniaxial material. One of the two waves that corresponds to any particular wave-normal direction is an ordinary wave with a velocity independent of the direction of propagation, the other an extraordinary wave with velocity depending on the angle between the direction of propagation and the optic axis. The electric field of the ordinary light is polarized perpendicular to the optic axis, while the field of the extraordinary light is polarized parallel to the optic axis. The velocities of these two waves are only equal when the wave normal is in the direction of the optic axis. Figure 54.2 shows the velocities of these two waves. In this figure the velocity of the ordinary wave (sphere) v_{o} is larger than that of the extraordinary wave (ellipsoid) v_{e}. Such material is said to be a positive uniaxial crystal. If $v_{\mathrm{o}} < v_{\mathrm{e}}$, the material is called a negative uniaxial crystal.

As shown in Fig. 54.3a, the ordinary light obeys the low of refraction, while the extraordinary light, in general, dose not because of dependence of the velocity on the direction of propagation. When light propagates perpendicularly to the optic axis, the extraordinary wave travels with a velocity independent to the propagation directions (Fig. 54.3b). In this case we can define the refractive index for extraordinary light. The difference in refractive indices of extraordinary (n_e) and ordinary (n_o) light is called the *birefringence* of the material:

$$\Delta n = n_e - n_o \tag{54.3}$$

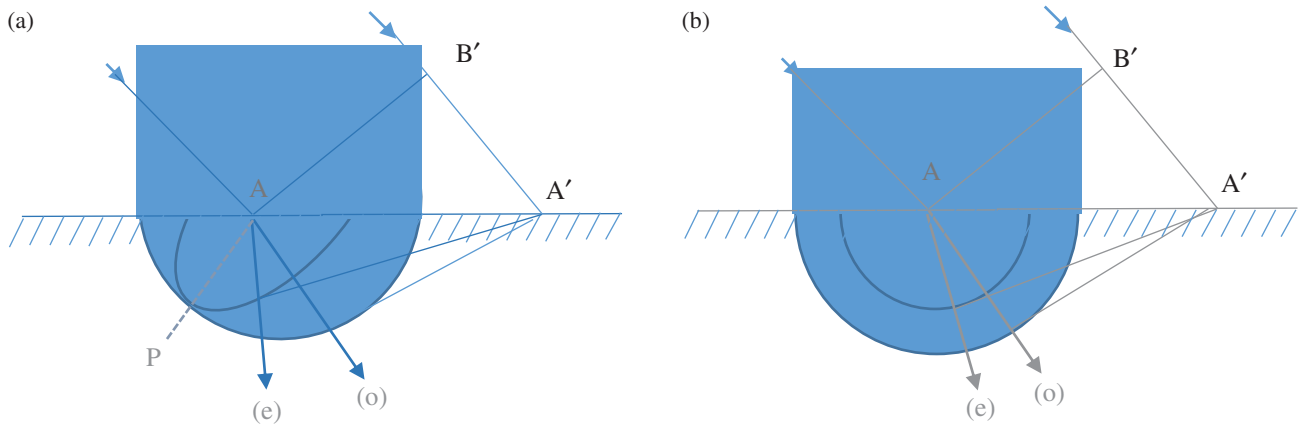

FIGURE 54.3 Propagation of a plane wave into a uniaxial medium: (a) the plane of incidence contains the optical axis; (b) the optical axis is perpendicular to the plane of incidence as well as parallel to the surface of refraction (o = ordinary wave; e = extraordinary wave).

It is noted that the electric vector of extraordinary light is polarized parallel to the optical axis, while the electric vector of the ordinary one is polarized perpendicular to the optical axis. The birefringence is one of principal parameters describing optical properties of anisotropic materials.

54.3 BIREFRINGENCE IN LIPID BILAYERS

Birefringence does not occur only in solid crystals but also in liquid crystals such as lipid bilayers or some surfactant aggregates. Nonrandom orientation of lipid molecules in a bilayer membrane creates an anisotropic system with a uniaxial optical axis with two principal refractive indices, namely, the extraordinary refractive index n_e and the ordinary refractive index n_o. In general, the birefringence Δn $(= n_e - n_o)$ observed in the system is the sum of an intrinsic birefringence of the molecule itself and the form birefringence [17]. *Intrinsic birefringence* results mainly from the anisotropic properties of the molecules itself, whereas *form birefringence* results mainly from anisotropy of a layered structure composed of isotropic or anisotropic molecules because of the continuo boundary conditions imposed by Maxwell's equations at the interfaces of layers [18]. Form birefringence arises on scales much larger than the molecular dimensions but smaller than the wavelength of incoming light. Many studies have attempted to calculate theoretically the effect of form birefringence on the optics of lipid membranes and biological cells [18–28].

One group of researchers has demonstrated relations between anisotropic refractive indices of a single lipid bilayer and the molecular properties such as polarizability tensor, shape, and orientation from spectroscopic measurements using coupled plasmon–waveguide resonance [17]. The relationship of the anisotropic refractive indices to the molecular properties is expressed as described in the following paragraph [17].

A local electric field is induced at the molecule of interest (E^{local}) by an averaged macroscopic electric field (E), which accompanies light propagation in a dielectric environment. Such a local field is a sum of the averaged macroscopic field and an additional component that is produced by the molecule itself. Thus the local field in a dielectric environment can be written as [24, 29]

$$E_i^{local} = E_i + L_i P_i \quad (i = x, y, z) \tag{54.4}$$

where P_i is the polarization per unit volume and L_i is a form factor that describes the influence of asymmetry in the shape of the molecule on the creation of the local electric field. In the case of isotropic media, $L_i = 4\pi/3$ and Eq. (54.4) becomes the Lorentz formula for the local field. The polarization is written by the dielectric constant and the averaged electric field as

$$P_i = (\varepsilon_i - 1)E_i/4\pi \tag{54.5}$$

where ε_i is the dielectric constant along the i axis. The polarization is also written by the molecular polarizability tensor and the local electric field as

$$P_i = \alpha_i E_i^{local}/V \tag{54.6}$$

where α_i is the ii-component of the molecular polarizability tensor whose principal axes are assumed to coincide with x, y, and z, and V is the molecular volume. For a dielectric materials that does not absorb light energy, the dielectric constant equals to the square of the refractive index: $\varepsilon_i = n_i^2$. Combining Eqs. (54.4)–(54.6) results in

$$n_i^2 - 1 = 4\pi\alpha_i/(V - \alpha_i L_i) \tag{54.7}$$

This equation implies that optical anisotropy can be due either to the anisotropy of the molecular polarizability tensor or to the asymmetry of the shape factors.

Another team provided the shape factor for a single lipid bilayer using the cavity field theory in a continuous dielectric medium [17, 30]. They considered that the lipid acyl chain can be represented as a cylindrical cavity. If the optical axis of the uniaxially anisotropic medium coincides with the cylinder axis and the electric field is applied in the i direction, either parallel to the cylinder axis or normal to it, the shape factors L_i can be written as

$$L_z = 4\pi(1 - l/\sqrt{d^2 + l^2}) \tag{54.8}$$

and

$$L_x = L_y = 2\pi\, l/\sqrt{d^2 + l^2} \tag{54.9}$$

where l is the average length of the acyl chain and d the diameter of the cylinder.

Equation (54.7) describes an ideal case when there is no spatial distribution of molecular orientation and the principal axes of the molecular polarizability tensor coincide with the x, y, and z axes. In the more practical case of a spatial distribution of molecular orientation, one should replace α_i and L_i with their average values, respectively. If $\alpha_x = \alpha_y = \alpha_t$ and $\alpha_z = \alpha_l$, which is the case for rodlike molecules, values of the average polarizability are written as

$$\alpha_z^{av} = \alpha^{av} + 2/3(\alpha_l - \alpha_t)S \tag{54.10}$$

$$\alpha_x^{av} = \alpha^{av} - 1/3(\alpha_l - \alpha_t)S \tag{54.11}$$

where

$$\alpha^{av} = 1/3(\alpha_l + 2\alpha_t) \tag{54.12}$$

and α_l and α_t are the longitudinal and transverse polarizabilities.

The average value of the shape factor can be obtained by projecting the long axis of the molecule onto the optical axis (z axis), and by projecting the cross section of the cylinder onto the membrane plane (the x–y plane). This will result in the replacement of the l and d parameters in Eqs. (54.8) and (54.9) with $l' = l\cos\theta$ and $d'^2 = d^2/\cos\theta$, where θ is the angle that the long axis of the molecule makes with the optical axis of an anisotropic system. In principle, this angle represents an average value that can be obtained from the angular distribution of the long axes of the molecules. In practice, this average value can be very well approximated by the degree of orientational order (S), which is defined as [31]:

$$S = 1/2(3\langle\cos^2\theta\rangle - 1) \tag{54.13}$$

where the brackets denote an average over all abundant orientations.

By replacing the l and d parameters by l' and d', and knowing the value of the S parameter, one can evaluate the average values of the shape factors. Furthermore, these values can then be used in Eq. (54.7), which also has to be modified by substituting individual polarizabilities with their averaged values. This will result in the following modified equation

$$n_z^2 - 1 = 4\pi\alpha_z^{av}/\left(V - \alpha_z^{av}L_z^{av}\right) \tag{54.14}$$

and

$$n_x^2 - 1 = 4\pi\alpha_x^{av}/\left(V - \alpha_x^{av}L_x^{av}\right) \tag{54.15}$$

from which one can evaluate the molecular polarizabilities along the principal axes of the molecule, knowing the value of the degree of orientational order (S) and the experimental values of the refractive index obtained by exciting light with the electric vector polarized parallel (yielding n_x) and perpendicular (yielding n_z) to the membrane plane. It should be noted that the birefringence is a measure of the order in in the bilayer membrane. By measuring birefringence, changes in the membrane structure can be monitored with high sensitivity.

54.4 INTERFERENCE WITH BIREFRINGENT MATERIALS

Interference between ordinary and extraordinary beams often occurs as a result of their phase difference. A birefringent plane plate placed between a polarizer and an analyzer is first considered. When a beam of linearly polarized light emerging from a polarizer incidents normally onto the plate, the beam is divided into two rays with different velocities of propagation, and with their electric displacement vectors vibrating in two mutually orthogonal directions to the plate normal. They emerge from the plate with a certain phase difference δ. Components of two vibrations in a certain direction are then singled out through the analyzer and may be brought to interference in the focal plane of a lens placed behind the analyzer (Fig. 54.4).

Intensity of the interference light is obtained as follows [15]. When D' and D'' are the two mutually orthogonal directions of vibration in the plate, and OP and OA are the directions of vibration that are passed by the polarizer and the analyzer respectively in Fig. 54.4, the amplitude of the light incident on the plate is represented by the vector OE. The components in the directions of D' and D'' are $OB = E\cos\varphi$ and $OC = E\sin\varphi$, respectively, where ψ is the angle of OP vector to the D' axis. The amplitude of the light passed by the analyzer is represented by the vector OA; its components are $OF = E\cos\varphi\cos(\varphi - \chi)$ and $OG = E\sin\varphi\sin(\varphi - \chi)$,

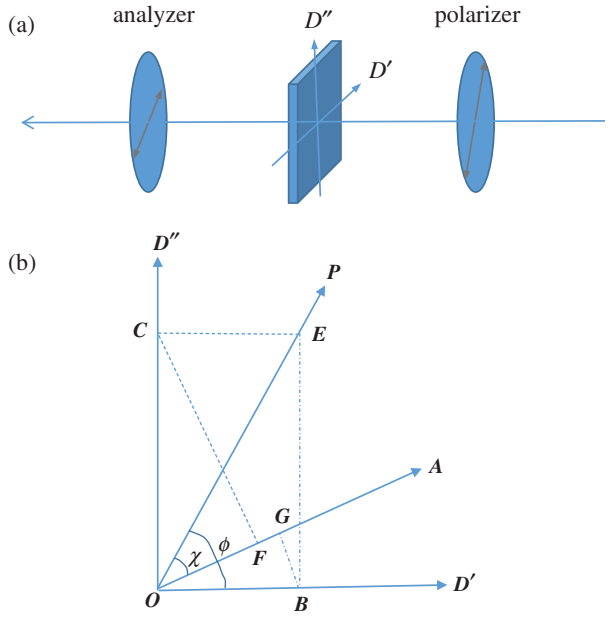

FIGURE 54.4 (a) Interference with a birefringent plane plate placed between a polarizer and an analyzer; (b) **c**onstruction of the vibration components transmitted by the polarizer and the analyzer.

where χ is the angle between OA and OP. On leaving the plate, two components differ in phase by the amount

$$\delta = \frac{2\pi}{\lambda}(n'' - n')\rho \tag{54.16}$$

where n'' and n' are refractive indices for two emerging rays, λ is the wavelength of the incident light, and ρ is the mean geometric path of the two beams. Difference in the refractive indices is written by the birefringence of the uniaxial crystal plate

$$n'' - n' = \Delta n \sin^2\theta \tag{54.17}$$

where θ is the angle between the optical axis of the crystal plate and the mean path of the two beams. The intensity obtained from interference of the two beams with phase difference δ is given by

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\delta \tag{54.18}$$

where I_1 and I_2 are the intensities (squared amplitudes) of the two beams. The intensity is written by using the amplitudes as

$$I = a\{\cos^2\chi - \sin 2\varphi \sin 2(\varphi - \chi)\sin^2(\delta/2)\} \tag{54.19}$$

where $a = E^2$, which is the intensity of the incident light on the plate per unit area

In the case where polarizer and analyzer are parallel ($\chi = 0$; parallel polarizers), the interference light intensity is written as

$$I = a\{1 - \sin^2 2\phi \sin^2(\delta/2)\} \tag{54.20}$$

When polarizer and analyzer are perpendicular ($\chi = \pi/2$; crossed polarizers), the interference light intensity is given by

$$I = a\sin^2 2\phi \sin^2(\delta/2)\} \tag{54.21}$$

In an earlier study we calculated the light intensity of interference with a hollow sphere placed between a polarizer and an analyzer [32]. The shell of the hollow sphere is considered to be a uniaxial crystal with the birefringence of Δn, and the optical axis of the crystal is radially oriented in the shell. Furthermore, it is assumed that the birefringence is far smaller than the refractive indices of the crystal n_o and n_e ($\Delta n \ll n_o, n_e$). This suggests that the refractive indices of two emerging rays n' and n'' are approximately equivalent. Direction of beams propagated in the shell changes when the direction of the optical axes is varied. However, this change is negligible, if $n' = n''$ is held. On this assumption, for the case of two beams propagated through only the shell (Fig. 54.5a), the mean geometric path of the beams with varying electric vibration can be easily expressed as

$$\rho = 2R_o\cos\beta \tag{54.22}$$

and for the case of the beams propagated from the shell to the inside medium (Fig. 54.5b)

$$\rho = 2(R_o\cos\beta - R_i\cos\beta') \tag{54.23}$$

where R_o and R_i are the outer and the inner radii of the shell, respectively, and β is the refractive angle between the optical axis and the light path. β' is the incident angle at the interface for the case of the propagation (Fig. 54.5b). In the limiting case of $\beta' = \pi/2$, Eq. (54.23) reduces to Eq. (54.22). Averaging over the light path for the factor $\sin^2\theta$ in Eq. (54.17), the difference in the refractive indices $n'' - n'$ for the case shown in Fig. 54.5b is given as

$$\begin{aligned} n'' - n' &= \Delta n\langle\sin^2\theta\rangle_{AV} \\ &= \frac{\Delta n}{2}\left(1 - \frac{\sin 2\beta - \sin 2\beta'}{2(\beta - \beta')}\right) \end{aligned} \tag{54.24}$$

The difference in the refractive indices $n'' - n'$ for the case shown in Fig. 54.5a is obtained by replacing β' with $\pi/2$ in Eq. (54.24). It is noted that the birefringence Δn is approximately equivalent to that of a plate composed of same uniaxial crystal, when the shell has a large curvature. If the optical

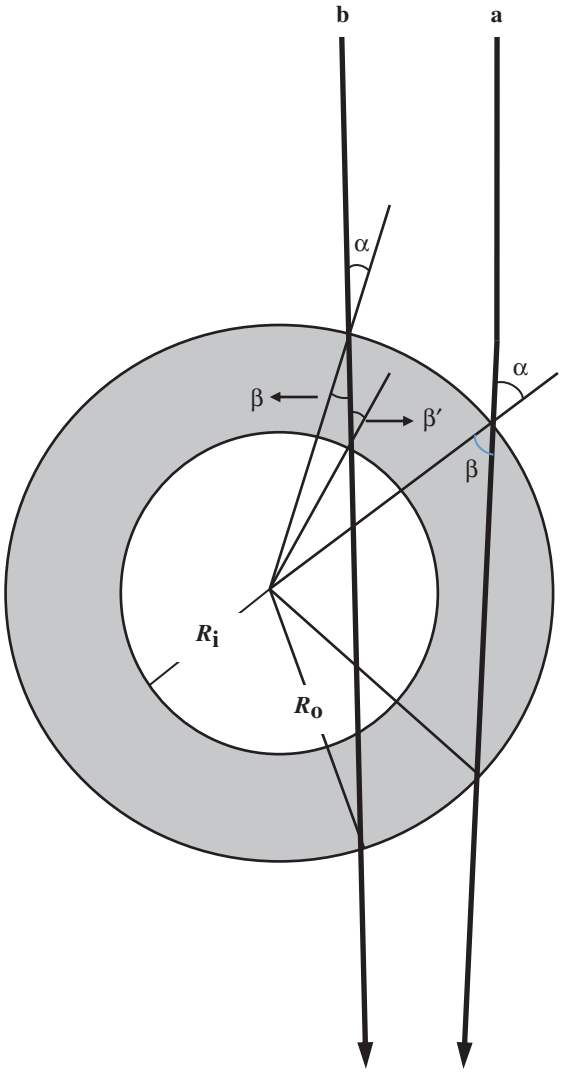

FIGURE 54.5 Mean geometric paths of ordinary and extraordinary beams propagated through (a) a shell and (b) both a shell and the inside medium.

axis of the crystal is not radially oriented, it is not easy to express the difference $n'' - n'$. However, when the direction of the optical axis is radial on average, Eq. (54.24) is valid. In this case, Δn is the mean birefringence. Then the phase difference δ for the hollow sphere is given as

$$\delta = \frac{2\pi}{\lambda}\Delta n\left(R_o\cos\beta - R_i\cos\beta'\right)\left(1 - \frac{\sin 2\beta - \sin 2\beta'}{2\left(\beta - \beta'\right)}\right) \tag{54.25}$$

where $\beta' = \pi/2$ for the case of the propagation shown in Fig. 54.5a.

Intensity of the interference light by the sphere is given by integration with the incoming angle α over the illuminated area of the sphere. In the case of crossed polarizers, the interference light intensity is expressed as

$$i = \int a\sin^2 2\phi\ \sin^2(\delta/2)\}dS \tag{54.26}$$

where adS is the intensity of the incident light flux with the cross-sectional area of dS. When the incident light flux illuminates an area of the shell surface dS' with the incoming angle α, the area dS is expressed as

$$dS = dS'\cos\alpha = R_o^2 d\phi\sin(2\alpha)d\alpha/2 \tag{54.27}$$

Thus, the interference light intensity is

$$i = \int_0^{2\pi}(a/2)R_o^2\sin 2\,\phi\ d\phi\int_0^{\pi/2}\sin^2(\delta/2)\sin 2\alpha\,d\alpha \tag{54.28}$$

Since the total intensity of the illuminated light i_o is $i_o = \pi aR_o^2$, the first integral is equal to $i_o/2$. The second integral is divided into two terms for the cases of propagation shown in (a) and (b) of Fig. 54.5 Therefore the interference light intensity per unit incident light with crossed polarization is expressed as

$$A = \frac{i}{i_o} = \frac{1}{2}\left(\int_0^{\alpha_o}\sin^2\left(\frac{\delta}{2}\right)\sin 2\alpha\,d\alpha + \int_{\alpha_o}^{\pi/2}\sin^2\left(\frac{\delta}{2}\right)\sin 2\alpha\,d\alpha\right) \tag{54.29}$$

where α_o is the incoming angle of the beam propagated on the interface between the shell and the inside medium of the hollow sphere. The angle is represented by $\alpha_o = \arcsin(mR_i/R_o)$ in which m is the relative refractive index of the shell to the medium. In the second term of Eq. (54.29), the phase difference is taken as Eq. (54.25) with $\beta' = \pi/2$. The interference light intensity A was numerically calculated by the Simpson method. Also, the interference intensity by a single vesicle was experimentally measured using a polarized microscopy with crossed polarizers with varying the wavelength of the incident light. Eq. (54.29) is used to analyze experimental data obtained by polarized transmitted-light spectroscopy.

54.5 BIREFRINGENCE TECHNIQUES FOR ANALYZING LIPID BILAYER MEMBRANES

Although much of our knowledge about structural and dynamic properties of lipid bilayer membranes was gained by many kinds of techniques, many fundamental questions about the structure and dynamics of these membranes have

not yet been answered. Many of structural biophysical techniques provide information about the steady-state condition of the membranes, rather than the dynamic information. To understand the function of biological membranes, more specific information is required regarding the interplay between lipid structure and protein function in the membranes. Recently, in order to reply such requests, several optical techniques based on the optical anisotropy in lipid membranes have been developed. These are the waveguide spectroscopy techniques as dual-polarization interferometry (DPI) [33–36], optical waveguide lightmode spectroscopy (OWLS) [14, 37–41], and coupled plasmon–waveguide resonance (CPWR) [42–44], and polarized transmitted light spectroscopy (PTL) [32, 45]. In the waveguide spectroscopic measurements, planar lipid bilayers formed on a solid support are used, while liposomes are used in the transmitted-light measurement. In contrast to the structural techniques, such as X-ray and neutron scattering, these birefringence techniques can indicate dynamic changes in the lipid bilayer structure in real time. In addition, most of the birefringence techniques are label-free methods.

54.5.1 Dual-Polarization Interferometry (DPI)

Dual-polarization interferometry (DPI) was developed for analyzing supported lipid bilayers using a dual optical waveguide interferometric technique [33–36]. The *supported lipid bilayer* (SLB) is a planar lipid membrane supported on a solid substrate such as silicon oxynitride. SLBs are commonly prepared by adsorption of liposomes to the surface and by inducing rupture and fusion of the liposomes to a coherent planar bilayer [46,47]. Although formation of SLBs has been extensively investigated by many workers [48–56], understanding the mechanism of the SLB formation is not yet thorough [36]. The DPI technique provides information about several properties such as refractive index, density, thickness, mass, and birefringence of supported lipid bilayers. The details of the experimental arrangement and methods of data analysis have been described in the literature [36, 57]. We will give a brief summary. DPI consists of a dual-slab waveguide sensor chip with an upper sensing waveguide that supports the lipid bilayer, and a lower optical reference waveguide illuminated by an alternating polarized beam (HeNe laser). The sensor chip consists of a four layer dielectric stack of deposited silicon oxynitride on a silicon wafer surface and works as an integrated Young's interferometer, generating interference fringes at its output. Two orthogonal polarizations are passed through the sensor chip creating two different waveguide modes, called *transverse electric* (TE) and *transverse magnetic* (TM) waveguide modes. Each mode generates an evanescent field from the top sensing waveguide surface interacting with materials coming into contact with the sensor surface and resulting in a change in refractive index. When this occurs, the phase difference between the sensing waveguide and the buried reference waveguide is altered and the position of the interference fringes changes. In this way the sensor is capable of measuring very subtle molecular changes that occur on the sensor surface. The interference fringe pattern for each TM and TE waveguide mode shown as the diffraction fringe image, illuminates an element-imaging device in the far field, the output of which is passed to the digital signal processing unit. The relative phase position is updated every 2 ms using a spatial Fourier transform method. Two separate measurements of fringe shift TM and TE data are transferred to computer for further analysis to provide a real-time data display and to further resolve the data into thickness and refractive-index values for the growing layer.

Birefringence of the layer Δn $(= n_e - n_o)$ can be obtained by calculating the difference between the two effective refractive indices, namely, refractive index of transverse magnetic waveguide mode (n_{TM}) and refractive index of transverse electric waveguide mode (n_{TE}). The analysis can be replicated by instead fixing one of the two refractive indices, thickness of the layer, or $n_{TM} - n_{TE}$ to determine the other two from the measured change in propagation constants for the two modes. The n_{TM} refractive index is affected by the layer thickness and by both n_e and n_o as $n_{TM} = \sqrt{n_e^2 \sin^2\theta + n_o^2 \cos^2\theta}$, where θ, the mode angle, denotes the angle between the optical axis of the bilayer and the mean path of the two-wave mode, while the n_{TE} is affected only by the layer thickness and n_o as $n_{TE} = n_o$.

According to the equations above and the propagation constants for the two modes in the device, both n_e and n_o can be calculated from n_{TM} and n_{TE}. The respective effective indices n_{TM} and n_{TE} corresponding to the measured TM and TE phase changes are calculated by fitting the data to a waveguide equation. When a correct thickness is used for an anisotropic layer, the difference between the n_{TM} and n_{TE} will be the true effective birefringence of the layer [59]. For deposition of a lipid bilayer, a constant thickness is assumed for the entire process, corresponding to the steric thickness obtained by neutron scattering and X-ray reflectivity. When the thickness is fixed for an anisotropic lipid bilayer, changes in refractive index and therefore density and mass can be further calculated for the supported lipid bilayer. Similarly, changes in the thickness of the deposited bilayer can also be resolved by fixing the refractive index at a predetermined value. The effective birefringence $(n_{TM} - n_{TE})$ can be determined only by calculating the two different refractive indices, n_{TM} and n_{TE} for each waveguide mode by fixing the thickness or the refractive index of the deposited layer and assuming a uniform layer coverage. In practice, the refractive index n_e is approximately equal to the refractive index of transverse magnetic mode (n_{TM}) because the contribution of n_o to the TM mode is small. There is only a discrepancy of about 2% between the calculated effective birefringence $(n_{TM} - n_{TE})$ and the layer birefringence $(n_e - n_o)$.

TABLE 54.1 Properties of Supported Lipid Bilayers Obtained by DPI

Lipid	Density (g/cm^3)	Thickness (Å)	Mass (ng/mm^2)	Birefringence	Area/lipid (Å^2)
20°C: gel phase					
DMPC[a]	1.002±0.002	47.2±0.8	4.73±0.08	0.0223±0.0003	47.6±0.82
30°C: fluid phase					
DMPC	1.003±0.003	45.1±0.6	4.52±0.06	0.0193±0.0007	49.9±0.7

[a]DMPC = 1,2-dimyristoyl –sn-glycero-3-phosphocoline.

Mass of the adsorbed layer formed on the solid support m can be calculated from DPI measurements using de Feijter formula [60]

$$m = d(n_{iso} - n_{\text{buffer}}) \left(\frac{dn}{dc}\right)_{\text{lipid}} \tag{54.30}$$

where d is the thickness of the layer, n_{buffer} is the refractive index of the buffer used for the experiments, and n_{iso} denotes the average or corresponding isotopic refractive index of the layer as

$$n_{iso} = \sqrt{\left(n_{\text{TM}}^2 + 2n_{\text{TE}}^2\right)/3} \tag{54.31}$$

Assume that $(dn/dc)_{\text{lipid}}$ is the specific refractive-index increment of the lipid layer. The de Feijter formula assumes that $(dn/dc)_{\text{lipid}}$ remains constant throughout the experiment. The value is, however, not well known, and an equivalent alternative model is used for convenience, assuming a commonly used approximate fixed isotropic refractive index of the lipid layer of 1.47 [36]. The DPI technique has been applied to investigate bilayer structure and formation [61–63], membrane insertion of protein and peptide [33,34, 57,58, 64], and so on. DPI is of great advantage to monitor changes in membrane structure in real time during binding of biomolecules such as peptide. As an example, birefringence values of SLBs obtained by DPI technique are listed in Table 54.1 [65].

54.5.2 Optical Waveguide Lightmode Spectroscopy (OWLS)

Optical waveguide lightmode spectroscopy (OWLS) is one of the waveguide spectroscopy techniques using SLBs. The technique was also developed for analyzing kinetics of protein association with lipid membranes [66–69] and applied to study structure of lipid membrane and interaction of various kinds of biomolecules with lipid membranes [37–41, 70–73]. The OWLS instrument is capable of recording effective refractive indices of the waveguide modes [74–76] with a precision of 10^{-6} [14]. We will briefly describe a procedure and analysis of OWLS measurement for analyzing the interaction of detergent with SLB [71]. A small flowthrough cuvette sealed to the waveguide with an O-ring is used as a sample cell. This ensures that the free detergent concentration is constant and equal to the bulk dissolved concentration. The assembly is then transferred to the goniometer head of an integrated optical scanner. In this instrument a monochromatic, polarized lightbeam (HeNe laser) is directed to the grating coupler area of the chip [77] and the angle α between the grating normal, and the incident laser beam is varied with microradian precision by a computer-driven stepping motor. At certain angles the light is coupled into the waveguide and can be detected with photodiodes positioned at the ends of the waveguide. The angles corresponding to the incoupling maxima are then used to calculate the effective refractive indices N of the transverse electric TE. and transverse magnetic TM. modes, according to the incoupling relation [75]

$$N = n \sin\alpha + \ell\,\lambda/\Lambda \tag{54.32}$$

where n is the refractive index of air and ℓ is the diffraction order.

Pure buffer was allowed to flow through the cuvette in order to determine the parameters of the waveguiding film in the absence of an adlayer, for example, n_{F}, the refractive index of the waveguiding film and d_{F}, the thickness of the film, from the measured N by solving the three-layer-mode equations [75]. Subsequently the chip is removed from the instrument in order to deposit a Langmuir–Blodgett (LB) bilayer. The lipids deposited on the surface form an adlayer whose thickness d_{A} and mean refractive index n_{A} can be found by solving the four-layer mode equations [75]. The amount L of lipid deposited on the surface is determined using the de Feijter formula of Eq. (54.30). Finally the detergent solution is allowed to flow over the membrane. Throughout the experiments a constant flow rate is maintained. The mass of the lipid bilayer–detergent mixture was calculated according to Eq. (54.30). The absolute mass can be determined by a precision of 1 ng/cm^2 [46].

54.5.3 Coupled Plasmon–Waveguide Resonance (CPWR)

Coupled plasmon–waveguide resonance (CPWR) spectroscopy was also developed to analyze kinetic and structural characterization of membrane–protein systems using supported lipid membranes [42, 78]. Resonant excitation by photons of collective electronic oscillations (plasmons) in a

[c] Form factor is defined in Eq. (54.4). The membrane is parallel to the x–y plane.
[d] α_1 and α_t are the longitudinal and transverse polarizabilities of the molecule.
Abbreviations: BODIPY = dipyrromethene boron difluoride; POPC = 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocoline.

thin metallic film provides a source of an evanescent electromagnetic field, which can probe the optical properties of materials in direct contact with the plasmon-generating medium [43].

The principle of CPWR spectroscopy is explained [17] as follows. Plasma oscillations in metals are collective longitudinal excitations of the conductive electron gas, and plasmons are the quanta corresponding to these charge–density oscillations. Such oscillations can be localized on an interface between metallic and dielectric surfaces, along which they propagate as electromagnetic waves with the electric field normal to this interface and decay exponentially with penetration distance from the interface. Surface plasmons can be excited only with certain metallic materials (gold and silver are the best examples) and only by evanescent waves when the wavevector of the evanescent wave is in resonance with that of the surface plasmon wave. Furthermore, plasmon excitation can be achieved only by an evanescent wave generated by polarized incident light with the electric vector perpendicular to the film surface, namely, transverse magnetic (TM-) or p-polarized light [43, 44, 79]. However, when the metal film is covered with a thin dielectric layer that supports waveguide modes, there is the possibility of coupling the incident light into both the plasmon mode of the metal film and the guided mode of the dielectric adlayer. This allows resonance excitation using polarized light with the electric vector parallel to the film surface, called *transverse electric* (TE-) or s-polarized light, because exciting the guided mode reverses the phase shift of the light and the metal sees it as if it were a p-polarized excitation. By precisely adjusting the thickness and refractive index of the dielectric film, the guided mode conditions and surface plasmon conditions can be made coincident for both polarizations at two different incident angles, resulting in two very sharp resonances [42, 80, 81].

The CPWR technique combines advantages of both plasmon resonance and waveguide spectroscopies. Such a combination uses a simple light detection system that involves measurement of the intensity of totally reflected p- and s-polarized light and that is characterized by a high sensitivity due to the resonance phenomenon on which the measurement is based. These properties, taken together with a proper analysis of resonance spectra, allow evaluation of the refractive index, the adsorption coefficient, and the thickness of anisotropic lipid membranes [43, 44, 78, 82–84]. These parameters of the sample reflect three parameters of CPWR spectra: the light incident angle (or light wavelength), the spectral width, and the resonance depth. Thin-film electromagnetic theory based on Maxwell's equations provides an analytical relationship between the spectral parameters and the sample properties [78], where the sample is modeled as a uniform layer (or layers) of anisotropic dielectric material. This allows a unique evaluation of these parameters by fitting theoretical curves to the experimental ones. Table 54.2 lists refractive indices of supported lipid membranes measured by CPWR technique [17].

54.5.4 Polarized Transmitted Light Spectroscopy (PTL)

Polarized transmitted light spectroscopy (PTLS) was developed for analyzing molecular orientation order of liposomal bilayer membranes in bulk solution [32], and has been applied to study the effects of hydrophilic and hydrophobic additives on the molecular order of liposomal membranes [85–90]. As shown in Eq. (54.29), the interference light with crossed polarization strongly depends on the birefringence of liposomal membranes. In PTL measurements, intensity of the interference light with crossed polarization is obtained from transmitted light intensities with parallel and crossed polarization. The details of the procedures of PTL measurements and the method of data analysis have been described in the literature [45]. Here we will provide a brief summary.

We consider lipid dispersion containing various vesicles in size. Since the interference light with crossed polarization also depends on the vesicle size, intensity of the interference light observed by the lipid dispersion is a sum of the individual interference light by the vesicles. The mean intensity of the interference light $\langle A \rangle$ is written as

$$\langle A \rangle = \sum_j \sum_k A(R_{oj}, R_{ik}) f(R_{\mathrm{oj}}, R_{\mathrm{ik}}) \qquad (54.33)$$

where $A(R_{oj},R_{ik})$ is the interference light by a vesicle with an inner radius of R_{ik} and an

outer radius of R_{oj}, and $f(R_{oj},R_{ik})$ the number fraction of the vesicle. Using the mean intensity of the interference light, the total interference light per unit area is given by $\langle A\rangle N\ell$ for the dispersion with the number density of N and the light pathlength of ℓ. Also, the total scattered light is $\langle S\rangle N\ell$, where $\langle S\rangle$ is the mean intensity of scattered light as defined by a similar way as Eq. (54.33). We consider the polarized light transmitted through the dispersion with a small pathlength of $d\ell$. Deviation of the light intensity with crossed polarization I_1 to the polarized incoming light is written as

$$\frac{dI_1}{d\ell} = \langle A\rangle NI_2 - \langle A\rangle NI_1 - \langle S\rangle NI_1 \tag{54.34}$$

where I_2 is the light intensity with parallel polarization. The first term is an increase by the interference light crossly polarized to the incoming light, the second term is a reduction by the interference light polarized in parallel, and the last term is a reduction by scattering light. Since the light intensity of parallel polarization is far larger than that of crossed polarization, namely, $I_2 \gg I_1$, the second term is neglected comparing with the first term:

$$\frac{dI_1}{d\ell} = \langle A\rangle NI_2 - \langle S\rangle NI_1 \tag{54.35}$$

Deviation of the light intensity with parallel polarization is similarly written as Eq. (54.34). However the effect of the scattered light rather than that of the interference light is dominant, so that the deviation is written as

$$\frac{dI_2}{d\ell} = -\langle S\rangle NI_2 \tag{54.36}$$

The light intensity transmitted through the light path of ℓ is given by

$$I_2 = I_0 \exp(-\tau\, l) \tag{54.37}$$

where I_o is the incident light intensity and $\tau = \langle S\rangle N$ is the turbidity.

The transmitted light intensity with crossed polarization is obtained by combining Eqs. (54.35) and (54.37) as

$$I_1 = I_0\,(\varphi + \langle A\rangle N\, l)\exp(-\tau\, l) \tag{54.38}$$

where φ is a ratio I_1/I_0 in the absence of vesicles, namely, a background of the optical system. Ratio of the transmitted-light intensities I_1/I_2 is related only to the interference light as

$$\frac{I_1}{I_2} = \varphi + \langle A\rangle N\, l \tag{54.39}$$

The mean interference light intensity $\langle A\rangle$ can be determined from the slope of a linear dependence on the number density of vesicles and the light pathlength.

However, when the interference light intensity is much larger than the scattered light intensity, such as $\langle A\rangle I_2 \gg \langle S\rangle I_1$, the intensity ratio becomes a nonlinear dependence. In this case, Eq. (54.35) is reduced to

$$\frac{dI_1}{d\ell} = \langle A\rangle NI_2 \tag{54.40}$$

Combining Eqs. (54.37) and (54.40), we can express the transmitted light intensity with crossed polarization as

$$I_1 = I_0\left(\varphi + \frac{\langle A\rangle}{\langle S\rangle}(1 - \exp(-\tau\ell))\right) \tag{54.41}$$

The ratio of the transmitted light intensities I_1/I_2 is

$$\frac{I_1}{I_2} = \left(\varphi + \frac{\langle A\rangle}{\langle S\rangle}\right)\exp(-\tau\ell) - \frac{\langle A\rangle}{\langle S\rangle} \tag{54.42}$$

The intensity ratio deviates positively from a linear dependence.

Experimentally, it is easy to determine the interference light intensity from the ratio of transmitted light intensities with a linear dependence. To obtain a linear dependence of the intensity ratio I_1/I_2 on $N\ell$, vesicles with appropriate size and incident light with a larger wavelength should be employed. It is necessary to test whether the linear relation actually holds. In addition, use of incident light with a larger wavelength is helpful to analyze data of the interference light. As seen in Eq. (54.25), the phase difference δ is in proportion with the birefringence Δn, and becomes small with increasing the wavelength. For the small phase difference, the interference light intensity is approximately proportional to the square of δ[Eq. (54.29)]. This leads to a linear dependence between the interference light intensity and the square of the birefringence Δn. In fact, this square relation is experimentally observed for the small birefringence at a range of large wavelength, as shown in the literature [45, Fig. 4].

As mentioned above, the birefringence of lipid bilayers relates not only to the acyl chain order but also to the molecular orientation order in the bilayers. Let's consider the relation between the birefringence and the molecular order. According to the theory of an uniaxial liquid crystal, the ordinary and extraordinary refractive indices n_o and n_e are related to the principal polarizabilities α_o and α_e as [91]

$$\frac{n_e^2 - 1}{n_e^2 + 2} = \frac{4\pi}{3}\frac{N\alpha_e}{1 + A_1\alpha_e} \tag{54.43}$$

$$\frac{n_o^2 - 1}{n_o^2 + 2} = \frac{4\pi}{3}\frac{N\alpha_o}{1 + A_2\alpha_o} \tag{54.44}$$

TABLE 54.3 Birefringence Values of Liposomal Bilayer Membrane Measured by PTL

Lipid	Birefringence
DPPC (23–25°C; gel phase)	0.020±0.002
DPPC[a] (37°C; ripple phase)	0.028±0.002

[a]DPPC = 1,2-dipalmitoyl –sn-glycero-3-phosphatidylcholine.

where N is the number density of molecules, and A_1 and A_2 are constants by which the Clausius–Mosotti relation is adapted to the uniaxial crystal. Since the birefringence of lipid bilayers is small, at $n_o \approx n_e$, these adapted factors can be neglected and $(n_e + 1)/(n_e^2 + 2) \approx (n_o + 1)/(n_o^2 + 2)$. Thus, the birefringence Δn is obtained from the following equation

$$\Delta n = \left(\tilde{n} - 1 - \frac{\Delta n}{3}\right)\left(\frac{\alpha_e - \alpha_o}{\alpha_o}\right) \tag{54.45}$$

with the mean refractive index $\tilde{n}$

$$\tilde{n} = \frac{n_e + 2n_o}{3} \tag{54.46}$$

The birefringence calculated using Eq. (54.45) is a large value of 0.079 on the assumption that lipid molecules with fully extended chains are uniformly arrayed [32]. In this assumption, the polarizabilities of the bilayer α_e and α_o are equal to polarizabilities of the lipid molecule, $\alpha_\parallel$ and $\alpha_\perp$, specifically, $\alpha_e = \alpha_\parallel$ and $\alpha_o = \alpha_\perp$, where the indices $\parallel$ and $\perp$ denote the principal direction of the molecule and a direction perpendicular to it, respectively. As shown in Table 54.3, birefringence values of bilayer membranes are far smaller than the calculated values. These smaller values arise from disorders of chains and molecular orientation in the bilayer. In particular, the birefringence of the multilamellar bilayers is strongly affected by a disorder in the longitudinal orientation. The degree of order of the uniaxial liquid crystal is defined by the ratio of the polarizabilities of the crystal to the molecular polarizabilities as [91]

$$S = \frac{\alpha_e - \alpha_o}{\alpha_\parallel - \alpha_\perp} \tag{54.47}$$

In the case of lipid bilayers, the term $\Delta n/3$ in Eq. (54.45) is approximately neglected compared with $\tilde{n} - 1$ since the $\Delta n/3$ value is about 2.5% of the $\tilde{n} - 1$ value. In this case, the degree of order S is written as

$$S = \left(\frac{\Delta n}{\tilde{n} - 1}\right)\left(\frac{\alpha_\perp}{\alpha_\parallel - \alpha_\perp}\right) \tag{54.48}$$

where it is assumed that $\alpha_o \approx \alpha_\perp$. This equation indicates that the order S is in proportion with the birefringence. Considering the square relation of the birefringenceΔn with the interference light intensity ($A \propto \Delta n^2$), the order S is proportional to the square root of the interference light intensity, that is, $S \propto \sqrt{A}$.

Polarized transmitted light measurements are performed using a spectrophotometer or a laser diode optical system equipped with two polarizers. The polarizers used are Glan–Thompson prisms with extinction ratio of 5×10^{-5} or polarization filters with a ratio of 10^{-4}. The incident light is reduced by use of a *ND* filter at the measurement of transmitted light with parallel polarization. The sample cell made of quartz was used in order to reduce the effect on the optical background at the crossed polarization measurement. There are two types of measurements of the transmitted light with crossed polarization I_1 and parallel polarization I_2, since the ratio I_1/I_2 depends on the light pathlength ℓ and the number density of vesicles N: (1) measurement by varying the light pathlength ℓ using a sample cell of a syringe type and (2) measurement by varying the number density of vesicles N by diluting the lipid dispersion using a square cell. It is convenient to express the number density N in terms of more directly measurable parameter. Using the lipid concentration c, the number density is given by $N = c/M$, where M is the mean anhydrous mass of a single vesicle. The mean anhydrous mass is a constant value when no vesicle disruption occurs at the dilution.

Experimental results show the linear dependence on the lipid concentration and the cell length at low values [45]. The interference light intensity is determined from the slopes of the lines. To obtain a linear dependence of the intensity ratio I_1/I_2 on $N\ell$, multilamellar vesicles with appropriate size were prepared. Small unilamellar vesicles (SUVs) are not suitable for measuring the interference light because of their weak intensity. Sometimes, a SUV was removed by filter to avoid vesicle aggregation by addition of additives. The suitable size is roughly more than $\lambda/\tilde{n}$, where λ is the wavelength of the incident light and $\tilde{n}$ is the mean refractive index of lipids. Since the interference light strongly depends on vesicle size, the vesicle aggregation and disruption are usually monitored by the turbidity obtained from the transmitted light with parallel polarization. Occasionally, the size distribution of vesicles in the dispersion should be measured by dynamic light scattering. The PTL technique was applied mainly to study the effects of hydrophilic and hydrophobic additives on the molecular order of liposomal membranes using the square- root relation between the order S and the interference light intensity A, namely, S $\propto \sqrt{A}$ [85–90]. Finally we show the birefringence values of liposomal membranes obtained by PTL using a spectrophotometer in Table 54.3 [32].

SURFACE STATES OF LIPID MONOLAYERS CONTAINING GANGLIOSIDES

SHOKO YOKOYAMA

School of Pharmaceutical Sciences, Kyushu University of Health and Welfare, Miyazaki, Japan

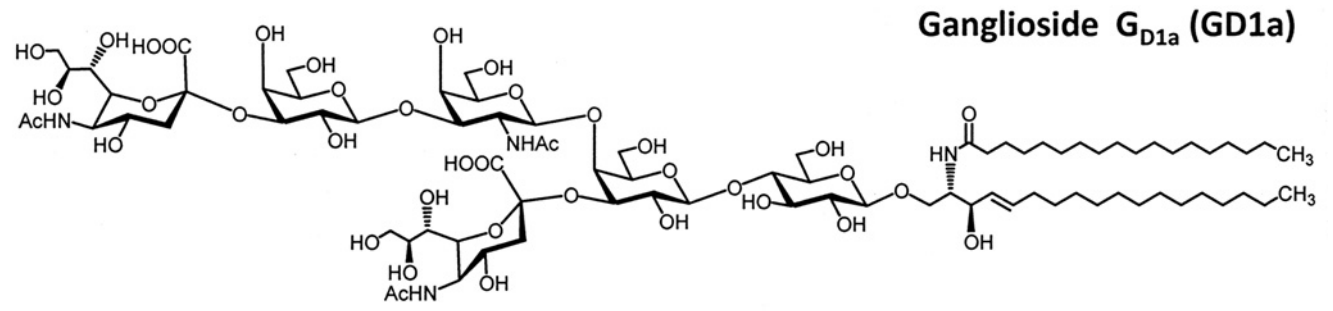
55.1 INTRODUCTION

Biological membranes are composed of phospholipids, glycolipids, cholesterol, and glycoproteins. Several models of biological membranes have emerged since Singer and Nicolson [1] proposed the fluid mosaic model. Simons and coworkers [2, 3] proposed "rafts" and "caveolae" at the cell surface, which are rich in glycolipid, phospholipid, and cholesterol. Another team [4] proposed that gangliosides form microdomains at the cell surface, through which signal transduction occurs. The role of membrane organization and the structure of rafts are interesting subjects in membrane structural biology.

We have studied the surface states of ganglioside G_{M1} (GM1) monolayer and mixed GM1–phospholipid monolayers using atomic force microscopy [5–7]. *Atomic force microscopy* (AFM) is a surface imaging technique capable of nanometer-scale resolution, which operates by measuring the forces acting between a probe and the sample [8]. The surface states of the monolayers containing GM1 changed as the surface pressure was varied, suggesting that GM1 participates in specific cell recognition or signal transduction. The surface pressure-responsive change in morphology of GM1 was affected by the surrounding environment, suggesting that the GM1 localized in each organ has a specific role [5–7]. Another group [9] reported the distribution of GM1 in model membranes of lipidrafts.

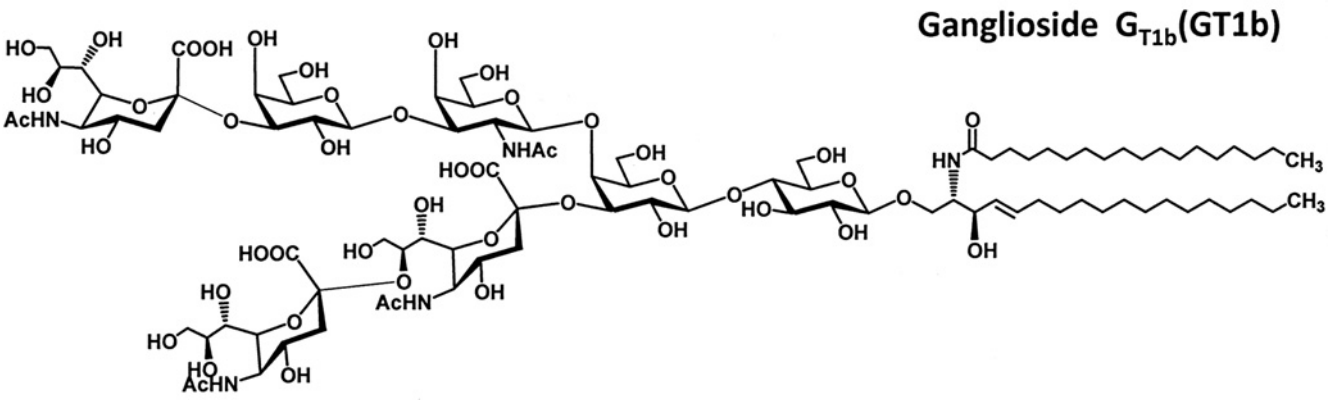
In this chapter, I report the surface states of lipid monolayers containing ganglioside G_{D1a} (GD1a), ganglioside G_{T1b} (GT1b) and cholesterol (Chol), as a raft model. The results for ternary, quaternary and five-component systems of monolayers are mainly shown in this chapter, while single and binary systems of ganglioside monolayers are briefly described.

55.2 EXPERIMENTAL MATERIALS



Ganglioside G_{D1a} (GD1a), ganglioside G_{T1b} (GT1b), L-α-dipalmitoylphosphatidylcholine (DPPC), dioleoylphosphatidylcholine (DOPC), and cholesterol (Chol) were purchased from Sigma Chemical Co. In this experiment, superpure water (Super-Q system) was used. Chemical structures of GD1a and GT1b are shown in Scheme 55.1

55.3 MEASUREMENT OF SURFACE PRESSURE



The surface pressures of monolayers for gangliosides, phospholipids, and mixed ganglioside–phospholipid at the air–water interface were determined at 25 ± 0.5°C (or 25–50 ± 0.5°C) by the Wilhelmy plate method using a surface pressure meter of type HBM-A (Kyowa Interface Science Co. Ltd.) with a bar made of Teflon. The speed of compression on the monolayer was 20 mm/min.

The surface pressure (π) *vs*. area (A) isotherms and the collapse pressures for DPPC [10], DOPC [7], GM1 [10], GD1a [11–13], and GT1b [11,14] monolayers have been presented. The phase transition from the liquid-expanded film to the liquid-condensed film was observed for DPPC,

Scheme 55.1 Chemical structures of GD1a and GT1b.

DOPC, GM1, GD1a, and GT1b monolayers, while only the liquid-expanded film was observed for DOPC monolayer.

55.4 PREPARATION OF LB FILM

Single-layer Langmuir–Blodgett (LB) films for AFM were obtained as follows. The monolayers were transferred at 25°C using a vertical dipping method onto freshly cleaved mica. Deposition proceeded at 5 mm/min, under various surface pressures.

55.5 AFM OBSERVATION

A model JSPM-5200 atomic force microscope (JEOL Ltd.) was used for AFM observations. The AFM probe used was a Micro Cantilever CSC38 (JEOL Ltd.) made of silicon and coated with Au, which had a spring constant of 0.08 N/m, a length of 250 μm, and a thickness of 1.0 μm. AFM observation was carried out with the contact mode in the air. In this study, observation of monolayer was carried out by varying the surface pressure, since surface pressure at the biological membrane should rise when cells or signals approach the membrane.

55.6 RESULTS AND DISCUSSION

55.6.1 Single System of Ganglioside Monolayer

The surface states of GD1a and GT1b monolayers, as a model of glycolipid microdomain, were observed using AFM. Changes in morphology were found in GD1a and GT1b monolayers when the surface pressure was raised. A swelling pattern and a ripple pattern were observed for the GD1a and GT1b monolayers, respectively [15]. The morphology and the responsive surface pressure were different among GD1a, GT1b, and GM1.

55.6.2 Binary System of Ganglioside–Phospholipid

Surface states of binary GD1a/DPPC, GT1b/DPPC, GD1a/DOPC, and GT1b/DOPC monolayers were measured.

55.6.2.1 Binary GD1a/DPPC Monolayer [12]. AFM images of the GD1a/DPPC (6:4) monolayer showed DPPC domains in flat matrix at 10 mN/m. The flat state of the matrix changed to a percolation pattern by varying the surface pressure from 10 to 28 mN/m. A similar percolation pattern was observed in GM1/DPPC (1:9) monolayer [10]. The amount of GD1a forming a percolation pattern in the monolayer was larger than GM1. This phenomenon may be related to the higher content of GD1a than GM1 in the biological membrane: 13 % GM1 and 38 % GD1a in human brain tissue [16]; 2% GM1 and 45 % GD1a in the synapse membrane of rats [17].

55.6.2.2 Binary GT1b/DPPC Monolayer [18]. AFM images of the GT1b/DPPC (4:6) monolayer showed GT1b domains (50–100 nm) together with DPPC domains (2 μm) in the matrix at a surface pressure of 15 mN/m, the GT1b domains disappeared and the DPPC domains (0.5–1 μm) embedded in the matrix at 20 mN/m. When surface pressure further increased to 28 mN/m, the DPPC domains disappeared and the monolayer became flat and uniform.

55.6.2.3 Binary GD1a/DOPC Monolayer [19]. The rafts are surrounded by unsaturated phospholipid [2, 3]. Thus, surface states of ganglioside/DOPC binary monolayer were measured before studying ternary ganglioside/DPPC/DOPC monolayer.

AFM images of the GD1a/DOPC (4:6) monolayer showed flowerlike and petal-like domains of GD1a embedded in DOPC-rich matrix, where the matrix was uniform and flat, at a surface pressure of 10 mN/m. When surface pressure increased to 15 mN/m, the uniform and flat matrix changed to a spotted pattern. At surface pressures above 20 mN/m, flowerlike and petal-like domains disappeared and the membrane became almost flat at 30 mN/m.

55.6.2.4 Binary GT1b/DOPC Monolayer [20]. AFM images of the GT1b/DOPC (4:6) monolayer showed flowerlike domains of GT1b and a spotted pattern in the matrix at a surface pressure of 10 mN/m. When surface pressure increased to 20 mN/m, the spotted pattern in the matrix almost disappeared, and the flowerlike domains were embedded in the flat matrix. When surface pressure further increased to 25 mN/m, the flowerlike domains changed to the spotted pattern.

The pattern for both of GT1b and GD1a systems was similar. However, the order of pattern with increasing surface pressure was different between them.

55.6.3 Ternary System of Ganglioside/DPPC/DOPC

The rafts are surrounded by unsaturated phospholipid [2, 3]. Thus, surface states of ternary ganglioside/DPPC/DOPC monolayer were studied before studying quaternary ganglioside/DPPC/DOPC/Chol monolayer.

55.6.3.1 Ternary GD1a/DPPC/DOPC Monolayer. AFM images of the GD1a/DPPC/DOPC (4:6:6) monolayer [21] are shown in Fig. 55.1, where bright areas in the images indicate topographic highs.

At a surface pressure of 25 mN/m (Fig.55.1a), largely circular domains of DPPC with a flat surface are embedded in the matrix. Furthermore, the matrix shows two phases, namely snow crystal-like domains, which consist of GD1a and a small amount of DOPC, embedded in the DOPC matrix.

At a surface pressure of 30 mN/m (Fig. 55.1b), DPPC domains are found, however, the morphology of the matrix drastically changed by varying the surface pressure from 25 to 30 mN/m. A percolation pattern was formed in the matrix. This behavior of the GD1a ternary monolayer is quite contrary to the previous GM1 ternary monolayer; a

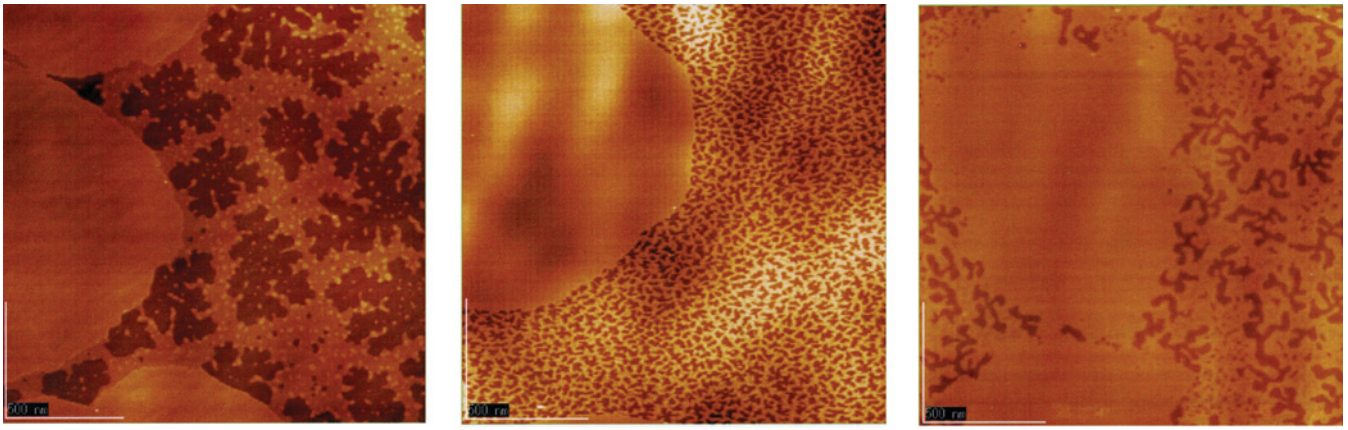

FIGURE 55.1 AFM images of ternary GD1a/DPPC/DOPC (4:6:6) monolayer, with surface pressure (a) 25, (b) 30, and (c) 35 mN/m and scan area 1.5×1.5 μm.

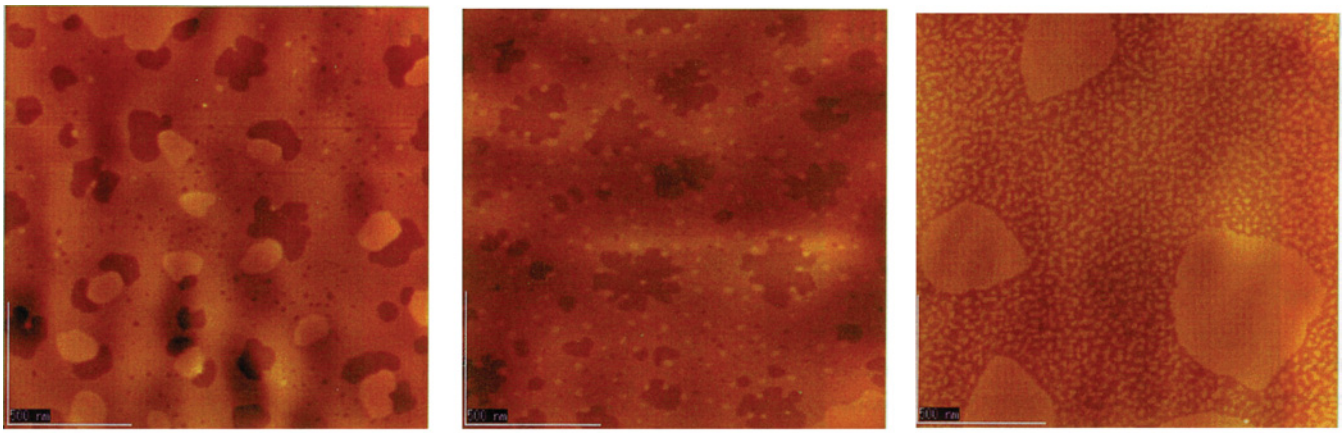

FIGURE 55.2 AFM images of ternary GD1a/DPPC/DOPC (6:4:4) monolayer, with surface pressure (a) 10, (b) 15, and (c) 20 mN/m and scan area 1.5 × 1.5 μm.

percolation pattern was formed in the DPPC-rich domain for the GM1/DPPC/DOPC ternary system [7], while a percolation pattern was formed in the DOPC-rich matrix for the GD1a/DPPC/DOPC ternary system.

When surface pressure increased to 35 mN/m (Fig. 55.1c), the percolation pattern disappeared and the matrix changed to a waterweedlike pattern.

A ternary system containing a higher ratio of GD1a was then chosen to examine the effect of membrane composition on the surface state of the GD1a ternary monolayer. AFM images of the GD1a/DPPC/DOPC (6:4:4) monolayer [19] are shown in Fig. 55.2.

At a surface pressure of 10 mN/m (Fig. 55.2a), brightly elliptical domains of DPPC and dark domains of GD1a were embedded in the matrix. When surface pressure increased to 15 mN/m (Fig. 55.2b), the elliptical domains of DPPC disappeared, and flowerlike and petal-like domains of GD1a were embedded in the matrix. The membrane morphology changed markedly by varying the surface pressure from 15 to 20 mN/m. The flowerlike and petal-like domains of GD1a disappeared and elliptical domains of DPPC appeared again. Furthermore, the matrix formed a percolation pattern. The morphology shown in Fig. 55.2c was maintained at surface pressures of 20∼35 mN/m. Similar morphology, as shown in Fig. 55.2c, was observed not only in the ternary GD1a/DPPC/DOPC (4:6:6) monolayer (Fig. 55.1b) but also in the binary GD1a/DPPC monolayer ($X_{GD1a} = 0.4$ and 0.6 [12]). The change in morphology of the GD1a/DPPC/DOPC (6:4:4) monolayer with increasing surface pressure was more complicated than the GD1a/DPPC/DOPC (4:6:6) monolayer.

Next, a ternary system with a lower ratio of GD1a was examined. AFM images of the GD1a/DPPC/DOPC (2:6:6) monolayer [19] at surface pressures of 15∼35 mN/m are shown in Fig. 55.3.

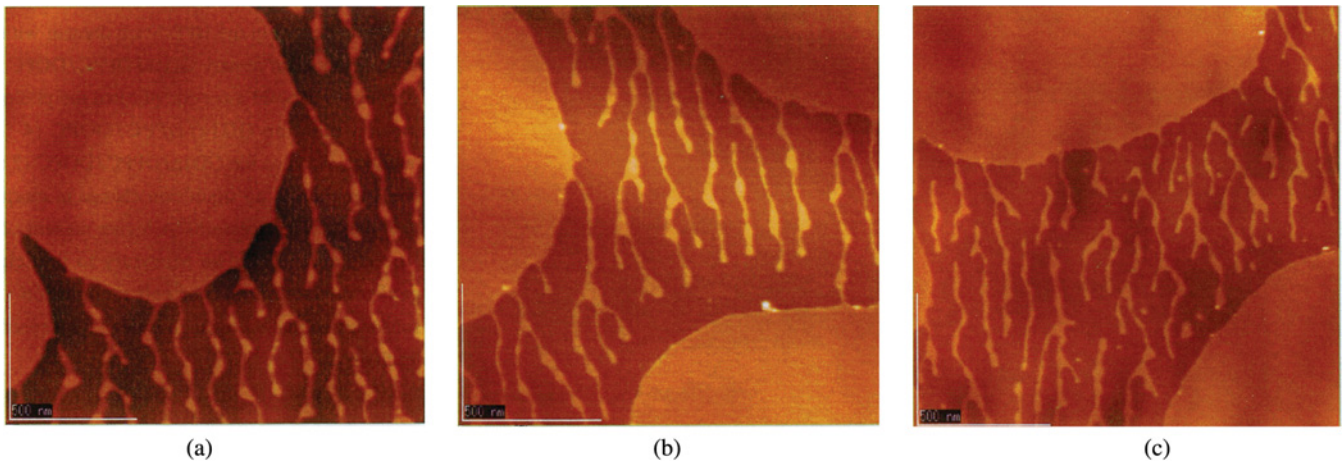

FIGURE 55.3 AFM images of ternary GD1a/DPPC/DOPC (2:6:6) monolayer, with surface pressure (a) 15, (b) 20, and (c) 35 mN/m and scan area 1.5 × 1.5 μm.

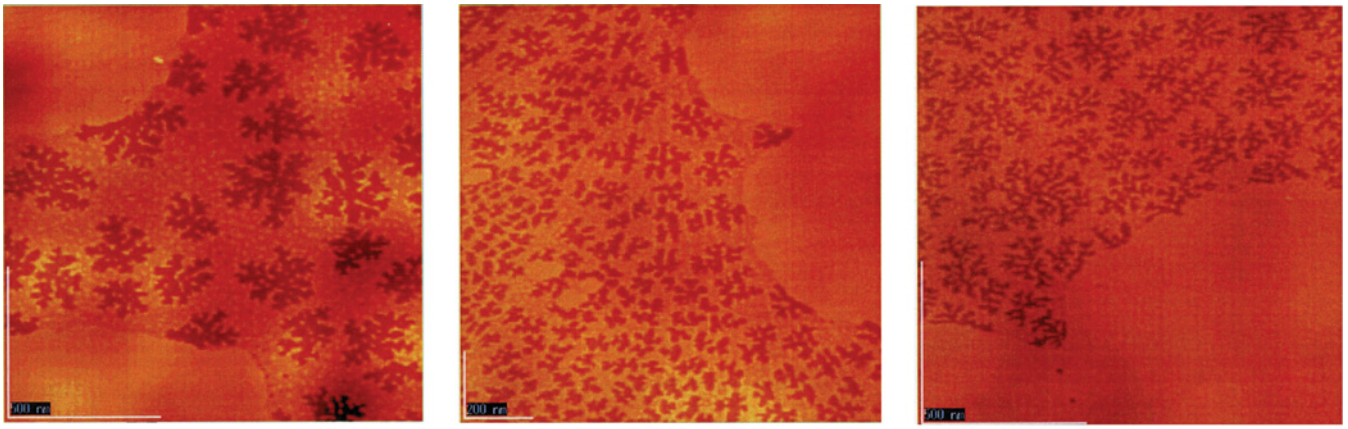

FIGURE 55.4 AFM images of ternary GT1b/DPPC/DOPC (4:6:6) monolayer, with surface pressure (a) 25, (b) 30, and (c) 35 mN/m and scan area 1.5 × 1.5 μm.

Largely circular domains of DPPC are embedded in the matrix. The matrix composed of DOPC and GD1a shows a dripping pattern, which indicates higher fluidity of the matrix. No significant change in the morphology of the GD1a/DPPC/DOPC (2:6:6) monolayer was found by varying surface pressure. A higher content of GD1a in membrane may be necessary to participate in signal transduction compared with GM1, since the content of GD1a in the biological membrane is higher than GM1: 45% GD1a and 2% GM1 in the synapse membrane of rats [17].

55.6.3.2 Ternary GT1b/DPPC/DOPC Monolayer [20]. AFM images of the GT1b/DPPC/DOPC (4:6:6) monolayer are shown in Fig. 55.4.

Largely circular domains of DPPC with a flat surface are embedded in the matrix. Furthermore, snow crystal-like domains of GT1b were formed in the DOPC matrix at 25 mN/m (Fig. 55.4a). When surface pressure increased to 30 mN/m, the snow crystal-like pattern in the matrix changed to a sleety pattern (Fig. 55.4b). Then the sleety pattern in the matrix returned to the snow crystal-like pattern again at 35 mN/m (Fig. 55.4c). The change in morphology of the GT1b/DPPC/DOPC (4:6:6) monolayer with increasing surface pressure was a little compared with the GD1a/DPPC/DOPC (4:6:6) monolayer. Furthermore, the GT1b ternary monolayer showed no percolation pattern as observed for the GD1a ternary monolayer (Fig. 55.1b).

A ternary system containing a lower ratio of GT1b was then chosen to examine the effect of membrane composition on the surface state of the GT1b ternary monolayer. AFM images of the GT1b/DPPC/DOPC (2:6:6) monolayer are shown in Fig. 55.5.

At a surface pressure of 20 mN/m, largely circular (1-μm) domains of DPPC and dark flowerlike domains of GT1b were embedded in the matrix. The membrane morphology

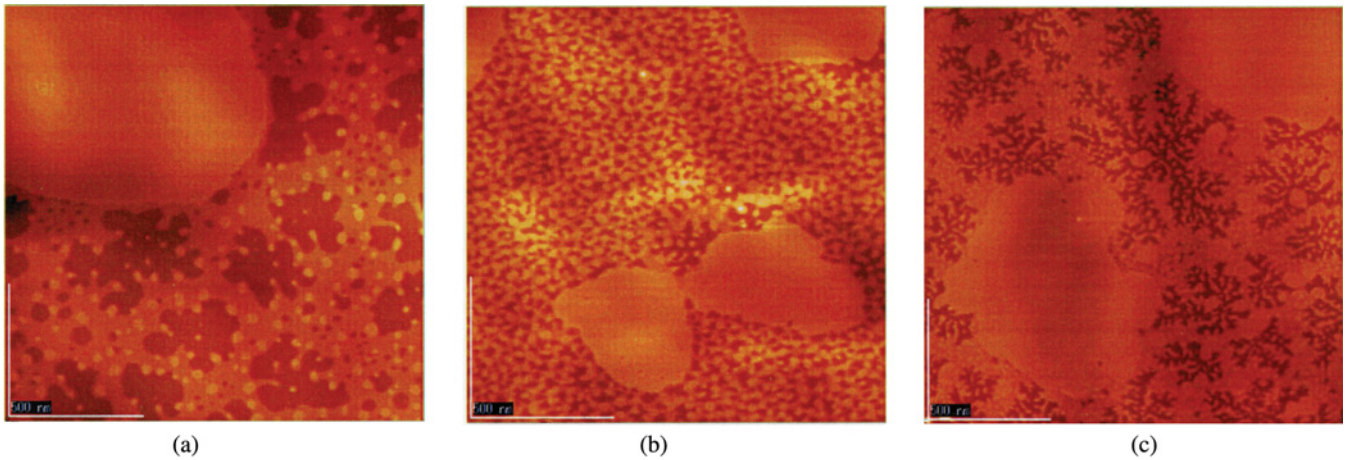

FIGURE 55.5 AFM images of ternary GT1b/DPPC/DOPC (2:6:6) monolayer, with surface pressure (a) 20, (b) 25, and (c) 30 mN/m and scan area 1.5 × 1.5 μm.

changed markedly by varying the surface pressure from 20 to 25 mN/m. The flowerlike domains completely disappeared, and a percolation pattern was formed in the matrix (Fig. 55.5b). When surface pressure further increased to 30 mN/m, the membrane morphology changed again; the percolation pattern disappeared and snow crystal-like domains appeared in the matrix (Fig. 55.5c).

The membrane morphology of the GT1b/DPPC/DOPC (2:6:6) monolayer (Fig. 55.5) was quite different from that of the GD1a/DPPC/DOPC (2:6:6) monolayer (Fig. 55.3). The GD1a ternary (2:6:6) monolayer showed the dripping pattern in the matrix, while the GT1b ternary (2:6:6) monolayer showed no dripping pattern but the more complicated patterns at various surface pressures. Furthermore, the GD1a ternary monolayer showed no significant change in the morphology by varying the surface pressure, while the GT1b ternary monolayer changed markedly the membrane morphology by varying the surface pressure.

A percolation pattern, as observed for the GD1a/DPPC/DOPC (4:6:6) monolayer, was not shown for the GT1b/DPPC/DOPC (4:6:6) monolayer but was shown for the GT1b/DPPC/DOPC (2:6:6) monolayer. Specifically, a percolation pattern seems to be formed in the GT1b ternary monolayer with a lower ratio of GT1b, while a percolation pattern was formed in the GD1a ternary system with a higher ratio of GD1a. A lower content of GT1b in the membrane seems to be convenient to participate in signal transduction compared with GD1a. The content of GT1b in the biological membrane is lower than GD1a: 38% GD1a and 16% GT1b occur in the brain tissue [13]. The specific morphology of the GT1b/DPPC/DOPC (2:6:6) monolayer may be related to the lower content of GT1b in the biological membrane.

55.6.4 Ternary System of Ganglioside/DPPC/Chol

The rafts are rich in Chol. Thus, surface states of ganglioside/DPPC/Chol ternary monolayer were studied before studying gaglioside/DPPC/DOPC/Chol quaterrnary monolayer.

55.6.4.1 Ternary GD1a/DPPC/Chol Monolayer [22]. AFM images of the GD1a/DPPC/Chol (0.5:6:3) monolayer are shown in Fig. 55.6. At a surface pressure of 20 mN/m, a dendritic cell-like domain, which have never been seen, appeared in the matrix. Dendritic cell-like domains increased at 28 mN/m, and then the domains disappeared when surface pressure further increased to 35 mN/m.

A small amount of GD1a contributed to form the specific morphology in the ternary monolayer containing Chol. Whereas ternary systems with higher ratio of GD1a showed no dendritic cell-like domains: the GD1a/DPPC/Chol (4:6:3) monolayer showed dotted pattern at surface pressures of 20–35 mN/m; the GD1a/DPPC/Chol (2:6:3) monolayer showed flowerlike domains at 25 mN/m and spotted pattern at 30 mN/m.

55.6.4.2 Ternary GT1b/DPPC/Chol Monolayer [23]. AFM images of the GT1b/DPPC/Chol (0.5:6:3) monolayer are shown in Fig. 55.7.

At surface pressures of 15–28 mN/m, amebiform domains appeared in the matrix. When surface pressure further increased to 30 mN/m, the amebiform domains disappeared. A small amount of GT1b contributed to form the specific morphology, as well as GD1a, in the ternary monolayer

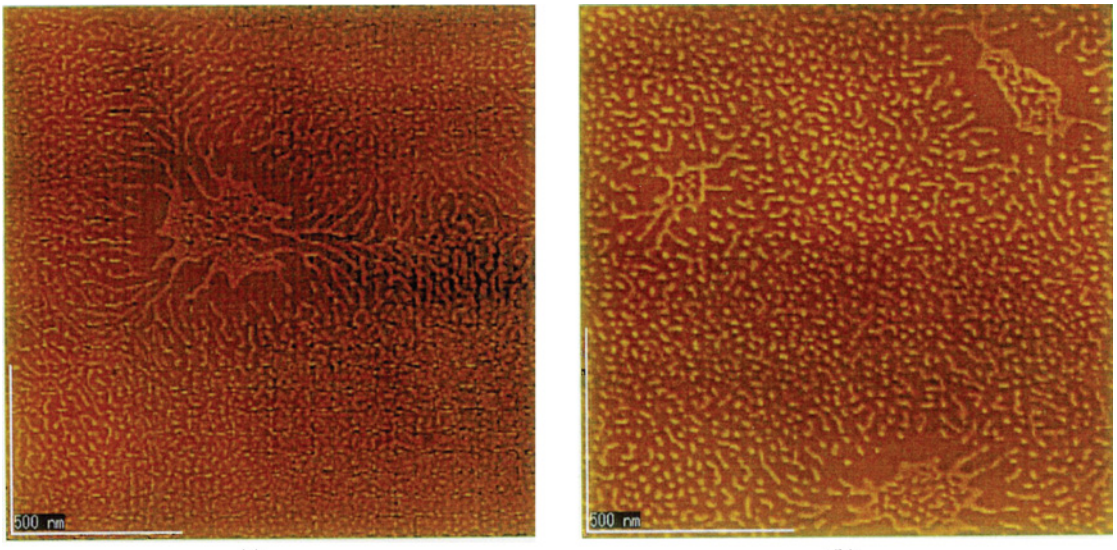

FIGURE 55.6 AFM images of the GD1a/DPPC/Chol (0.5:6:3) monolayer, with surface pressure (a) 20 and (b) 28 mN/m and scan area 1.5 × 1.5 μm.

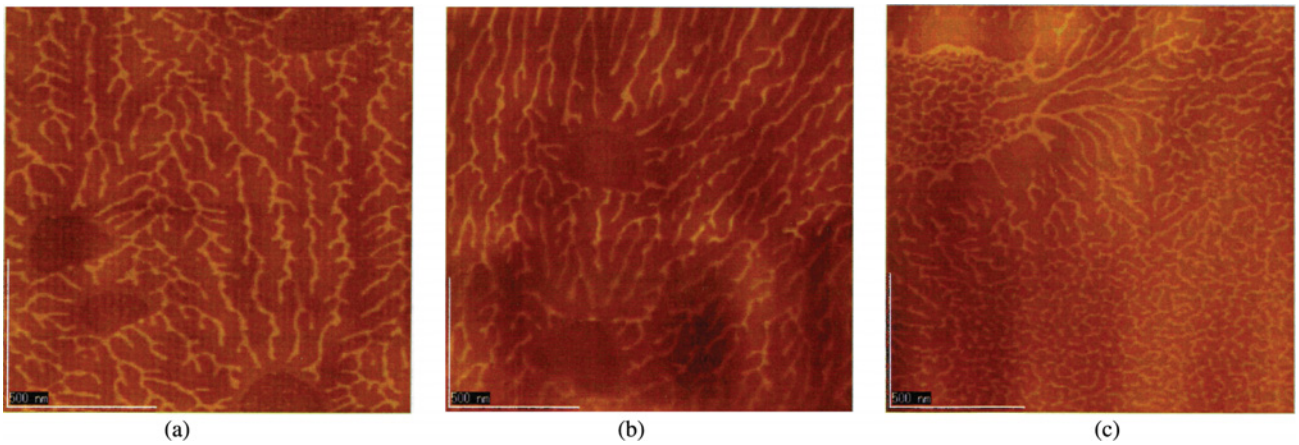

FIGURE 55.7 AFM images of ternary GT1b/DPPC/Chol (0.5:6:3) monolayer, with surface pressure (a) 15, (b) 20, and (c) 28 mN/m and scan area 1.5 × 1.5 μm.

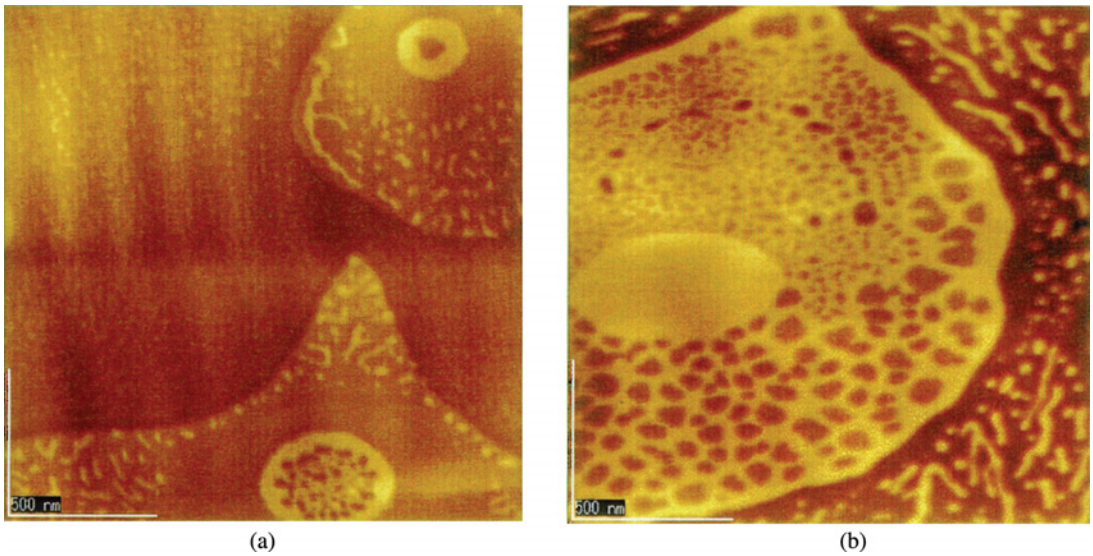
containing Chol. Whereas ternary systems with higher ratio of GT1b showed no amebiform domains. AFM images of the GT1b/DPPC/Chol (2:6:3) monolayer showed a spotted pattern at 25 mN/m and flowerlike domains at 28 mN/m. The AFM image of the GT1b/DPPC/Chol (4:6:6) monolayer showed no specific morphology and no significant change in morphology by varying the surface pressure from 15 to 35 mN/m.

55.6.5 Quaternary System of Ganglioside/DPPC/DOPC/Chol

The rafts are rich in Chol and are surrounded by unsaturated phospholipid [2, 3]. Surface states of quaternary ganglioside/DPPC/DOPC/Chol monolayer as a raft model were studied.

55.6.5.1 Quaternary GD1a/DPPC/DOPC/Chol Monolayer [22]. First, the GD1a/DPPC/DOPC/Chol (0.5:6:6:3) monolayer was chosen for measurement, since the GD1a/DPPC/Chol (0.5:6:3) monolayer showed specific morphology (Fig. 55.6). AFM images of the GD1a/DPPC/DOPC/Chol (0.5:6:6:3) are shown in Fig. 55.8.

At a surface pressure of 15 mN/m, mononuclear cell-like domains, which have never been seen, appeared in the matrix (Fig. 55.8a). When surface pressure increased to 35 mN/m, the domain developed a more complicated morphology: spotted and dotted patterns coexisted in the domains (Fig. 55.8b). Furthermore, a percolation pattern appeared in the matrix.



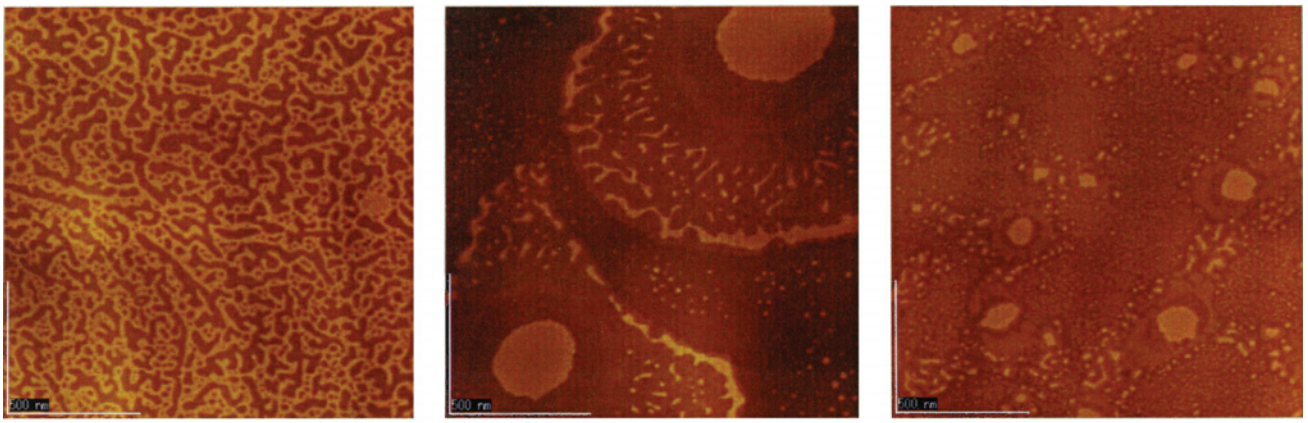


FIGURE 55.8 AFM images of quaternary GD1a/DPPC/DOPC/Chol (0.5:6:6:3) monolayer, with surface pressure (a) 15 and (b) 35 mN/m and scan area 1.5 × 1.5 μm.

(a) (b) (c)

FIGURE 55.9 AFM images of quaternary GT1b/DPPC/DOPC/Chol (0.5:6:6:3) monolayer, with surface pressure (a) 15, (b) 28, and (c) 30 mN/m and scan area 1.5 × 1.5 μm.

On the other hand, the GD1a/DPPC/DOPC/Chol (2:6:6:3) moonolayer, containing a higher ratio of GD1a, showed no mononuclear cell-like domain [20].

In the previous ternary systems without Chol, the GD1a/DPPC/DOPC (4:6:6) monolayer showed specific morphology (Fig. 55.1). In contrast, a small amount of GD1a contributed to form the extremely specific morphology in the quaternary monolayer containing Chol. These results suggest that a small amount of GD1a plays a specific role in rafts.

55.6.5.2 Quaternary GT1b/DPPC/DOPC/Chol Monolayer [23]. AFM images of the GT1b/DPPC/DOPC/Chol (0.5:6:6:3) monolayer are shown in Fig. 55.9.

At a surface pressure of 15 mN/m, a percolation pattern is shown (Fig. 55.9a). When surface pressure increased to 28 mN/m, the percolation pattern disappeared, and mononuclear cell-like domains appeared in the matrix (Fig. 55.9b). When surface pressure further increased to 30 mN/m, the mononuclear cell-like domains deformed (Fig. 55.9c).

The mononuclear cell-like domain was found in systems of both GT1b and GD1a; however, it was observed within a narrow range of surface pressure in the GT1b quaternary system. Furthermore, the GT1b quaternary system showed a percolation pattern. These results suggest that GT1b plays a more specific role in rafts than GD1a.

The GT1b/DPPC/DOPC/Chol (2:6:6:3) monolayer containing a higher ratio of GT1b showed no mononuclear cell-like domain [23]. A small amount of GT1b contributed to form the mononuclear cell-like domain.

55.6.6 Five-Component System of Gangliosides/ DPPC/DOPC/Chol [24]

Surface states of five-component GD1a/GT1b/DPPC/DOPC/Chol monolayers as a biological membrane were investigated. In the previous quaternary systems, the GD1a/DPPC/DOPC/Chol (0.5:6:6:3) monolayer showed a mononuclear cell-like domain, while the GD1a/DPPC/DOPC/Chol (2:6:6:3) monolayer showed no mononuclear cell-like domain and no significant change in morphology by varying the surface pressure. Thus, we chose 0.5 the total molar ratio of GD1a and GT1b in this measurement. First, the GD1a/GT1b/DPPC/DOPC/Chol (0.25:0.25:6:6:3) monolayer was chosen for measurement. AFM images of the monolayer are shown in Fig. 55.10.

At a surface pressure of 15 mN/m, a mononuclear cell-like domain was embedded in the matrix (Fig. 55.10a) as in the previous GD1a quaternary monolayer (Fig. 55.8). When surface pressure increased to 20 mN/m, the nucleus disappeared in the cellular domain (Fig. 55.10b). When surface pressure further increased to 25 mN/m, a nucleus began to appear in the cellular domain (Fig. 55.10c), and the mononuclear cell-like domain pattern recovered at surface pressures above 30 mN/m (Fig. 55.10d).

The quaternary GD1a/DPPC/DOPC/Chol (0.5:6:6:3) monolayer without GT1b indicated mononuclear cell-like domains at surface pressures of 15-35 mN/m (Fig. 55.8). Thus, addition of a small amount of GT1b may contribute to control the disappearance and appearance of the nucleus in the cellular domain, which seems to be related to an on/off function.

A five-component system containing a lower ratio of GT1b was then examined. AFM images of the GD1a/GT1b/DPPC/DOPC/Chol (0.4:0.1:6:6:3) monolayer are shown in Fig. 55.11.

Mononuclear cell-like domains and cellular domains without a nucleus alternately appeared every additional 5 mN/m of surface pressure, which seemed to be an on/off function.

A five-component system containing a lower ratio of GD1a was then examined. AFM images of the GD1a/GT1b/DPPC/DOPC/Chol (0.1:0.4:6:6:3) monolayer are shown in Fig. 55.12.

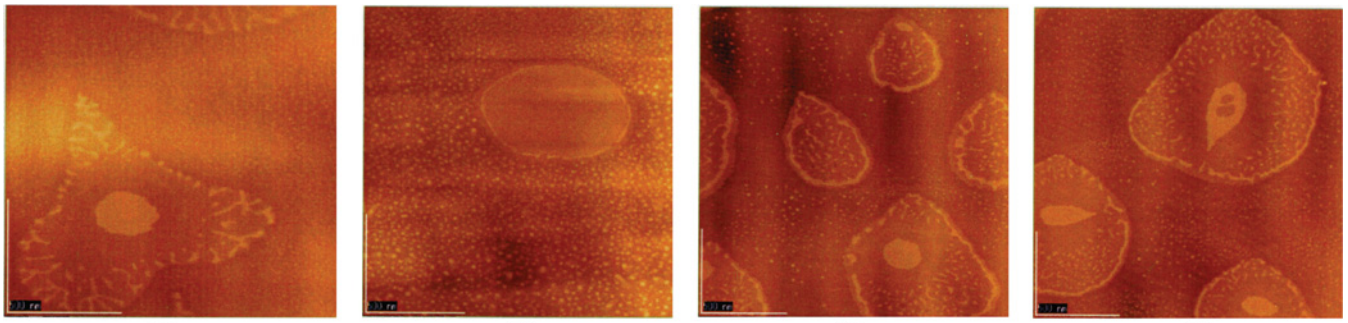

FIGURE 55.10 AFM images of the GD1a/GT1b/DPPC/DOPC/Chol (0.25:0.25:6:6:3) monolayer, with surface pressure (a) 15, (b) 20, (c) 25, and (d) 30 mN/m and scan area 1.5 × 1.5 μm.

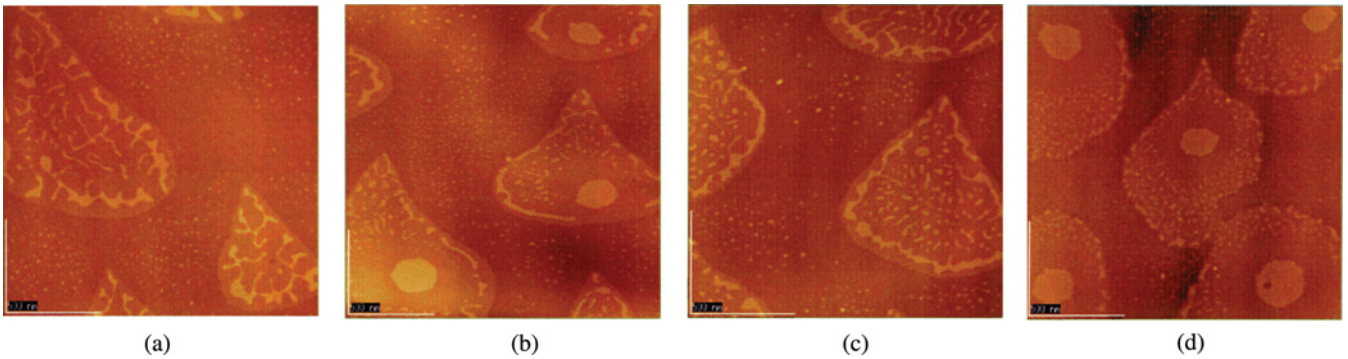

FIGURE 55.11 AFM images of the GD1a/GT1b/DPPC/DOPC/Chol (0.4:0.1:6:6:3) monolayer, with surface pressure (a) 15, (b) 20, (c) 25, and (d) 30 mN/m and scan area 1.5 × 1.5 μm.

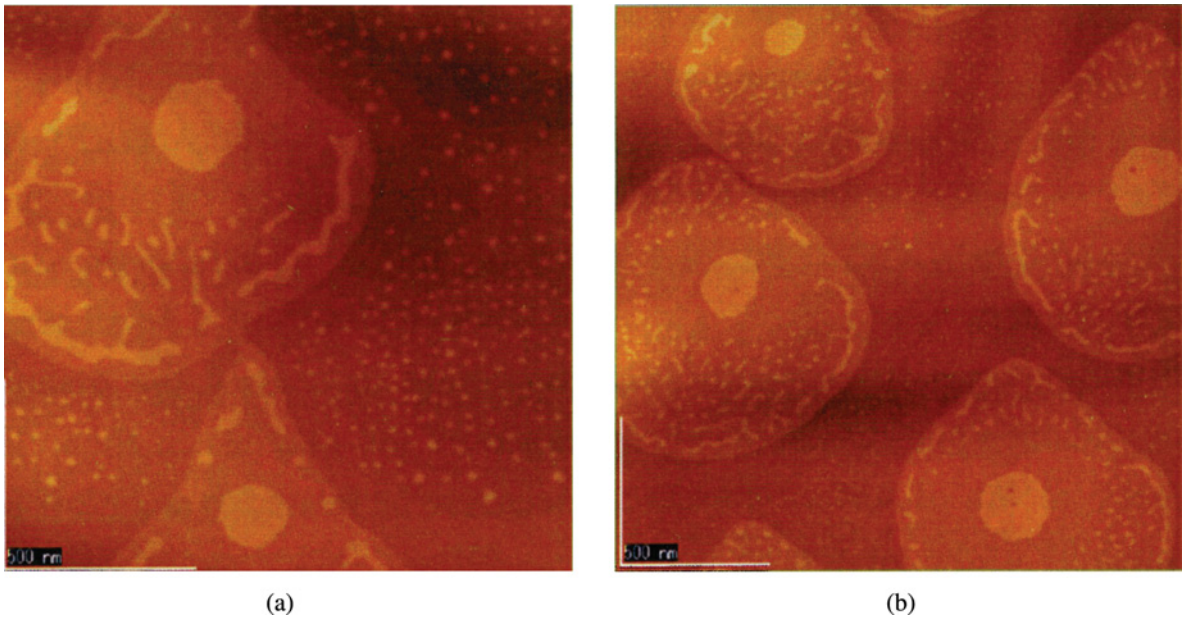

FIGURE 55.12 AFM images of GD1a/GT1b/DPPC/DOPC/Chol (0.1:0.4:6:6:3) monolayer, with surface pressure (a) 15 and (b) 30 mN/m and scan area 1.5 × 1.5 μm.

Mononuclear cell-like domains are found at surface pressures of 15–30 mN/m. The quaternary GT1b/DPPC/DOPC/Chol (0.5:6:6:3) monolayer without GD1a showed a mononuclear cell-like domain at 28 mN/m, and the domains deformed at 30 mN/m (Fig. 55.9). Furthermore, the quaternary monolayer showed a percolation pattern at 15 mN/m (Fig. 55.9). The addition of a small amount of GD1a to the quaternary GT1b/DPPC/DOPC/Chol (0.5:6:6:3) monolayer contributed to the formation of mononuclear cell-like domains at all surface pressures of 15–30 mN/m.

These results suggest that a small amount of each ganglioside plays a specific role in another ganglioside-rich monolayer; a small amount of GD1a functions as a structure maker of the mononuclear cell-like domain, while a small amount of GT1b functions as a structure breaker of the mononuclear cell-like domain. GT1b occurs in higher amounts in the cerebellum. The cerebellum plays a central role in athletic motor functions, where frequent switching on and off of signals is required. When signals or cells approach the ganglioside domains, the surface pressure at the domain should rise. We reported [5] that the conformational change of GM1 at the membrane surface with increasing surface pressure is thought to be related to specific cell recognition or signal transduction. Therefore, the change in morphology of the five-component monolayer by varying the surface pressure and the composition may contribute to the promotion of various physiological events in biological membranes, one of which may be an on/off function, although the role of ganglioside in the biological membrane has not yet been made so clear in the biochemical field.

55.7 CONCLUSION

Surface states of monolayer containing ganglioside changed in morphology by varying the surface pressure. The morphology and the responsive surface pressure of monolayers containing ganglioside were affected by the surrounding environment, suggesting that ganglioside localized in each organ has a specific role.

The GD1a/DPPC/Chol (0.5:6:3) monolayer and the GT1b/DPPC/Chol (0.5:6:3) monolayer showed a dendritic cell-like domain and an amoebiform domain, respectively. The GD1a/DPPC/DOPC/Chol (0.5:6:6:3) monolayer and the GT1b/DPPC/DOPC/Chol (0.5:6:6:3) monolayer, as a raft model, showed a mononuclear cell-like domain, suggesting that ganglioside plays a specific role in rafts.

The GD1a/GT1b/DPPC/DOPC/Chol (0.4:0.1:6:6:3) monolayer showed two patterns of mononuclear cell-like domain and cellular domain without a nucleus every additional 5 mN/m of surface pressure, while the GD1a/GT1b/DPPC/DOPC/Chol (0.1:0.4:6:6:3) monolayer showed mononuclear cell-like domains at all surface pressures of 15–30 mN/m. These results suggested that a small amount of each ganglioside played a specific role in another ganglioside-rich monolayer; a small amount of GD1a functioned as a structure maker of the mononuclear cell-like domain, while a small amount of GT1b functioned as a structure breaker of the mononuclear cell-like domain, which seemed to be related to an on/off function.

LIPONANOCAPSULE: A NANOCAPSULE BUILT FROM A LIPOSOMAL TEMPLATE

YUUKA FUKUI AND KEIJI FUJIMOTO

The Center for Chemical Biology, School of Fundamental Science and Technology, Graduate School of Science and Technology, Keio University, Yokohama, Japan

56.1 INTRODUCTION

In this introductory section, we describe liposome as a template for nanocapsules.

In diverse biological systems, amphiphilic phospholipid molecules are assembled into a bilayer structure to form cell membranes where they are coated with various biomolecules such as polysaccharides and proteins. Cell membranes are fluid and thereby allow for lateral and rotational diffusion of biomolecules embedded in the lipid bilayer. Cytoplasmic organelles are also enclosed by the lipid bilayer, which provides a barrier that determines their boundary and allows for compartmentalization of many biological entities into each organelle. For the molecular transport in the cell and the intercommunication among cells, lipid vesicles are known to serve as a delivery vehicle of functional biomolecules. In this regard, the bilayer structures play important roles to induce many biological reactions and maintain robustness and the total integrity of a cell.

Inspired by such lipid bilayer structures, a nanometer-sized phospholipid vesicle, namely, a liposome, has been developed and utilized as a biocompatible and versatile tool to encapsulate and deliver molecules of interest with possible applications in cosmetics [1] and pharmaceutics [2, 3]. However, liposomes are fluid and fragile against external stimuli such as temperature, pH, shear, adsorption, and enzymatic reactions. Therefore, development of an innovative technique to provide the liposome with robustness has been of considerable interests among many researchers. There have been numerous studies to develop reliable techniques to stabilize the liposome [4–6], such as polymerization inside the bilayer for solidifying the capsule, insertion of polymer chains into the lipid bilayer for stilling the ruffled membrane, adsorption or coating of polymer chains over the lipid surface via the intermolecular interactions for providing steric stabilization [7, 8] and formation of inorganic shells for reinforcing the capsule [9–11]. As another possible way, we here propose a strategy to create a "capsule wall" over the liposome surface with the layer-by-layer assembly of polyelectrolytes. The layer-by-layer assembly is a sophisticated approach to fabricate a thin multilayer of polyelectrolytes, which is based on the alternate deposition of anionic polymers and cationic polymers [12]. This is believed to be driven by the complex formation via electrostatic attractions between anionic and cationic polymers. To produce capsules, the polymer deposition has been carried out onto organic or inorganic cores [13–15], biological cells [16], and even to liquid crystals and emulsions [17]. In our approach, the layer-by-layer deposition of polyelectrolytes over the liposome made it possible to create a bioderived nanocapsule (liponanocapsule) with a variety of polymeric capsule walls. We expected that the multilayer coating over the liposomes would not only make the nanocapsule robust but also endow it with diverse structures and functions thanks to synergistic effects of functional polymer shells and dynamic lipid membranes. In addition, a multilayer shell produced over the liposomal template could serve as a locus for diverse reactions such as mineralization, polymerization, and enzymatic reactions.

56.2 MULTILAYER COATING TO PRODUCE *LIPONANOCAPSULE*

Many of polyelectrolytes are applicable to construct the multilayer shell and Fig. 56.1 summarizes the alternate deposition of polyelectrolytes over the liposomal template [18, 19]. Polyelectrolytes were selected from bioderived polymers where cationic polymers of poly-L-lysine (PLL), polyarginine (PArg), chitosan (CHI) and anionic polymers of poly-L-aspartic acid (PAsp), dextran sulfate (DXS), and DNA were used to prepare bioderived nanocapsules.

The first polymeric layer was generated by the adsorption of cationic polymers onto the negatively charged liposomes, which were prepared from a mixture of dilauroyl phosphatidic acid (DLPA) with a negative charge and dimyristoylphosphatidylcholine (DMPC). It was found that the amount of adsorbed polymers was dependent on lipid ratios, pH values, salt concentrations, and temperatures. PLL is a cationic polypeptide and undergoes unique conformational changes in response to pH and temperature. There have been reports on conformational changes of PLL from random coil to β-sheet on adsorption [20, 21]. It was observed that adsorbed PLL was transformed from random coil into β-sheet structure. This is probably because the positive charge of the adsorbed PLL chain was canceled out by the negative charge of the liposome surface, and thereby the adsorbed PLL chain could adopt the extended conformation sufficiently to form the β-sheet structure.

Next, the second layer could be produced over the first cationic layer by depositing anionic polymers to improve the mechanical robustness of nanocapsule. In this manner, the alternative adsorptions of cationic polymers and anionic polymers were carried out. The ζ-potentials of liponanocapsules changed between positive and negative values at each deposition. TEM images revealed that the shape and the structure of nanocapsules remained intact even after the construction of several polymeric layers. Durability of nanocapsules against surfactants was improved by the layer-by-layer deposition over the lipid membrane. By the addition of Triton-X 100, bare liposomes were ruptured while the liponanocapsule remained suspended without rupturing. Fluorescent substances were incorporated inside the inner cavity of the liponanocapsule prepared with CHI and DXS, and the leakage was measured to investigate the effect of the treatment with the surfactant on the lipid membrane [19]. As a result, the leakage was gradually reduced with increasing the number of layers, indicating that the layer-by-layer coating is an effective way to improve the mechanical robustness of nanocapsules.

56.3 RELEASE BEHAVIOR OF LIPONANOCAPSULES

Liposomes have been utilized as a carrier to encapsulate and deliver many substances, including drugs, proteins, and nucleic acids. As described above, liposomes are fluid and fragile against external stimuli. Furthermore, it is of great importance to improve the release behavior of substances for applications in the biomedical field, especially the drug delivery system. A negatively charged fluorescent probe, 1-hydroxypyrene-3,6,8-trisulfonic acid (HPTS) was encapsulated into bare liposomes and liponanocapsules. Liposomes showed 30–40% release of the encapsulated HPTS after 72 h, whereas the release from liponanocapsules was suppressed by means of layer-by-layer multilayer formation over the liposome [18, 19, 22]. It was found that the release rate was tunable by the surface coverage and the layer number of the polymer deposition. Then, an amphoteric alendronate, a commonly known bone-targeting drug and a nonionic glucose, were encapsulated in liponanocapsules and the release behavior was investigated in the same manner as HPTS. Figure 56.2 shows the result of alendronate. Irrespective of the charge of the encapsulated substance, the release was greatly suppressed compared with bare liposomes. At the same time, the polymer deposition reduced the membrane fluidity of the lipid bilayer. It is thought that the release of the encapsulated substances is greatly influenced by the fluidity. Therefore, it can be concluded that the release proceeds in the diffusion-limited manner, resulting in low permeability of substances through the capsule wall.

In addition, it is expected that the release is tunable by the selection of the capsule wall. For instance, when DNA was chosen to prepare a polymeric layer, the liponanocapsule exhibited a switching release in response to temperature. It is known that DNA is denatured into the random-coil structure

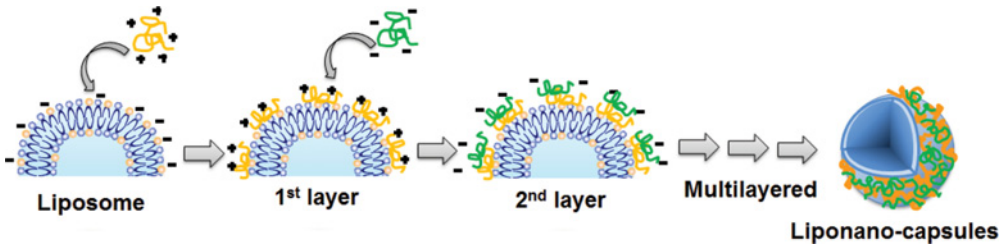

FIGURE 56.1 Schematic illustration of layer-by-layer deposition of polyelectrolytes over a liposome to prepare liponanocapsule.

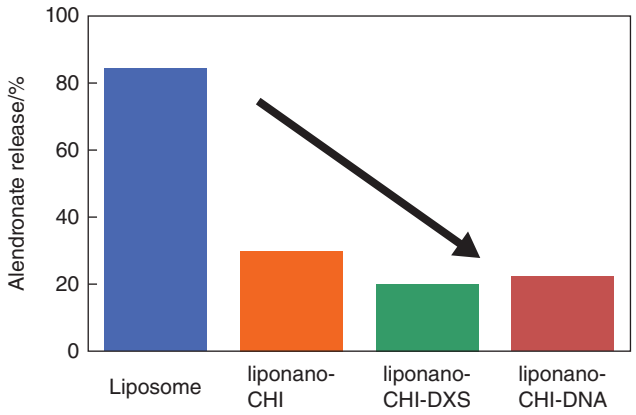

FIGURE 56.2 Percentage release of alendronate from a liposome and liponanocapsules after 85 h incubation (pH 4.5, 20°C).

by heating. As expected, the release from DNA-deposited nanocapsules was clearly increased by raising temperature from 25°C to 60°C. As denatured DNA was partially desorbed and removed from the surface of the liponanocapsule, it is thought that the capsule wall was greatly perturbed by desorption of DNA and consequently the release was triggered in a temperature-dependent manner [19].

56.4 INTERACTION OF LIPONANOCAPSULES WITH CELLS

As described above, the polymer layer formed over the liposomal template would render diverse properties to the capsule surface. When we intend to apply the liponanocapsules as a tool in the pharmaceutical and medical fields, it is important to consider their interactions with an external system such as proteins and cells. Here, we selected CHI and DNA as the outermost layer because they are known to exhibit good inertness on the interaction with cells [22]. We also carried out the surface deposition of PArg to provide the liponanocapsule with abilities to overcome the permeability barrier of the plasma membrane and transfect encapsulated substances into the cytosol. Arginine oligopeptides are well known to possess a cell-penetrating activity, which serve a function in delivering various substances [23–28]. Cellular uptake assays demonstrated that all of liposomes and liponanocapsules were internalized at 37°C. When experiments were carried out at 4°C, bare liposomes showed a suppressed uptake and the CHI-deposited nanocapsules with a positive charge underwent binding onto the cell surface rather than internalization. The cell penetration of arginine peptides occurs in a temperature-independent manner [29]. In fact, PArg-coated nanocapsules could be internalized at 4°C, indicating that the internalization is attributed to the cell-penetrating activity of the PArg layer. It was also found that cell-penetrating activity remained even after the deposition of DNA over the PArg-deposited nanocapsule and cellular uptake of liponanocapsules decreased with increasing the surface coverage of DNA.

56.5 ASSEMBLY OF LIPONANOCAPSULES TO CREATE FREESTANDING BIOSCAFFOLD

Freestanding thin films such as a nanosheet and a nanocarpet have attracted considerable attention in diverse applications including electronics, separation technology, pharmaceutical science, and biomedical engineering. In particular, it is expected that they will be utilized as a bioscaffold for wound healing, cardiovascular stent coating, and tissue engineering [30]. The fabrication of freestanding membranes has been achieved by various methods, including detachment of membranes built on the solid surface and formation of membranes at the air–liquid and the liquid–liquid interfaces [31]. Also, freestanding membranes can be obtained by assembling of nanoparticles through confinement of nanoparticles in microdroplets and further drying-mediated assembly of nanoparticles and microdroplets [32]. The use of liponanocapsules as a building block to create a bioscaffold is advantageous because individual bioderived liponanocapsules possess versatility, for example, biocompatibility and bioresorbability, abilities for controlled release, and cell penetration. They will be able to serve not only as a scaffold for tissue repair and regeneration but also as a supplier for the controlled release of drugs and growth factors. Therefore, we carried out the microhole-confined assembly to prepare a freestanding membrane from nanocapsules (Fig. 56.3). An aqueous suspension of nanocapsules was blotted over a metal mesh with the microholes [22]. As water evaporation proceeded

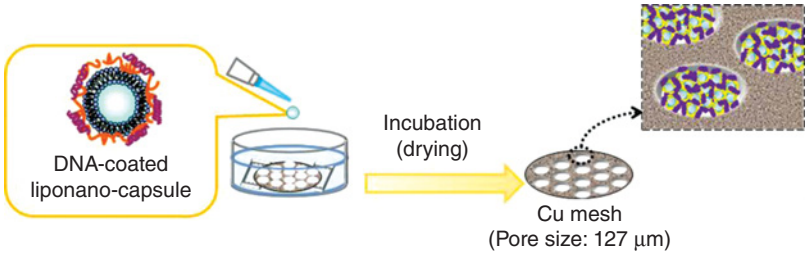

FIGURE 56.3 Schematic illustration of fabrication of freestanding membranes from DNA-coated liponanocapsules by drying-mediated assembly over the microholes of the mesh grid.

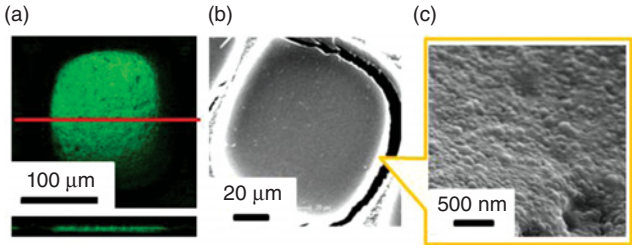

FIGURE 56.4 Confocal laser microscopic (a) and scanning electron microscopic images (b,c) of membranes produced from DNA-coated liponanocapsules.

from the suspension, dewetting took place so as to trap nanocapsules into each individual microhole.

We could not prepare membranelike structures from bare liposomes, and a partially ruptured membrane was obtained by the assembly of PArg-coated nanocapsules. In such a bottom–up assembly, DNA often acts as a "dry ligand" to produce a freestanding nanosheet of nanoparticles [32–34]. The organization of DNA coronas makes it possible to build up freestanding nanoparticle superlattices through the ordering of nanoparticles and nonspecific DNA–DNA interactions. Therefore, we prepared liponanocapsules displaying the DNA layer and intended to fabricate a freestanding membrane by the drying-mediated DNA organization. As a result, we could obtain the freestanding membrane. After drying, the shape and the structure of each nanocapsule remained the same and the fluorescent-labeled dextran was kept inside each nanocapsule (Fig. 56.4). Although other polyelectrolytes were tested, DNA was the best dry ligand among them. DNA-assisted assembly of nanoparticles is an effective method to create a bioscaffold from liponanocapsules.

56.6 COATING WITH MINERALS TO PREPARE ORGANIC–INORGANIC HYBRID LIPONANOCAPSULE

Mineralization found in nacre and bone is highly controlled within closed compartments, such as vesicles and insoluble extracellular organic matrices under mild conditions, resulting in the formation of hierarchical architectures that provide multifunctional properties [35–37]. Inspired by such a system, there have been numerous studies on mineralization using a liposomal template to give rise to organic-inorganic hybrid nanocapsules. Here, we focused on calcium phosphate (CaP) as a mineral, which is the main constituent of hard tissues in vertebrates, such as bones and teeth, and is the most abundant inorganic material in living organisms. In terms of materials design, the pH-dependent dissolution of CaP is advantageous to render pH-responsivity to carriers for drug or gene delivery [38]. CaP formation over the liposomal surface has often been conducted by adding both calcium and phosphate ions to the outer water phase and subsequently controlling reaction conditions such as pH and temperature [39]. In our approach, we utilized liponanocapsules with various polymeric layers as templates for mineralization [40]. Figure 56.5 summarizes the strategy for preparation of hybrid organic–inorganic liponanocapsules. In order to conduct a spatial control of CaP formation, calcium ions and phosphate ions were compartmentalized into the outer phase and the inner cavity of the capsule, respectively. This can allow for phosphate ions and calcium ions to mutually diffuse across the capsule wall (counterdiffusion-driven mineralization). The release of phosphate ions from a bare liposome was so fast that CaP formation could not be observed on the surface. Therefore, it is required to conduct the slow and mutual diffusion for the formation of hybrid nanocapsules; that is, the control of the ion diffusion with the polysaccharide layer of the capsule wall is a key to tune mineralization.

In addition, it is expected that ions captured by ionic moieties of the polymeric layer could facilitate the precipitation of CaP on the surface. There have been numerous studies on the template effect of organic or polymeric compounds on CaP growth from aqueous media. In this regard, sophisticated approaches based on bioinspired and biomimetic mineralization have been employed to control crystal properties and determine the site for CaP formation [41–46]. We focused on polyelectrolytes containing functional groups such as phosphate and carboxyl, which are implicated in CaP

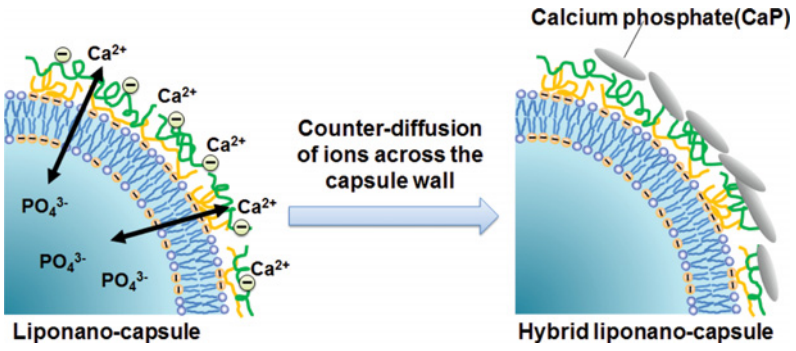

FIGURE 56.5 Schematic illustration of preparation of hybrid organic–inorganic liponanocapsules via counterdiffusion of ions across the capsule wall.

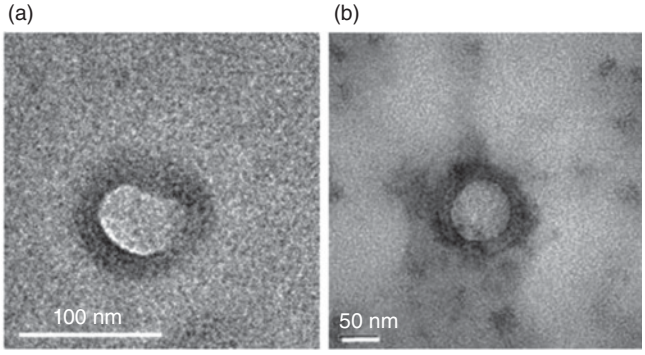

FIGURE 56.6 TEM images of hybrid nanocapsules after deposition of CaP over a liposome (a) and DNA-coated liponano-capsule (b). Reaction was carried out at 37°C for 1 h using $Ca(NO_3)_2$ and $(NH_4)HPO_4$ as ion species.

crystallization. Carboxyl groups of collagen are supposed to be responsible for nucleation of hydroxyapatite (HAp) on collagen from a simulated body fluid (SBF). Phosphate groups, which are displayed on bare liposomes and DNA-coated nanocapsules, are expected to function as a site for CaP nucleation. TEM observations showed that CaP was precipitated selectively over both surfaces as a result of the mutual diffusion of calcium ions and phosphate ions and the high affinity of the phosphate moiety for calcium ions (Fig. 56.6). The thickness of the CaP layer changed with the reaction time. From the results of electron diffraction and infrared analysis, CaP precipitated over the DNA-coated nanocapsules showed high crystallinity compared with bare liposomes. These suggest that the high affinity for calcium ions and the locus suitable to promote CaP nucleation and crystallization in addition to the control of the release of ions are needed to create the hybrid nanocapsule. Finally, it is also noted that the combination of mineralization with liponanocapsules could provide multifunctional hybrid nanocapsules with bioinertness, biocompatibility, and resorbability derived from biominerals.

56.7 CONCLUSIONS

We have described a facile and useful approach for design and synthesis of bioderived nanocapsules, liponanocapsules, based on the concept of layer-by-layer assembly of polyelectrolytes over a liposomal template. This approach allowed for diverse selections of the polymer ranging from synthetic polymers to bioderived polymers such as polypeptides, polysaccharides, and DNA. The resultant liponanocapsules exhibited excellent properties, including mechanical robustness, controlled release of substances, and enhanced cell membrane permeability. Furthermore, the liponanocapsules were assembled into a freestanding membrane by linking with the outermost DNA layer as a dry ligand. Such a hierarchical structure is advantageous in use as a bioscaffold for gene transfection, cell culture, and tissue regeneration because various substances, including drugs and growth factors, can be encapsulated and their release is also controllable. Finally, we presented a novel strategy in creating hybrid nanocapsule via mineralization of calcium phosphate over the surface of liponanocapsules.

The liponanocapsule is a designable material and will open a promising opportunity for potential applications in a variety of fields, especially cosmetics and pharmaceutics.

PHYSICAL PHENOMENA OF MAGNETIC SUSPENSIONS FOR APPLICATION TO BIOENGINEERING

Akira Satoh

Faculty of Systems Science and Technology, Akita Prefectural University, Honjo City, Akita Prefecture, Japan

57.1 INTRODUCTION

A representative application of magnetic suspensions to the bioengineering field is a magnetic drug delivery system (magnetically targeted drug) employing a gradient magnetic field [1–3]. As schematically shown in Fig. 57.1, the concept of the magnetic delivery system is that composite particles composed of thermo-sensitive polymeric material loading (anticancer) drugs and magnetic materials (particles) are administered to a targeted region such as a tumor or cancer cells intensively and effectively by means of a gradient applied magnetic field. There are two main approaches to synthesize magnetic composite particles for transporting anticancer drugs in a magnetically targeted drug delivery system. The first approach for synthesizing these functional composite particles is to use a particle with a magnetic core or a composite magnetic core that is coated with polymeric materials that function to adsorb and load (store) the drugs [4–13]. The second approach is to coat the surface of a non-magnetic core particle with small magnetic particles in addition to the polymeric materials that adsorb and load drugs [14–17]. On the application of a nonuniform magnetic field, both types of composite particle will experience a body force acting in the direction of the field gradient, so that it is possible to use this effect to administer drug agents to a specific site (tumor or cancer cells) in the human body intensively and effectively by means of an appropriate arrangement of magnets [18–21].

Surface modification technology plays an important role in successful synthesis of composite particles for magnetic drug delivery. Moreover, according to the synthesis method, diffusion and sedimentation phenomena in the gravity field may have a significant effect on the final quality of these functional particles. In particular, the sedimentation behavior of the magnetic composite particles has a significant relationship with the drug concentration on the surface properties of biological membranes [22]. Furthermore, it is necessary to develop the technology for controlling self-assembled layers, aggregation structures, and orientational features of magnetic particles on a material surface after sedimentation, by means of an applied magnetic field. From the above consideration, it is clear that, in developing functional composite particles for the magnetic drug delivery system, physical phenomena such as aggregation phenomena, orientional distribution, and phase change of magnetic particles on a material surface have a significant relationship with the synthesis procedure.

From this background, in the present chapter we address suspensions of magnetic spherical and axisymmetric particles in order to focus on the following two physical phenomena for discussion; we consider (1) the dependence of the magnetic particle behavior on a material surface on various factors such as the magnetic field and the magnetic particle–particle interaction strength [23–26] and (2) sedimentation characteristics of magnetic particles in the gravity field and also the integrated structures on a material surface after sedimentation, which are dependent on various factors such as the magnetic field strength [27].

Monte Carlo, molecular dynamics, and Brownian dynamics methods [28–31] are powerful simulation techniques for the detailed microscopic analysis of the above-mentioned physical phenomena. In the present chapter, we treat

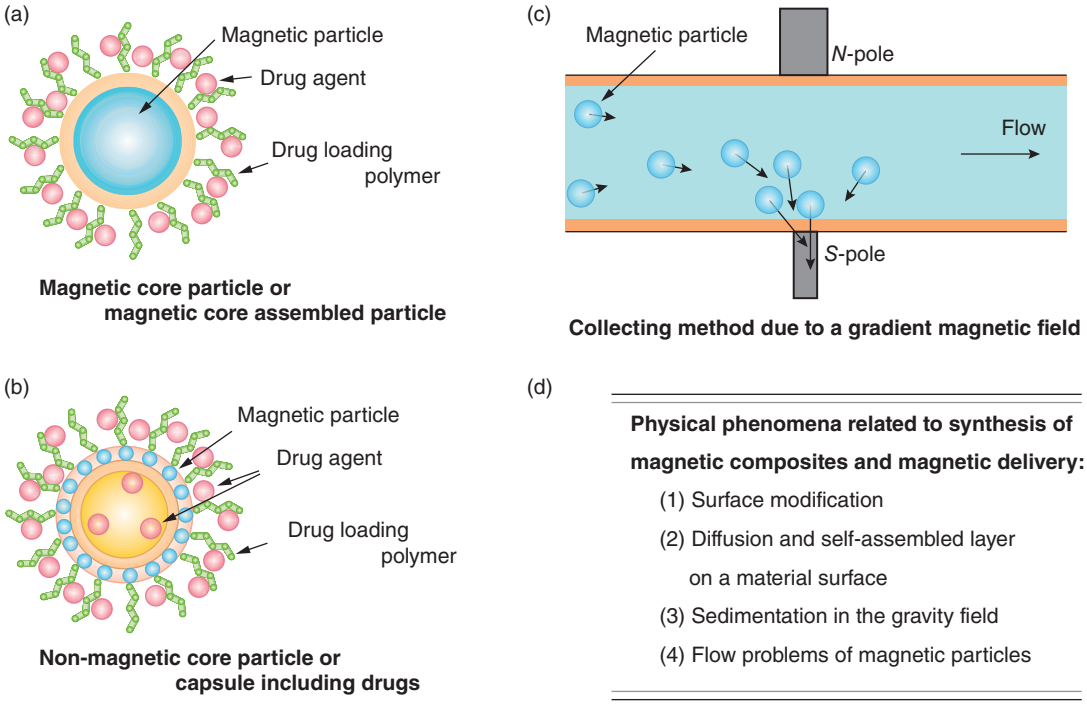

FIGURE 57.1 Concept of a magnetic drug delivery system and related physical phenomena: (a) magnetic core particle coated with drug loading polymers; (b) nonmagnetic core particle or capsule including drugs coated with drug-loading polymers; (c) collecting method due to a magnetic body force acting on magnetic particles; (d) physical phenomena related to the synthesis of magnetic composites and a magnetic delivery.

suspensions composed of magnetic particles for which Monte Carlo and Brownian dynamics are significantly useful simulation techniques. Hence, in the following text we first outline these simulation methods and then discuss the above-mentioned physical phenomena. Finally, we expect that the present discussion on the application examples of molecular simulations to the physical phenomena of interest yields a significant guide for the microscopic analysis of the physical problems that will be encountered in generating new magnetic composite particles for the loading of drugs in a magnetic delivery system.

57.2 SIMULATION METHODS FOR COLLOIDAL SUSPENSIONS

57.2.1 Monte Carlo Method

The Monte Carlo method generates a series of microscopic states conforming to a certain stochastic law, irrespective of the equations of motion of particles (or molecules), and this method is suitable mainly for phenomena in thermodynamic equilibrium [28–30]. In the following text, we explain the important concepts of the Monte Carlo method.

We consider how microscopic states are stochastically derived. We here treat a system composed of N interacting spherical particles with temperature T and volume V of the system; these quantities are values given and are assumed to be constant. If the position vector of an arbitrary particle i ($i = 1,2,\ldots,N$) is denoted by $\boldsymbol{r}_i$, the total interaction energy U of the system can be expressed as a function of the particle positions, that is, can be expressed as $U = U(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)$. For the present system specified by given values of N, T and V, the appearance of a microscopic state that particle i ($i = 1,2,\ldots,N$) exits within the small range of $\boldsymbol{r}_i \sim(\boldsymbol{r}_i + \Delta\boldsymbol{r}_i)$ is governed by the probability density function $\rho(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)$, and this may be expressed from statistical mechanics as

$$\rho(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N) = \frac{\exp\{-U(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)/kT\}}{\int_V \cdots \int_V \exp\{-U(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)/kT\} d\boldsymbol{r}_1 d\boldsymbol{r}_2 \cdots d\boldsymbol{r}_N} \tag{57.1}$$

If a series of microscopic states are generated with an occurrence according to this probability, a simulation may have a physical meaning. However, this approach is impracticable, since there is considerable difficulty in the analytic evaluation of the definite integral of the denominator in

Eq. (57.1). It is the Metropolis method [32] that is able to overcome this difficulty for Monte Carlo simulations.

In the Metropolis method, the transition probability from microscopic states i to j, p_{ij}, is expressed as

$$p_{ij} = \begin{cases} 1 & (\text{for } \rho_j/\rho_i \geq 1) \\ \dfrac{\rho_j}{\rho_i} & (\text{for } \rho_j/\rho_i < 1) \end{cases} \tag{57.2}$$

in which ρ_i and ρ_j are the probability density functions for microscopic states i and j appearing, respectively. The ratio of ρ_j/ρ_i is obtained from Eq. (57.1) as

$$\begin{aligned} \frac{\rho_j}{\rho_i} &= \exp\left[-\frac{1}{kT}(U_j - U_i)\right] \\ &= \exp\left[-\frac{1}{kT}\left\{U(\boldsymbol{r}^j_1, \boldsymbol{r}^j_2, \ldots, \boldsymbol{r}^j_N) - U(\boldsymbol{r}^i_1, \boldsymbol{r}^i_2, \ldots, \boldsymbol{r}^i_N)\right\}\right] \end{aligned} \tag{57.3}$$

In the above equations, U_i and U_j are the interaction energies of microscopic states i and j, respectively, and the superscripts attached to the position vectors denote the same meaning in regard to the microscopic states. Equation (57.2) implies that, in the transition from microscopic state i to j, the new microscopic state j is adopted if the system energy decreases, and if the system energy increases, it is adopted with the probability ρ_j/ρ_i (<1). It is clearly seen from Eq. (57.3) for ρ_j/ρ_i that the denominator in Eq. (57.1) is not required in Eq. (57.3) since ρ_j is divided by ρ_i and the term is canceled through this operation. This is the main reason of great success of the Metropolis method for Monte Carlo simulations. That a new microscopic state is adopted with the probability ρ_j/ρ_i even in the case of the increase in the interaction energy, verifies the accomplishment of the minimum free-energy condition for the system. In other words, the adoption of microscopic states yielding an increase in the system energy corresponds to an increase in the entropy.

The above discussion is directly applicable to a system composed of nonspherical particles. The situation of nonspherical particles in thermodynamic equilibrium is specified by the particle position of the mass center, $\boldsymbol{r}_i$ ($i = 1,2,\ldots,N$), and the unit vector $\boldsymbol{e}_i$ ($i = 1,2,\ldots,N$) denoting the particle direction. The transition probability from microscopic state i to j, p_{ij}, can be written in similar form to Eq. (57.2), and the expression for ρ_j/ρ_i becomes

$$\begin{aligned} \frac{\rho_j}{\rho_i} &= \exp\left[-\frac{1}{kT}(U_j - U_i)\right] \\ &= \exp\left[-\frac{1}{kT}\left\{U_j\left(\boldsymbol{r}^j_1, \boldsymbol{r}^j_2, \ldots, \boldsymbol{r}^j_N, \boldsymbol{e}^j_1, \boldsymbol{e}^j_2, \ldots, \boldsymbol{e}^j_N\right)\right.\right. \\ &\quad \left.\left. - U_i\left(\boldsymbol{r}^i_1, \boldsymbol{r}^i_2, \ldots, \boldsymbol{r}^i_N, \boldsymbol{e}^i_1, \boldsymbol{e}^i_2, \ldots, \boldsymbol{e}^i_N\right)\right\}\right] \end{aligned} \tag{57.4}$$

For a strongly interacting particle system, the addition of a cluster-moving algorithm may be necessary for correctly simulating a magnetic spherical particle suspension [30]. This is because the usual Metropolis MC algorithm [32] does not take into account the cooperative behavior between the groups of particles that form clusters. In the case of a conventional MC algorithm, should a number of clusters be formed, they will remain scattered because there is no facility for them to join with each other. The cluster-moving MC algorithm regards such scattered clusters as temporary unitary particles, and moves the clusters according to a transition probability similar to the conventional Metropolis method, so that an additional mechanism for particle aggregation can be achieved.

57.2.2 Brownian Dynamics Method for Axisymmetric Particles

When we treat a colloidal dispersion or a polymeric solution, the Stokesian dynamics [33, 34] and Brownian dynamics methods [28] are usually employed as a microscopic or mesoscopic analysis tool. Since the translational and rotation motion has to be simulated simultaneously in the case of nonspherical particles, the simulation is much more complex than for a spherical particle system. We here summarize the theory of the Brownian dynamics method for an axisymmetric particle system [31], which is more useful for the numerous simulations based on realistic materials.

Dispersed particles or polymers are modeled as idealized spherical or dumbbell particles [35], and the motion of these particles will be pursued by the equation of motion. In a particle suspension, the base liquid is usually assumed to be a continuum medium, and its effect is included in the equations of motion of the particles or the polymers only as friction terms [28]. If particle size approximates to or is smaller than micrometer order, the inertia terms may be considered as negligible. In the present section, we treat this type of small particle and neglect the inertia terms.

We consider the translational and rotational Brownian motion of rodlike particles in a simple shear flow field $\boldsymbol{U}$ with angular velocity vector $\boldsymbol{\Omega}$ and rate-of-strain tensor $\boldsymbol{E}$, as shown in Fig. 57.2. The theory shown below is applicable to a dilute dispersion where the multi-body hydrodynamic interactions among particles are negligible, but it may also be relevant as a first approximation in the case of a nondilute suspension.

For an axisymmetric particle, the translational motion can be decomposed into the motion in the long-axis direction and the motion in a direction normal to the particle axis. Similarly, the rotational motion can be decomposed into the rotation about the particle axis and the rotation about a line normal to the particle axis through the center of mass.

An arbitrary vector is decomposed into the two vectors parallel and normal to the particle axis, and these vectors are

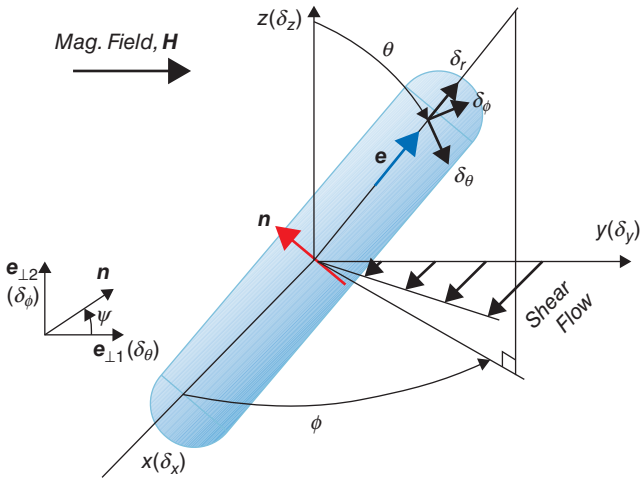

FIGURE 57.2 Magnetic spherocylinder particle in a simple shear flow under the circumstance of an applied magnetic field.

denoted by subscripts || and⊥, respectively. The equation of translational motion, providing the particle position $\boldsymbol{r}(t)$, is then expressed as [30]:

$$\boldsymbol{r}_{||}(t+\Delta t) = \boldsymbol{r}_{||}(t) + \boldsymbol{U}_{||}\Delta t + \frac{1}{kT} D^T_{||} \boldsymbol{F}^P_{||}(t)\Delta t + \Delta r^B_{||}\boldsymbol{e}(t) \tag{57.5}$$

$$\boldsymbol{r}_{\perp}(t+\Delta t) = \boldsymbol{r}_{\perp}(t) + \boldsymbol{U}_{\perp}\Delta t + \frac{1}{kT} D^T_{\perp} \boldsymbol{F}^P_{\perp}(t)\Delta t + \Delta r^B_{\perp 1}\boldsymbol{e}_{\perp 1}(t) + \Delta r^B_{\perp 2}\boldsymbol{e}_{\perp 2}(t) \tag{57.6}$$

in which k is Boltzmann's constant, T is the system temperature, $\boldsymbol{F}^p_{||}$ and $\boldsymbol{F}^p_{\perp}$ are the forces acting on the particle of interest, $\boldsymbol{e}(t)$ is the unit vector denoting the particle direction, the vectors $\boldsymbol{e}_{\perp 1}$ and $\boldsymbol{e}_{\perp 2}$ are the unit vectors normal to each other in the plane normal to the particle axis, and $D^T_{||}$ and $D^T_{\perp}$ are the translational diffusion coefficients [30,36,37]. The quantities $\Delta r^B_{||}$, $\Delta r^B_{\perp 1}$, and $\Delta r^B_{\perp 2}$ are the random displacements inducing the translational Brownian motion and have the following stochastic characteristics:

$$\left\langle \Delta r^B_{||} \right\rangle = \left\langle \Delta r^B_{\perp 1} \right\rangle = \left\langle \Delta r^B_{\perp 2} \right\rangle = 0,$$
$$\left\langle \left(\Delta r^B_{||}\right)^2 \right\rangle = 2D^T_{||}\Delta t,\ \left\langle \left(\Delta r^B_{\perp 1}\right)^2 \right\rangle = \left\langle \left(\Delta r^B_{\perp 2}\right)^2 \right\rangle = 2D^T_{\perp}\Delta t \tag{57.7}$$

For the case of a particle with a magnetic moment normal to the particle axis such as the rodlike hematite particle, it is required to specify the spin Brownian motion about the particle axis in addition to the ordinary rotational motion about a line normal to the particle axis [38]. The equation for the particle direction $\boldsymbol{e}(t)$ and the magnetic moment direction $\boldsymbol{n}(t)$ are expressed as

$$\boldsymbol{e}(t+\Delta t) = \boldsymbol{e}(t) + \boldsymbol{\Omega}_{\perp}\times\boldsymbol{e}\Delta t + \frac{1}{kT} D^R_{\perp}\boldsymbol{T}^P_{\perp}(t)\times\boldsymbol{e}\Delta t - \frac{Y^H}{Y^C}\left((\boldsymbol{\varepsilon}\cdot\boldsymbol{ee}):\boldsymbol{E}\right)\times\boldsymbol{e}\Delta t + \Delta\phi^B_{\perp 1}\boldsymbol{e}_{\perp 1} + \Delta\phi^B_{\perp 2}\boldsymbol{e}_{\perp 2} \tag{57.8}$$

$$\boldsymbol{n}(t+\Delta t) = \boldsymbol{n}(t) + \boldsymbol{\Omega}_{||}\times\boldsymbol{n}\Delta t + \frac{1}{kT} D^R_{||}\boldsymbol{T}^P_{||}(t)\times\boldsymbol{n}\Delta t + \Delta\phi^B_{||}\boldsymbol{e}\times\boldsymbol{n} \tag{57.9}$$

in which Y^C and Y^H are the resistance functions [36], and $\boldsymbol{\varepsilon}$ is the third-rank tensor, called *Eddington's epsilon*, and $D^R_{||}$ and $D^R_{\perp}$ are the rotational diffusion coefficients. Also, $\boldsymbol{T}^P$ is the torque acting on the particle of interest and is evaluated from summation of the torques due to, for example, magnetic and steric repulsive forces.

The quantities $\Delta\phi^B_{||}$, $\Delta\phi^B_{\perp 1}$, and $\Delta\phi^B_{\perp 2}$ are the random displacements inducing the rotational Brownian motion and have the following stochastic characteristics:

$$\left\langle \Delta\phi^B_{||} \right\rangle = \left\langle \Delta\phi^B_{\perp 1} \right\rangle = \left\langle \Delta\phi^B_{\perp 2} \right\rangle = 0,\ \left\langle \left(\Delta\phi^B_{||}\right)^2 \right\rangle = 2D^R_{||}\Delta t,$$
$$\left\langle \left(\Delta\phi^B_{\perp 1}\right)^2 \right\rangle = \left\langle \left(\Delta\phi^B_{\perp 2}\right)^2 \right\rangle = 2D^R_{\perp}\Delta t \tag{57.10}$$

The quantities in the parallel and the normal directions to the particle axis are expressed using the unit vector $\boldsymbol{e}$, denoting the particle axis direction, as

$$\left.\begin{aligned} &\boldsymbol{F}^{||} = (\boldsymbol{F}\cdot\boldsymbol{e})\,\boldsymbol{e}, \quad \boldsymbol{F}^{\perp} = \boldsymbol{F} - \boldsymbol{F}^{||}, \quad \boldsymbol{T}^{||} = (\boldsymbol{T}\cdot\boldsymbol{e})\,\boldsymbol{e}, \\ &\boldsymbol{T}^{\perp} = \boldsymbol{T} - \boldsymbol{T}^{||}, \quad \boldsymbol{\Omega}^{||} = (\boldsymbol{\Omega}\cdot\boldsymbol{e})\,\boldsymbol{e} \quad \boldsymbol{\Omega}^{\perp} = \boldsymbol{\Omega} - \boldsymbol{\Omega}^{||} \end{aligned}\right\} \tag{57.11}$$

57.3 SURFACE MODIFICATION

57.3.1 Magnetic Spherical Particle System

57.3.1.1 Introductory Remarks. If ferromagnetic nanoparticles are dispersed on a nonmagnetic substrate, these nanostructured films acquire very attractive magnetic properties. One simple method for preparing self-organized monolayers of particles is to dry a colloidal dispersion. When a droplet of the dispersion is deposited on a substrate, reduction in size of the droplet due to evaporation of the solvent produces ordered microstructures of monolayers through the phenomenon of self-organization.

Molecular simulation is a powerful method for investigating in detail the influence of the governing parameters such as the areal density of particles and the external magnetic

field strength. Various two-dimensional (2D) and quasi-two-dimensional (Q2D) simulations have been conducted on a monolayer composed of ferromagnetic spherical particles [39]. If the magnetic field is applied in the direction normal to the plane of a Q2D monolayer, it can be expected that the formation of chainlike structures will be prevented by a repulsive magnetic interaction between particles [40]. This fact suggests that properties of the monolayer can be changed significantly by adjusting the direction and/or the strength of an applied magnetic field. Hence, investigation of the influence of both the magnetic field strength and the areal density on the microstructures is quite important for developing new nanogranular magnetic thin films.

In this section, therefore, we consider a Q2D system of a monolayer composed of ferromagnetic particles under an external magnetic field applied in the direction normal to the monolayer plane. Monte Carlo simulations were carried out in order to clarify the influence of the magnetic field strength and the areal density on the microstructures in the state of thermodynamic equilibrium [23].

57.3.1.2 Particle Model and Quasi-Two-Dimensional Monte Carlo Simulation. We consider a Q2D system composed of N monodispersed spherical particles that have a magnetic dipole at their center. This system is assumed to be in thermodynamic equilibrium with system temperature T. The particle is modeled as a sphere with a magnetic moment $\boldsymbol{m}_i$ at the particle center, of diameter d and coated with a uniform steric surfactant layer of thickness δ. Employing the notation r_{ij} for the separation between particles i and j, $\boldsymbol{n}_i$ ($=\boldsymbol{m}_i/m$) for the magnetic moment direction of particle i and $\boldsymbol{H}$ ($=H\boldsymbol{h}$, $H = |\boldsymbol{H}|$) for the applied magnetic field, the magnetic particle-field interaction energy $u_i^{(H)}$ and the magnetic particle-particle interaction energy $u_{ij}^{(m)}$ are expressed as [23]

$$u_i^{(H)} = -kT\xi \boldsymbol{n}_i \cdot \boldsymbol{h},$$
$$u_{ij}^{(m)} = kT\lambda \frac{d^3}{r_{ij}^3}(\boldsymbol{n}_i \cdot \boldsymbol{n}_j - 3(\boldsymbol{n}_i \cdot \boldsymbol{t}_{ij})(\boldsymbol{n}_j \cdot \boldsymbol{t}_{ij})) \quad (57.12)$$

in which ξ and λ are the dimensionless parameters, representing the strength of particle–field and particle–particle interactions, respectively, relative to the thermal energy. These parameters are written as

$$\xi = \mu_0 mH/kT, \quad \lambda = \mu_0 m^2/4\pi d^3 kT \quad (57.13)$$

in which k is Boltzmann's constant, μ_0 is permeability of free space, and $\boldsymbol{t}_{ij}$ is the unit vector denoting the direction of the relative position of particle i to j, given by $\boldsymbol{t}_{ij} = \boldsymbol{r}_{ij}/r_{ij}$ ($r_{ij} = |\boldsymbol{r}_{ij}|$).

If the steric layers of the two particles of interest overlap, a repulsive interaction arises between the two particles. This repulsive interaction $u_{ij}^{(V)}$ is expressed as [23]

$$u_{ij}^{(V)} = kT\lambda_V \left\{ 2 - \frac{2r_{ij}/d}{2\delta/d} \ln\left(\frac{d+2\delta}{r_{ij}}\right) - \frac{r_{ij}/d - 1}{\delta/d} \right\} \quad (57.14)$$

in which λ_V is the dimensionless parameter representing the strength of the repulsive interaction due to the particle overlap relative to thermal energy.

The particles can move only within the xy plane, but their magnetic moment can incline in any direction in 3D space. A uniform external magnetic field $\boldsymbol{H}$ is applied in the direction normal to the material surface (or in the z direction). The results shown below were obtained for $\lambda = 8$ and $\lambda_V = 150$ for comparison with the previous results.

57.3.1.3 Results and Discussion. Figure 57.3 shows the influence of the magnetic field strength on the microstructure of the monolayer for the case of the areal density of particles, $\phi_a = 0.3$. A numerous number of chainlike structures are formed in the absence of the magnetic field (not shown as a figure), and these chain-like structures still remain even in the case of the relatively weak magnetic field $\xi = 10$, shown in Fig. 57.3a. This is because the magnetic particle–particle interaction is more dominant than the effect of the magnetic field, so that the magnetic moments can remain inclining in directions in the xy plane. As the influence of the magnetic field increases further to $\xi = 20$ and 30, the chainlike microstructures gradually disappear (Fig. 57.3b) and random liquidlike structures appear (Fig. 57.3c).

Figure 57.4 shows the dependence of the orientational distribution function Ψ on the magnetic field strength in order to investigate quantitatively the influence of the magnetic field strength on the orientation of the magnetic moment. The abscissa of the figure indicates the polar angle θ from the field direction. In the case of $\xi = 10$, the orientational distribution has a wide and relatively flat profile with a peak at $\theta \simeq 73°$. As the magnetic field is increased to $\xi = 20$, a broad peak profile appears in the magnetic field direction ($\theta = 0°$) and the peak becomes higher. This implies that, although the magnetic moment still has a weak tendency to incline in the magnetic field direction, it can incline in neighboring directions relatively freely. For the case of $\xi = 30$, the orientation of the magnetic moments is strongly restricted toward the field direction, so that the peak of the profile becomes much higher.

Figure 57.5 shows the dependence of the radial distribution function on the magnetic field strength where r in the figure is the particle–particle distance. For the cases of $\xi = 0$ and 10 (Fig. 57.5a,b), sharp peaks appear at $r/(d+2\delta) \simeq 1.0$, 2.0, and so on, which implies that chain-like clusters are significantly formed. As the magnetic field is increased to $\xi = 20$

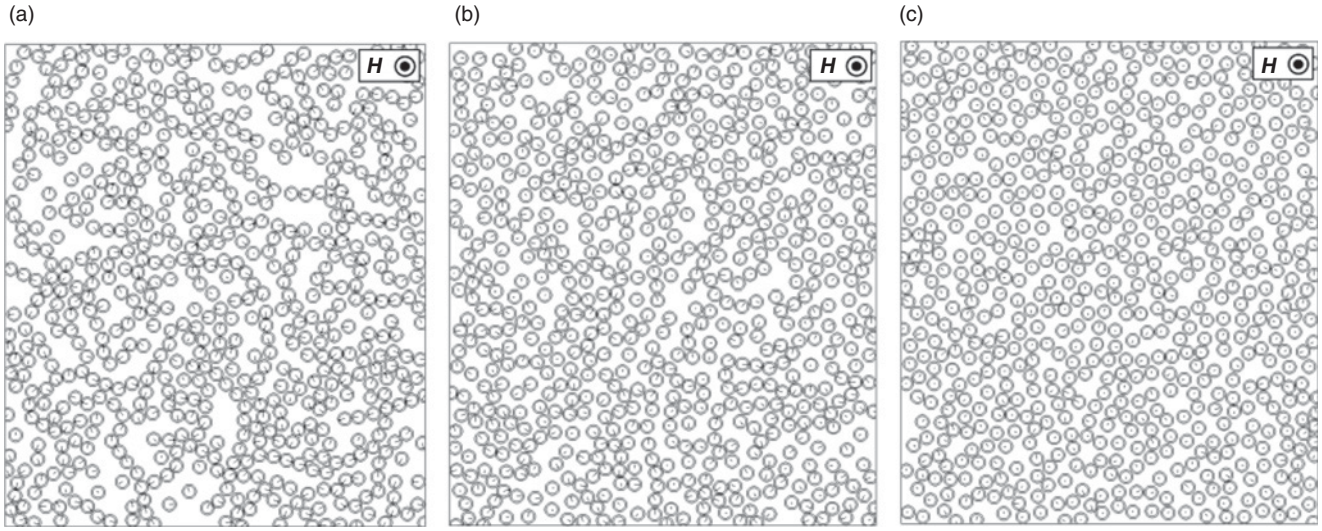

FIGURE 57.3 Influence of the magnetic field strength on microstructures for $\phi_a = 0.3$: (a) $\xi = 10$; (b) $\xi = 20$; (c) $\xi = 30$.

(Fig. 57.5c), the second peak becomes much lower and therefore this implies that chainlike clusters become much shorter. For the case of a further stronger magnetic field, $\xi = 30$ (Fig. 57.5d), the magnetic repulsive interaction due to the dipole–dipole interaction between particles is much more dominant, and the chainlike formation is no longer found. This leads to liquidlike characteristics in the radial distribution function.

57.3.2 Rodlike Particle System

57.3.2.1 Introductory Remarks. New functional materials may be developed by artificially controlling the particle microstructure in order to give rise to desired functional properties. If magnetic rodlike particles are sedimented in the gravitational field, the particle orientational distribution may be controlled by an applied magnetic field, and on the evaporation of the base liquid we may obtain a surface modified material, frequently via a process of self-organization.

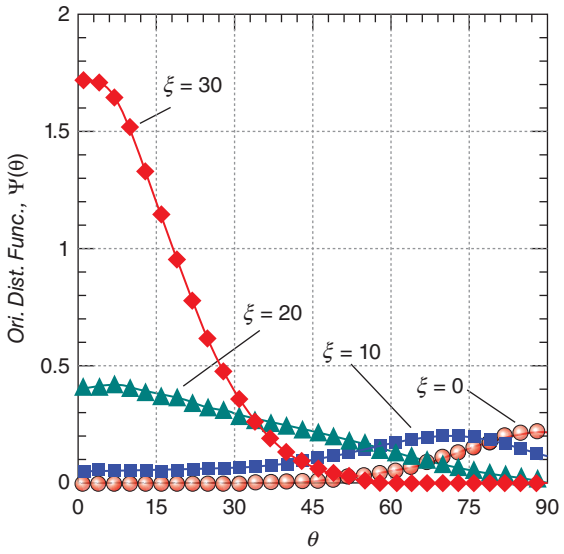

FIGURE 57.4 Dependence of the orientational distribution function on the magnetic field strength ξ.

Ferromagnetic rodlike particles are ordinarily magnetized in the major-axis direction and the different types of magnetic rodlike particles are also an attractive subject from an application perspective. A suspension composed of hematite particles with a magnetic moment normal to the particle axis has already been synthesized [41, 42]. Several theoretical work relating to this type of suspension show that under a simple shear flow a rodlike particle can rotate freely to a certain degree but with the magnetic moment remaining inclined toward the magnetic field direction [43, 44]. This behavior is completely different from that of a suspension composed of rodlike particles magnetized in the direction of the particle axis. In addition to the magnetorheological perspective, these suspensions are an attractive research subject from the viewpoint of developing the techniques for controlling the orientational features of magnetic rodlike particles.

In this present section, we discuss the dependence of the aggregate structures and the orientational distribution on various factors such as the magnetic particle–particle and particle–field interactions. The results shown below were obtained by means of the cluster-moving Monte Carlo method explained in Section 57.2.1, for a two-dimensional system [24].

57.3.2.2 Particle Model and Simulation Method. Experimental observation shows that rodlike hematite particles have the shape of a spheroid [41, 42]. However, it is quite difficult to assess whether the spheroidal particles overlap during a simulation procedure; therefore, we use the simpler approach

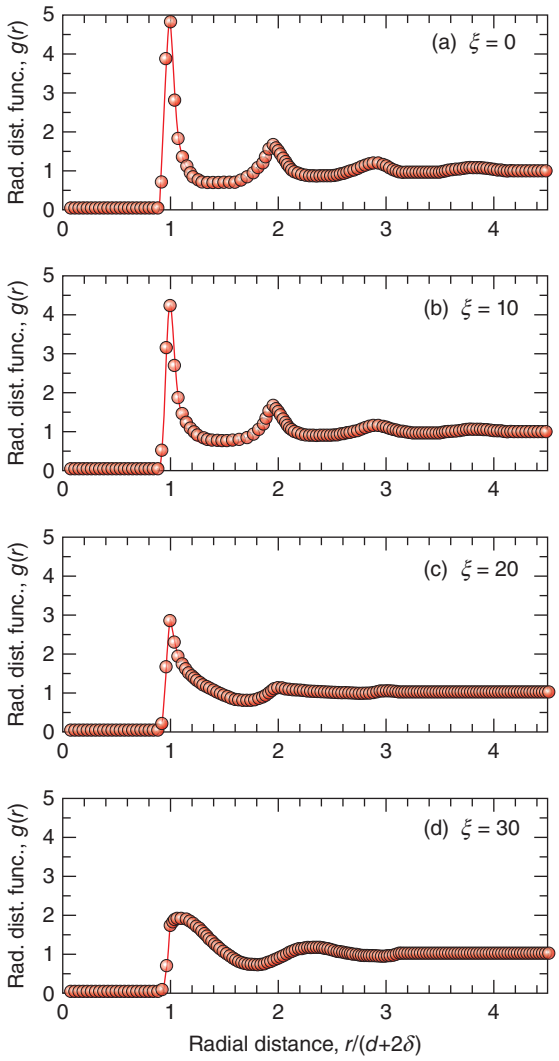

FIGURE 57.5 Influence of the magnetic field strength on the radial distribution function for $\phi_a = 0.3$: (a) $\xi = 0$; (b) $\xi = 10$; (c) $\xi = 20$; (d) $\xi = 30$.

of a linear sphere-connected model. In this particle model, a rodlike particle is modeled by a number of linearly connected spheres. The length of the rod-like particle is expressed by the number N_P of constituent particles and is covered by a surfactant layer (steric layer) with constant thickness δ. Hence, the present phenomenon is characterized by the particle length N_p, the areal fraction ϕ_a, and the three nondimensional parameters ξ, λ, and λ_V, shown in Eq. (57.13), where ξ, λ, and λ_V imply the strength of the magnetic particle-field, the particle–particle interactions, and the streic interaction relative to the thermal energy, respectively.

57.3.2.3 Results and Discussion. Figure 57.6 shows snapshots for the particle length $N_P = 3$ and the areal fraction $\phi_a = 0.2$. For the case of $\lambda = 5$ (Fig. 57.6a), there are numerous short clusters composed of two or three particles that are observed to move independently. This is because the magnetic interaction between particles is not sufficiently strong to allow the formation of longer clusters. On the other hand, for the case of $\lambda = 10$ (Fig. 57.6b), numerous long raftlike clusters are observed to be formed. In this case, the magnetic interaction between particles is sufficiently strong to promote the short clusters to aggregate to form longer raftlike clusters that are generally observed to have a relatively nonlinear form.

Figure 57.7 shows snapshots for a strong magnetic field for the case such as $\xi = 20$. The magnetic field is applied in the upward direction of the paper. For the case of $\lambda = 5$ (Fig. 57.7a), the magnetic particle–particle interaction is relatively weak so that significantly long clusters are not formed over the whole region; nevertheless, relatively long clusters are partially observed. This is because a strong applied magnetic field enhances the alignment of the magnetic moments in the field direction and this alignment induces the cluster formation. For a strong magnetic particle–particle interaction in the case of $\lambda = 10$ (Fig. 57.7b), there is a significant tendency for numerous long raftlike clusters to be formed in the field direction, however, it is not observed that these long raftlike clusters aggregate further to form thicker columnlike clusters. This is in significantly contrast to the behavior observed in a spherical particle system [45] where thick chainlike clusters are formed in the case of a relatively strong magnetic interaction. This is because, in a rodlike particle system, sufficiently strong forces do not act between two raftlike clusters that are in a parallel arrangement.

Figure 57.8 shows the cluster size distribution for $\xi = 20$, $\lambda = 10$, and $\phi_a = 0.2$, and the results were obtained for the three cases of the particle length, $N_p = 3,5,7$. It is seen that for the same conditions the number of longer clusters decreases with increasing particle length, but this tendency is not so significant. The curve of $N_P = 7$ almost coincides with that for $N_P = 5$, and even the curve for $N_P = 3$ does not deviate significantly from the other two curves. These characteristics may be explained as follows. The magnetic interaction strength between the neighboring particles in the same cluster does not change for different particle lengths, but the influence of Brownian displacements appears to be strongly dependent on the particle length. That is, the rotational motion of a longer particle induces a more severe overlap effect between the neighboring particles of the same cluster, which leads to a more stable cluster formation for the cluster composed of shorter particles.

57.3.3 Disklike Particle System

57.3.3.1 Introductory Remarks. A suspension composed of disklike or platelike fine particles shows interesting behavior in regard to the phase transition from a disordered isotropic to a nematic phase [46], magnetic-field-induced

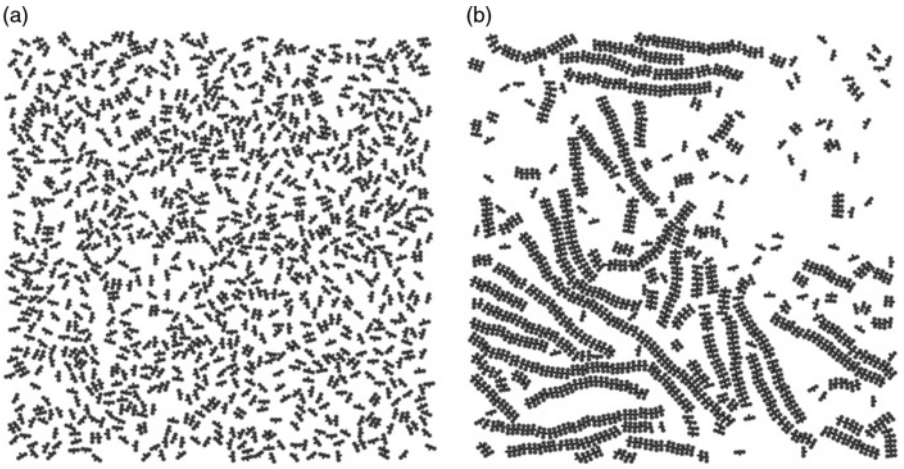

FIGURE 57.6 Influence of the magnetic particle–particle interaction on aggregate structures for $N_P = 3$ and $\phi_a = 0.2$: (a) $\lambda = 5$; (b) $\lambda = 10$.

orientational characteristics [47], and isotropic–nematic interfacial phenomena [48]. Also, the aggregation phenomena of platelike particles have been shown to be controlled by changing the surface roughness of such particles [49, 50]. Moreover, the structure and thermodynamics of nonmagnetic platelike particles has been discussed widely concerning the influence of the particle shape and the polydispersity in size on the internal structures (interparticle pair correlation), the equation of state, the static structure factor, the isothermal compressibility, the orientational order properties, and so on [51]. This type of platelike nanoparticle has been successfully synthesized by the sonochemical method [52, 53]. On the other hand, hematite particles exhibit a characteristic feature in that the particles are magnetized in a direction normal to the particle axis direction.

In this section, we address a dispersion composed of oblate hematite particles magnetized in a direction normal to the particle axis direction, and discuss the dependence of aggregation phenomena on various factors such as the magnetic particle-field and the magnetic particle-particle interactions [26].

57.3.3.2 Particle Model and Simulation Method. We use for the particle model a platelike particle that has the cross-section shape of a spherocylinder and with a magnetic moment oriented normal to the particle axis at the particle center. The disklike particle is composed of a short cylinder with diameter d and thickness b_1, with the cylinder surrounded by a torus with a semicircular cross section; this particle is assumed not to be coated with a surfactant layer. The present phenomenon is characterized by the two nondimensional parameters ξ and λ, expressed in Eq. (57.13). An external magnetic field is assumed to be applied in the direction normal to the material surface.

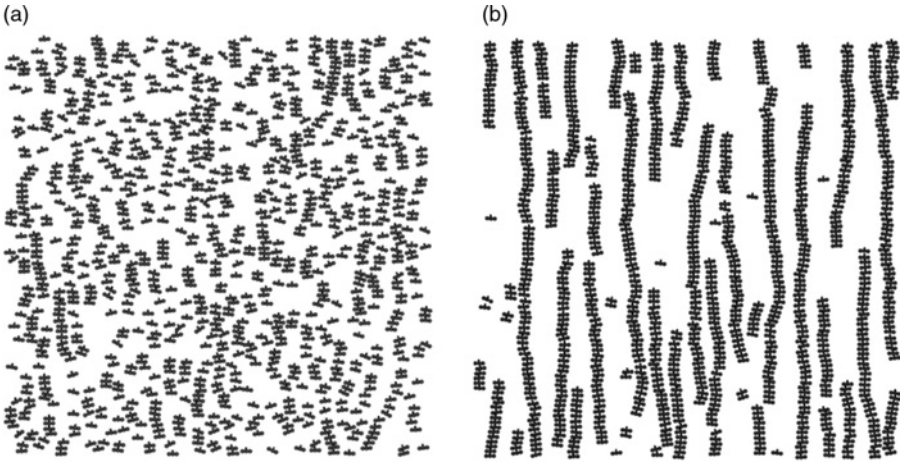

FIGURE 57.7 Influence of the magnetic particle–particle interaction on aggregate structures for $\xi = 20$, $N_P = 3$, and $\phi_a = 0.2$: (a) $\lambda = 5$; (b) $\lambda = 10$.

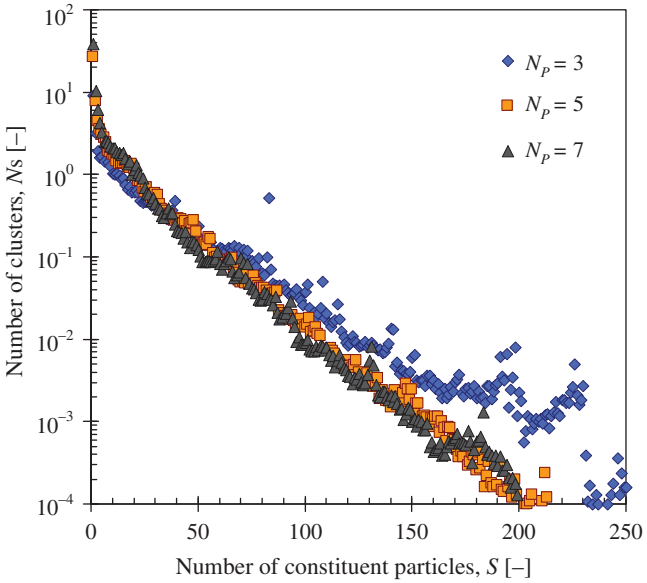

FIGURE 57.8 Cluster size distribution for $\xi = 20$, $\lambda = 10$, and $\phi_a = 0.2$.

We consider a quasi-2D model system for a dispersion composed of platelike particles in thermodynamic equilibrium, and Monte Carlo simulations were carried out in order to investigate the orientational phenomena [26]. A quasi-2D system implies that platelike particles are limited to move in a two-dimensional plane, but are free to incline with an unrestricted orientation.

57.3.3.3 Results and Discussion. Figure 57.9 shows snapshots obtained for the volumetric fraction $\phi_V = 0.56$ and the magnetic interaction between particles, $\lambda = 5$. For the case of $\xi = 5$ (Fig. 57.9a), the particles form long columnlike clusters, although the influence of an external magnetic field is of the same order of that of the magnetic particle–particle interaction with $\xi = 5$ and $\lambda = 5$. This is because the distance between particles becomes shorter as the volumetric fraction increases, as for $\phi_V = 0.56$, so that the translational and rotational movement are restricted. For the strong magnetic field $\xi = 10$ (Fig. 57.9b), it can be seen that only short columnlike clusters are formed and long clusters are not observed in the system. Moreover, the particles are located in an edge-to-edge contact formation that gives rise to brick-wall-like aggregates. In this formation, the particles on the upper and lower sides are separated by approximately $d_1/2$ ($d_1 = d+b_1$) along the direction normal to the particle axis, relative to the particle of interest. For the case of a significantly strong magnetic field, $\xi = 15$ (Fig. 57.9c), columnlike clusters are not observed. In contrast, brick-wall-like aggregates are formed and extended over the whole area of the system. This can be explained as follows. In a strong applied magnetic field, the magnetic moments are restricted to the magnetic field direction, and the repulsive interactions among the magnetic moments become stronger as the magnetic field strength increases. In this situation the particles cannot form columnlike clusters. If the particles form aggregates in the face-to-face formation with their magnetic moment inclining in the magnetic field direction, the repulsive interactions become dominant. Hence the particles are located at the separation distance of approximately $d_1/2$ along the direction normal to the particle axis in order to reduce the repulsive interaction, which yields the brick-wall-like aggregates.

We now discuss the influence of the volumetric fraction on the internal structures under the situation of a significantly strong magnetic field strength $\xi = 15$. For $\phi_V = 0.54$ shown in Fig. 57.10a, the magnetic moment of the particles tends to incline in the magnetic field direction while the particle axes point in various directions within the xy plane; that is, the system shows an isotropic structure. For $\phi_V = 0.55$ shown in Fig. 57.10b, the snapshot exhibits different characteristics compared with that in Fig. 57.10a. Thus, in some areas the particles are located in the edge-to-edge contact formation and also form brick-wall-like aggregates. For $\phi_V = 0.60$ shown in Fig. 57.10c, these brick-wall-like structures are formed over the whole area of the system, and the particles

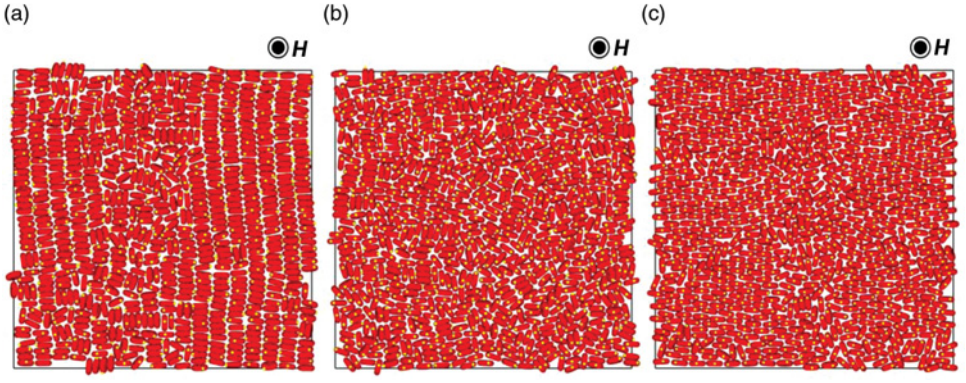

FIGURE 57.9 Aggregate structures of magnetic disklike particles in an applied magnetic field for $\phi_V = 0.56$ and $\lambda = 5$: (a) $\xi = 5$; (b) $\xi = 10$; (c) $\xi = 15$.

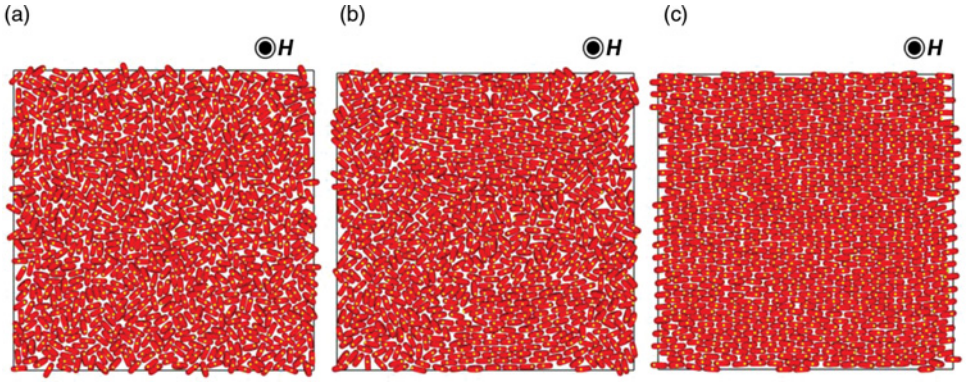

FIGURE 57.10 Aggregate structures of magnetic disklike particles in an applied magnetic field for $\xi = 15$ and $\lambda = 5$: (a) $\phi_V = 0.54$; (b) $\phi_V = 0.55$; (c) $\phi_V = 0.60$.

have a more significant tendency to incline in a single direction than in the case of $\phi_V = 0.55$. This is because the particle–particle distances are smaller and therefore the translational and rotational movements become significantly restricted as the volumetric fraction increases. Thus the particle axes come to exhibit this specific directional characteristic.

In order to discuss the orientational order of particles quantitatively in detail, it is desirable to address the nematic order parameter. The nematic order parameter S is a measure of the orientational correlation between the direction of the particle axis and the nematic director, which, in the present case, is the magnetic field direction (y direction $\boldsymbol{\delta}_y$). The influence of the volumetric fraction on the nematic order parameter is shown in Fig. 57.11 for the case of a strong magnetic field, $\xi = 15$. In the region of small volumetric fractions, the nematic order parameter shows a value of approximately $S \simeq 0.2$ that does not significantly increase with the volumetric fraction. In contrast, the curve shows a significantly steep increase converging to unity during the very small region of volumetric fraction change from $\phi_V = 0.54$ to 0.60.

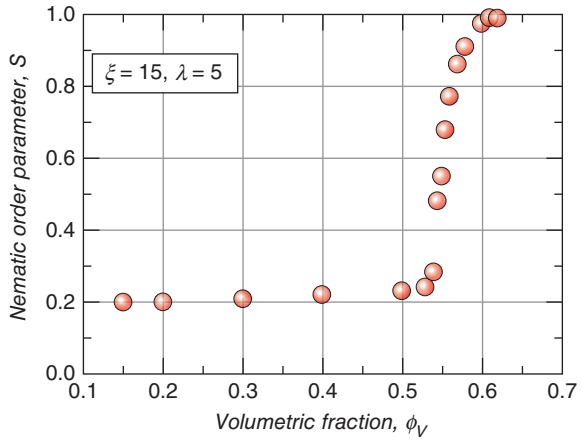

FIGURE 57.11 Nematic order parameter for $\xi = 15$ and $\lambda = 5$.

This indicates that the brick-wall-like structures abruptly appear during a very small change in the volumetric fraction. From these results concerning the behavior of the order parameter, it is suggested that a phase transition occurs between $\phi_V = 0.54$ and 0.60 for the case of $\xi = 15$ and $\lambda = 5$.

57.4 SEDIMENTATION

57.4.1 Introductory Remarks

Ultra-high-density recording materials based on FePt particles have been studied from various perspectives in the context of developing new devices [54–56]. One representative method for preparing self-organized monolayers of particles is to dry a colloidal dispersion on the material surface. As already mentioned in Section 57.3.1.1, in this method a droplet of the dispersion is deposited on a substrate, the solvent is evaporated to reduce the size of the droplet, and thereby ordered microstructures may be obtained. It is clear from this example that it is significantly important to control the sedimentation and the crystallization of the colloidal particles deposited on the surface of the substrate. If the orientational characteristics of the magnetic particles can be controlled by an applied magnetic field after the sedimentation, we may have sufficient possibility for developing an effective surface modification technique. We have therefore investigated the influence of the magnetic field strength and the particle areal density on the microstructure of a quasi-two-dimensional (Q2D) monolayer composed of ferromagnetic particles by means of Monte Carlo simulations [23]. In order to develop a precise technique for generating a uniform monolayer on a substrate surface under the gravitational field, a significant requirement is necessitated to investigate the behavior of fine particles in this situation.

In the present section, we discuss the sedimentation phenomena of a colloidal dispersion composed of ferromagnetic spherical particles in the gravitational field, by means of Brownian dynamics simulations [57].

57.4.2 Particle Model and Simulation Method

As mentioned above, a particle is modeled as a spherical particle with central point dipole and is coated with a uniform surfactant layer (or a steric layer) with thickness δ. The magnetic force between particles i and j, $\boldsymbol{F}_{ij}^{(\mathrm{m})}$, the magnetic torque $\boldsymbol{T}_{ij}^{(\mathrm{m})}$, and the torque $\boldsymbol{T}_i^{(H)}$ acting particle i due to the deviation of the magnetic moment from an applied magnetic field $\boldsymbol{H}$ ($H = |\boldsymbol{H}|$), are straightforwardly obtained from the interaction energies expressed in Eq. (57.12). Moreover, the force due to the overlap of the steric layers $\boldsymbol{F}_{ij}^{(V)}$ is also obtained from Eq. (57.14). In addition, since we consider sedimentation phenomena, it is also necessary to take into account the gravitational force $\boldsymbol{F}_i^{(G)}$. Hence, the net force acting on particle i, $\boldsymbol{F}_i$, and the net torque acting on particle i, $\boldsymbol{T}_i$, are obtained by summation.

The present particle is spherical and geometrically point-symmetric, but requires a degree of freedom for the magnetic moment in addition to the particle position, so that it is necessary to treat both the translational and the rotational motion as in the case of the rod-like particles; that is, during the simulation the particle position $\boldsymbol{r}_i$ and the orientation of the magnetic moment $\boldsymbol{n}_i$ will be treated simultaneously. The equations for simulating the translational and the rotational Brownian motion are straightforwardly derived from Eqs. (57.5) to (57.9) as

$$\boldsymbol{r}_i(t+\Delta t) = \boldsymbol{r}_i(t) + \frac{1}{kT} D^T \boldsymbol{F}_i(t)\Delta t + \Delta r_{||}^B \boldsymbol{n}_i(t) + (\Delta r_{\perp 1}^B \boldsymbol{n}_{\perp 1(i)}(t) + \Delta r_{\perp 2}^B \boldsymbol{n}_{\perp 2(i)}(t)) \tag{57.15}$$

$$\boldsymbol{n}_i(t+\Delta t) = \boldsymbol{n}_i(t) + \frac{1}{kT} D^R \boldsymbol{T}_i(t) \times \boldsymbol{n}_i(t)\Delta t + \left\{ \Delta \phi_{||}^B \boldsymbol{n}_i(t) + (\Delta \phi_{\perp 1}^B \boldsymbol{n}_{\perp 1(i)}(t) + \Delta \phi_{\perp 2}^B \boldsymbol{n}_{\perp 2(i)}(t)) \right\} \times \boldsymbol{n}_i(t) \tag{57.16}$$

The particle direction $\boldsymbol{e}_i$ is equal to the magnetic moment direction $\boldsymbol{n}_i$ for the present spherical magnetic particle. The random displacements $\Delta r_{||}^B$, $\Delta \phi_{||}^B$, and so on have to satisfy the stochastic characteristics in Eqs. (57.7) and (57.10). The vectors $\boldsymbol{n}_{\perp 1(i)}$ and $\boldsymbol{n}_{\perp 2(i)}$ are the unit vectors normal to each other in the plane normal to the particle axis (or the magnetic moment direction), as explained in Section 57.2.2. Nondimensionalization of quantities provides three nondimensional parameters R_B, R_H, and R_m that characterize the present sedimentation phenomenon. R_B is the ratio of the representative Brownian motion, R_H is the ratio of the representative torque due to an applied magnetic field, and R_m is the ratio of the representative magnetic force, to the representative gravity. Specification of the values of the nondimensional parameters, the volumetric fraction ϕ_V of particles, and so on, enables us to conduct the present Brownian dynamics simulations.

57.4.3 Results and Discussion

Figure 57.12 shows results of the snapshots after a macroscopic steady state had been attained to. For the case of $R_m = 1$ (Fig. 57.12a), magnetic forces between particles are weak and particles cannot aggregate to form complex clusters but rather form many simple chainlike clusters from the substrate surface that align in the opposite direction to the gravity field. The formation of these chainlike clusters can be explained in the following. Since the magnetic field is very strong for $R_H = 10$, during the first stage of the sedimentation the magnetic particles sediment with their magnetic moment inclined toward the field direction and attain to the substrate surface without forming aggregates. During the second stage, due to the field alignment of the magnetic moments, the particles tend to sediment directly onto the presedimented particles, leading to the growth of almost linear chainlike clusters as this sedimentation process is repeated. For the case of $R_m = 6$ shown in Fig. 57.12b, the magnetic forces between particles are relatively strong, and consequently the direction of their magnetic moments is as not strongly restricted to the magnetic field direction. In this situation, the particles tend

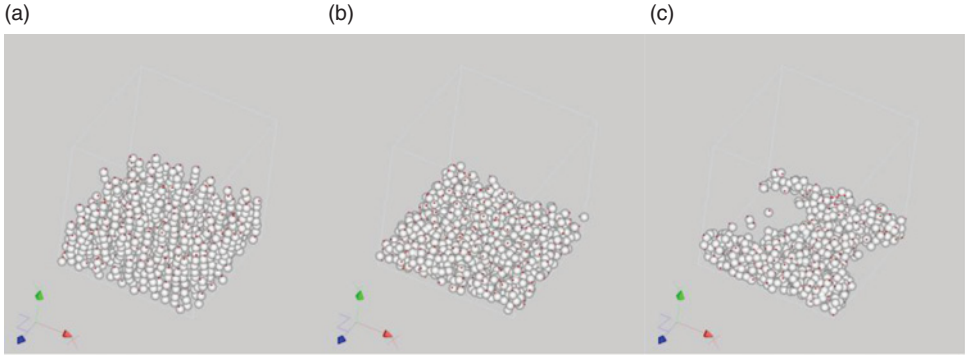

FIGURE 57.12 Aggregate structures for the volumetric fraction $\phi_V = 0.1$ and the magnetic field strength $R_H = 10$ for the three cases of the magnetic particle–particle interaction strength: (a) $R_m = 1$; (b) $R_m = 6$; (c) $R_m = 10$.

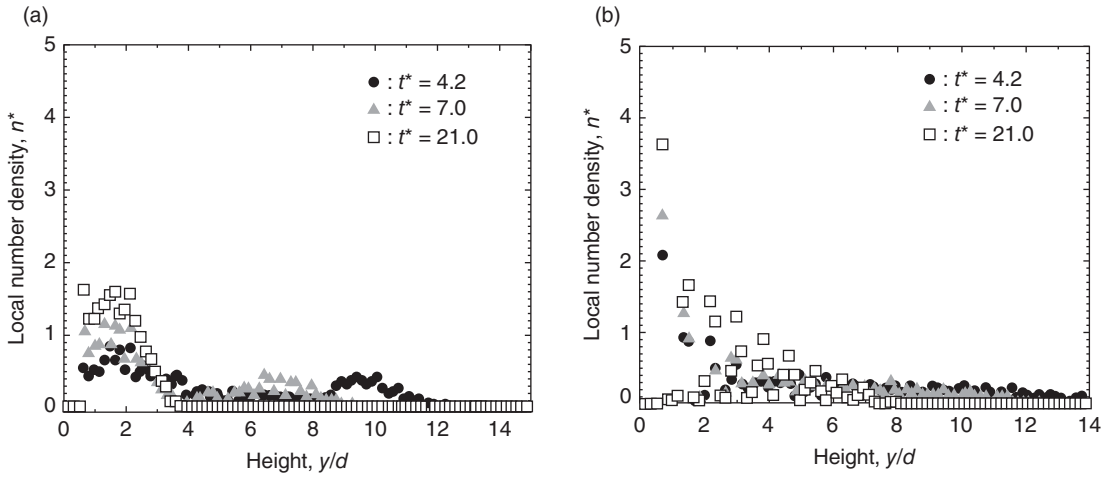

FIGURE 57.13 Time change in the local number density n^* for $\phi_V = 0.1$ and for (R_H, R_m) = (a) (1,10) and (b) (10,1).

to aggregate to form clusters during the sedimentation process, although these clusters are not necessarily linear chainlike aggregates because the particle–particle interaction is relatively strong. For the case of $R_m = 10$ shown in Fig. 57.12c, the magnetic particle–particle force is now more dominant than the Brownian random force, so that larger clusters are formed during the sedimentation process. These clusters do not significantly change their aggregate formation after the attainment to the substrate surface because the particle–particle interaction is significantly strong. This behavior gives rise to some large void spaces among the aggregated particles, as clearly shown in Fig. 57.12c.

In order to discuss the sedimentation process quantitatively, we focus on the time change in the local number density of each layer that is made by slicing the simulation region in a direction normal to the plane of the substrate material: t^* in the figure is the nondimensionalized time. For the case of larger magnetic forces between particles such as $R_m = 10$ in Fig. 57.13a, the magnetic force between particles is relatively strong, so that particles can aggregate during the initial stage of the sedimentation. Hence, at the earlier time of 4.2, relatively large clusters are already observed in the regions around at $y/d = 2.0$ and 9.5. After this initial aggregate formation, all particles sediment and combine with the already-sedimented particles to form larger aggregates. In Fig. 57.13b, where the magnetic force between particles is relatively weak, particles usually sediment without significant aggregates forming during the initial stage until around until $t^* = 7.0$. At a further advance in time $t^* = 21.0$, sharp peaks appear in the distribution at approximately the positions of integer times the distance of $y/d \simeq 0.85$. This is a quantitative proof for the observation that clusters are formed to stand in the upright formation along the direction of the gravity field. This characteristic clearly demonstrates the internal feature that was observed in snapshot in Fig. 57.13a. The reason why peaks appear at the positions of integer times the distance of $y/d \simeq 0.85$ is that the steric layers of particles partially overlap due to effects of the gravitational and magnetic interactions, and also that the chainlike clusters are not formed in perfectly linear formation. Additionally, we can see that particles exist in the upper region, which clearly shows that longer chainlike are formed in the magnetic field direction.

57.5 CONCLUSION

In addition to the application of magnetic suspensions to the magnetic drug delivery system, surface-modified magnetic particles (e.g., silica-coated magnetic particles) may be used for recovering specific substances such as hazardous heavy-metal molecules (environmental waste and pollutants) or valuable noble metal molecules from water (sea, lake, etc.) by processes that make use of a gradient external magnetic field (based on magnetic separation) [58–60]. Attempts are being made to synthesize multifunctionalized composite particles for developing a more effective drug delivery system and a bioadsorption system [14,61,62]. Since the application of an alternating magnetic field on magnetic composite particles induces a heating effect, this heat dissipation phenomenon may be used as a mechanism for releasing the drugs transported by the composite particles [63–66]. The development of a technology for transporting magnetic composite particles in blood vessels and collecting them at specific sites (cancer cells) in the body requires analysis of the flow behavior of magnetic particles in blood vessels or tracheae [67–70]. In order to analyze this kind of flow problem for a suspension, it is necessary to simulate both the behavior of particles and the ambient flow field simultaneously. The methods of lattice Boltzmann [71–73], dissipative particle dynamics [74–76],

and multiparticle collision dynamics [77] are potential simulation techniques in order to address the important problem of taking into account the multi-body hydrodynamic interactions among particles.

58.1 INTRODUCTION

Surface-active agents or *surfactants* are compounds that lower interfacial tension at different interfaces and are a fascinating area of research in different fields such as chemistry, biology, and engineering because of their important practical applications. Surfactants are usually amphiphilic organic compounds containing a hydrophilic polar headgroup and a lipophilic part consisting of hydrocarbonated chains generally with a $(CH_2)_n$ motif. Most commonly, they are classified into four groups according to the charge on the hydrophilic group: anionic, cationic, zwitterionic, or nonionic. Surfactants are produced in large amounts and are widely used for industrial and domestic purposes [1]. For a long time they have been among the most versatile of process chemicals in industry and biotechnology [2].

Anionic surfactants are widely used in modern households in products such as soaps, toothpastes, cosmetics, washing liquids, laundry detergents, textiles, and also in mining [3]. Cationic surfactants also have widespread use in the manufacture of commercial products and pharmaceutical formulations including textile softeners, anticorrosion agents, disinfectants, cosmetics, and household cleaning products [4]. Detergents are also routinely used in research laboratories. Sodium dodecyl sulfate (SDS), cetyltrimethylammonium bromide (CTAB), Triton-X 100 and 114, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS), sodium deoxycholate (NaDC), NP40, and other compounds are used to solubilize chemical species by dissociating aggregates, disrupting lipid bilayers, and by solubilizing proteins. SDS used during electrophoresis denature proteins by disrupting their secondary and tertiary structures allowing separation of proteins according to their molecular weights. For solubilizing proteins keeping their structures intact, nonionic surfactants like octylthioglucoside can be used and are preferred for studying protein conformation and function [5].

Several microorganisms such as bacteria and yeast synthesise surface-active agents. When grown on hydrocarbon sources, these microorganisms synthesize a wide range of chemicals with surface activity such as those of glycolipids and phospholipids. These chemicals emulsify the hydrocarbon substrates and facilitate their transport into cells [6, 7]. Pulmonary surfactants consisting mostly of dipalmitoylphosphatidylcholine are secreted by the type II cells of the lung alveoli in mammals [8]. These types of surfactants synthesized by living cells are called *biosurfactants*. They can be diverse and environment friendly, and have potential applications in environment protection [9]. By enhancing emulsification of hydrocarbons, they accelerate bioremediation of hydrocarbon-contaminated sites [10]. They can also be used in enhanced oil recovery, herbicide and pesticide formulations, detergents, healthcare and cosmetics, pulp and paper, coal, textiles, and other applications [11].

Because of their anthropogenic origin and extensive use, surfactants are considered a common environmental

pollutants [1]. The diversity of existing surfactants and their widespread presence in both industrial products and the environment has created a need for analytical tools to accurately determine and monitor their concentrations in aqueous environments [3]. Initially, the most widely used technique for surfactant analysis was the standard method of two-phase titration. This however, had several drawbacks and a number of alternative analytical methods have been developed based on ion pair formation such as titrimetry [12], flow injection analysis [13], spectrophotometry [14], chromatography [15], and optical sensing [16]. None of these methods are however suitable for *in situ* or at-site quantitative determination.

As an alternative, ion-selective electrodes (ISEs), namely potentiometric ion sensors have been developed for determining ions in aqueous environment [17]. Since their invention in 1906 [18], they have become one of the most important forms of chemical sensors [19]. ISEs applied to surfactants in solution are called *surfactant ion-selective electrodes* (SISEs), which have become a major tool for analyzing surfactants in environmental wastewater, industrial process control, and pharmaceutical domains [20–23]. Compared to other analytical methods, SISEs are simple to use, environment friendly, robust, durable, and suitable for use in field environments. Other advantages include automation of routine sample analysis. Complying with good laboratory practice, low consumption of reagents, results that are independent of sample turbidity or coloring, minimum sample preparation, continuous monitoring of surfactant ion concentrations, and response to cationic and anionic surfactants depending on the nature of the electroactive material used [3,23,24]. Major limitations include inability to detect concentrations in the μM or nM range (real matrices) and the short lifetime of these devices due to gradual loss of response characteristics.

Biopolymer–surfactant interaction is an important field of study due to its relevance in many biological, pharmaceutical, and industrial applications. Protein–surfactant interactions also provide models for studying lipid–protein interactions existing in cell membranes. Since proteins interact mostly with ionic surfactants, interactions with SDS has been most widely studied. Interactions with other surfactants such as bile salts CTAB, and cetylpyridinium chloride (CPC) have also been investigated [25, 26] to some extent. Among proteins, serum albumins have been mostly studied. Other proteins studied include gelatin, lysozyme, hemoglobin, and myoglobin [27]. Research on development and application of SISEs have been carried out for more than three decades and they are found to be more suitable for determining the binding isotherm of surfactant–polymer interactions and determining surfactant concentration in dilute solution [28]. The main purpose of this chapter is to provide a systematic summation of the development of SISEs and their uses and applications in studying surfactant interactions with biopolymers.

58.2 DEVELOPMENT OF SURFACTANT ION-SELECTIVE ELECTRODES (SISEs)

Potentiometric surfactant sensors are used to either determine the endpoint of titration or directly determine surfactant concentration. The most popular sensors of this group are the poly(vinyl chloride) (PVC)-based solid membranes, coated wire-type sensors, and ISFET (ion-selective field effect transistor) sensors. These sensors are suitable for determining cationic, anionic, or nonionic surfactants [2] and are used primarily to determine monomer concentration of surfactants, in environmental samples such as wastewater, in food and cosmetic formulations, phase transfer catalysts, etc. [3, 29–31].

At first, potentiometric sensors determined surfactants by indirect measurements such as interference on calcium ion-selective electrodes [32] or by titrating with sodium salt of tetraphenylborate (TPB^-) [33]. Liquid membrane electrodes selective toward multiple anionic surfactants were first developed using ion pairs as exchange systems [34].

The development of liquid and solid (PVC) membranes specifically designed to estimate surfactant ion concentrations came in the second stage of development featuring preparation of many different kinds of sensors, and the first commercial ISEs were prepared.

58.2.1 Liquid Membrane Electrodes (LMEs)

To form a liquid membrane system, a water insoluble carrier complex (comprising the ionophore) is dissolved in a low-polarity solvent (toluene, nitrobenzene, etc.) taken in a U-tube and partitioned between water and the solvent in the two limbs. The carrier complex can be changed to sense different surfactant ions as needed.

The first potentiometric sensors selective for anionic surfactants were developed by describing the principle for liquid membrane electrodes specific for dodecylsulfate (DS^-), tetrapropylenebenzenesulfonate ($TPBS^-$), and dioctylsulfosuccinate ($DOSS^-$) ions and were used to determine the critical micelle concentrations (CMC) of each [35]. This was followed by an electrode developed by Birch and Clarke [36], who used the carrier complex cetyltrimethyl–dodecyl sulfate (CTA-DS) in nitrobenzene. This electrode responded to DS^- and was used for monitoring DS^- adsorption over numerous polymers and proteins, and for potentiometric titration of various commercial detergents [37, 38]. LMEs responsive to anionic surfactants containing cationic colorants such as crystal violet [39] as ion exchanger were also developed.

Two other researchers prepared liquid membranes for DS^- using Co^{3+} complexes that could be used for titrating various alkylsulfates (between C8 and C18) separately, or in binary mixtures [40]. Similarly, using other metallic complexes anionic detergents in oil residues could be determined [41]. Another researcher developed a different kind

of a polymeric sensor (mercurated polystyrene) for titrating and to study physicochemical properties of commonly occurring anionic surfactants [42]. Cation-selective LMEs were developed on the basis of their complex formation with TPB^- [43].

Although easy to build, liquid membrane electrodes had several disadvantages. The major problems encountered were drifting of potentiometric signal with time, lack of robustness, and risk of membrane dissolution in the aqueous phase near the CMC of the surfactant. Because of temporal variability, LMEs require continuous recalibration, making them unsuitable for direct potentiometric techniques [3,44].

Liquid membranes are discussed further in the context of bile-salt-selective electrodes in Section 58.2.2.6.

58.2.2 PVC-Based ISEs

Liquid membranes were superseded by solid membranes when Moody and Thomas first showed the possibility of keeping liquid membrane immobilized on PVC [45, 46]. Since then, liquid membranes have been replaced by plasticized polymeric membranes, where PVC serves as the matrix for holding the dispersed carrier complex. These membranes are robust, less soluble in aqueous media, and simple in design. The most widely used formulation comprises three components: ionophore, plasticizer, and PVC. The analytical response depends on a suitable combination of the plasticizer and the ionophore. Membrane selectivity can be altered by modifying the relative proportions of membrane components. Figure 58.1 compares the electrode assemblies for determination of surfactant ion concentrations using liquid and solid membrane electrodes.

Plasticizers are organic compounds that improve a membrane's elasticity and mechanical properties. When added to PVC, they also help in designing and improving membrane selectivity by fixing its dielectric constant. Choosing an appropriate plasticizer, an adequate membrane component, and sometimes an additive is essential for constructing an ion-selective electrode with high analytical performance and longer lifetime [47]. The proportion of plasticizer, however, must be optimized to minimize electrical asymmetry of the membrane, to keep the sensor clean, and to prevent it from leaching into the aqueous phase [48]. The nature of the plasticizer used affects sensitivity, linear range of electrodes, and possibly also selectivity. It should also be compatible with both the polymer and the ionophore [49]. The most popular plasticizers for PVC membranes are *o*-nitrophenyl octyl ether (NPOE) and *o*-nitrophenylphenyl ether (NPPE).

58.2.2.1 Conventional ISEs. These devices are prepared by dissolving PVC, plasticizer, and the carrier complex in an appropriate organic solvent (tetrahydrofuran or cyclohexanone) by gentle heating. The organic solvent is then allowed to evaporate at room temperature, leaving a dry membrane. The membrane then can be sliced and mounted on the body of an electrode filled with a reference system, normally Ag/AgCl. These electrodes are known as *conventional ISEs*.

The first PVC-based electrodes for titrating surfactants were actually ISEs selective to nitrate and calcium ions [43]. Although these electrodes could also sense anionic and cationic surfactants, the major drawback however was interference from anions for the nitrate electrodes, and from bivalent cations for calcium electrodes [50, 51].

The first PVC electrode prepared specifically for anionic surfactants was designed by Tanaka [52, 53]. A mixture comprising of a ferroin cation and the anions alkylbenzenesulfonate and perchlorate was used as the ionophore.

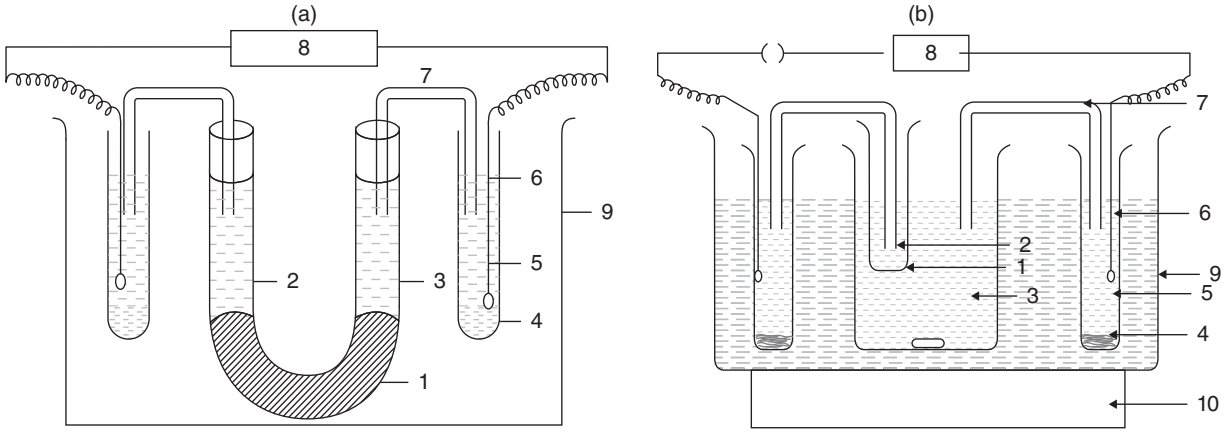

FIGURE 58.1 Electrode assembly for surfactant ion detection by SISEs: (a) liquid membrane electrode; (b) PVC-based membrane electrode (1–membrane; 2–internal reference solution; 3– test solution; 4—KCl; 5–saturated KCl solution; 6–calomel electrode; 7–salt bridge; 8–voltmeter; 9–water bath, 10–magnetic stirrer).

Membranes prepared by another team [54] had cations or anions bound chemically to the polymeric chain. Although these stable permselective membrane electrodes could be used to determine surfactant ion activities above and below their CMC, they showed little selectivity between surfactants of similar charge [54].

A different idea for membrane preparation was tried using only a polymer and a plasticizer, based on the principle that the ion pair being formed in solution by titration becomes the carrier complex that is gradually incorporated in the matrix. This gradual incorporation protects overconcentration of the complex in the membrane, which negatively affects the detection limit [55].

Two other researchers prepared another sensor membrane using NPOE as plasticizer and a suitable ionophore, and showed that these types of electrodes could be used to detect amphoteric and cationic surfactants [56]. At low pH, the amphoteric surfactant becomes cationic and could be titrated with TPB^-. Using this method, zwitterrionic surfactants could also be detected [56].

A number of reports on electrodes sensitive to nonionic surfactants also exist in the literature [56–58]. The basic principle is the formation of a complex by associating the ethoxylated part of the nonionic surfactants with Ba^{2+} and titrating the positively charged complex with TPB^-. Although a detection limit of 10^{-7} was reported for Antarox 880 [57], the analysis took more than an hour. To prepare more stable, reproducible and long-lived devices, another team [59] used PVC membranes containing TPB^- complexes with Ba^{2+} and polyethoxylate-based nonionic surfactant as sensing material.

To investigate a variety of ionic surfactants, a sensor membrane plasticized with NPOE and containing an additive to improve electrical conductivity was developed [60]. This membrane needed no preconditioning and yielded good results during potentiometric titrations with SDS and hyamine as anionic and cationic standards, respectively.

For estimating anionic surfactants in solution, DS^- or TPB^- is used as standard, and for cationic surfacatnts, *N*-benzyl-*N*,*N*-dimethyl-*N*-[4,1,3,3-tetramethylbutyl)-phenoxyethyl]ammonium chloride (commercial name Hyamine 1622), cetylpyridinium chloride (CPC), or 1,3-dodecyl-2-methyl imidazolium [61–64] (commercial name TEGOtrant A100; Metrohm) are used as standards. On the basis of this principle, several commercial electrodes were prepared that were specially constructed for analyzing surfactants; examples are electrodes by Orion [65, 66], "high-sensitivity tenside" electrodes by Metrohm [67], which is stable for several months and yielded results with relative standard deviation between 0.2% and 1.3% for anionic surfactants. Other advantages are its stability over a wide pH range and linear response over a large range of surfactant concentration.

More recent advances in preparation of membrane electrodes for better selectivity and lower detection limit involved preparation of a variety of carrier complexes. A ligand 7-methyl-7,13-di-octyl-1,4,10-trioxa-13-aza-7-azoniacyclopentadecane was synthesized and used as an ionophore for detecting anionic surfactants [23]. The membrane prepared using this ligand and NPOE as plasticizer showed Nernstian response to DS^- had a detection limit of 6×10^{-7} M, showed reasonable response toward alkyl sulfates and alkylbenzene sulfonates, but showed no response toward carboxylates, cationic, or nonionic surfactants. In another report, a cyclam derivative 1,4,8,11-tetra(*n*-octyl)-1,4,8,11-tetraazacyclotetradecane was used as carrier complex [1]. The most effective membrane composition involved 56% dibutyl phthalate, 3.4% ionophore, 3.8% tetra-*n*-octylammonium bromide (a cationic additive), and 36.8% PVC. This electrode showed Nernstian response toward DS^- with a detection limit of 4×10^{-6} M. Calculation of selectivity coefficients showed poor response toward commonly occurring inorganic cations and anions. Except for bicarbonate, electrode selectivity followed the Hoffmeister series. With the exception of linear alkylsulfates, response toward other anionic and nonionic surfactants was poor. In addition, it showed nonlinear response toward certain cationic and zwitterionic surfactants.

A DS^- selective electrode containing CTA^+-DS^- as ionophore showed Nernstian response, 2.9×10^{-6} M detection limit, wide pH range, small response time, and low selectivity toward common inorganic anions [68]. Another team of investigators used the same ionophore for preparing CTAB-selective SISEs for studying CTAB interactions with various biopolymers [69, 70].

A membrane electrode using CPC based Sn(IV) phosphate (CPC-SnP) as the electroactive material was prepared showing a linear response for CPC [71]. Although the response slope was sub-Nernstian (29.1 mV/decade), determination of CPC concentration using this electrode compared favorably with those obtained by the two-phase titration method. The electrode has a pH range of 2–6 and a response time of 30 s.

Another group prepared two conventional plastic membrane electrodes selective toward tetradecyltrimethylammonium cation (TTA^+) [4]. The ion exchangers were the ion associate TTA-PT, and the aggregate TTA-PSS, where PT and PSS are phosphotungstate and polystyrene sulfonate, respectively. Electrodes showed Nernstian response and had pH ranges of 4–10.5 and 3.8–10.7. Electrodes with the ion aggregate as exchanger had lifespans of 28 weeks, while electrodes with the ion associate as exchanger had lifespans of 20 weeks. Surface analysis using electron microscopy and X-ray photoelectron spectroscopy showed that the limited lifespans of plastic electrodes was due to topographical changes at the electrode surface and leaching of active ingredient from the surface.

A sensor based on 1,3-didecyl-2-methylimidazoliumtetraphenylborate (DMI^+-TPB^-) as the ionophore, and *o*-NPOE as plasticizer was used to titrate SDS and sodium dodecyl benzene sulfonate (SDBS) using DMI and CPC. Usable titration curves could be obtained in a concentration range of 10 μM [72].

58.2.2.2 Modified PVC-Based Electrodes. A decrease in the performance ability of these surfactant ion-sensing electrodes due to loss of sensitivity, electrode response slope, and aging, restrict their long-term use. To overcome this, a number of new methods and new materials were designed. A series of them were prepared using long and flexible open-chain polyethers that could be used for determining quaternary ammonium cationic surfactants [73].

Although most membranes described in the literature are PVC-based, other approaches mainly to improve membrane selectivity were also tried. Thus membranes based on silicon rubber matrix using CTA^+-DS^- as ionophore were prepared. They could detect millimolar concentrations of DS^- when titrated with cetylpyridinium bromide (CPB), due to their response toward cationic surfactants [74].

An extensive study compared PVC with other polymers such as polybutadiene, polymethylmetacrylate, and polystyrene by preparing membranes with same ionophores and plasticizers. Relatively acceptable results were obtained only when vinyl polychloride was substituted with vinyl polybromide [54].

In a separate attempt to fix the electroactive material to the membrane to reduce its solubilization, PVC chains were functionalized. Hayakawa [75] synthesized modified PVC copolymerizing vinyl chloride with 3-acrylamido-*N*,*N*-dimethylpropylamine in different ratios followed by alkylation of the amine segments with methyl iodide. Membrane electrodes showed near-Nernstian response and could be used to determine SDS concentrations reasonably accurately below CMC. In mixtures of SDS and other surfactants, however, the concentration of the secondary surfactant could not be determined without large errors [75]. A PVC-based electrode reversible to SDS was prepared [76] in which a fraction of chlorine atoms bound to the poly(vinyl chloride) backbone was functionalized by nucleophilic substitution using trimethylamine. A number of studies have been published describing the use of mixed membranes comprising PVC and polypyrrole. Another team [77] prepared dodecylbenzenesulfonate ($DDBS^-$)-doped polypyrrole electrochemically and used this as the ionophore for constructing the sensor. This electrode showed Nernstian behavior and was stable for 6 months.

A solid-contact sensor for cationic surfactants using CP^+-TPB^- as the ion exchanger was developed and characterized. It was found that the surface of the sensor could be modified with PVC molecular sieves, and the modified electrodes could separately determine alkylpyridinium homologs with different lengths of hydrocarbon radicals (C10–C18) [78]. Another team prepared two neutral sensing materials SDS-SWCNT (single-walled carbon nanotubes) and SWCNT-CTAB, and incorporated them into a plasticized PVC membrane. Electrodes exhibited Nernstian response for SDS and near-Nernstian response for CTAB below their CMC, and showed acceptable selectivity over common anions. Results obtained were comparable to those obtained using classical methods [79]. For potentiometric flow injection analysis of anionic and polyethoxylate nonionic surfactants, PVC-based ISEs were constructed with an all-solid-state tubular flow-through design. Ion exchangers appropriate for detection of surfactant ions were incorporated into the plasticized PVC membranes [80, 81].

58.2.2.3 Coated-Wire Electrodes (CWEs). In 1970s surfactant titration using ion-selective electrodes with no inner solution was developed using a coated-wire electrode. Preparations involved introducing a conductive material (a Pt, Ag, Cu, or Al wire or a graphite rod) inert toward the membrane components into a sensor cocktail containing the ionophore repeatedly, and allowing the membrane forming solution to evaporate until a polymeric film of desired thickness was formed. If the coating was nonuniform, the wire interfered with electrode response [82, 83]. Because of their simplicity and low preparation costs, they were widely used in laboratories. The first coated-wire electrode for anionic surfactants was prepared by Fujinaga et al. [84], but Vytras first reported a device coated with a two-component membrane [85]. Vytras tested a PVC membrane plasticized with 2,4-dinitrophenyloctyl ether that enabled the possibility of titrating various kinds of surfactants, even in mixed systems [83]. Like conventional electrodes, Vytras prepared CWEs for titrating [86, 87] cationic and zwitterionic surfactants by TPB^-, and nonionic surfactants by adding Ba^{2+} in the membrane.

The major drawback of CWEs is shorter lifetime, higher potential drift, and low reproducibility compared to conventional PVC electrodes. Hence these are more suited for flow injection analysis where contact between the sample plug and the electrode surface is brief and for detecting endpoints in titrations that are guided by jumps in the electrode potential. In all other cases conventional membrane electrodes are more suitable [3].

58.2.2.4 Ion-Selective Electrode Field-Effect Transistors (ISFETs). To design sensors that can be mass-produced and retain reproducibility during use, ISFETs have been developed. These are cost-effective miniature devices with very low response times [88] and hence are more suitable for *in vivo* applications with small sample volumes. An added advantage over conventional membrane electrodes is that several ISEFETs can be integrated in a single chip and produce single-piece multiparametric sensors [89].

The first ISFET measurements of anionic surfactants were reported by Masadome et al. [90]. Subsequently, an ISFET of a PVC membrane was developed for the cholate ion by a design known as *ChemFET* (chemically modified field effect transistor). These devices showed super-Nernstian behavior with an improved detection limit [91]. ChemFETs specifically designed for measuring anionic surfactants were prepared and used in potentiometric titrations of different anionic detergents and commercial samples containing them. The results were consistent with the standard two-phase method [92]. These sensors were stable for 4 months, showed Nernstian response to the primary ion, had detection limits of about 10^{-6} M, and showed linear response. Three ChemFETs for measuring cationic surfactants were also fabricated and characterized. These devices used a PVC-sebacate matrix containing benzyldimethyl–hexadecylammonium reineckate, dodecyltrimethylammonium reineckate, and hexadecylpyridinium phosphotungstate as exchangers and were used not only to estimate cationic surfactants' concentration but also to evaluate their CMCs [93].

Limitations of ISFETs include manual application of membranes, low adherence to transistor gates, drifts in potential response, and limited working life. One of the strategies used to overcome these limitations and make large-scale preparations possible, involved reformulations for automatic implantations by designing membranes based on photocurable polymers. These could be manipulated via photolithography procedures. Thus photocurable membranes for anionic surfactants were prepared, characterized, and optimized [88,94]. Comparison with conventional electrPodes showed similar results.

58.2.2.5 Screen-Printed Electrodes (SPEs). More recently, SPEs have been developed for detecting surfactant ion concentration in solution. One team reported SPEs for determining CPC concentrations in solution directly or by potentiometric titrations using TPB^- [95]. They involve in situ modified and unmodified screen-printed ion-selective electrodes that were stable, had low response times, showed near-Nernstian response in the concentration range from 10^{-2} to 10^{-6} M, and had a pH range of 2–8. Analytical performances of these electrodes were similar to those of carbon paste electrodes (CPEs) and conventional PVC electrodes, and the results were comparable to those obtained using classical methods. In another report SPEs were used for potentiometric titration and determination of CTAB in different pharmaceuticals and water samples [96]. Results were comparable with those obtained for carbon paste, coated-wire, coated-graphite, and pol(yvinyl chloride) electrodes.

58.2.2.6 Membranes Reversible to Biological Surfactants: The Bile Salts. In 1977, Gilligan et al. [97] reported a liquid membrane electrode capable of measuring activity of the bile salts, sodium taurocholate (NaTC) and sodium taurodeoxycholate (NaTDC). This electrode could also detect SDS in solution. The ion-sensing complex comprised a 1:1 mixture of hexadecyltributylammonium ion and either of the tauro salts. CMC obtained for SDS using this electrode was comparable to that obtained using conventional SDS-selective electrodes. This electrode could also be used to measure bile ions in presence of phosphatidylcholine (mixed micellar solution).

A cholate (C^-) ion-selective liquid membrane electrode was prepared [98] using benzyldimethylcetylammonium cholate in 1-decanol as sensor. This electrode was used to estimate the pool of cholic acid in human bile [98]. In addition to detecting C^-, this electrode could also detect other anionic surfactants such as DS^-, $DDBS^-$, and $DOSS^-$ [99]. Campanella et al. then used the same ion exchanger to prepare a PVC-based bile-salt-selective electrode. Bile salt estimations by both types of membrane electrodes were similar [100]. Another pair of investigators [101] prepared liquid membrane electrodes reversible to five bile salts: sodium cholate (NaC), deoxycholate (NaDC), chenodeoxycholate NaCDC), ursodeoxycholate (NaUDC), and dehydrocholate (NaDHC). The ion exchanger in each case was hexadecyl tributylammonium bromide and the corresponding bile salt dissolved in 1-octanol. Electrode responses were near-Nernstian in the premicellar region, and the CMC values determined were in the range obtained by other methods. The electrodes were used to study binding interaction of bile salts with bovine serum albumin (BSA). Nitrobenzene-based liquid membrane electrodes were prepared containing CTAB-NaDC or CTAB-NaCDC as carrier complexes. To prepare NaC-selective membranes, however, dimethyldioctadecyl ammonium bromide (DDOAB)-NaC was used instead to resolve solubility constraints. These electrodes were used to determine the CMC of the bile salts in pure and in mixed states [102].

There are also some reports on preparation of bile ion-selective microelectrodes. Kunz and Lindenbaum [103] prepared NaC, NaDC, and NaCDC sensitive microelectrodes, and compared their Nernstian behavior under different conditions of temperature and pH. These microelectrodes showed selectivity over the physiologically important inorganic anions in bile. Another team [104,05] tested several organic compounds for preparing microelectrode sensitive to cholic acid. A mixture of benzyldimethylhexadecylammonium cholate/decanol with hexadecyltributylammonium taurocholate/5% hexachlorobenzene +0.5% bromoacetanilide in *o*-dichlorobenzene was used for preparing a double-barrel microelectrode because of overall low detection limit (10^{-4} M), low interference from common anions, and low drifts. This electrode was also sensitive toward NaDC, NaCDC, and NaUDC.

A PVC-based NaDC-sensitive electrode was prepared using CTA^+-DC^- as the sensing material [106]. Another

group [107] prepared PVC membranes containing CTA^+ and a mixture of anions (DS^-, $DDBS^-$, $DOSS^-$, DC^-, and $TCDC^-$) in 1:1 molar ratio using cyclohexanone as the solvent. This membrane showed selectivity separately toward all component anions and was stable for 3 months, although it showed sub-Nernstian behavior. Later Chatterjea et al. developed a multiple-bile ion-sensing membrane electrode [108] selective toward NaC, NaDC, and NaCDC, and their glycine and taurine conjugates, which could change selectivity following appropriate conditioning. This electrode had a low response time, was stable for 5 months, had a detection limit of ~10 nM, and showed low selectivity toward interfering bile ions and SDS. Selectivity toward commonly occurring anions followed the Hoffmeister series except phosphate. This electrode could be used to kinetically follow bile salt interactions with macromolecules.

58.3 STUDY OF SURFACTANT BIOPOLYMER SYSTEMS USING SISEs

Surfactant interaction with polymers has been the subject of investigation since the early 1950s. Apart from academic interests, studying these type of interactions are important because of their applications in pharmaceutical, biomedical, and food industries; enhanced oil recovery; mineral processing; and so on [28,109].The dominant forces involved in these interactions are charge–dipolar interactions, hydrophobic interactions, hydrogen bonding, and van der Waals forces.

It is known that polyelectrolytes induce aggregation of oppositely charged surfactants [110]. When a surfactant is gradually added to a polyelectrolyte (biopolymer) in solution, the formation of surfactant–biopolymer complexes can generally be described in terms of two critical concentrations. The first is the concentration at which small surfactant assemblies start binding to the polymer, normally called the *critical aggregation concentration* (CAC). With increasing surfactant concentration, micellar aggregates of similar or different forms become attached to the polymer sites and saturate them. This state is called the *polymer saturation concentration* (C_s) representing the surfactant concentration at which the polymer becomes saturated with bound surfactants. In the surfactant concentration region CAC-C_s, micelle-like aggregates develop [111]. At higher surfactant concentrations, free (nonbound) surfactant monomers associate at a critical concentration C_e to form free larger micelles. C_e is also called the *extended critical micelle concentration*. Normally, CAC is appreciably lower than C_e. Other reports [112,113] have shown that the surfactant aggregates are similar to free micelles. A "necklace bead" model has been recognized for the depiction of a polymer–surfactant complex where the polymer induced micellar aggregates begin to form at CAC, decorate the polymer strand up to C_s, and then begin to form free micelles at C_e. Stagewise interaction of surfactant molecules with a polymer with gradual increase in surfactant ion concentration in aqueous medium is pictorially illustrated in Fig. 58.2. SISEs, tensiometry, and *isothermal titration calorimetry* (ITC) can be used to determine CAC, C_s, and C_e (111,114,115). Figure 58.3 shows representative tensiometric and ITC profiles of surfactant–polymer interaction in arbitrary scale. These techniques have been used to investigate a number of polymer–surfactant systems [116].

Polymer–surfactant interactions can occur between neutral polymers and surfactants, between charged polymers (polyelectrolytes) and surfactants, or between biopolymers and surfactants. All of these interactions could be studied using SISE. In this chapter, we focus on the interactions of surfactants with biopolymers and biologically active polyelectrolytes.

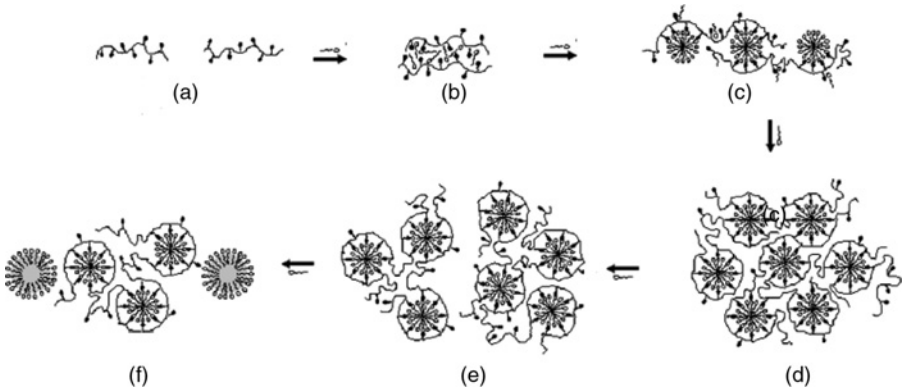

FIGURE 58.2 Pictorial representation of different stages of polymer–surfactant interaction with gradual addition of surfactant to a polymer in aqueous medium: (a) surfactant-monomer-loaded polymer; (b) CAC-forming state; (c) induced micelles formed on the polymer strands; (d) aggregation to coacervation above C_S; (e) deaggregation of coacervate; (f) "necklace beads" with free micelles at and above C_M.

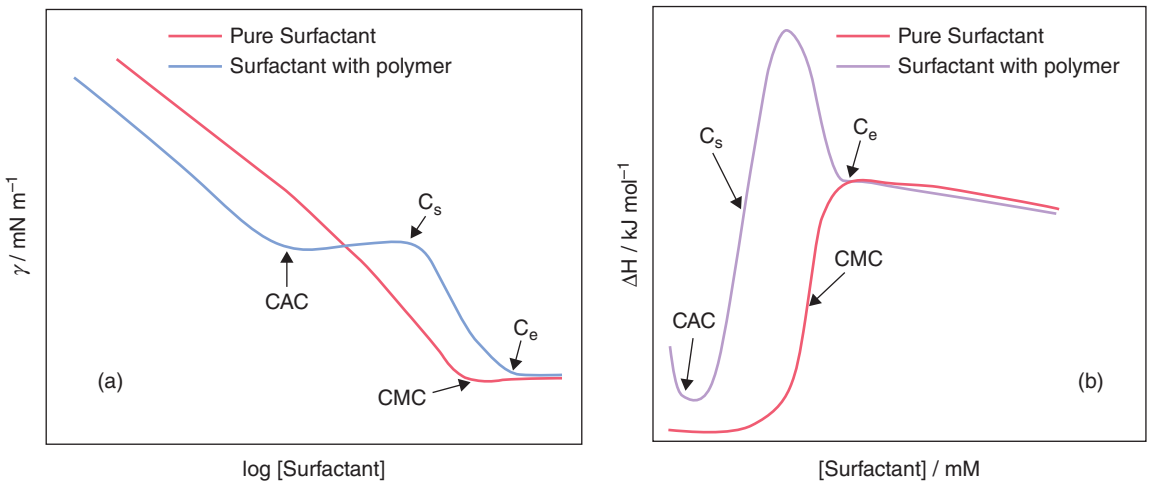

FIGURE 58.3 Representative plots for polymer–surfactant interactions (arbitrary scale): (a) tensiometric results; (b) calorimetric results (CMC–critical micelle concentration of pure surfactant; CAC–critical aggregation concentration; C_s–maximum surfactant-binding concentration; C_e–extended critical micelle concentration).

Interactions between ionic surfactants and biopolymers, for example proteins, have been widely investigated because of their biological importance. Interactions of surfactant-synthetic polymer systems showed physicochemical similarities with surfactant-biopolymer systems. Binding of charged surfactants to protein can be viewed as occurring in two distinct stages. In the first stage, the surfactant binds to a specific site on the protein surface known as the *high-energy binding region* guided by both electrostatic and hydrophobic interactions. In the second stage, the protein unfolds, exposing its hydrophobic interior and additional potential binding sites [117]. The binding of cationic surfactants to biopolymers of low charge density occurs by way of combination of noncooperative and cooperative binding [118]. Structural investigation of protein–surfactant complexes by NMR and neutron scattering showed that formation of protein–surfactant aggregates could also be described by the "necklace bead" [119, 120] model. The model assumed that the unfolded polypeptide chain is flexible in solution and that micelle-like clusters of surfactants are distributed along the unfolded polypeptide chain. Another team [121] carried out a series of small-angle neutron-scattering (SANS) investigations of BSA-SDS and ovalbumin-SDS complexes. From the quantitative interpretations of SANS intensity distributions, they came up with a well-defined structural model for these complexes and renamed the model the 'correlated necklace model." It is noted that the aggregate sizes are always smaller than the micellar aggregation number under the same solvent conditions.

Formation of biopolymer-surfactant aggregates in dilute solutions have been extensively investigated using different techniques such as surface tension, conductivity, viscosity, fluorescence microscopy, light scattering, neutron scattering, and NMR [122–124]. Results obtained using all these techniques consistently showed these interactions to be cooperative in nature. Although surface tension and electrical conductivity are used mostly for determining concentrations, they are not suitable for unambiguous determination of CAC, C_s, and C_M in presence of salts. SISEs were able to monitor continuous changes in surfactant concentrations, thus providing a versatile and alternative technique to determine monomeric surfactant concentration in dilute polymer–surfactant mixtures in presence of salts [125]. Earlier studies focused mainly on surfactant polymer systems at relatively higher polymer or surfactant concentrations. Introduction of SISEs have allowed extension of these studies to very low surfactant concentrations [126].

Binding constants and cooperativity parameters for an interaction can be estimated by studying their binding isotherms. Analysis of binding isotherms of surfactant–biopolymer interactions (curves representing amount of bound surfactant ion as a function of concentration of nonbound surfactant ion) provide insights into how binding interactions are influenced by surfactant chain length, polyelectrolyte linear charge density, and ionic strength. Although other methods are available [127, 128], potentiometric methods involving SISEs have been found to be the method of choice for studying binding isotherms and the degree of micellar counterion ionization of ionic surfactant–biopolymer systems.

58.3.1 Interactions between Ionic Surfactants and Biopolymers

Studies of surfactant interaction with biopolymers mostly involved proteins and biologically active polyelectrolytes.

The nature of the interaction depended mainly on the type of biopolymer, surfactant, pH, ionic strength, and temperature. A number of biopolymer–surfactant systems have so far been studied using SISEs, of which the most frequently studied surfactant is SDS. Other anionic surfactants including some bile salts and a few cationic surfactants like CTAB and CPC were also studied.

Since the introduction of SDS-selective liquid membrane electrodes by Birch et al., these have been used to study binding interactions of SDS with polymers such as poly(vinyl alcohol), poly(vinyl pyrrolidone), and biopolymers such as dextran, and BSA in premicellar solutions. Results obtained showed that the electrode gave rapid and reliable data in solutions containing polymer–surfactant complexes [37].

Binding properties of dextran sulfate (DS) with surfactants could be investigated using SISEs. This biocompatible polyanionic dextran derivative mimics natural mucopolysaccharides like chondroitin sulfates and have applications in the healthcare sector. Binding of DTAB determined using a DTA-DS carrier complex was found to be highly cooperative [129]. Binding interactions were also studied in presence of multivalent cations such as Mg^{2+}, Ca^{2+}, Zn^{2+}, and La^{3+} [130]. Dependence of chain length on binding of alkylpyridinium cations (undecyl-, dodecyl-, tridecyl-, and tetradecylpyridinium ions) to dextran sulfate was studied using solid membrane electrodes selective for each surfactant ion. Binding isotherms showed high cooperativity indicating a significant effect of hydrophobic interactions [131]. Studies of temperature dependence of DTA^+ binding to dextran sulfate in the range 278–323 K showed small but significant temperature dependence. Equilibrium thermodynamic parameters (free energy, entropy, and enthalpy) were also calculated from this study [132]. The results were comparable with that obtained from binding of dodecylpyridinium ions (DoP^+) with DNA as a function of temperature [133]. Values obtained for the thermodynamic parameters indicated the importance of hydrophobic interactions in the polyion–surfactant binding process. Another team reported binding isotherms of sodium dextran sulfate to DoP^+ [134].

Binding isotherms of SDS bound to biologically active polyelectrolytes poly(L-ornithine), poly(D,L-ornithine), and poly(L-lysine) at neutral pH were determined using SISEs. All three binding curves showed high cooperativity suggesting micelle-like clustering of the surfactant ions onto the polypeptide side groups [135]. Another team used DTA^+ - and TTA^+ -selective electrodes to study binding isotherms of DTAB and TTAB interactions with carboxylic polyelectrolytes such as alginate, pectate, and (carboxy)methyl cellulose in presence and absence of NaCl [136]. Interactions of (carboxy)methylcellulose (sodium salt) with salts, dyes, and surfactants have been studied by viscometry, conductometry, spectrophotometry, and CTAB-selective SISEs [137]. Binding of CTAB with the polyelectrolyte was Langmuirian in absence of KCl, and strongly cooperative in its presence. Thermodynamic parameters were calculated using Langmuir and Scatchard equations. (Carboxy)methyl cellulose interaction with a mixture of cationic surfactants [DTAB, DTA-chloride, TTAB, CTAB, triphenylphosphonium bromide, and tetradecylpyridinium bromide (TeP)] have been examined by tensiometry, viscosimetry, SISEs, and dynamic light scattering. The effect of varying surfactant chain length, headgroup size, counterion, and ionic strength on the CAC of mixed polymer surfactant systems and the collapse of the polymer molecule under different solution conditions were studied [138].

The interaction of CTAB and CPC with *Aspergillus niger* cellulose (ANC) has been studied using SISEs, fluorescence, and turbidimetric techniques [139, 140]. Using the Wyman binding potential model, the binding was found to be entropy-controlled. Another team [141] investigated the interaction of CTAB with α-amylase from *Bacillus subtilis* at 25°C at different pH, ionic strength, and concentrations of urea using CTAB-selective membrane electrodes. The binding isotherms obtained were also analyzed using the Wyman binding potential concept.

Chitosan, a cationic biopolymer, has a number of applications in food and pharmaceutical industries because of its unique nutritional and physicochemical properties. Many of these properties depend on its ability to interact with anionic surface-active molecules such as phospholipids, surfactants, and bile acids. Thongngam et al. [142] characterized the interaction of chitosan with SDS using ITC, SISEs, and turbidity measurements. Binding interaction was found to be highly exothermic. Another study provided information that can be used to design chitosan-based products with specific nutritional and functional characteristics, such as lowering of cholesterol [143]. SISEs, surface tension, ITC, turbidity, and zeta-potential measurements were used to study SDS binding with chitosan to obtain information on the structure of the surfactant-polyelectrolyte complexes in the bulk phase. At optimal ionic ratio, the SDS-chitosan system is suitable for the encapsulation of hydrophobic molecules [144].

Another team described the interaction of TeP^+ and DoP^+ with sodium poly(aspartate) at different molecular weights and found that with decreasing molecular weights CAC increased while the binding cooperativity decreased. Polyaspartates resemble real proteins in several respects [145].

Interaction of gelatin with surfactants has also been extensively investigated. SISEs have been used to provide information regarding the effect of surfactant on the gelling capacity of the protein. Binding isotherms of SDS to alkali-processed and acid-processed bone gelatin were determined using DS^- reversible electrodes. Results obtained were comparable to that obtained using viscosity [146]. A surfactant-selective LME comprising the carrier complex CTA^+-DS^-

in *o*-nitrotoluene was used by Fruhner et al. [147] to construct binding isotherms of gelatin interactions with alkyl sulfates and alkyltrimethylammonium ions in dilute aqueous solutions. At pH $\geq$ 7 the degree of binding was independent of pH. At pH $\leq$ 6 the extent of binding increased steeply with decreasing pH. Extent of binding also increased strongly with increasing chain length. Octyl sulfate showed low binding even at low pH. Cationic surfactants showed weaker interactions than anionic surfactants of comparable alkyl chain length. The photobehavior of pyrene in both fluid and gel states of gelatin in absence and presence of SDS and DTAB was studied [148]. SISEs were used to determine binding capacities of SDS and DTAB to gelatin in both states. Results obtained from these studies complemented with viscosity and gel strength measurements could be used to relate surfactant–gelatin interactions with macroscopic or microscopic properties of gels. Other investigators[149] studied interactions between SDS and gelatin using a wide variety of physicochemical methods such as turbidity, conductometry, surface tension, ITC, and potentiometry to better understand the bulk behavior of SDS-gelatin systems and to obtain optimal ionic ratio of these complexes for forming capsules using the coacervation process. Binding isotherms obtained using SDS selective electrodes correlated with surface tension measurements.

Maulik et al. studied binding isotherms of BSA, β-lactoglobulin, hemoglobin, gelatin, lysozyme, and deoxyribonucleic acid with both CTAB and SDS by using SISEs at different pH, ionic strength, and temperature [150]. Reversibility of binding was established by studying the association and dissociation process. Another group used SISEs to study sodium alkyl sulfate ($C_nH_{2n+1}OSO_3Na$, where n = 8,10,12) binding to human erythrocytes [151] to clarify the mechanism of shape changes induced by the anionic surfactants.

Mokus et al. [152] described the construction of a DS^- sensitive electrode with CTA^+-DS^- complex as the ionophore in a siloxane polymer membrane and used it to measure the activity of SDS in biological samples. By comparing with results obtained from equilibrium dialysis, they showed that the electrode could be used to detect both the high-affinity binding sites of human serum albumin (HSA) for SDS and to follow its cooperative binding to serum albumin, ovalbumin, and β-lactoglobulin. Binding of CTAB with HSA at various ionic strengths [153] and that of CPC with HSA at different pH were studied using SISEs and fluorescence spectroscopy. Binding isotherms were analyzed to determine the Hill parameters. Results indicated two sets of binding sites under all experimental conditions and suggested a role of hydrophobic interactions in binding [154]. The interaction of a fluorinated surfactant sodium perfluorooctanoate with HSA was studied using potentiometry and a combination of ultraviolet (UV)–circular dichroism (CD) spectroscopy [155]. Results indicated that the surfactant molecules had a high affinity for HSA and stabilized the protein structure. Aggregates formed by HSA interaction with sodium perfluorooctanoate–sodium octanoate, and sodium perfluorooctanoate–sodium dodecanoate systems were investigated by conductance, SISEs, electrophoresis, and spectroscopy measurements [156]. Interactions between a homologous series of cationic surfactants [DTAB, TTAB, hexadecyltrimethyl ammonium bromide (HTAB)] and BSA were studied using SISEs at various temperatures [157]. The method was fast and accurate and data analysis revealed two sets of binding sites. Binding of *n*-hexadecylpyridinium bromide to BSA was also studied [158].

Binding isotherms of hemoglobin interaction with TTAB and CTAB were obtained [157] using ion-selective electrodes and apparent binding constants were calculated using the Wyman binding potential model. It was found that the binding of surfactant molecules induced unfolding of hemoglobin, resulting in exposure of the heme pocket facilitating heme oxidation. The binding process was endothermic since affinity increased with temperature. CTAB binding to, oxyhemoglobin, and carbaminohemoglobin were also studied [159]. Binding of CPC with glucose oxidase was studied as a function of ionic strength, concentrations of urea, and pH using CPC-selective membrane electrodes, UV-visible absorption spectroscopy, and enzymatic activity assay method. Binding parameters revealed two sets of binding sites and were used to calculate intrinsic Gibbs free energy of binding [160].

Interaction of CTAB with large T4 DNA was studied using CTAB selective electrode combined with fluorescence microscopy. Using potentiometric techniques, the binding equilibrium was studied, while a globule-to-coil reversible transition was established using fluorescence microscopy. The cooperativity of binding was attributed to bimodality in the distribution between the elongated coil and the compact globule states of T4 DNA chains [161].

Other investigators [101] studied binding interactions of bile salts NaC, NaDC, NaCDC, NaUDC, NaDHC with BSA using bile-salt-selective electrodes. From the Scatchard plots using nonlinear least-squares fit, binding constants and the number of binding sites were estimated. The relative order of binding was NaDC $\approx$NaCDC>NaUDC $\gg$NaC >NaDHC. Estimation of thermodynamic parameters showed that bile salts bound to hydrophobic sites on BSA.

Theoretical models for potentiometric titration curves of some ionic and nonionic surfactants were proposed by Sak-Bosner et al. [162]. They estimated response parameters for a few surfactant sensors using data generated by previously described liquid membrane surfactant-sensing electrodes. The models were optimized using *Solver* (Microsoft Excel) and Wolfram Research *Mathematica v*. 7.1.

58.3.2 Kinetic Studies of Surfactant–Biopolymer Interactions Using SISEs

Interaction between surfactants and biopolymers proceed through intrinsic mechanistic stages to reach equilibrium. The mechanistic courses of a reaction can be understood by following its kinetics. Kinetic courses of such interactions have been studied by Maulik et al. [69] using SISEs. Using a CTAB-selective membrane electrode, they have followed the kinetics of binding of CTAB with sodium salt of carboxymethyl cellulose. The binding process followed a first-order kinetics and yielded three rate constants. Binding affinity increased with increasing CTAB concentration, and decreased with ionic strength. Thermodynamic parameters evaluated for activation, showed the reactions to be entropy-controlled. The same authors also studied the kinetics of interaction of CTAB with BSA [70]. Least-square curve fitting gave three rate constants of binding. Parameters of activation showed that the entropy and enthalpy of activation closely compensated each other. Kinetic interactions of CTAB with gelatin, hemoglobin β-lactoglobulin, and lysozyme were also studied [163]. Reaction occurred in three stages for the denatured protein gelatin, but in two stages for the native proteins hemoglobin, β-lactoglobulin, and lysozyme under the same conditions. In each case, reaction rates increased with temperature following the trend $k_1 \gg k_2 > k_3$. CTA^+ interactions with proteins were both electrostatic and hydrophobic. All reactions were entropy-controlled, and the phenomenon of isokinetic entropy–enthalpy (164) compensation was also observed.

The study was extended to the binding interactions of CTAB with DNA [165], which also followed first-order kinetics. Reactions occurred in three stages for native DNA and in two stages for denatured DNA. In another study, kinetic interaction of CTAB with DNA was carried out in water and in sodium chloride solution. The results can be explained in terms of a reaction mechanism involving two consecutive reversible steps. The first step corresponds to the union/separation of the surfactant with/from the DNA, and the second step corresponds to a conformational change of the surfactant-DNA complex [166]. The equilibrium constant calculated from the forward and reverse rate constants of these steps agreed with the results obtained by another team [165].

The representative values of rate constants obtained with CTAB interactions with different biopolymers are shown in Table 58.1. It may be observed that under the same conditions of ionic strength, pH, CTAB concentrations and temperature, different amounts of biopolymers were needed to obtain rate constants of similar magnitudes reflecting differences in their reaction propensities.

Very recently, Chatterjea et al. [108] developed a multiple-bile ion-sensing membrane electrode using which rate constants of binding of NaC, NaDC, and NaCDC with a biocompatible polymer polyethylene, glycol were found. Single-stage first-order reaction kinetics was observed. Preparation and use of this multiple-ion-sensing electrode is a unique development and immensely promising for the study of polymer–surfactant/biosurfactant interactions. Further work involving kinetics of bile salt interactions with other proteins and biopolymers is in progress.

TABLE 58.1 Representative Rate Constants of CTAB interactions with Different Biopolymers Determined Using CTAB-Selective SISE at [CTAB] = 50 μM dm^{-3}, pH = 5, μ = 0.05, T = 310 K

Biopolymer	k_1 (h^{-1})	k_2 (h^{-1})	k_3 (h^{-1})
Carboxymethyl cellulose (0.056% w/v)	327	46.8	18.0
Gelatin (0.08% w/v)	345	46.8	18.3
BSA (0.2% w/v)	367	47.9	12.6
Hemoglobin (0.01% w/v)	356	50.4	-
Lysozyme (0.02% w/v)	302	13.3	-
β-Lactoglobulin (0.015% w/v)	360	55	-
DNA (0.001% w/v)	414	48.9	10.8

58.4 CONCLUSION

Surfactant interactions with biopolymers is an important field of study where determination of surfactant concentration at different stages, particularly at low concentration (μM), may be required. For this purpose, among different available techniques, electrochemical methods using SISEs are potentially useful. Both liquid and solid membrane electrodes have been developed with different ionophores resulting in reversibility of a membrane towards a surfactant. The exchange of ions between solutions and the ionophore develops a potential across the membrane making them successful ion sensors. Monitoring of this membrane potential measures the activity (or concentration) of the surfactant ions which helps probe the process of interaction with polyelectrolytes, synthetic polymers, or biopolymers. Although the development of such electrodes has a long history, they are still in the process of improvement in terms of sensitivity, stability, durability, interference, detection limits, to make them feasible for multiple use that could make them commercially viable. Although different types of ISEs have been developed, reports on electrodes selective to multiple surfactant ions are rare. There has been a recent development in this direction [108], opening up the scope of developing SISEs capable of monitoring multiple ions with high selectivity and detection limit in the range in the nM range. Although there has been several reports on different ISEs detection limit in the nM range has not yet been reported for any.

An important use of SISEs apart from equilibrium studies is the investigation of kinetics of interaction, which is not which is not easily accomplishable using other methods. Although there are reports on reaction rates and associated thermodynamic parameters for a few synthetic surfactant–biopolymer systems, reports on biosurfactant/biopolymer systems are very rare.

The information gathered and discussed in this chapter should hopefully help researchers and practitioners become updated in this field, enabling them to advance the field by further development and use of SISEs.

ACKNOWLEDGMENT

S.M.C and K.P. thank the Department of Science and Technology, Government of India for financial support for this work with a Woman Scientist position to the former (Sanction Order SR/WOS-A/LS-201/2010 C). S.P.M. acknowledges with thanks the Indian National Science Academy, New Delhi for an Honorary Scientist Position, and Jadavpur University, Kolkata for an Emeritus Professorship, and infrastructural facilities.

MEMBRANE POTENTIAL AS A FUNCTION OF DIELECTRIC CONSTANT

Akihiko Tanioka and Hidetoshi Matsumoto

Department of Organic and Polymeric Materials, Tokyo Institute of Technology, Tokyo, Japan

59.1 INTRODUCTION

There has been increasing interest in analyzing the ion transport phenomena in a charged membrane in electrolyte aqueous organic solution systems [1] or low-water-content systems [2] across a charged membrane for industrial and medical applications. The measure of membrane potential is a significant method for characterizing transport phenomena across a charged membrane [3, 4]. Theoretically the membrane potential in a charged membrane–electrolyte aqueous solution system developed by Teorell, Meyer, and Sievers (TMS) [5–7] can be treated by Donnan equilibrium theory [8, 9] and the Nernst–Planck equation [10–13], if it is assumed that the fixed-charge groups are homogeneously distributed in the membrane [14] and the effect of the mean activity coefficient of electrolyte in external solution is negligible.

The ion transport phenomena across a charged membrane in an aqueous solution system have been studied by many authors [15–23]. Usually in the theoretical treatment the membrane is considered to be a gel material that is filled with enough water to allow ions and fixed-charge groups to behave as if they were in aqueous solution. On the other hand, if organic solvent is added or the membrane water content is significantly decreased, it is highly unlikely that the system is in aqueous solution. The studies and experimental data, however, available for electrolyte aqueous organic solution and low-water-content systems are limited [24, 25]; thus the transport phenomena in the systems are not very clear.

Ionic transport phenomena through a charged membrane are strongly affected by the fixed-charge groups in the membrane. All of the fixed-charge groups in the membrane do not function perfectly. The fixed-charge density of the membrane estimated by the ionic transport procedure (membrane potential method) is less than that estimated by equilibrium analysis (titration method) [22,26,27]. This phenomenon has been attributed to a decrease in the activity of fixed-charge groups in the membrane due to ion pair formation between the fixed-charge group and the counterion in the membrane [28–34].

One research team proposed a theoretical model considering the ion-pairing effect between the fixed-charge group and the counterion in the membrane [16]. According to their model, the ion-pairing effect is more significant under low-dielectric-constant conditions (e.g., a nonaqueous solution system or a low-water-content membrane system). Another team studied the ion-pairing effect in a nonaqueous solution system and revealed that theoretical predictions agreed well with the experimental results, based on the membrane potential and permeability measurements [17–20]. Another group indicated that the effect of ion-pair formation was significant in low-water-content cation exchange membranes with inhomogeneous fixed-charge distribution. They also systematically verified the ion-pairing effect in low-water-content membranes by preparing cation and anion exchange membranes with various water content levels and homogeneous fixed-charge distribution by radical copolymerization and examined the ion-pairing effect with respect to membrane potential measurements. This is the first comprehensive study

on the ion-pairing effect in low-water-content charged membranes.

59.2 THEORETICAL BACKGROUND

According to the TMS studies [5–7], the potential across a membrane separating two cells having different concentrations of aqueous solutions can be expressed by the sum of the Donnan potential between the membrane surface and the external solution, and a diffusion potential in the membrane. We will confirm that their idea is applicable to the pure organic solution or aqueous organic solution system, and the low-water-content membrane.

59.2.1 Donnan Potential

The electrochemical potentials of the ith ion in an external solution and in a charged membrane filled with solution are given by μ_i and $\bar{\mu}_i$, respectively

$$\mu_i = \mu_i^0 + RT \ln \gamma_i C_i + z_i F \phi \quad i = +, - \tag{59.1}$$

$$\bar{\mu}_i = \bar{\mu}_i^0 + RT \ln \bar{\gamma}_i \bar{C}_i + z_i F \bar{\phi} \quad i = +, - \tag{59.2}$$

where μ_i^0 and $\bar{\mu}_i^0$ are the standard electrochemical potentials, z_i is the valence of ion, R is the gas constant, T is the absolute temperature, γ_i and $\bar{\gamma}_i$ are the ion activity coefficients, C_i and $\bar{C}_i$ are the ion concentrations, F is the Faraday constant, and ϕ and $\bar{\phi}$ are the electrical potentials; the overbar denotes the values in the charged membrane. At the interface between the membrane and the external solution, the electrochemical potentials in the two phases are equilibrated:

$$\mu_i = \bar{\mu}_i \quad i = +, - \tag{59.3}$$

The Donnan potential $\Delta\phi_{\text{Don}}$ between the membrane surface and the solution is given from Eqs. (59.1)–(59.3) by

$$\Delta\phi_{\text{Don}} = \bar{\phi} - \phi = -\frac{RT}{z_i F} \ln \frac{\bar{\gamma}_i \bar{C}_i}{k_i \gamma_i C_i} \quad i = +, - \tag{59.4}$$

where k_i is the distribution coefficient of the ion i defined as

$$\bar{\mu}_i^0 - \mu_i^0 = -RT \ln k_i \quad i = +, - \tag{59.5}$$

Under the condition $z_+ = -z_-$, the relationship between the concentrations of ions in the membrane and in external solution can be obtained

$$\bar{C}_+ \bar{C}_- = \frac{\gamma_\pm^2 C_s^2}{Q^2} \tag{59.6}$$

where C_s is the electrolyte concentration in external solution equated as $(C_+ C_-)^{1/2}$, $\gamma_\pm$ is the mean activity coefficient of electrolyte equated as $(\gamma_+ \gamma_-)^{1/2}$, and Q is defined by

$$Q = \left(\frac{\bar{\gamma}_+ \bar{\gamma}_-}{k_+ k_-} \right)^{1/2} \tag{59.7}$$

On the other hand, the condition of electroneutrality in the membrane is given by

$$\sum_{i=+,-} z_i \bar{C}_i + z_x C_x = 0 \tag{59.8}$$

where z_x is the valence of fixed charge groups, and C_x is the fixed-charge density. Inserting Eq. (59.6) into Eq. (59.8) and solving a quadratic equation, we can express the concentrations of ions in membrane as follows:

$$\bar{C}_+ = \sqrt{\left(\frac{z_x C_x}{2 z_+} \right)^2 + \left(\frac{\gamma_\pm C_s}{Q} \right)^2} - \frac{z_x C_x}{2 z_+} \tag{59.9}$$

$$\bar{C}_- = \sqrt{\left(\frac{z_x C_x}{2 z_+} \right)^2 + \left(\frac{\gamma_+ C_s}{Q} \right)^2} + \frac{z_x C_x}{2 z_+} \tag{59.10}$$

The most important point in Eqs. (59.9) and (59.10) is that the mean activity coefficient of electrolyte in external solution $\gamma_\pm$ is multiplied by the electrolyte concentration C_s. The effect of mean activity coefficient of electrolyte is usually neglected in solution. The Donnan potential on the left- and right-hand sides of the interface between the membrane and the surrounding solution are given by inserting Eq. (59.9) into Eq. (59.4). If it is assumed that the activity coefficients of ions are not a function of the ion concentrations in the membrane [14], the total Donnan potential through the membrane can be expressed by the sum of the Donnan potentials at the left- and right-hand sides for an aqueous organic solution system cited above

$$\Delta\phi_{\text{Don}(1\to\text{r})} = -\frac{RT}{z_+ F} \ln \left[\frac{\gamma_+'' C_s'' \bar{C}_+'}{\gamma_+' C_s' \bar{C}_+''} \right] \tag{59.11a}$$

where C_s' and C_s'' are the concentrations of the solution in left- and right-hand sides and $\bar{C}_+'$ and $\bar{C}_+''$ are the cation concentrations at the left- and right-hand sides of the charged membrane, which are given by Eq. (59.9). The value of γ_+''/γ_+' cannot be obtained individually, thus we approach it by $\gamma_\pm''/\gamma_\pm'$ and will not make obvious errors. Therefore Eq. (59.11a) becomes

$$\Delta\phi_{\text{Don}(1\to\text{r})} = -\frac{RT}{z_+ F} \ln \left[\frac{\gamma_\pm'' C_s'' \bar{C}_+'}{\gamma_\pm' C_s' \bar{C}_+''} \right] \tag{59.11b}$$

59.2.2 Membrane Diffusion Potential

The ionic flux across the membrane is given by the Nernst–Planck equation, which can be applied to the phase of the membrane

$$J_i = -\bar{\omega}_i RT \frac{d\bar{C}_i}{dx} - z_i F \bar{\omega}_i \bar{C}_i \frac{d\bar{\phi}}{dx} \quad i = +, - \tag{59.12}$$

where $\bar{\omega}_i$ is the ionic mobility of the ion i in the membrane. The electroneutrality condition in a membrane requires that

$$J_+(x) = J_-(x) \tag{59.13}$$

By differentiating Eq.(59.8), we can obtain

$$\frac{d\bar{C}_+}{dx} = \frac{d\bar{C}_-}{dx} \tag{59.14}$$

Inserting Eqs. (59.12) and (59.14) into Eq. (59.13), we can express the diffusion potential $\Delta\phi_{\text{diff}}$ as

$$\Delta\phi_{\text{diff}} = \bar{\phi}'' - \bar{\phi}' = -\frac{RT}{z_+ F}\frac{r-1}{r+1}\ln\left[\frac{(r+1)\,\bar{C}''_+ + \dfrac{z_x}{z_+}C_x}{(r+1)\,\bar{C}'_+ + \dfrac{z_x}{z_+}C_x}\right] \tag{59.15}$$

where r is the cation-to-anion mobility ratio in the membrane defined by

$$r = \frac{\bar{\omega}_+}{\bar{\omega}_-} \tag{59.16}$$

where $\bar{\omega}_+$ and $\bar{\omega}_-$ are the cation and anion mobilities in the membrane, respectively.

59.2.3 Mean Activity Coefficient in Mixed Solvent–Salt Systems [38–45]

The mean activity coefficient of electrolyte in external aqueous organic solution can be predicted by combining the Tan's modified Wilson model though it is convenient one, the vapor pressure model of electrolyte solutions and the Gibbs–Duhem equation. In previous papers, this observation has not been considered. Therefore the error resulting from this treatment has always been included in calculation of the effective charge density. The model calculation presented in this section should reduce such an error. According to our work, the ionic mean activity coefficient $\gamma_\pm$ in a ternary system (containing two solvents and one salt) at constant temperature and pressure is given by the following equation:

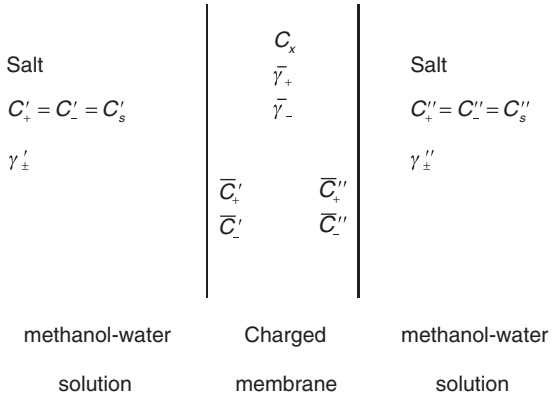

FIGURE 59.1 Solution system studied in this chapter.

$$\ln\left(\gamma_\pm\right)\Big|_{m=m} = \int_{m=0}^{m=m} \frac{1}{m}\mathrm{d}\left\{m\left[\alpha\bar{\phi}_1 + (1-\alpha)\,\bar{\phi}_2 - 1\right]\right\} \tag{59.17}$$

Here, m is the molality of the solution, $\bar{\phi}_n$ is the partial osmotic coefficient for solvent n, and α is a constant.

59.2.4 Membrane Potential

The membrane potential $\Delta\phi$ is the sum of the Donnan and the membrane diffusion potentials, which are given by Eqs. (59.11b) and (59.15), respectively

$$\Delta\phi = \Delta\phi_{\text{Don}(1\to\text{r})} + \Delta\phi_{\text{diff}} \tag{59.18}$$

The solution system of this work is shown in Fig. 59.1, and Eq. (59.18) will be applied to calculation the membrane potential in this kind of system.

59.2.5 Effective Membrane Charge Density

Ion-pairing theories have been studied by some authors [46, 47]. To explicitly evaluate the interaction of ion pairs between the counterion and fixed-charge group in the membrane phase, we have used a very simple model that is based on the Fuoss approach to ion pairing in electrolyte solutions [47, 48] as shown in Fig. 59.2. The theoretical basis of the Fuoss approach to ion pairing is the linear Poisson–Boltzmann equation. Linearization of the Boltzmann factor might not be justified when the electrostatic potential energy is greater than kT. However, it is likely that the screened Coulomb potential may be used in this case over a range of concentrations greater than that for which the linearization of the Poisson–Boltzmann equation can be justified [35]. We have resorted to this approach because of its simplicity. Some

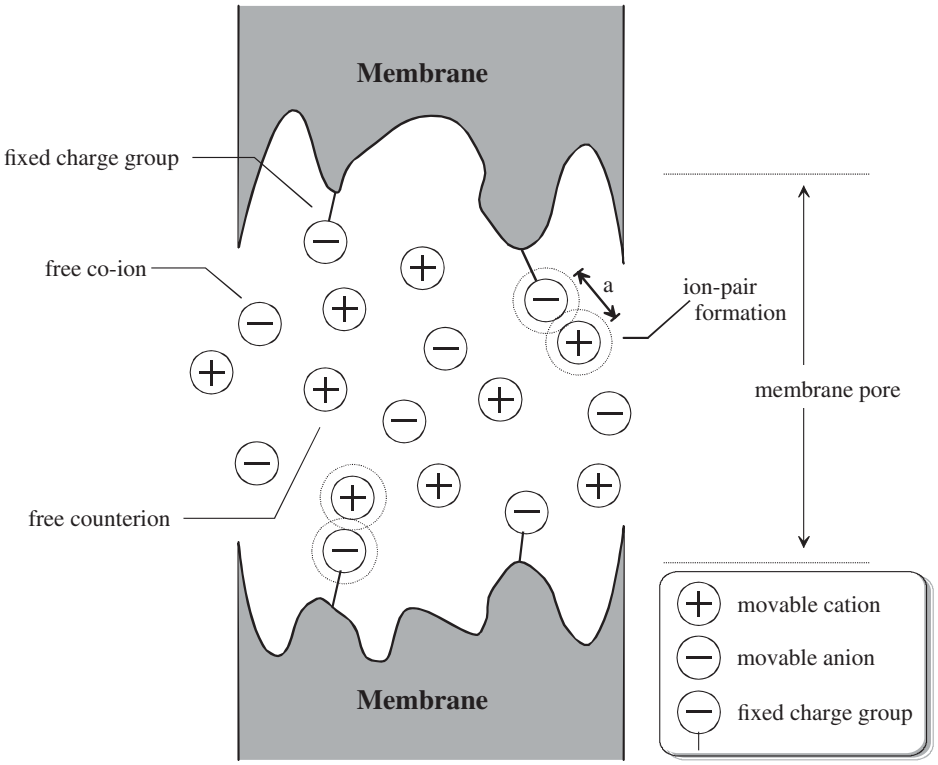

FIGURE 59.2 Simplified view of ion pairing in a negatively charged membrane.

of the assumptions introduced by Fuoss may also be questionable, since in our case, one of the ions in the ion pair is fixed [49]. The deviation which is caused by this problem can be compensated by the regressing process of two parameters in the new model. Application of the Fuoss formalism to the ion pair in a membrane would lead to the association constant [47,48]

$$K_A = \frac{4\pi N_A}{3 \times 10^{-3}} a^3 \exp(b) \tag{59.19}$$

$$b = \frac{e^2}{4\pi\varepsilon_0\varepsilon_s akT} \tag{59.20}$$

where N_A is Avogadro's number, e is the electronic charge, ε_s is the dielectric constant of the solvent, ε_0 is the vacuum permittivity, k is the Boltzmann constant, and a is the contact distance. If the interaction by which the immobilized reactant is formed proceeds very rapidly compared with the diffusion process, a local equilibrium can be assumed to exist between the free and immobilized components of the diffusing substance. As the first approximation, it is assumed that the rate of immobilization is proportional to the concentration of nonimmobilized position and association constant and that the rate of separation is proportional to the concentration of immobilized components. Therefore, according to these assumptions, the relationship between the effective membrane charge density QC_x and the association constant K_A is derived as follows

$$QC_x = \frac{1}{k'K_A + 1} C_x \tag{59.21}$$

where k' is a constant that indicates the effect of the association constant on the membrane charge density. Clearly the effect of the ion pairing will decrease the effective membrane charge density. In the limited case, K_A will tend to infinity if the ion pair strongly associates together, and then QC_x will become zero. On the other hand, K_A will tend to zero if the ion pair interaction is very weak, and QC_x will become C_x. The dielectric constant of a mixed solvent can be estimated from Oster's mixing rule [50]

$$\varepsilon_s = \varepsilon_1 + [(\varepsilon_2 - 1)(2\varepsilon_2 + 1)/2\varepsilon_2 - (\varepsilon_1 - 1)]x_2V_2/V \tag{59.22}$$

where ε_1 and ε_2 are the dielectric constants of solvents 1 and 2, respectively, and V is the partial molar volume of a mixed solvent that can be simply estimated by

$$V = x_1V_1 + x_2V_2 \tag{59.23}$$

where V_1 and V_2 are the partial molar volume of solvents 1 and 2, respectively. Inserting Eqs. (59.19) and (59.20) into

Eq. (59.21), and applying Eqs. (59.22) and (59.23), we can obtain the theoretical formalism for estimating QC_x as follows

$$QC_x = \frac{C_x}{\frac{4\pi N_A}{3\times 10^{-3}} k' a^3 \exp\left\{\frac{e^2}{4\pi\varepsilon_0 akT\left\{\varepsilon_1 + \Delta\varepsilon x_2' V_2/V\right\}}\right\} + 1} \tag{59.24}$$

where

$$\Delta\varepsilon = (\varepsilon_2 - 1)(2\varepsilon_2 + 1)/2\varepsilon_2 - (\varepsilon_1 - 1) \tag{59.25}$$

59.2.6 Permeability Coefficient

The ionic flux across the membrane J_i can be obtained by the Nernst–Planck equation, which can be applied to the phase of the membrane without considering the associated effect of ions in the external solution as shown in Eq. (59.12). Also the electroneutrality condition in a membrane is required as shown in Eqs. (59.8) and (59.13). By inserting Eqs. (59.12) and (59.14) into Eq. (59.13), we can obtain the term of $d\bar{\phi}/dx$ in Eq. (59.12) as follows:

$$\frac{d\bar{\phi}}{dx} = -\frac{RT}{z_+ F}\frac{\bar{\omega}_+ - \bar{\omega}_-}{\bar{\omega}_+\bar{C}_+ + \bar{\omega}_-\bar{C}_-}\frac{d\bar{C}_+}{dx} \tag{59.26}$$

Finally, the electrolyte flux across the membrane J can be estimated by inserting Eq. (59.26) into Eq. (59.12)

$$J = J_+ = -\frac{\bar{\omega}_+ RTC_x}{(r+1)\,d} \times\left[\frac{2}{C_x}\left(\bar{C}_+'' - \bar{C}_+'\right) + \frac{r-1}{r+1}\frac{z_x}{z_+}\ln\frac{(r+1)\,\bar{C}_+'' + \frac{z_x}{z_+}C_x}{(r+1)\,\bar{C}_+' + \frac{z_x}{z_+}C_x}\right] \tag{59.27}$$

where d is the thickness of the membrane, r is the cation-to-anion mobility ratio in the membrane, and $\bar{C}_+'$ and $\bar{C}_+''$ are the cation concentrations on the left- and right-hand sides of the charged membrane, respectively, which are as given in Eq. (59.9) [38]:

$$\bar{C}_+ = \sqrt{\left(\frac{z_x C_x}{2z_+}\right)^2 + \left(\frac{\gamma_\pm C_s}{Q}\right)^2} - \frac{z_x C_x}{2z_+} \tag{59.28}$$

Here, $\gamma_\pm$ is the mean activity coefficient of the electrolyte in an external solution and can be calculated by application of certain theories [41,43,45]. The nonideality caused by the associating effect of ions in organic solution systems can be estimated by the mean activity coefficient of the electrolyte. The same method has been adopted to calculate the vapor pressure and the mean ionic activity coefficient in organic solution systems by some authors [51–53]. The permeability coefficient P can be easily obtained by the original definition

$$P = -\frac{J}{C_s'' - C_s'} \tag{59.29}$$

where C_s' and C_s'' are the concentrations of the solution on the left- and right-hand sides, respectively.

59.2.7 Mobility of Ions in a Membrane

If the interaction by which the immobilized reactant is formed proceeds very rapidly compared with the diffusion process, a local equilibrium can be assumed to exist between the free and immobilized components of the diffusing substance. As the first approximation, the concentration of immobilized substance C_{im} is directly proportional to the concentration of a substance free to diffuse C_f:

$$C_{\text{im}} = RC_f \tag{59.30}$$

According to the diffusion theory with chemical reaction, the relationship between the apparent diffusion constant D_a and the actual diffusion constant D' can be expressed as follows [54–56]

$$D_a = \frac{1}{R+1}D' \tag{59.31}$$

where R has a similar physical meaning with the association constant K_A of ion pairing in the membrane phase if the reactant corresponds to the fixed-charge group [57–63]. Therefore, the following relationship can be obtained between R and K_A

$$R = \beta K_A \tag{59.32}$$

where β is a constant that indicates the effect of the association constant on the mobility of the counterion in the membrane. Taking into account Eq. (59.31), the relationship between the counterion mobility in the membrane $\bar{\omega}_{\text{counterion}}$ and the association constant K_A is

$$\bar{\omega}_{\text{counterion}} = \frac{1}{\beta K_A + 1}\frac{\omega_{\text{counterion}}}{q^2} \tag{59.33}$$

where θ is the tortuosity factor [64, 65] and $\omega_{\text{counterion}}$ is the mobility of a counterion in an external solution. Clearly the effect of the ion pairing is to decelerate the mobility of the counterion. In the limited case, K_A will tend to infinity if the ion pair strongly associates together, and then $\bar{\omega}_{\text{counterion}}$ will become zero. On the other hand, K_A will tend to zero if the ion pair interaction is very weak, and $\bar{\omega}_{\text{counterion}}$ will become

$\omega_{\text{counterion}}/q^2$ as the behavior appearing in the charged gel membrane [65]. If it is assumed that $\omega_{\text{counterion}}$ in a mixed solvent linearly changes with the consistency of the pure solvent, then the mobility of the counterion in an external solution can be estimated by

$$\omega_{\text{counterion}} = \omega_{\text{counterion},1}x_1 + \omega_{\text{counterion},2}x_2 \qquad (59.34)$$

where x_1 and x_1 are the salt-free mole fractions of solvents 1 and 2, respectively. Inserting Eqs. (59.19), (59.20), and (59.34) into Eq. (59.33), and applying the relationships of Eqs. (59.22) and (59.23), we can obtain the theoretical formalism for estimating $\bar{\omega}_{\text{counterion}}$ as follows:

$$\bar{\omega}_{\text{counterion}} = \frac{(\omega_{\text{counterion},1}x_1 + \omega_{\text{counterion},2}x_2)/q^2}{\dfrac{4\pi N_A}{3\times 10^{-3}}\beta a^3 \exp\left\{\dfrac{e^2}{4\pi\varepsilon_0 akT\{\varepsilon_1 + \Delta\varepsilon x_2 V_2/V\}}\right\} + 1} \qquad (59.35)$$

The mobility of coion in a membrane $\bar{\omega}_{\text{co-ion}}$ can then be obtained from Eq. (59.16).

59.3 MATERIALS AND EXPERIMENTAL PROCEDURES

59.3.1 Materials

59.3.1.1 Commercial Ion Exchange Membrane for Organic Solution System. A cation exchange membrane (K171, Asahi Chemicals), which is composed of poly(divinylbenzene-*co*-styrene) containing sulfonic acid groups, and an anion-exchange membrane (A201, Asahi Chemicals), which is composed of poly(butadiene-*co*-styrene) containing quaternary amine groups in a polymer matrix, were used for the measurements. The thickness, water content, and ion exchange capacity of these membranes are given in Table 59.1. Before measurements were carried out, both membranes were immersed in 3 mol/L LiCl for 3 days to ensure that counterions were exchanged for the same species. After both membranes were thoroughly washed with ion-exchanged water, they were immersed in ion-exchanged water for 3 days to remove the excess ions in the membrane matrix [23].

TABLE 59.1 Physicochemical Properties of Ion Exchange Membranes

Membrane	Thickness (mm)	Water content (wt%)	Ion exchange capacity (mol/L)
K171	0.11–0.13	20–23	5.5–5.8
A201	0.22–0.24	26–27	3.9–4.4

59.3.1.2 Prepared Ion Exchange Membranes for Low-Water-Content System. Three kinds of cation exchange membranes (CEMs) with different water contents, composed of poly(styrene-*co*-divinylbenzene) [poly(St-*co*-DVB)] containing sulfonic acid groups, and three kinds of anion exchange membranes (AEMs) with different water contents, composed of poly(styrene-*co*-4-vinylpyridine-*co*-divinylbenzene) [poly(St-*co*-4VP-*co*-DVB)] containing quaternary pyridinium groups were prepared by radical copolymerization [66–68]. The PE porous membranes were used as reinforcement for the charged membranes. The PE membranes (area = 4 × 4 cm^2) were soaked in MeOH for 24 h and vacuum-dried at room temperature. They were immersed in the monomer solutions, which were composed of St, DVB, and polymerization initiator (*t*-butylperoxy-2-ethylhexanoate) for CEMs, and St, 4VP, DVB, and the initiator for AEMs, under reduced pressure. The membranes containing monomer solution were placed between two polyethylene terephthalate (PET) films and heated in a hot press at 70°C for 32 h to form the base membranes. The poly(St-*co*-DVB) membranes were soaked in NMP for 30 min at room temperature and then sulfonated with 95% H_2SO_4. The poly(St-*co*-4VP-*co*-DVB) membranes were quaternized with 40 wt% CH_3I/*n*-hexane solution shielded from light at 40°C for 20 h. The prepared membranes were washed thoroughly with MeOH and deionized water.

The physicochemical properties of the prepared membranes are summarized in Table 59.2. Aciplex K501/A501 (Asahi Kasei Corporation, Japan), commercial hydrocarbon ion exchange membranes, were used for comparison. We succeeded in preparing charged membranes with various water content levels by radical copolymerization, particularly low-water-content charged membranes, whose water contents are <10 wt%.

59.3.2 Potentiometric Titration and Measurement of Equilibrium Water Content

The potentiometric titration was performed with an automatic titrator (DMS Titrino 716, Metrohm, Switzerland) as previously described [66, 67]. A combined pH glass electrode (#6.0218.010, Metrohm, Switzerland) and a combined Ag electrode (#6.0450.100, Metrohm, Switzerland) were used for the titration of CEMs and AEMs, respectively. Two pieces of CEMs and AEMs (each membrane area was 4×4 cm^2) were immersed in 2 mol/L HCl and 2 mol/L KCl for 12 h in order to convert the counterion to the H^+ and Cl^- form, respectively. They were then washed sufficiently with deionized water. Thereafter, the CEMs were immersed in 50 mL of 2 mol/L KCl with stirring under N_2 gas flow for 1 h, and the AEMs were immersed in 50 mL of 2 mol/L $NaNO_3$ with stirring for 1 h. These treatments were repeated 4 times in order to elute H^+ or Cl^- thoroughly from the membranes, and all eluents were collected. The collected solutions were titrated with 0.1 mol/L KOH and 0.1 mol/L $AgNO_3$, respectively. The titers of KOH and $AgNO_3$ correspond to the amount of fixed-charge groups in the CEM and AEM, respectively, N_X (mol). The weight of the equilibrium swollen membrane w_{wet} (g), was measured after carefully removing the surface water with filter paper; and the weight of dried membrane w_{dry} (g) was measured after vacuum drying at 100°C for 6 h. The equilibrium water content of the membranes w_w (%) is given by

$$w_w = \frac{w_{wet} - w_{dry}}{w_{wet}} \times 100 \tag{59.36}$$

The ion exchange capacity IEC (mol/g-dry membrane), and the fixed-charge density C_X(mol/L) are determined by the following equations

$$IEC = \frac{N_X}{w_{dry}} \tag{59.37}$$

$$C_X = \frac{\rho N_X}{w_{wet} - w_{dry}} \tag{59.38}$$

where ρ is density of water at 25°C ($=0.99704 \times 10^3$ g/L). All measurements were carried out at 25±1°C.

59.3.3 Membrane Potential Measurements

The membrane potentials of both membranes used in this study were measured to obtain the effective membrane charge densities and the cation-to-anion mobility ratios in the membrane. A charged membrane was installed at the center of the measuring cell, which had two glass containers, one on either side of the membrane. The volume of each container was 200 cm^3, and the membrane area was 7.55 cm^2. Electrolyte solutions of different concentrations were poured into these containers; the concentration in the left container was varied from 0.001 to 4.0 mol/L, and that in the right one was kept constant at 0.001 mol/L. The weight fractions of methanol in mixed solvents were 0%, 20%, 50%, 80%, and 100%. An electrometer (TOA HM-20E) connected to glass electrodes (TOA HS-205C) was used for measurement of the electrical potential. Two glass electrodes were placed in saturated KCl solutions that were connected to the containers by salt bridges. The solutions in both containers were stirred by magnetic stirrers to minimize the effect of the boundary layers on the membrane potential.

59.3.4 Measurement of Modified Degree of Hydration

The modified degree of hydration H, similarly defined as the degree of hydration presented by other authors [18,65], was the volume fraction of the mixed solvent in a wet membrane. It could be estimated from the following equation

$$H = \frac{(W_w - W_d)/\rho_s}{(W_w - W_d)/\rho_s + W_d/\rho_m} \tag{59.39}$$

where W_w and W_d are the weights of a membrane at the equilibrium wet and dry states, respectively, and ρ_s and ρ_m are the densities of the mixed solvent and membrane, respectively. For simplicity, the density of the mixed solvent was calculated using the following empirical equation

$$\rho_s = \frac{1}{\sum_n x'_n/\rho_n} \tag{59.40}$$

where x'_n and ρ_n are the salt-free weight fraction and density of solvent n, respectively.

59.3.5 Measurement of Permeability Coefficient

The permeability coefficients of both membranes used in this study were measured to obtain the mobilities of ions in the membrane. A charged membrane was installed at the center of the measuring cell, which had two glass containers, one on either side of the membrane. The volume of each container was 200 cm^3, and the membrane area was 7.55 cm^2. Electrolyte solutions of different concentrations were poured into these containers; the concentration in the left container was varied from 0.01 to 2.0 mol/L, and the container on the right side was filled with the non-electrolyte-containing solvent. The data were measured by using a digital conductivity meter (TOA CM-20E) connected to a conductivity cell (TOA CG-511B). The solutions in both containers were stirred by magnetic stirrers to minimize the effect of the boundary layers on the flux of ions. The permeability coefficient P was

estimated from the ion concentration change with time on the right-hand side using the following equation

$$P = -\frac{V\Delta C_s'}{\left(C_s'' - C_s'\right) SH\Delta t} \tag{59.41}$$

where V is the volume of the right container, $\Delta C_s'$ is the ion concentration change on the right side at time interval Δt, and S is the membrane area. If the value of C_s' were kept smaller than $0.01C_s''$ at time interval Δt, then the value of $C_s'' - C_s'$ could be adopted as C_s'' without leading to any obvious errors.

59.4 RESULTS AND DISCUSSION

59.4.1 Organic Solution System

The results for the membrane potentials of K171 and A201 are shown in Figs. 59.3 and 59.4, respectively, where the theoretical results for the LiCl methanol–water solutions are shown as lines, and the experimental data agree well with the calculated results. For the cation exchange membrane, the membrane potential experiences a maximum as the electrolyte concentration increases, and the maximum of membrane potential decreases with increase in the weight fraction of methanol. On the other hand, for the anion exchange membrane, the membrane potential undergoes a minimum as the electrolyte concentration increases, and the minimum of membrane potential increases with increase in the weight fraction of methanol.

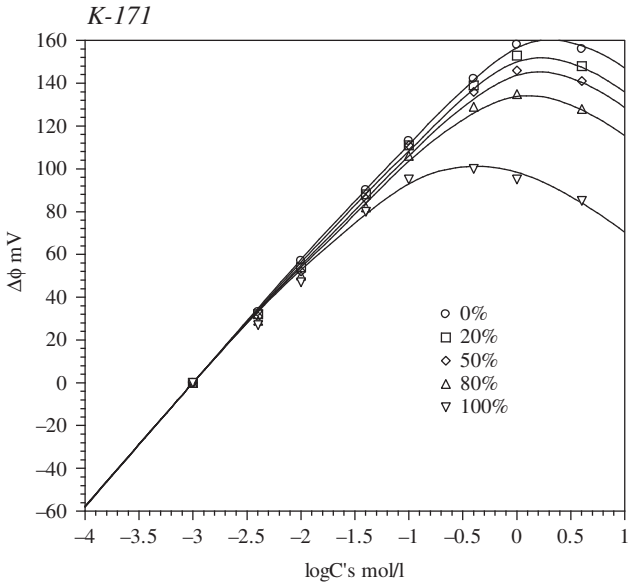

FIGURE 59.3 Membrane potential of cation exchange membrane for various weight fractions of methanol from 0% to 100%. Solid lines represent the theoretical results obtained by fitting the experimental data to Eq. (59.18).

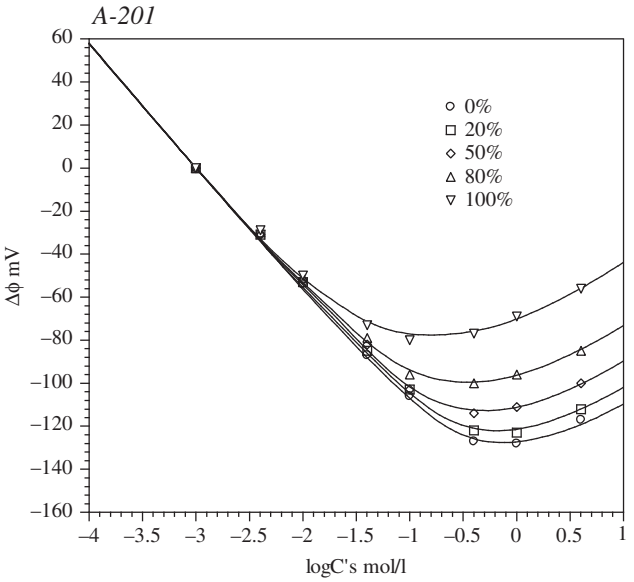

FIGURE 59.4 Membrane potential of anion exchange membrane for various weight fractions of methanol from 0% to 100%. Solid lines represent the theoretical results obtained by fitting the experimental data to Eq. (59.18).

The effective membrane charge density QC_x and the cation-to-anion mobility ratio in the membrane r can be estimated by fitting the experimental data to the transport theory based on the Donnan equilibrium and the Nernst–Planck equation considering the effect of the mean activity coefficient of electrolyte in external solution. A nonlinear parameter estimation program UNCMIN [69] is used to fit the experimental data. In the process of estimation, C_s' and C_s'' are the experimental results QC_x and r are the unknown parameters. The values of QC_x and r in various weight fractions of methanol solutions are given in Table 59.3. The calculated results of Q in various weight fractions of methanol are shown in Fig. 59.5. The solid lines in Fig. 59.5 represent the theoretical results obtained by fitting the effective membrane charge density to Eq. (59.24). This can well describe the

variation tendency of the effective membrane charge density with the weight fraction of methanol. The parameters a and k' obtained by fitting to Eq. (59.24) are listed in Table 59.4. From Fig. 59.5, it can be found that the effective membrane charge density decreases with the increase in weight fraction of methanol. It is assumed that most of the fixed-charge groups are occupied by the counterion due to the formation of the ion pairs, and the effect will decrease the amount of the effective fixed-charge groups. This is one reason why the effective membrane charge density decreases with the increase of the weight fraction of methanol.

It is shown in Eq. (59.18) that the ion mobility ratio in membranes have a greater influence on the membrane diffusion potential than on the Donnan potential. In general, the ion mobility ratio is kept constant when the solute and the fixed-charge groups in the membrane are both strong electrolytes, even if their signs change from negative to positive. On the other hand, if the fixed-charge group is the weak electrolyte and the solute is a strong one, a large shift in the ion mobility ratio is observed, as has been reported previously [23,70]. It is very important to clarify which ionic mobility, that of the counterion or of the coion, is more variable.

	$a \times 10^{10}$m	$k' \times 10^{-6}$
Cation exchange membrane	5.3	0.58
Anion exchange membrane	6.6	1.7

It is generally known that charged groups in the membrane have a greater influence on the counterion than on the coion [14]. The ion mobility ratios of LiCl in pure water and pure methanol are 0.507 and 0.757, respectively. From Table 59.3, we can find that the values of the ion mobility ratio in cation exchange membranes are smaller than those in pure water or pure methanol, and are larger in anion exchange membrane. The results are the same as those obtained by other authors [16,19,23]. The ionic mobility will be discussed further with respect to the data obtained by electrolyte permeation measurements.

The results for the permeability coefficients of K171 and A201 are shown in Figs. 59.6 and 59.7, respectively, where the theoretical results for the LiCl methanol–water solutions calculated by Eqs. (59.27) and (59.29) are shown as lines, and the experimental data were in good agreement with the calculated results. In both membranes, the permeability coefficient slightly increases with the concentration on the left side in the low-concentration range. When the concentration on the left side is around that of the effective membrane charge density, a sharp increase in the permeability coefficient appears. After that, with the increase in concentration on the left side, the increasing rate of the permeability coefficient decelerates again and finally reaches a maximum. From Figs. 59.6 and 59.7, it can be found that the maximum of the permeability coefficient will decrease as the weight fraction of methanol increases.

The mobility of a cation in a membrane $\bar{\omega}_+$ can be estimated by fitting the experimental data of the permeability coefficient to Eqs. (59.27) and (59.29). A nonlinear parameter

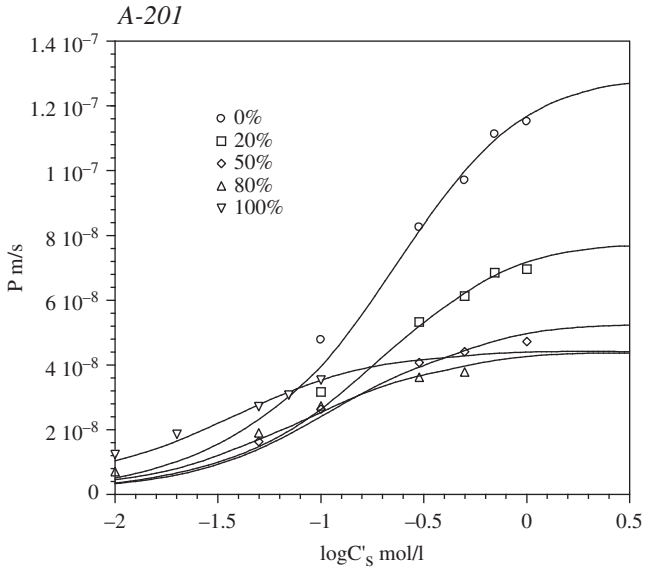

FIGURE 59.7 Permeability coefficient of anion exchange membrane for various weight fractions of methanol from 0% to 100%. Solid lines represent the theoretical results obtained by fitting the experimental data to Eqs. (59.27) and (59.29).

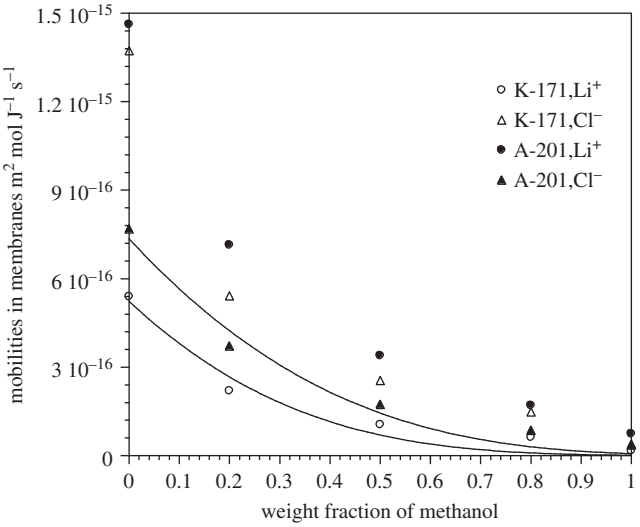

FIGURE 59.8 Mobility of ions in cation exchange and anion exchange membranes with various weight fractions of methanol. Solid lines represent the theoretical results obtained by fitting the data to Eq. (59.35).

estimation program (UNCMIN [69]) is used to fit the experimental data. In the estimation process, C_s' and C_s'' are the experimental results, while the effective membrane charge density and the cation-to-anion mobility ratio are obtained from a previous paper [24] and are listed in Table 59.2, and $\bar{\omega}_+$ is the unknown parameter. The mobility of the anion in a membrane $\bar{\omega}_-$ can be calculated by Eq. (59.16). The calculated results of $\bar{\omega}_+$ and $\bar{\omega}_-$ in various weight fractions of methanol are shown in Fig. 59.8. The solid lines in Fig. 59.8 are the theoretical results obtained by fitting the mobilities of the counterion in a membrane to Eq. (59.35) using the nonlinear parameter estimation program UNCMIN [53]. This can accurately describe the variation tendency of mobility of a counterion in a membrane with the weight fraction of methanol. According to one definition [64], the tortuosity factor θ can be expressed by

$$q = \frac{2 - H}{H} \tag{59.42}$$

In the case of a commercial ion exchange membrane, the modified degree of hydration H is approximately 0.2–0.4, which corresponds to a q value of 9–4. For simplicity, we fixed the tortuosity factor at $q = 5$, for the general charged membranes without causing any obvious errors, and the parameters a and β obtained by fitting to Eq. (59.35) are listed in Table 59.5. From Fig. 59.8, it can be found that the mobilities of a counterion in a membrane are smaller than those of a coion in a membrane, and that the mobilities of a counterion in a membrane are smaller than their corresponding values in a mixed solvent. It is assumed that most of the counterions are adsorbed by the fixed-charge groups, and the entrapped counterions have difficulty in moving to the adjoining sites. This is one reason why the mobilities of counterions are very low. One team also suggested [35] that the mobility of a coion in a membrane is the same as that in pure solvent, and that the mobility of a counterion in a membrane is a function of the fixed-charge groups in the membrane for a very low-water-content membrane system. The equations by that team [35] are modified and adapted to the systems in this study as follows:

$$\frac{\bar{\omega}_{\text{co-ion}}}{\omega_{\text{co-ion}}} = \alpha \tag{59.43}$$

$$\frac{\bar{\omega}_{\text{counterion}}}{\omega_{\text{counterion}}} = \alpha \frac{\bar{C}_{\text{co-ion}} + \phi C_x}{\bar{C}_{\text{co-ion}} + C_x} \tag{59.44}$$

Here, α is a parameter for reducing the effect that results from the difference of the structure, and ϕ is a parameter that is a function of the ion concentration. The ratios of ionic mobility for both membranes, which is the in membrane-to-mixed solvent ratio, $\bar{\omega}_i/\omega_i$, are shown in Table 59.6. Because $\phi < 1$ in

Solvent	$\bar{\omega}_+/\omega_+ \times 10^3$	$\bar{\omega}_-/\omega_- \times 10^3$	$\bar{\omega}_+/\omega_+ \times 10^3$	$\bar{\omega}_-/\omega_- \times 10^3$
Water[a]	1.3	1.7	3.5	0.94
Methanol[b]	0.040	0.069	0.17	0.065

[a]In water: $\omega_{Li^+} = 4.154 \times 10^{-13}$ m^2 mol J^{-1} s^{-1} and $\omega_{Cl^-} = 8.201 \times 10^{-13}$ m^2 mol J^{-1} s^{-1}.
[b]In methanol: $\omega_{Li^+} = 4.254 \times 10^{-13}$ m^2 mol J^{-1} s^{-1} and $\omega_{Cl^-} = 5.618 \times 10^{-13}$ m^2 mol J^{-1} s^{-1}.

all regions of the ion concentration, the ratio of $\bar{\omega}_i/\omega_i$ for the coion will be larger than that for the counterion. The results in Table 59.3 agreed with this conclusion. From Table 59.6, it can also be found that the ratio of $\bar{\omega}_i/\omega_i$ in methanol is much smaller than that in water in both membranes of K171 and A201 (see also Table 59.6). One reason is that the counterions tend to form ion pairs with the fixed-charge groups in a mixed-solvent system since the dielectric constant of methanol is smaller than in water. Thus the ion pairs between counterions and fixed-charge groups will increase with the increase in methanol concentration, and the mobilities of the counterion will decrease.

59.4.2 Low-Water-Content System

59.4.2.1 Membrane Potential. A theoretical prediction of membrane potentials was performed on the basis of our theoretical model (details of calculation are described in the Section 59.2). Before the calculation of membrane potentials, we estimated (1) the partition coefficients of ions between the membrane phase and the external electrolyte solution phase and (2) the diffusion coefficient of ions in the membranes. The partition coefficients of the ions could not be obtained experimentally; therefore, we adapted Ferry's statistical calculation of partition coefficients k_i, based on the assumptions that (1) the solutes are spherical and the pores are cylindrical and (2) the interaction between the membrane matrix and a solute molecule is negligible [71]:

$$k_i = (1 - r_i/r_{pore})^2 \tag{59.45}$$

Here, r_i is the ionic radius of the ith species (we used the crystallographic radius in Table 59.7 [72] as the ionic radius) and r_{pore} is the pore radius of the membrane, and we estimated the pore radius of the membrane by water permeability measurements using the Hagen–Poiseuille equation (actually the prepared membranes appear to have a dense structure; however, another author adapted this treatment for fine-pore synthetic membranes and estimated the mean pore radii within several nm [73]):

$$J_v = \frac{\theta r_{pore}^2}{8\eta\tau}\frac{\Delta P}{\Delta x} \tag{59.46}$$

Here, J_v is the flux of water, η is the viscosity of water, ΔP is the pressure difference, Δx is the membrane thickness, θ is the porosity of the membrane [θ = (*water volume*)/(*membrane volume*)], and τ is the tortuosity factor of the membrane [$\tau = (2 - \theta)/\theta$ [64]]. The mean pore radius and the partition coefficient of the membranes are listed in Table 59.8. The diffusion coefficient of ions in the membranes was given by

$$\bar{D}_{\text{im}} = \frac{D_i}{\tau^2} \tag{59.47}$$

where $\bar{D}_{\text{im}}$ and D_i represent the diffusion coefficient of the ith species in the membrane and that in the solution [74], respectively. The diffusion coefficients in the membranes are summarized in Table 59.9.

The theoretical calculations of membrane potentials were fitted to the experimental data. Here, the dielectric constant in the membrane ε_r and the center-to-center distance of ion pair a are the fitting parameters with the following conditions

$$2 < \varepsilon_r < 78 \tag{59.48}$$

$$r_c^c < a < r_h^c + r_h^f \tag{59.49}$$

where r_c^c, r_h^c, and r_h^f are the crystallographic radius of the counterion, hydrated radius of the counterion, and hydrated radius of the fixed-charge group, respectively. The values of

the dielectric constants, 2 and 78, correspond to that of the bulk polymer of the membrane matrix, poly(St-*co*-DVB), and bulk water, respectively. We assumed that the center-to-center distance of the ion pair changed from the crystallographic radius of the counterion to the sum of the hydrated radii of the fixed-charge group and counterion. The sizes of ions used in the calculation are summarized in Table 59.7 [72]. We used the hydrated radii of SO_4^{2-} and $N(CH_3)_4^+$ as that the of fixed-charge group of the CEMs and AEMs, respectively, for approximation. In the calculations, the ion activity coefficient in the membrane $\bar{\gamma}_{im}$ was used as the concentration of the external electrolyte solution.

Figure 59.9 shows typical experimental results for the membrane potential for (a) CEM and (b) AEM. The points and solid lines represent the experimental data and the theoretical results, respectively. All the calculated results of membrane potential agreed well with the experimental values. This supported the belief that the ion-pairing effect was significant in a low-water-content membrane system. In the following section, we examine the fitting parameters ε_r and a, obtained from our theoretical analysis.

59.4.2.2 Dielectric Constant in Membranes and Center-to-Center Distance of an Ion Pair. Figure 59.10 and Table 59.10, respectively demonstrate the water content dependence of the dielectric constant ε_r in the membranes and the center-to-center distance of an ion pair a, based on our theoretical analysis. As can be seen in Figure 59.10,

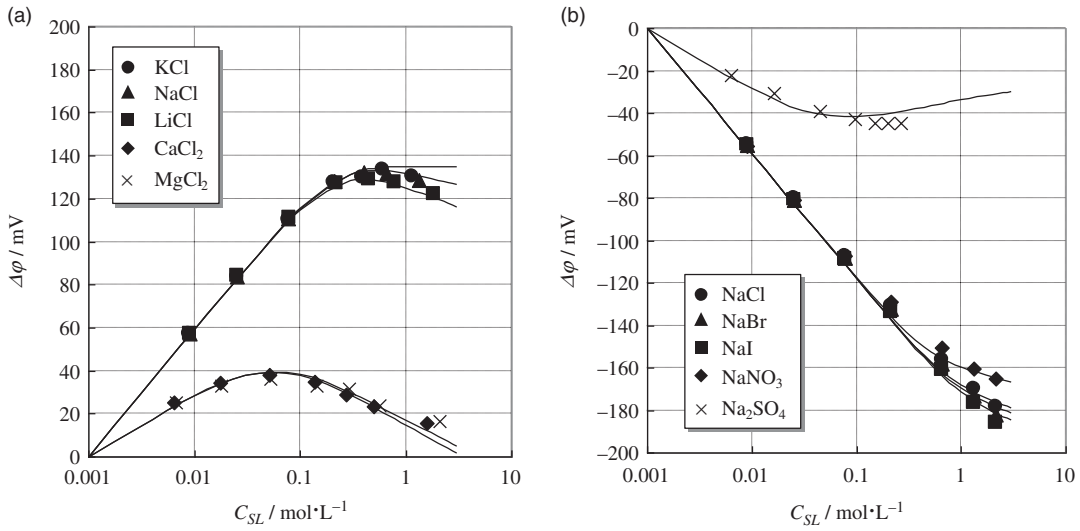

FIGURE 59.9 Membrane potential across the membranes as a function of electrolyte concentration in bulk solutions (C_{SL}): (a) CEM2; (b) AEM2. Solid lines indicate the theoretical results obtained by fitting our theory considering ion pair formation between fixed-charge groups and counterions to the experimental data.

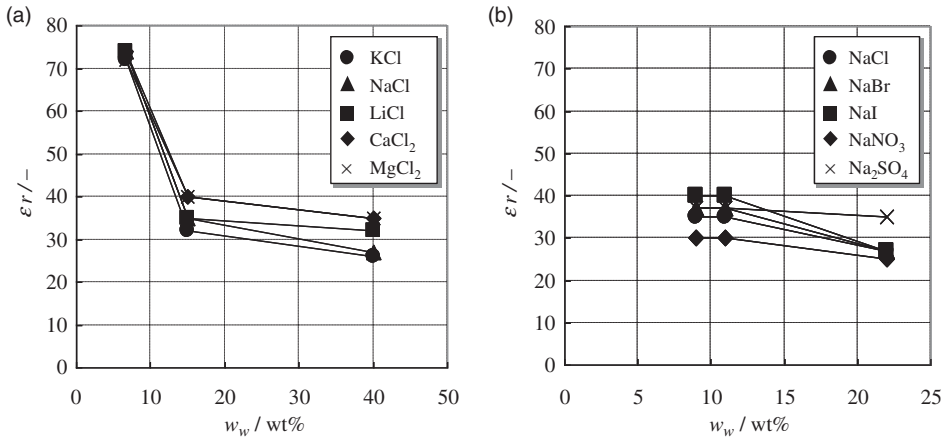

FIGURE 59.10 Dielectric constants in membranes ε_r as a function of water content obtained by theoretical analysis: (a) CEM; (b) AEM.

the dielectric constant in the membranes is smaller than the value in the bulk water ($\varepsilon_r = 78$). Table 59.10 indicates that the center-to-center distance of an ion pair is independent of the water content of the membranes and within the range from the crystallographic radius to the hydrated radius of a counterion (see Table 59.7). These results suggested that fixed-charge groups in the membrane were neutralized by associated counterions. This is attributed to dielectric saturation. Water content dependences of the dielectric constant behaved differently between CEMs and AEMs; the dielectric constant in a CEM remarkably increased with a decrease in the water content of ~10 wt%, while that in an AEM did not show a water content dependence. This interesting discrepancy of the dielectric constant for a CEM contradicts the general prediction that the dielectric constant in a low-water-constant membrane would be low as a result of dielectric saturation [75]. For the sulfonated poly(St-*co*-DVB) membranes, however, another team of investigators reported that the amount of nonfreezing water in the membrane, whose mobility is strongly restricted by the interactions between the polymer matrixes and water molecules, decreased with a decrease in the water content, according to their differential scanning calorimetry measurements [76]. Under such conditions, it is presumed that the dielectric constant in the membrane increased with a decrease in water content.

TABLE 59.10 Center-to-Center Distance of Ion Pair in Membranes from Theoretical Calculations

	a (Å)				
Membrane	K^+	Na^+	Li^+	Ca^{2+}	Mg^{2+}
CEM1	1.8	1.6	2.2	3.3	3.4
CEM2	1.8	1.7	1.7	3.6	3.7
CEM3	1.8	1.7	1.5	3.7	3.7
	a (Å)				
	Cl^-	Br^-	I^-	$NO3^-$	SO_4^{2-}
AEM1	3	2.9	3.0	2.8	3.3
AEM2	3	2.9	3.0	2.8	3.5
AEM3	2.6	2.6	3.0	2.8	3.5

59.4.2.3 Charge Effectiveness of the Membranes. All of the fixed-charge groups in the membrane do not function perfectly, as a result of the neutralization by the counterion. Therefore, the effectiveness of fixed-charge groups in the membrane is an important index for the discussion on the ionic transport phenomenon across charged membranes. The charge effectiveness of the membrane Q represents the effectiveness of the fixed-charge groups in the membranes and is defined as follows:

$$Q = \frac{\frac{1}{d}\int_0^d \bar{C}_{Xm}(x)dx}{C_{Xm}} \tag{59.50}$$

Figure 59.11 shows the charge effectiveness of the membranes as a function of water content of the membranes. The charge effectiveness of the membranes was small (< 0.35). The water content dependence of the charge effectiveness of the membrane obeyed that of the dielectric constants in the membranes; the charge effectiveness of the CEM showed a critical point around the 10 wt% water content (this result implies that charged membranes may show large charge effectiveness and high permselectivity even under low-water-content conditions). The charge effectiveness of the membrane in a divalent counterion system ($MgCl_2$ and $CaCl_2$ for CEMs; Na_2SO_4 for AEMs) was much lower than that in a monovalent counterion system. This phenomenon can also be explained by the ion-pairing effect; the electrostatic interaction between a fixed-charge group and a counterion depends on the valence of the counterions [75].

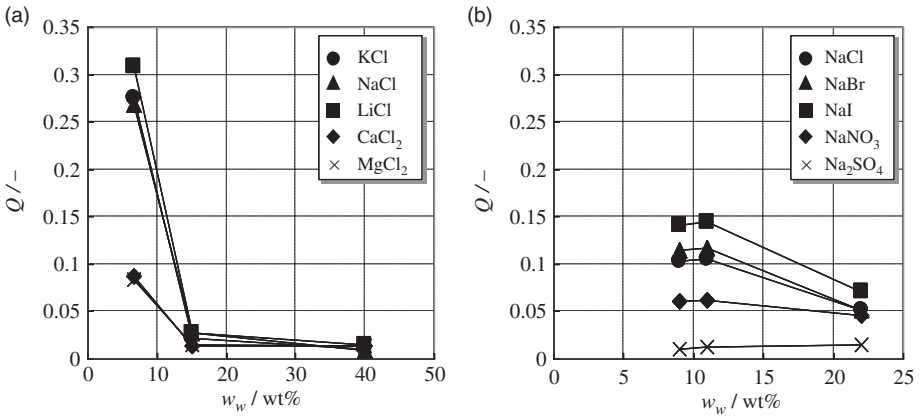

FIGURE 59.11 Charge effectiveness of membranes Q as a function of water content: (a) CEM; (b) AEM.

In the present study, we verified the ion-pairing effect in low-water-content charged membranes on the basis of membrane potential measurements. Analysis of the experimental results was based on the Donnan equilibrium, the Nernst–Planck equation for ion flux, and the Fuoss formalism for ion pair formation between the fixed-charge groups and counterions in the membranes. The theoretical predictions agreed well with the experimental results, demonstrating that the ion-paring effect was significant in the low-water-content membrane system. Our first-approximation theoretical approach also revealed the following findings:

1. Dielectric constants in the membrane were smaller than the value in bulk water. The dielectric constant in the CEM showed a critical point near the 10 wt% water content level, while that in the AEM did not show a water content dependence.
2. The center-to-center distance of an ion pair was independent of the water content of membranes.
3. The charge effectiveness of the membrane was small (< 0.35). The water content dependence of the charge effectiveness of the membranes obeyed that of the dielectric constants in the membrane.

These results provide fundamental knowledge for the development of not only polyelectrolyte membranes for fuel cells but also high-performance membranes for other applications. Another group of investigators has also studied the local structure of counterions in ion exchange resins by X-ray absorption fine structures (XAFS) [77]. They evaluated the direct ion pairs between the fixed-charge groups and counterions. A more detailed discussion on ion pairing in the membranes based on both membrane potential measurements and other spectroscopic measurements (e.g., XAFS, NMR, dielectric relaxation measurements in the GHz region [78]) will be required.

60.1 α-CRYSTALLIN

α-Crystallin is a member of the small heatshock protein (sHSP) superfamily and a key component of the mammalian eye lenses. It consists of two highly homologous chains, α,A- and α,B-chains, containing 173 and 175 amino acids, respectively, with a molecular mass of ∼20 kDa [1–3]. In the eye lens, α,A- and α,B-crystallins assemble into large oligomeric complex of molecular mass ∼800 kDa with a 3:1 stoichiometry. Recombinant α-crystallins also show extensive oligomerization leading to a rather homogenous 24mer aggregate for α,B-crystallin and heterogeneous aggregates for α,A-crystallin varying from 300 – 700 kDa [3–6]. Although initially considered to be a lenticular protein, α-crystallin was eventually detected in several other tissues, and implicated in different neurological pathophysiologies; thus its function has been redefined from that of a mere structural protein [7,8]. α-Crystallin is a potent chaperone. It prevents nonspecific hydrophobic interaction mediated protein aggregation and helps to refold unfolded states leading to folded functional forms. This chaperone function of α-crystallin is thus essential for maintaining transparency and integrity of the lens [9].

60.2 A BRIEF INTRODUCTION TO FLUORESCENCE IN PROTEINS

Fluorescence spectroscopy has been a key element of a biophysicist's toolset in terms of exploring protein structure and function. It can provide a host of valuable information about structural stability, ligand binding, conformational changes, and allostery.

The fluorescent probes used for protein structure characterization can be either extrinsic or intrinsic. Intrinsic fluorophores consist of fluorescent amino acids such as phenylalanine, tyrosine, and tryptophan and sometimes fluorescent cofactors such as NADP [10]. Tryptophan is most widely used for structural studies because of its environment sensitivity, making it useful for unfolding, ligand binding, or any other structural transition studies. Tyrosine, while not as widely used as tryptophan, still remains the intrinsic probe of choice in tryptophan-less proteins. Although it is not as sensitive as tryptophan, tyrosine fluorescence can still give important structural information. Phenylalanine has weak fluorescence and is not of much value from a biophysical perspective. Unlike intrinsic probes, extrinsic probes can be extremely diverse [11]. They can be either covalent or noncovalent. Covalent fluorophores conjugate with sidechain functionalities of the amino acid residues in protein. Covalent labeling can be site-selective and can provide crucial regiospecific information of the immediate microenvironment. Noncovalent probes, on the other hand, bind via noncovalent interactions such as H-bonding, electrostatic, hydrophobic, and Van-der Waals interaction. Noncovalent probes can be used as markers for hydrophobic or charged pockets and as ligand analogues.

Fluorescent techniques used to study protein structure can be varied. Steady-state fluorescence is a rather simple

and inexpensive yet very powerful technique that can provide information such as solvent accessibility from emission maximum and Stern–Volmer plots, ligand binding from quenching or enhancement studies, and protein–protein interaction using polarization studies. Fluorescence lifetime is a more advanced technique that gives more specific details about microenvironment such as salvation and local polarity. Time-resolved fluorescence anisotropy may be used to assess the dynamics of a domain [10–12]. Another recent yet powerful technique is single-molecule fluorescence spectroscopy, where signals from single molecules are detected. Single-molecule fluorescence detection can be realized on several platforms, such as a confocal microscope, total internal reflection fluorescence (TIRF) microscope, or near-field scanning optical microscope (NSOM). Such studies provide information about the dynamics of a protein at single-molecule level instead of information of an en masse average obtained from ensemble techniques [13].

Often the high-resolution structure of a protein remains inaccessible in situations when crystals cannot be obtained and often the large size of the protein limits the use of NMR. In this chapter we demonstrate the use of fluorescence techniques to decipher key structural and biophysical aspects of protein structure and function even in absence of high-resolution structure, with the case of the oligomeric lens chaperonin α-crystallin. Interestingly, most of the data fit well with high-resolution structure obtained rather recently using a combination of solid state NMR, SAXS, and cryo-EM.

60.3 CHALLENGES IN DETERMINING α-CRYSTALLIN STRUCTURE AND PRELIMINARY STRUCTURAL MODELS BASED ON MICELLAR ARCHITECTURE

Initially α-crystallin was regarded as a structural lens protein, and its extensive oligomerization has been an element of curiosity. However, despite persistent efforts, its high-resolution structure remained elusive for a long time. The oligomeric heterogeneity and possible flexible structural motifs were thought to be the causes of failures to crystallize the protein. Such a huge oligomeric assembly was beyond the scope of conventional protein NMR techniques. Hence several models were proposed on the basis of some experimental findings to understand the oligomeric structure [14].

Studies in 1981 involved cross-linking α-crystallin oligomers with bifunctional imido esters [15]. Earlier studies using SAXS had already shown α-crystallin to have a semispherical structure. Its hydrodynamic diameter and the stiochiometry of α,A and α,B were also determined [16]. The study suggested random orientations of all the subunits indicating equivalent positions within the oligomer.

One research team proposed a layered micellar model where each subunit was treated as an ampliphile and the entire oligomer had a hydrophobic micelle-like core and presented hydrophilic facets on the surface (Fig 60.1a) [17]. Pyrene fluorescence was used to support the model. Pyrene shows strong excimer fluorescence when one pyrene molecule is in close proximity to the other one. Taking in consideration that only αA can react with the pyrene derivative as αB has no cysteine residues and that high pyrene excimer fluorescence indicates close proximity of αA subunits, they proposed possible compositions of the three layers of the micelle. Changes in excimer fluorescence with temperature were related to disassociation/reassociation of the different micellar layers associated with temperature-induced conformational change [17].

Based on oligomerization patterns of *N*-terminal and *C*-terminal fragments of α-crystallin, a rhombic decahedron-based model involving tetrameric α-crystallin building blocks (Fig. 60.1b) was proposed [18]. Another team then proposed a pitted flexiball model taking into account the robust nature of α-crystallin's oligomer (Fig. 60.1c). It combined the idea of tetrameric building blocks developed by Wistow [18] as well as some micellar features [19]. Despite having many failures and being extrapolative at times with no actual correlation with the experimental data, these early models led to certain key findings, including the equivalence of the subunits and the fact that α-crystallin oligomers are formed using different levels of intersubunit interaction involving smaller building blocks, which holds true even to this day [20].

60.4 HYDROPHOBICITY OF α-CRYSTALLIN AND ITS CHAPERONE FUNCTION

Similarity of α-crystallin with HSP members on a sequence level was identified as early as 1982 [21]. However, there was a paradigm shift in α-crystallin research when Horwitz showed that α-crystallin functions as molecular chaperone and prevented protein aggregation [22]. Soon several studies followed that reinstated its chaperone function [23–25].

However, due to lack of a detailed structural insight, understanding the basis of this chaperone function became a key focus of α-crystallin research. Another team showed α-crystallins to have several surface-exposed hydrophobic pockets using two hydrophobic fluorophores 1,8-ANS (1-anilinonaphthalene-8-sulfonic acid) and DPH (1,6-diphenyl 1,3,5-hexatriene) (Fig. 60.2) [26]. Fluorophores, like 1,8-ANS and DPH, have minimal emission in aqueous solutions, which increase several fold in apolar microenvironments such as membrane bilayers, and hydrophobic pockets in proteins, and hence such probes are widely used for protein characterization [11]. Hence, hydrophobic interactions, which are responsible for chaperone activity, were a reasonable line of

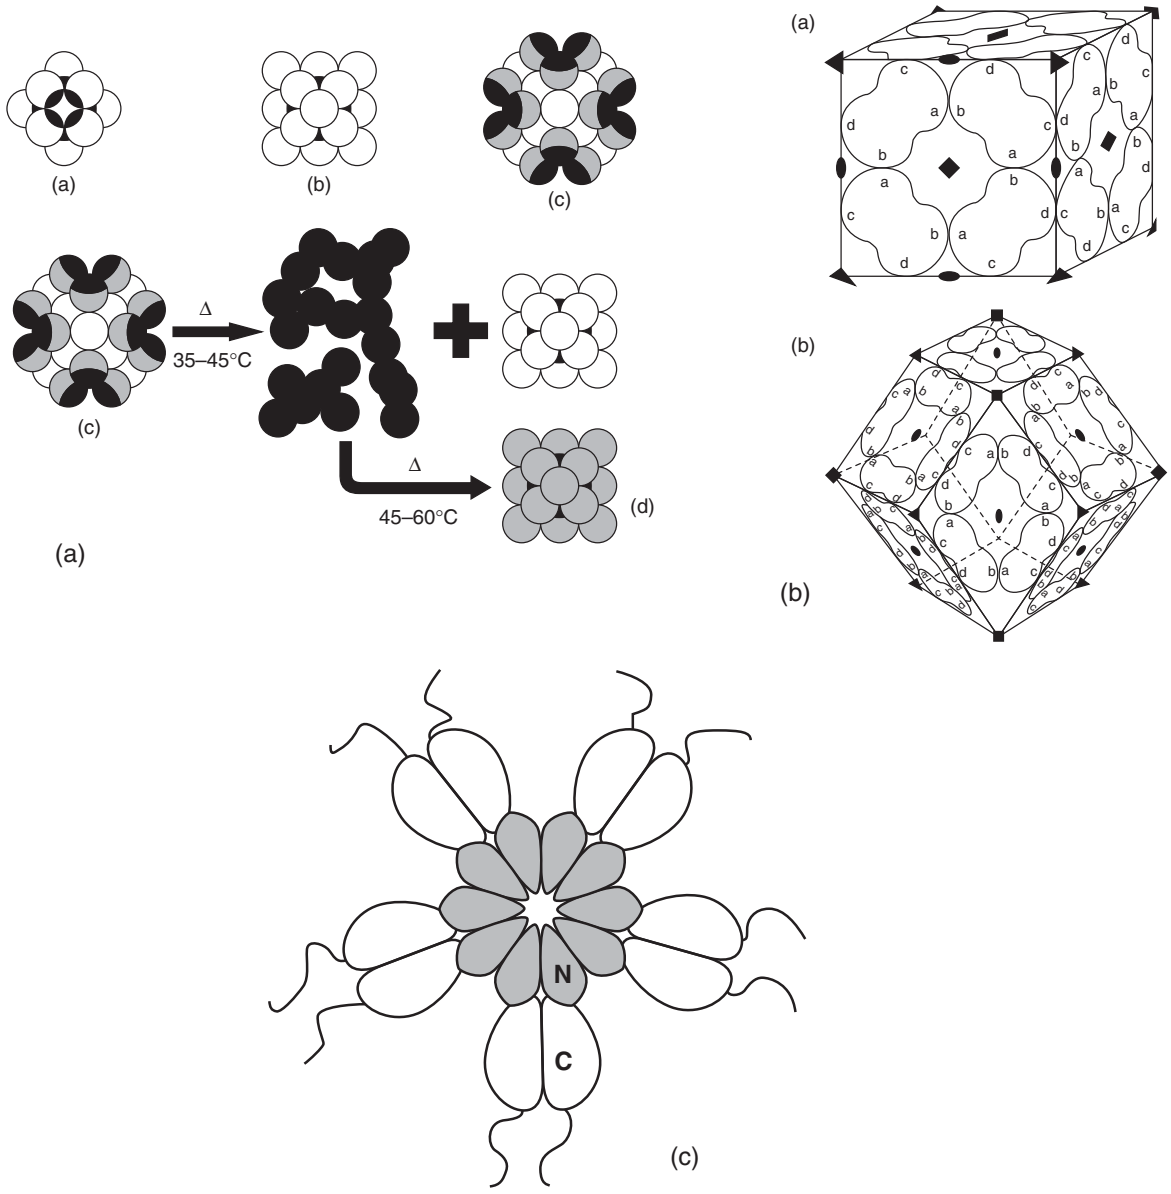

FIGURE 60.1 (a) Schematic representation of the three-layer red micelle model showing thermal transition between the different intermediates. (*a*) First (innermost) layer consists of 12 subunits: cuboctahedron. (*b*) First and second layers constitute a total of 18 subunits: octahedron. (*c*) First, second, and third layers make up a total of 42 subunits: cuboctahedron type. The hydrophobic portion is shown in black. (*d*) A two-layer structure, similar but not identical to that shown in subpart (*b*), found on heating of the original three-layer structure [subpart (*c*)]. (b) A diagrammatic representation of the quaternary structure of α-crystallin, showing the *C* terminal with a peanut shape and four contact points, *a*,*b*,*c*,*d*. Top (*a*) and bottom (*b*) show cubic and rhombic decahedron models, respectively. Symmetry axes are shown with oval (C_2), triangle (C_3), and square (C_4) conformations. (c) Micelle-like pitted–flexiball model for α-crystallin. The α,A- and α,B-crystallin subunits occupy equivalent positions. Each subunit is composed of two domains. The *N*-terminal domains (gray) constitute the center of the complex, while the larger *C*-terminal domains (open) are spaced at the periphery, providing a polar pitted coating around a hydrophobic core. The hydrophilic *C*-terminal extensions flex freely from the surface. Specific interactions between the *C*-terminal domains of the subunits result in the formation of tetrameric building blocks. Hydrophobic interactions between the *N*-terminal domains provide a micelle-like cohesion between the building blocks. The fivefold radial symmetry in this figure is arbitrarily chosen, and the arrangement of tetrameric building blocks may well be less regular than depicted. FIGURE 60.2 ANS fluorescence (a) and DPH fluorescence (b) spectra in various α-crystallins: (1) α-crystallin; (2) β-crystallin: (3) γ-crystallin. ANS concentration is 50 μM, and DPH is 7μM; protein concentration is 0.1 mg /mL in ANS measurements and 0.2 mg /mL in DPH measurements. Only α-crystallin shows significantly enhanced ANS and DPH fluorescence and is thus very hydrophobic. (Adapted from Liang and Li 1991 [26], pp. 61–66. © Elsevier, Inc.; reproduced with permission.)

thought. However, mere presence of hydrophobic pockets does not definitively prove the role of hydrophobic interaction in chaperone activity. One report used the hydrophobic fluorophore pyrene and ANS to characterize chaperone function of α-crystallin [27]. Pyerene fluorescence is characterized by a structured emission spectrum consisting of at least five distinct vibrionic bands. A ratio of the first and third vibrionic bands is a marker of microenvironment polarity [28,29]. This ratio increased with increasing temperature showing distinct transitions, suggesting decreased microenvironment polarity arising from more hydrophobic pockets opening up as a result of a temperature-dependent structural transition. The exposure of hydrophobic pockets was also observed with ANS fluorescence increasing with temperature. Interestingly, the chaperone function of α-crystallin as probed by its ability to protect photoaggregation of γ_L- crystallin, increased with temperature. This was for the first time a direct correlation between increased hydrophobocity and enhanced chaperone function, supporting the hypothesis that surface hydrophobic patches are responsible for α-crystallin's chaperone function.

60.5 EFFECT OF TEMPERATURE ON CHAPERONE FUNCTION OF α-CRYSTALLIN

A detailed systematic study of α-crystallin's change in surface hydrophobocity and chaperone function was carried out [30]. In this study, as a marker of hydrophobic patches, bis-ANS was used as the fluorescence probe. ANS, despite being used widely as a marker for hydrophobic pockets, does not bind proteins through hydrophobic interactions alone. It is an anionic small molecule, and electrostatic interactions play a key role in its binding with proteins. On the contrary, bis-ANS, which is a dimer of ANS as it is a much larger molecule, interacts with proteins predominantly through hydrophobic interactions, and charge plays a nominal role; so it possibly is a better marker of hydrophobic pockets in proteins than ANS due to lack of nonspecific electrostatic/charge-driven interaction with proteins. Bis-ANS fluorescence showed a temperature-dependent transition increasing after ~40°C (Fig. 60.3). Interestingly α-crystallin samples preincubated at elevated temperatures and then cooled down still showed greatly increased bis-ANS binding, suggesting an irreversible temperature-induced conformational change that opens up more hydrophobic sites. The chaperone activity of α-crystallin samples assessed by its ability to prevent insulin B-chain aggregation increased with preincubation temperature, with the trend showing a direct correspondence to the bis-ANS fluorescence [30]. This provides conclusive evidence that chaperone activity of α-crystallin primarily involved surface-exposed hydrophobic pockets.

Another team also found similar correspondence between temperature-dependent ANS fluorescence and chaperone activity [31]. Although these temperature-dependent studies of surface hydrophobocity using hydrophobic fluorophore clearly indicated the implication of hydrophobic patches in α-crystallins function, they also raised controversy as to whether thermal activation was required for α-crystallin to become functional. The authors argued that the temperature-dependent structural transition in α-crystallin,

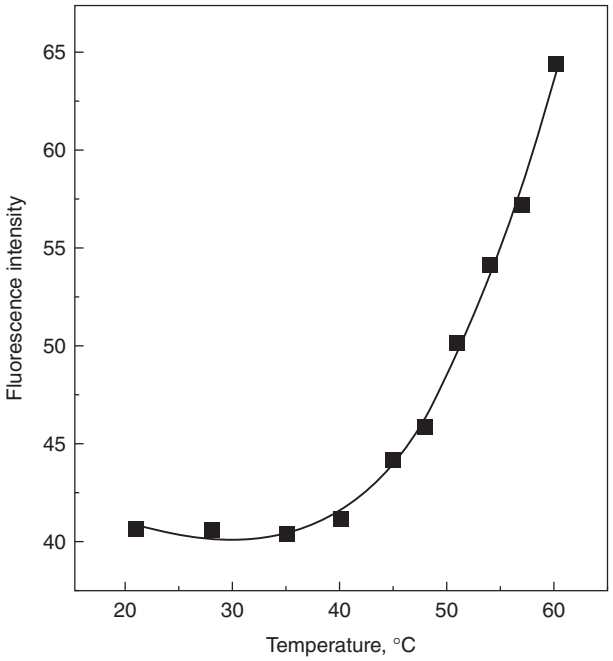

FIGURE 60.3 Fluorescence emission intensity at 22°C of bis-ANS (l 3 μM) in the presence of α-crystallin as a function of preincubation temperature. Samples of α-crystallin (0.06 mg/mL in 50 mM phosphate buffer) were preincubated at different temperatures for 15 min and cooled down to room temperature; bis-ANS (13 μm final concentration) was then added and fluorescence intensity measured at 490 nm at room temperature. (Adapted from Das and Surewicz [30], pp. 321–325. © Elsevier, Inc.; reproduced with permission.)

which exposes more hydrophobic patches, acts as a thermal switch between nonfunctional and functional states, drawing parallels with such structural transition-mediated activation of the classic chaperonin GroEL [31]. However, from a detailed temperature-dependent investigation of α-crystallin's chaperone ability to prevent aggregation of both natural and unnatural substrates, that is, γ_L-crystallin and insulin B chain respectively, it was concluded that even at temperatures well below 30°C, which Raman and Rao suggested as the activation temperature of α-crystallin, its chaperone activity was quite apparent [32]. Nonetheless, its activity increased at elevated temperatures. Hence the current opinion is that α-crystallin does not require a thermal activation for its chaperone function, which prevails even at low temperature, although it increases with temperature as a result of increased hydrophobic exposure.

60.6 IDENTIFICATION OF CHAPERONE SITES OF α-CRYSTALLIN USING HYDROPHOBIC FLUOROPHORES

α-Crystallin's interaction with bis-ANS not only was useful in demonstrating the role of hydrophobic interactions for its function but also led to crucial evidence for the region of the protein involved in binding substrate proteins. An obvious corollary of the correlation of bis-ANS binding with chaperone activity is that the same sites in the protein are responsible for binding bis-ANS and the client proteins. The first experimental evidence of this notion came from the work involving α-crystallin photolabeled with bis-ANS [33]. Bis-ANS under strong UV light forms covalent adducts with proteins. The photolabeled α-crystallin had significantly reduced chaperone function, as one might expect if bis-ANS binds and thus occupies the sites responsible for the chaperone function, impeding the docking of the substrate proteins (Fig. 60.4). On this idea, that same team subsequently developed an approach to identify the sequences involved in client protein recognition [34].The idea was simple; when the client protein-binding sites of α-crystallin are occupied by bis-ANS, photolabeling will fix the fluorophore to the binding site. Identification of the peptides containing the fluorophore after proteolysis will lead to the identification of the binding region. Figure 60.4 also shows the SDS, which demonstrates that the photolabeling is reduced after substrate binding. Using this approach, two peptide fragments in α,A crystallin lying in the *N*-terminal and α-crystallin domain and one fragment in α,B-crystallin from the α-crystallin domain were identified that contained the client protein-binding site. This investigation supplemented and confirmed previous notions about the identity of the chaperone actie sites [35].

60.7 SUBSTRATE CONFORMATION RECOGNIZED BY α-CRYSTALLIN: COMPARISON WITH OTHER CHAPERONES

With α-crystallin's role as a chaperone established and having obtained some insights into the structural basis of its function, it was crucial to compare α-crystallin's molecular recognition with other known sHSP members and classical chaperones such as GroEL/GroES. Hence, it was essential to identify conformational states of client proteins recognized by α-crystallin. For DnaJ and GroEL, intrinsic tryptophan fluorescence of the client proteins was used to characterize their conformation [36–38]. This was possible because DnaJ and GroEL did not have any tryptophan residues. However, α-crystallin had a single tryptophan residue, and its fluorescence overlapped with those of the substrate proteins posing problems. One team of investigators circumvented this problem by using tryptophan-free mutant W9F of α-crystallin, which was structurally and functionally very similar to the wild-type protein [39]. Tryptophan fluorescence of the substrates γ_L- crystallin and rhodanase was used to assess their structure after forming complexation with α-crystallin by heat treatment (Fig. 60.5). Tryptophan emission is a good marker of solvent polarity arising from the polarity-sensitive

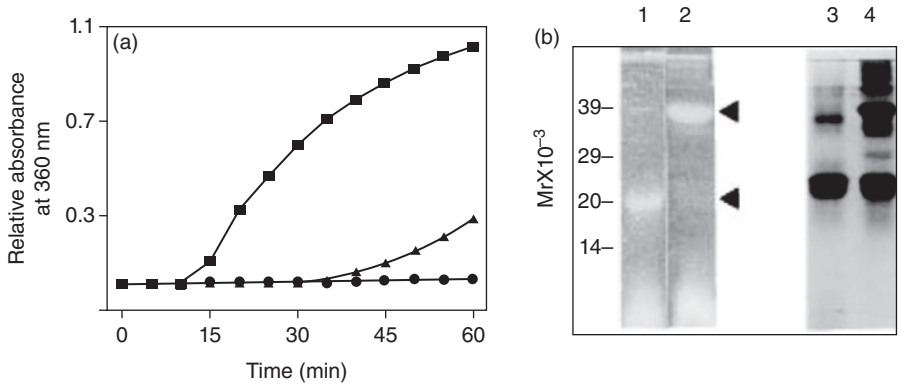

FIGURE 60.4 (a) Effect of bis-ANS binding on chaperonelike activity of α-crystallin. The assays were monitoring heat-induced aggregation of ADH and its suppression by α-crystallin, using apparent absorbance at 360 nm as a probe. [(■) ADH; (•) ADH + 25 μg of α-crystallin; (▲) ADH+ 25 μg bis-ANS- α-crystallin.] (b) Bis-ANS labeling of α-crystallin in the presence and absence of alcohol dehydrogenase. Lanes 1 and 3, bis-ANS + α-crystallin after photolysis; lanes 2 and 4, α-crystallin + ADH + bis-ANS after photolysis. Bis-ANS was added to sample in lanes 2 and 4 after 1-h incubation of the proteins at 48°C. The 20- and 39-kDa bands in lanes 1 and 2 are bis-ANS-labeled α-crystallin and ADH, respectively. (Adapted from Sharma et al. 1998 [33], pp. 8965–8970 and [34], pp. 15474–15478. © American Society for Biochemistry and Molecular Biology; reproduced with permission.)

fluorescence of the indole moiety. As a protein gets structurally compromised/unfolded, its core becomes progressively solvated, and this is reflected in the redshift of its tryptophan emission. Both rhodanase and γ_L- crystallin in complex with α-crystallin showed very little redshift of emission maxima from that of their native states. The denatured protein in presence of 6 M GdnHCl, however, showed significant redshifts due to full exposure of the tryptophan to the solvent, indicating complete collapse of structure. Stern–Volmer quenching plots with soluble quenchers acrylamide and iodide is another way to assess solvent accessibility of a fluorophore; from the parameter Stern–Volmer constant (K_{sv}) that increases with greater exposure to solvent. The K_{sv} values for the proteins bound to α-crystallin showed nominal increase from those of the native values when compared to the enhancement of K_{sv} value for the denatured protein. This reconfirmed that α-crystallin recognizes substrate conformers with core solvation very much like that in the native. Further experiments with bis-ANS indicated hydrophobic patches to be present on the α-crystallin-bound client protein. Another interesting observation was that the fluorescence of the α-crystallin-bound proteins remained unchanged even at high temperatures, much higher than temperatures at which the proteins unfold, suggesting remarkable stability of the protein/α-crystallin complex. Such mechanism of chaperone action is very different from GroEL/GroES system. *First*, the GroEL recognizes more extended/unfolded conformers of proteins while the α-crystallin identifies and binds the compact early unfolding intermediates with some hydrophobic surface pockets; this was demonstrated by a 10-nm redshift of rhodanese emission bound to GroEL compared to the native state [36,39]. In contrast, the redshift for rhodanese bound to α-crystallin is only 5 nm. *Second*, the GroEL/ GroES system involves three distinct steps of substrate protein binding, refolding, and release coupled with nucleotide hydrolysis, while after arresting early unfolding intermediates α-crystallin forms very stable complexes and does not release them [40]. This may have enormous implication in a cellular scenario, where GroEL/ GroES may be employed to initiate functional recovery of structurally compromised proteins while α-crystallin might arrest aggregation prone early unfolding conformers forming stable soluble complexes and maintains transparency of the refractive media.

Another key aspect of α-crystallin's chaperone function was its attenuation by nucleotide binding and the exact role of nucleotide in this process. ATP had been known to interact with α-crystallin from previous NMR studies [41]. However, one team had extended those reports by investigating the ATP binding through intrinsic fluorescence quenching studies [42]. The disassociation constant was in the millimolar molar range; nevertheless, despite such weak binding, ATP α-crystallin interaction is very crucial considering that lens ATP concentration may go up to 6 mM [43]. More recently it was shown that α,B-crystallin has a putative ATP binding sequence, and the binding was confirmed with by FRET between a fluorescent analog of ATP and covalently attached external fluorophor eosin to the thiol of a cysteine introduced by mutation of α,B-crystallin (Fig. 60.6) [44]. For the GroEL/GroES system, ATP hydrolysis is a key step for its function. However, whether α-crystallin

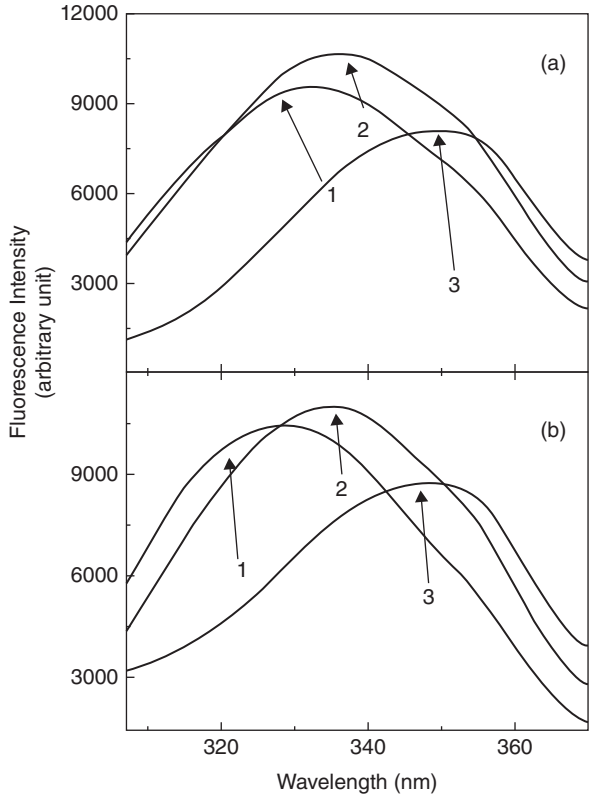

FIGURE 60.5 Fluorescence emission spectra of rhodanese (a) and γ-crystallin (b). Curve point 1, native protein; curve point 2, protein bound to W9F α,A-crystallin; curve point 3, protein unfolded in 6 M guanidine HCl. Spectra were recorded at 25°C. FIGURE 60.6 FRET analysis of interactions between fluorescent ATP analog azido-ATP-EDANS and the α,B-crystallin β8 mutant S135C-EMA. In the absence of an acceptor molecule, azido-ATP-EDANS had an emission maximum at 487 nm when excited at 340 nm (thick gray line). In the absence of a donor molecule, the fluorescent acceptor S135C-EMA had an emission maximum at 553 nm when excited at 340 nm (thin black line). When S135C-EMA was added to the solution containing the fluorescent donor azido-ATP-EDANS (thick black line), the emission of azido-ATP-EDANS at 524 nm decreased by 44% and the emission of the fluorescent acceptor, S135C-EMA at 553 nm, increased by ∼50%. The decrease in the emission fluorescence of the donor at 524 nm was due to energy transfer to the acceptor S135C-EMA, indicating close proximity of the donor and acceptor molecules. (Adapted from Ghosh et al. 2006 [44], pp. 364–375. © Elsevier, Inc.; reproduced with permission.)

has ATPase function remains controversial. Another group reported autokinase activity of α-crystallin [48]; however, other groups failed to find ATPase activity [14]. Hence the key questions involving ATP-α-crystallin interaction were the mechanism of α-crystallin's chaperone function after ATP binding and whether ATP hydrolysis is needed for the enhancement of its chaperone activity. In a study by our group we attempted to resolve these enigma [49]. We hypothesized that since α-crystallin's chaperone function arises from its hydrophobic pockets, its enhancement of chaperone function must be associated with increase in the number of hydrophobic pockets or better access to these hydrophobic pockets [49]. We found that bis-ANS fluorescence increased on interaction of ATP and α-crystallin. Further investigation of the binding parameters from fluorescence titration showed decreased disassociation constant for the binding, suggesting that α-crystallin has increased affinity for bis-ANS in presence of ATP (Fig. 60.7) [49]. We then used ATP, a nonhydrozable ATPγS analog, and the increased chaperone activity of α-crystallin was still reproduced in presence of ATP or ATPγS. Moreover, ATPγS, just like ATP, augmented α-crystallin's affinity for bis-ANS. Hence it was unambiguous demonstration that ATP played a structural or precisely an allosteric role in enhancing α-crystallin's chaperone function. It allosterically [49] promotes substrate interaction by increasing α-crystallin's affinity for protein substrates. Such role of a nucleotide as an allosteric modulator ligand in chaperone function was novel and distinctly different from GroEL/GroES chaperone systems. While the ATPase activity of α-crystallin still remains a controversy, our study was able to prove conclusively that ATP hydrolysis is not needed for enhancing α-crystallin's chaperone function [49].

60.8 SUBUNIT EXCHANGE OF α-CRYSTALLIN AND ITS DIVERSE ROLE

While discussing the preliminary models, we showed how the subunits in the oligomeric assembly of α-crystallin

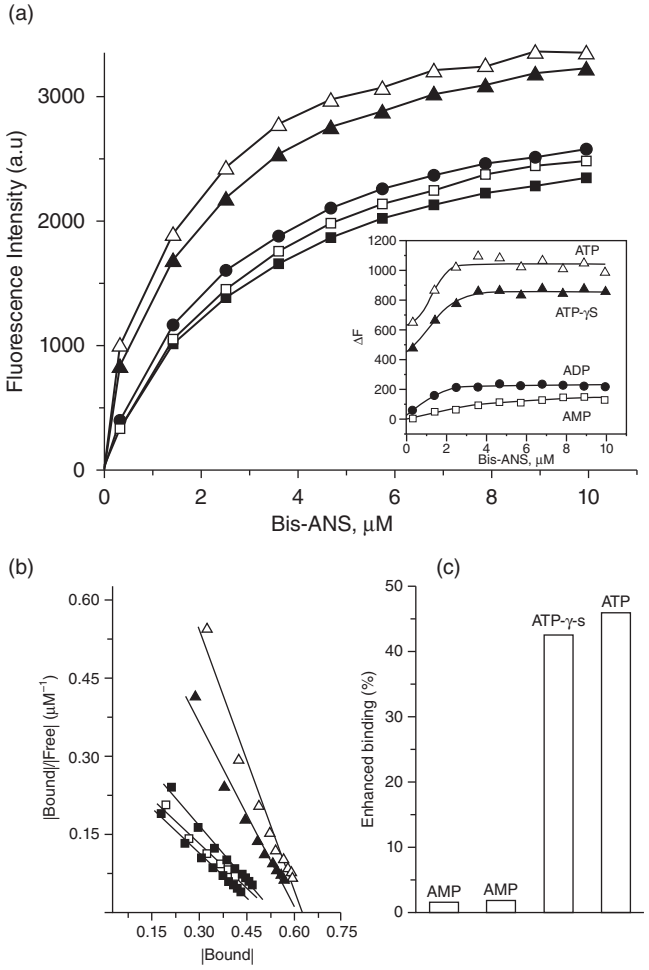

FIGURE 60.7 Effect of adenosine mono-, di-, and triphosphates on the bis-ANS binding to bovine α_L-crystallin and enhanced binding of γ-crystallin with α_L-crystallin at 37°C. (a) Bis-ANS fluorescence intensity as functions of bis-ANS concentration in the absence (■) and presence of 3 mM each of AMP (□), ADP (•), ATPγS (▲), and ATP (△). Inset shows increase in fluorescence intensity (ΔF) due to the addition of nucleotides as functions of bis-ANS concentration. (b) Scatchard plot for determination of the bis-ANS-binding parameters. (c) Binding enhancement of γ-crystallin to α_L-crystallin in presence of various nucleotides (3 mM).The data clearly show that ATPγS and ATP produce nearly equal enhancement of bis-ANS binding. appeared to be equivalent. This had two possible interpretations; either α-crystallin has a geometric arrangement where all the subunits had equivalent local symmetry or it has a dynamic oligomeric assembly. From structural perspectives the second idea seemed to be more viable. Experimental evidences of interaction between α-crystallin subunits and exchange between reconstituted α,A-crystallin and α B oligomers using gel-based assays were available [50]. However, since these studies used α-crystallin purified using denaturation renaturation cycles, the structural integrity of the protein was questionable. Another team showed in a 1994 paper that using a direct FRET-based approach provided the strongest experimental evidence in favor of subunit exchange [51]. They labeled two aliquots of α,A-crystallin with thiol reactive fluorophores AIAS (4-acetamido-4′-[(iodoacetyl)amino] stilbene-2,2′disulfonic acid) and LYI (Lucifer yellow iodoacetamide), which were good FRET donor–acceptor pairs [51]. When these two aliquots were mixed, a FRET signal was increased exponentially before it was saturated (Fig. 60.8). It is well known that FRET can occur only when the donor–acceptor pairs are in close proximity as the efficiency of FRET falls off with sixth power of distance. Hence, FRET in this case of α-crystallin labeled with AIAS and LYI is possible only when the donor and acceptor are located within the same oligomer via subunit exchange process. The FRET signal was saturated when all the hybrid oligomers formed had equal proportions of donor- and acceptor-labeled subunits. The change in FRET signal was described by a simple exponential model, and hence kinetic parameters such as first-order rate constant were deduced (Fig. 60.8) [51]. α-Crystallin showed marked increase in exchange kinetics with temperature, and this was used to evaluate the activation energy of the process by construction of Arrhenius plots. Dependence of subunit exchange kinetics with increasing ionic strength was also reported, suggesting the role of both hydrophobic and polar residues [51].

However, the role of subunit exchange in α-crystallin function was quite diverse. Several reports correlated subunit exchange kinetics with its chaperone function, and such studies were used to decipher several aspects of the α-crystallin biochemistry, including variation of its function in cataract causing or phosphorylation mimicking α-crystallin mutants [52, 53]. A reasonable way to interpret this correlation is to consider the equivalence of all the α-crystallin subunits despite the fact that all of them do not have the same local symmetry because of the subunit exchange. Thus, if the oligomers were static, all the subunits could not have interacted favorably with the client proteins, due to geometric restraints. Since the oligomers are dynamic, it is thus reasonable to assume that the oligomer substrate disassociation either is irreversible or occurs on a slower timescale than subunit exchange. Subunits bound to a client protein might exchange position with an unbound subunit that was previously in a position where substrate interaction was not favorable. This process will continue until all subunits associate with the client proteins, when the subunit and client protein stiochiometry become the limiting factor. Hence any change that impedes subunit exchange would decrease chaperone function. α-Crystallin is extremely efficient in suppressing aggregation of its natural substrates such as other members of the α-crystallin family, including β- and γ-crystallins. Based

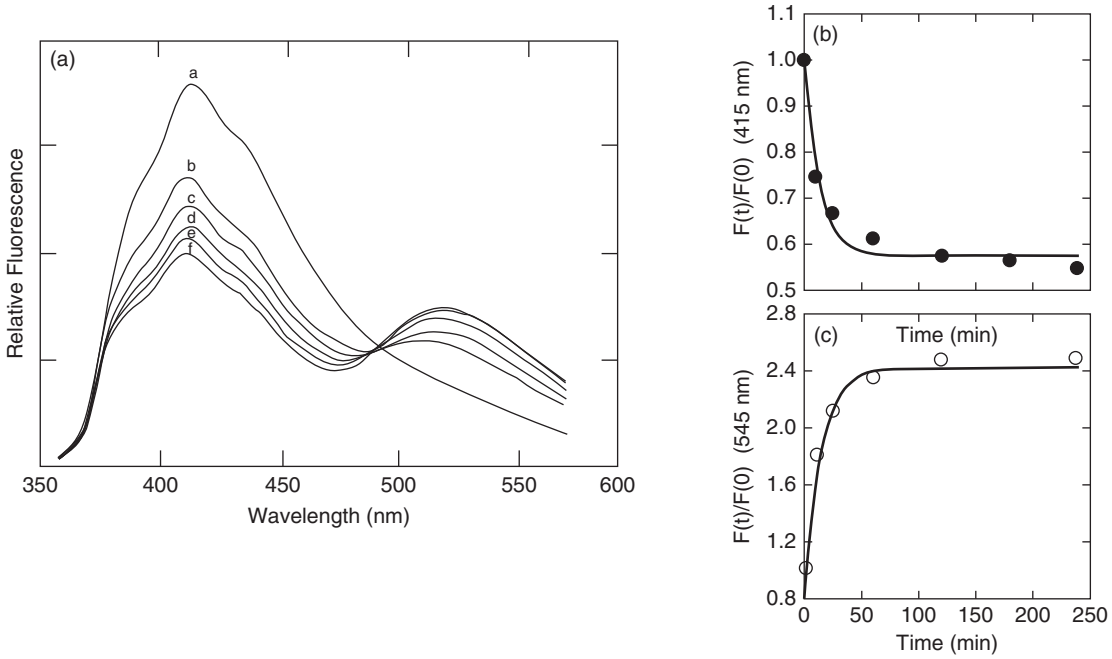

FIGURE 60.8 (a) Time-dependent changes in emission spectrum of AIAS-labeled α,A-crystallin due to subunit exchange. The emission spectra of α,A-crystallin excited at 335 nm were recorded at times equal to 0 (*a*), 10 (*b*), 25 (*c*), 60 (*d*), 120 (*e*), and 240 min (*f*) after mixing an equal amount of AIAS-labeled and LYI-labeled α,A-crystallin at 37°C. The decrease in fluorescence intensity at 415 nm of AIAS-labeled α,A-crystallin and the concomitant increase in fluorescence intensity at 525 nm of LYI-labeled α,A-crystallin are indicative of energy transfer due to subunit exchange of subunits between the two labeled populations. (b,c) Time-dependent changes in emission intensity due to subunit exchange. (b) Decrease in relative fluorescence intensity at 415 nm as a function of time after mixing an equal amount of AIAS-labeled and LYI-labeled α,A-crystallin. (c) Increase in relative fluorescence intensity at 545 nm due to fluorescence resonance energy transfer from AIAS-labeled α,A-crystallin to LYI-labeled α,A-crystallin. The *curves* represent the best statistical fit of the data to the exponential function $F(t) = C_1 + C_2\, e\, -kt$. The rate constants determined by curve fitting were 0.075 min^{-1} for data shown in (b) and 0.069 min^{-1} for data shown in (c). (Adapted from Bova et al. 1997 [51], pp. 29511–29517. © American Society for Biochemistry and Molecular Biology; reproduced with permission.)

on the idea that slow subunit exchange is associated with poorer chaperone function, we investigated the possibility of whether there is any preferential recognition of natural substrates over nonnatural substrates by α-crystallin and what role, if any, subunit exchange has in it [54]. Subunit exchange kinetics and the associated activation energy barrier, for α-crystallin bound to both natural and unnatural substrates, were measured (Fig. 60.9). We found that α-crystallin has a striking preference for natural substrates over nonnatural substrates such as ADH [54]. Interestingly, increased retardation of subunit exchange and higher activation energy in α-crystallin bound to nonnatural substrates compared to α-crystallin bound to natural substrates was also observed [54]. We rationalized this observation by taking into account the secondary structure propensities of the client proteins. While the natural substrates were all β-sheet major proteins, the unnatural substrate used had mainly helical structure. It is possible that for α-crystallin subunit bound with α-helical protein it is less favorable to undergo subunit exchange than for a subunit bound with β-sheet proteins. To get an in depth understanding of α-crystallin's substrate discrimination, detailed studies with several client proteins having different secondary structure need to be performed. Subunit exchange also helped us deduce a noncanonical mode of zinc ion binding by α-crystallin [55]. In an earlier study, we observed that α-crystallin bound to zinc ions with micromolar affinity and enhanced the chaperone function by increasing the number of hydrophobic patches [56]. Considering that α-crystallin does not have any putative zinc finger sequence, in a subsequent study we investigated the mode of this interaction [55]. MALDI and DLS data pointed toward the possibility of intersubunit bridging by zinc ions. Our hypothesis was confirmed when we found that zinc binding almost completely halted subunit exchange, as this

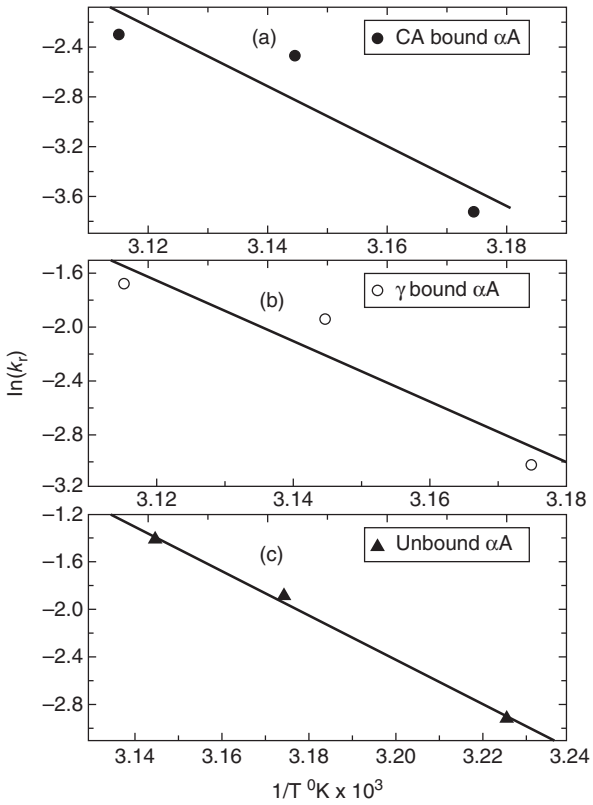

FIGURE 60.9 Determination of activation energy of subunit exchange of α,A-crystallin in absence and presence of different bound substrates. Arrhenius plot of the subunit exchange reaction of native α,A-crystallin (a), γ-crystallin-bound α,A-crystallin (b), and CA-bound α,A-crystallin (c). The complex was allowed to form by incubating different concentrations separately of each substrate protein with both 0.4 mg/mL AIAS-tagged and LYI-tagged α,A-crystallin at 65°C for 1 h. The solutions were cooled back to 25°C for 1 h. Then, equal amounts of AIAS-labeled and LYI-labeled α,A-crystallin were mixed containing the bound substrate, and the subunit exchange rate was measured at 42°C, 45°C, and 48°C, respectively. The rate constants at respective temperature were obtained by $\ln(k_r) = \ln A - E_a/RT$. The activation energy (E_a) was determined from the slope. could be rationalized only if the subunits were cross-linked by zinc (Fig. 60.10). The fact that zinc binding enhanced the chaperone activity while decreasing su-unit exchange may seem contrary to our previous discussion; however, this apparently anomalous exception can be explained by exposure of additional hydrophobic pockets that compensates the loss of chaperone activity from hindered subunit exchange.

60.9 OLIGOMERIC ASSEMBLY AND UNFOLDING OF α-CRYSTALLIN

In this last section we will focus on two very recent studies by our group that shed some light on the stability of the oligomer and unfolding properties of α-crystallin [58, 59]. Several attempts had been made to disrupt α-crystallin's oligomerization using small molecules, surfactants, or chemical modifications [60–62]. A key question was whether α-crystallin's oligomerization was necessary for function. Another team reported that sodium deoxycholate, a bile salt and mild

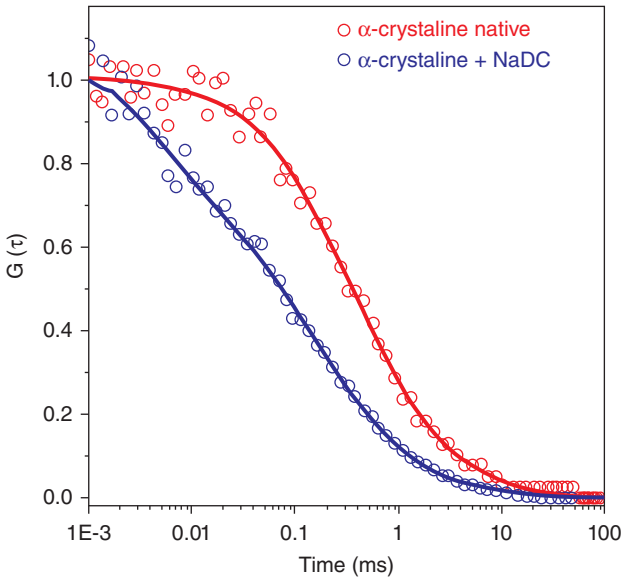

FIGURE 60.11 Normalized autocorrelation functions of acrylodan-α,A-crystallin system in the absence (red) and presence (blue) of 1 wt% NaDC. Actual autocorrelation curves are shown in the inset.The quicker decay of the correlation function and the increase in the number of particles all suggested tetramerization. surfactant, formed α-crystallin tetramers that showed increased autophosphorylation [63]. We confirmed the tetramerization using fluorescence correlation spectroscopy of α-crystallin labeled with acrylodan (Fig. 60.11) [58]. Using site-selective fluorescence studies, we demonstrated that the *N*-terminal domain gets exposed while the α-crystallin domain gets buried [58] (Fig. 60.12). We also showed, using ultrafast fluorescence of acrylodan, that solvation dynamics at the α-crystallin domain was slowed (or retarded) (Fig. 60.13). Exposure of the *N*-terminal domain explains why the tetrameraization as *N* terminal is known to promote higher-level oligomerization of smaller building blocks such as dimmers. We could also explain the phosphorylation pattern in presence of deoxycholate in terms of the region-specific conformation changes that we had observed without the need to account for the change in quaternary structure, suggesting that the increased phosphorylation was due largely to the subtle conformation change than tetramerization itself [58].

Another key question about α-crystallin is how it unfolds from such a massive structured architecture and the mechanism of breakdown at different levels of its structure, that is, secondary, tertiary, and quaternary elements. Previous studies showed that during unfolding α-crystallin passes through several intermediates along with incremental dissolution of oligomeric structure [64–68]. However, the steps of oligomer breakdown and the oligomeric status of the intermediates were unknown. We attempted to observe the effects of minimal perturbation of structure using a low concentration of denaturant leading to partial dissociation of the subunit assembly [59]. A detailed fluorescence study exploiting intrinsic tryptophan and extrinsic polarity probe acrylodan showed a degree of core solvation comparable to

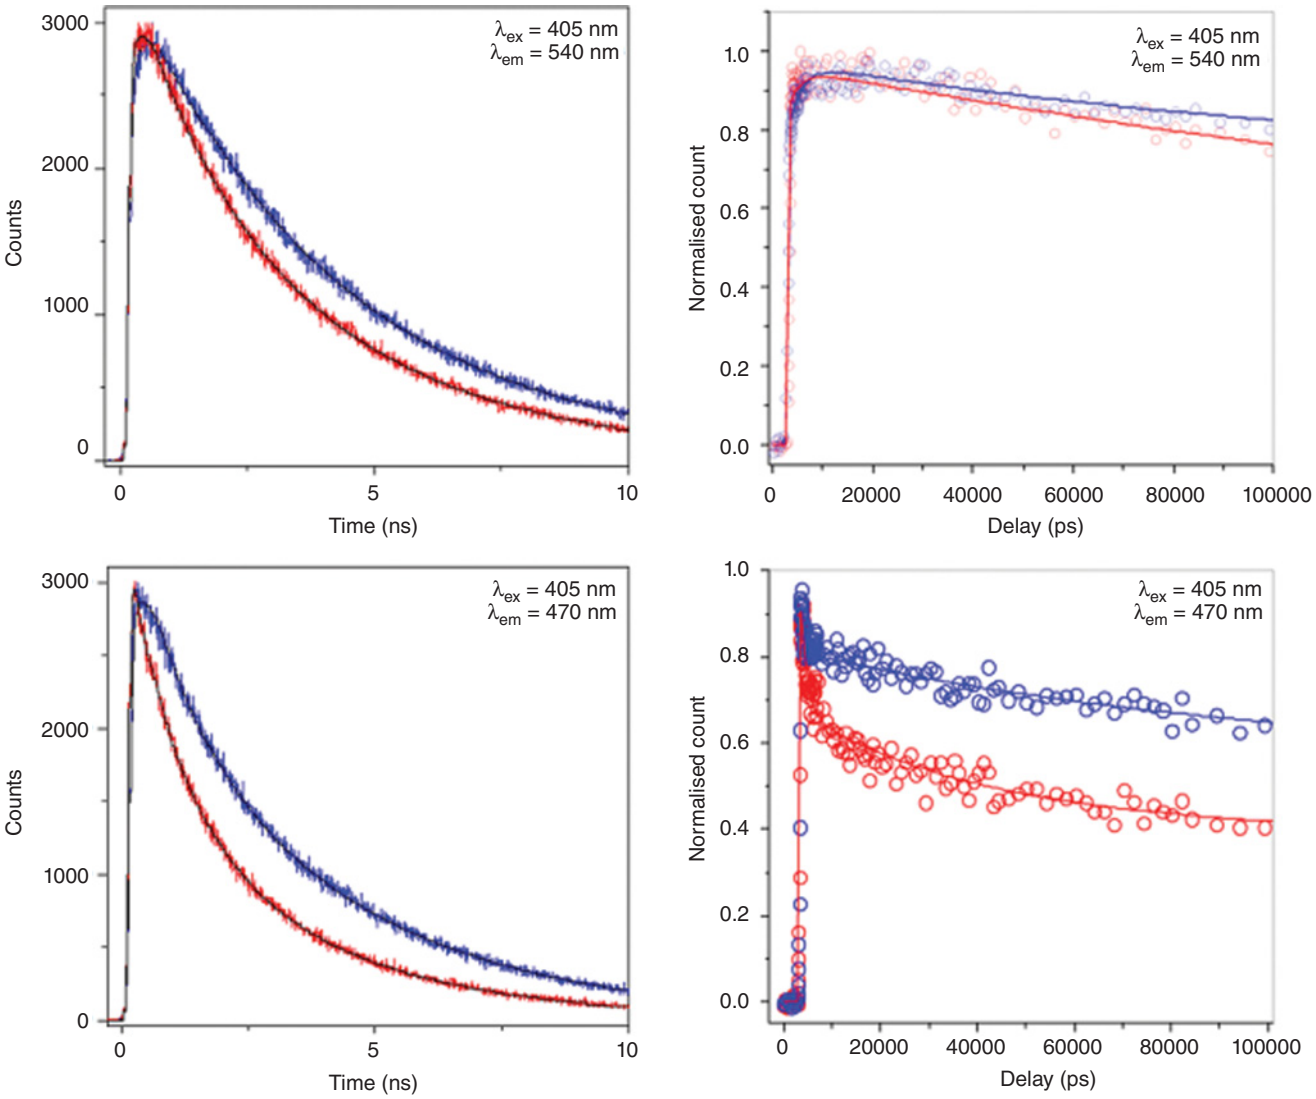

FIGURE 60.13 Left column: Picosecond transients of acrylodan -αA-crystallin system (at λ_{ex}= 405 nm) in the absence and presence of NaDC at λ_{em} = 540 nm (upper panel) and λ_{em} = 470 nm (lower panel). Right column: Femtosecond transients of acrylodan–α,A-crystallin system (at λ_{ex} = 405 nm) in the absence and presence of NaDC at (a) λ_{em} = 540 nm (upper panel) and (b) λ_{em} = 470 nm (lower panel). In all four panels, the lower and upper curves correspond to native alpha crystallin in absence and presence of NaDC respectively. The ultrafast data show that fluorescence relaxation kinetics of acrylodan is slowed in presence of deoxycholate, suggesting slower solvation. the native state, initially leading us to assume there is no structural breakdown at such low denaturant concentration as we had expected (Fig. 60.14). However, a bis-ANS fluorescence study showed a small but reproducible increase of fluorescence at this low denaturant concentration (Fig. 60.15) [59]. We also witnessed acceleration of subunit exchange [59], which was interpreted as a significant loss of tertiary structure. To our surprise, we also found that this intermediate state had unperturbed oligomerization [59]. A structural intermediate having such extensive oligomerization formed during unfolding had not been known before to the best of our knowledge. The identification of this intermediate was possible because of the extremely high sensitivity of bis-ANS fluorescence as this transition was silent to most of the other biophysical probes. We also identified another intermediate, which showed significant secondary structure loss and was formed at higher denaturation concentration and retained about two-thirds of its oligomeric size.

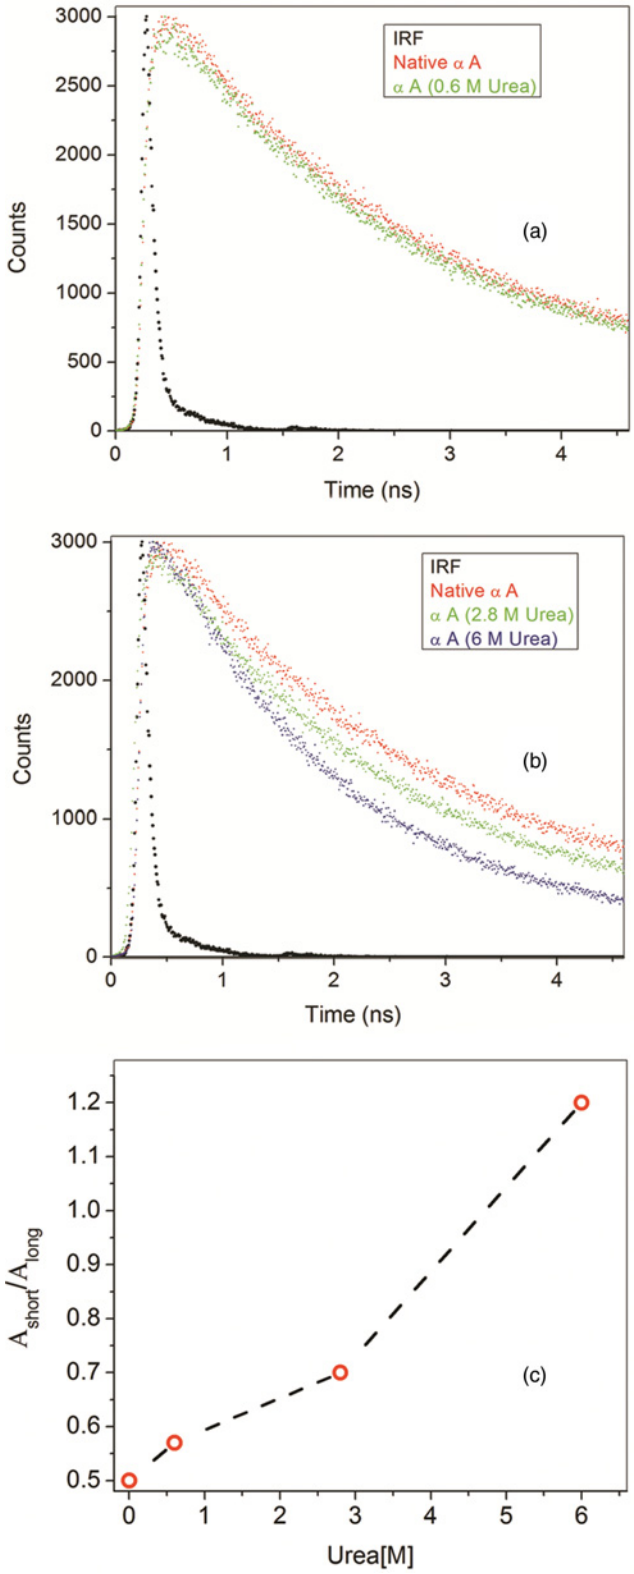

FIGURE 60.14 (a) Picosecond-resolved transients of acrylodan-labeled α-crystallin (at $\lambda_{ex} = 405$ nm) in native state (red) and in presence of 0.6 M urea (green) at 510 nm; (b) picosecond-resolved transients of acrylodan-labeled α-crystallin (at $\lambda_{ex} = 405$ nm) in native state (red) and in presence of 2.8 M urea (green) and 6 M urea (red) at 510 nm; (c) ratio of relative contributions (α) of the short (picosecond) and long (nanosecond) components of the transients; used as a marker of solvation. The time-resolved data show that in 0.6 M urea crystallin is as solvated as the native, suggesting minimal structure loss. FIGURE 60.15 Bis-ANS fluorescence of α,A-crystallin at various denaturant concentrations. Inset shows bis-ANS binding at denaturant concentrations from 0 to 1 M. Data points were fitted to a polynomial. The increased fluorescence around 0.6 M indicates presence of an intermediate. (Adapted from Chowdhury et al. 2014 [59], pp. 549–560. © John Wiley & Sons, Inc.; reproduced with permission.)

α-Crystallin's unfolding was clearly a case of nonhierarchical structure loss where tertiary structure loss preceded oligomer breakdown. From this we also concluded that the α-crystallin oligomeric structure is very robust and this can be justified considering the several layers of interactions that are responsible for oilgomerization in α-crystallin (Fig. 60.16). An implication of this is that oligomer formation may be a rather early folding event for α-crystallin where an amphiphile-like interaction drives the self -ssembly that propagates folding. However, this needs to be confirmed by experimentation.

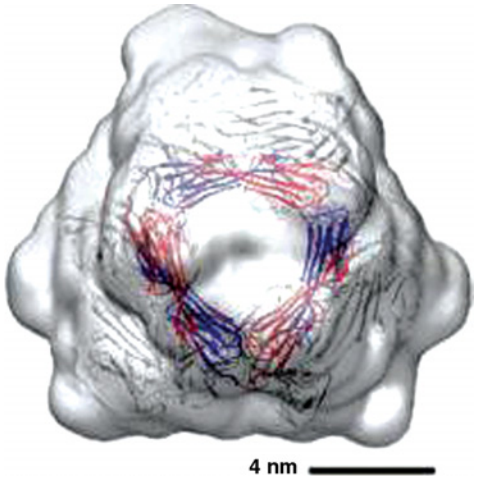

FIGURE 60.16 A model of 24mer α,B-crystallin. α-Crystallin dimer, (red and blue) fitted into the volumetric map of the SAXS data. This figure clearly shows the existence of dimeric building blocks. The oligomer is formed by *N*-terminal domain interaction of these building blocks. (Adapted from Jehle et al. 2010 [20], pp. 1037–1042. © Macmillan Publishers; reproduced with permission.)

60.10 SUMMARY AND CONCLUSIONS

Fluorescence-based techniques can provide useful structural information on proteins. In this chapter we have demonstrated how such techniques have been utilized to derive detailed structural and functional insight into a large oligomeric protein α-crystallin having micelle-like architecture. Using extrinsic hydrophobic probes, the surface hydrophobicity of α-crystallin was characterized. Temperature-dependent chaperone activity was correlated with exposure of surface hydrophobic pockets of α-crystallin. Covalent photolabeling of extrinsic fluorophore helped identify the client protein binding site on the surface of α-crystallin. Use of tryptophan-free mutant of α-crystallin helped us identify the conformation of substrate proteins recognized by α-crystallin. It has been shown that α-crystallin recognizes early folding intermediates of client proteins compared to extended conformation of the substrate proteins by other chaperone such as GroEL. Sununit exchange in α-crystallin could be demonstrated by covalently labeling α-crystallin separetly with fluorescent donor-acceptor pair, mixing them together, and following the FRET. Such FRET

studies have led to crucial understanding of the mechanism of discrimination between natural and nonnatural substrates by α-crystallin. Subunit exchange studies also provided important evidence of intersubunit bridging by Zn^{2+} ions. Using fluorescence correlation spectroscopy, site-selective fluorescence labeling, and ultrafast fluorescence decay, we were able to throw light on the mechanism of hyperphosphorylation of α-crystallin in its tetrameric form in presence of Na-deoxycholate. We were also able to identify crucial structural intermediates, one with compromised tertiary structure retaining full oligomeric assembly at low denaturant concentration and one with compromised secondary, tertiary, and quaternary structure at higher denaturant concentration. The study revealed that in the course of unfolding of α-crystallin, various levels of organization do not lose their structure in hierarchical order.

61.1 INTRODUCTION

The early history of muscle research was surveyed by A. Huxley in 1980 [1]. As described in Chapter II in Part II of Ref. 1, H. Huxley [2] found an overlapping double array of thick and thin filaments in striated muscle by electron microscope. On the basis of their electronmicroscopic observations, H. Huxley and Hanson [3] proposed the sliding-filament theory, which states that muscle contraction occurs by mutual sliding between the thick and thin filaments. Independently A. Huxley and Niedergerke [4] proposed the sliding theory based on their optical microscopic studies. Chapters III and the following chapters in Part II of Ref. 1 discuss the molecular model proposed by A. Huxley and his colleagues, which is usually called a *power stroke model*.

More recently Mitsui et al. [5–7] proved that the power stroke model is not consistent with the sliding-filament theory and proposed a model from a quite different perspective. Their model is in accordance with the sliding-filament theory and accurately explains major experimental results. Mathematical details of their study are described in the literature [5, 6] and are reviewed in one article [7]. The aim of the present chapter is to introduce their ideas, trying to make their contents [7] more readable.

Muscle structures and the sliding-filament theory are illustrated as an introduction in Section 61.2. The thermodynamic relationship that any models based on the sliding- filament theory should fulfill is derived in Section 61.3. Difficulties of the power stroke model are explained in Section 61.4. Requirements for any models based on the sliding- filament theory are listed in Section 61.5. A model that satisfies those requirements is presented in Section 61.6. Characteristics of the model that are helpful for numerical calculations are mentioned in Section 61.7. Section 61.8 demonstrates how the model explains major experimental data on muscles. Summary and discussion are given in Section 61.9.

61.2 MUSCLE STRUCTURES AND THE SLIDING-FILAMENT THEORY

As an introduction to the following discussion, the structure of muscle and the sliding-filament theory are illustrated in Figs. 61.1–61.4.

Figure 61.1 shows the structure of vertebrate skeletal muscle; part (a) shows the whole muscle, which is connected to bone by tendon. The whole muscle consists of many long muscle cells (single fibers). Part (b) shows a part of the cell. The cell is a bundle of many myofibrils. Part (c) shows a part of myofibril, which consists of many sarcomeres in series. Part (d) shows the sarcomere, which consists of thick filaments indicated as part € and thin filaments indicated as part (f). Part (e) shows that the thick filament has many myosin projections in microscopy. The lower illustration is the cross section at the myosin projection position. Part (f) shows that the thin filament consists of actin, troponin, and tropomyosin. Actin molecules produces force in cooperation with myosin molecules. Actin and myosin are called *contractile protein*. Part (g) shows the filament arrangement at the cross

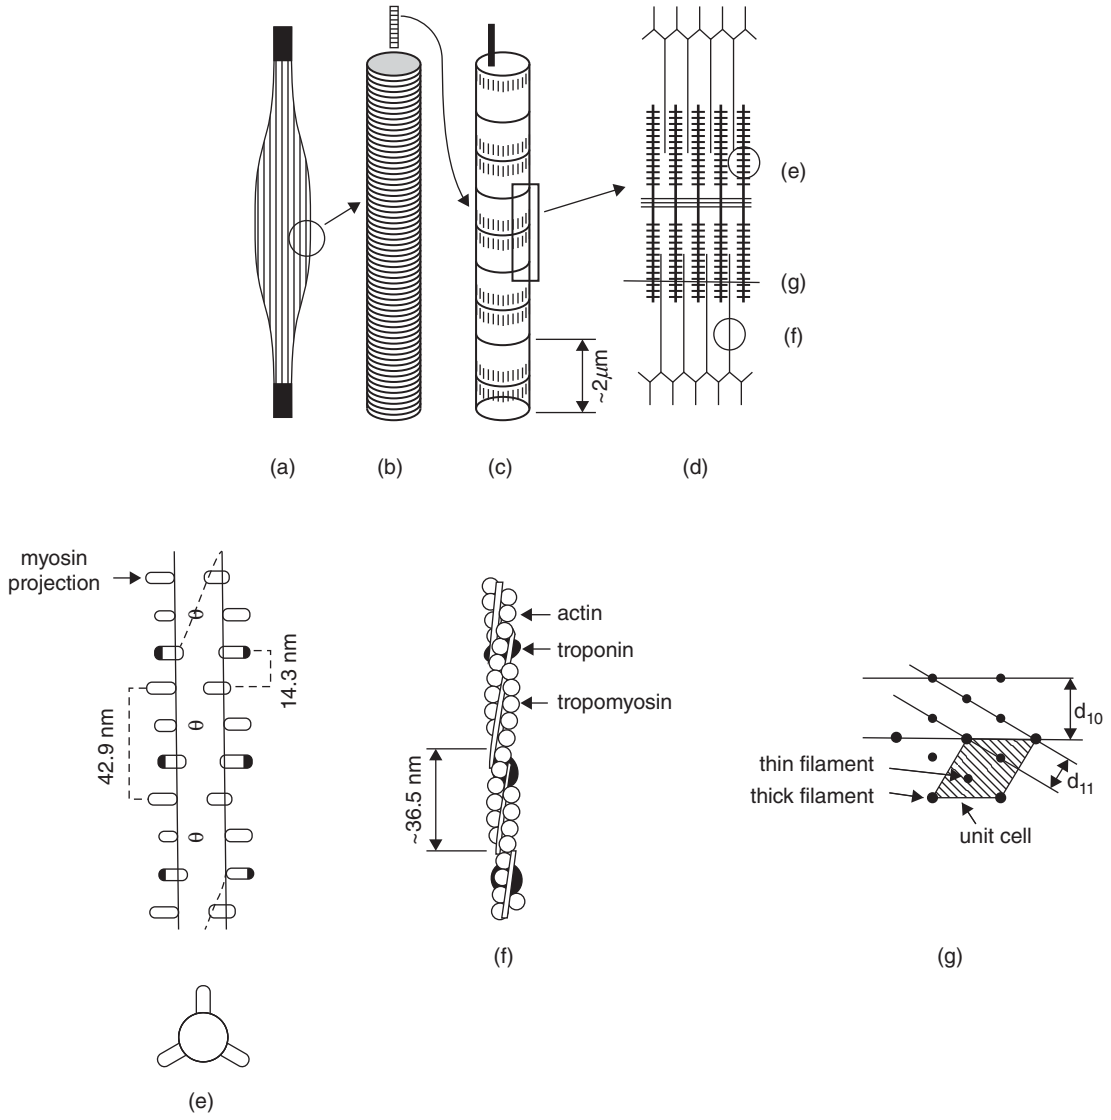

FIGURE 61.1 Structure of vertebrate skeletal muscle: (a) whole muscle; (b) unit cell (single-fiber); (c) myofibril; (d) sarcomere; (e) thick filament (lower cross-sectional view); (f) thin filament; (g) hexagonal array of filaments on the cross section indicated in (d).

section of the sarcomere indicated by g in (d). It has hexagonal symmetry.

The muscle contraction occurs by increasing overlap between the thick and thin filaments according to the sliding-filament theory. This is illustrated in Figure 61.2.

Figure 61.3 illustrates the structure of myosin molecule, which has two globular parts indicated as S-1 at the end. The part S-1 is called the *myosin head.*

Figure 61.4 illustrates how the contractile proteins interact for force production. The thick filament is a bundle of LMM. In microscopy, the myosin heads in Fig. 61.4 are observed as the myosin projections in Fig. 61.1e. It is generally accepted that the force for the filament sliding is produced only when myosin heads bind to the actin molecule as shown by the myosin heads *b* and *c*. The link between the thick and thin filaments formed by the myosin head *b* or *c* is called a crossbridge.

61.3 THERMODYNAMIC RELATIONSHIP THAT ANY MODELS BASED ON SLIDING-FILAMENT THEORY SHOULD FULFILL

Generally the first step in constructing a molecular model in material physics is to look for a thermodynamic relationship among parameters to appear in models. The relationship imposes restrictions on construction of models. Let us follow this procedure for a study of muscle contraction.

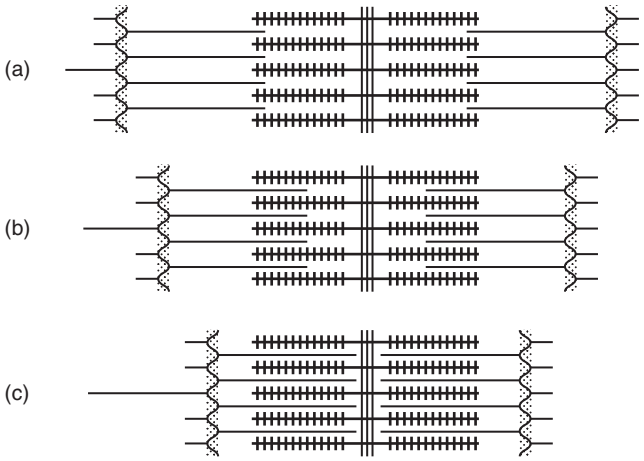

FIGURE 61.2 Illustration of the sliding-filament theory; contraction of muscle is caused by increasing overlap between the thick and thin filaments in sarcomere: (a) no overlap; (b) partial overlap; (c) full overlap.

61.3.1 Work Done by One Crossbridge Using ATP Hydrolysis energy

It is assumed that the myosin head exerts force on actin filament only when it is attached to actin as shown by the heads *b* and *c* in Figure 61.4. The force that causes the filament sliding is produced by spending ATP. The ATP hydrolysis energy per one molecule is denoted as e_A. In one cycle spending e_A, the mean force exerted on the actin filament by one attached myosin head is denoted as p and the translation distance of the attached head as D. Then pD gives the work done by the myosin head utilizing e_A. Measured macroscopic quantities during muscle contraction are the tension T, contraction velocity V, and the rate of heat production H. Unit of T is N/m^2. V is defined for unit length of muscle and its unit is 1/s. H is defined for unit volume of muscle and its units is

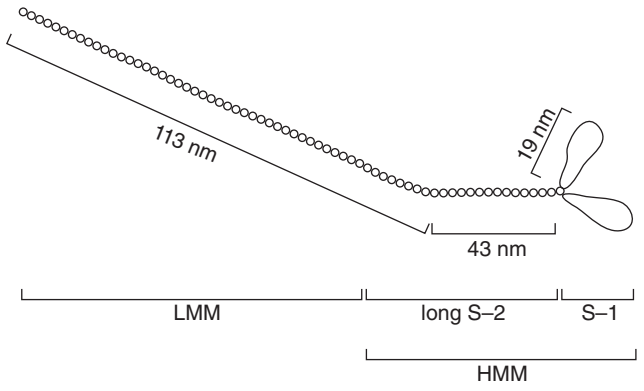

FIGURE 61.3 Structure of a myosin molecule (LMM, light meromyosin; HMM, heavy meromyosin; S-1, subfragment 1 (myosin head); S-2, subfragment 2).

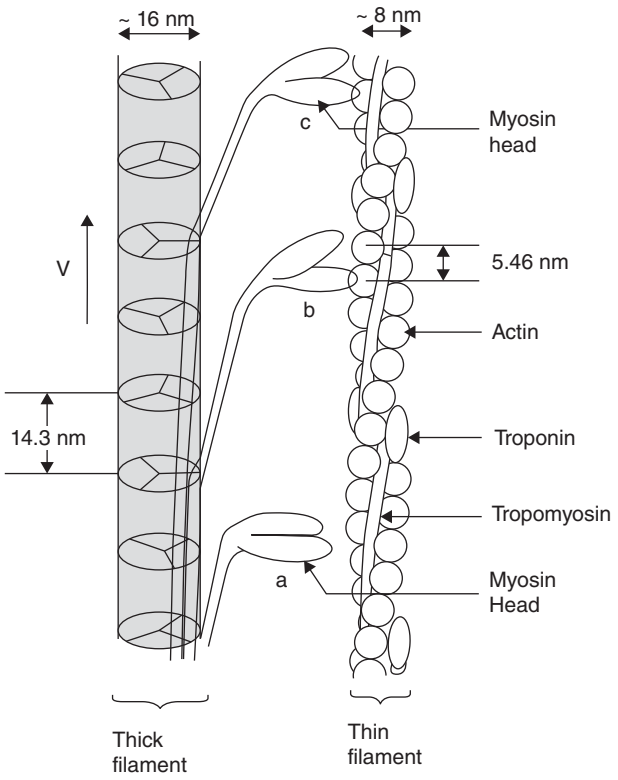

FIGURE 61.4 Thick and thin filaments in interaction. Myosin head a does not attach to the thin filament and does not produce force. Myosin heads *b* and *c* attach to the thin filament and produce force.

$W/m^3 = (N \bullet m)/sm^3 = N/(m^2 \bullet s)$. The rate of work done by unit volume of muscle W is given by TV:

$$W = TV \tag{61.1}$$

The unit of TV is $N/(m^2 \bullet s)$, the same as H. The rate of total energy production per unit volume is $W + H$. The portion of e_A used for work is given by $e_A\ W/(W + H)$. Hence, by the first law of thermodynamics, we have

$$pD = e_A W/(W + H) \tag{61.2}$$

61.3.2 Relation between p and T in Sliding-Filament Theory

Figure 61.5 schematically shows a portion of the sarcomere producing the tension T at full filament overlap: (a) side view and (b) projection of the sarcomere along the filament axis. The projection consists of hexagons or rhombus cells of edge a. The rhombus area contains one myosin filament and has the same area as the hexagon cell.

In Fig. 61.5a, the vertical thin rods are actin filaments. The thick vertical rods are backbones of myosin filament and

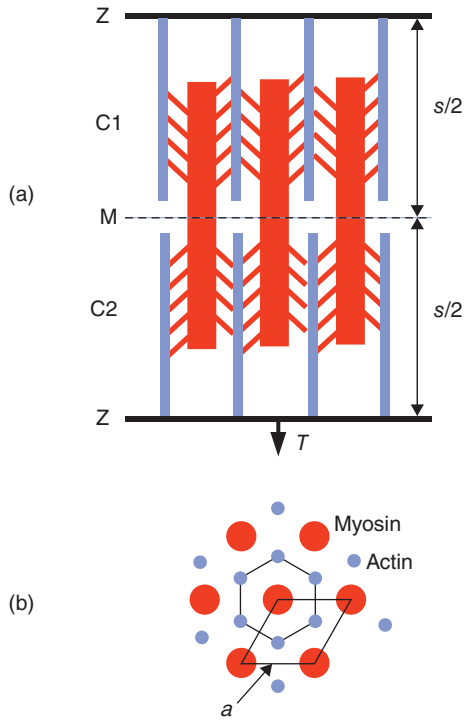

FIGURE 61.5 A portion of the sarcomere at the full filament overlap. (a) Side view. Myosin filaments are shown by thick vertical bars with branches and the actin filament by vertical thin rods. The thickness of half sarcomere is $s/2$. See text for more details. (b) Projection of the sarcomere along the filament axis. The projection consists of rhombus cells of edge a or of hexagons.

the oblique thin rods symbolically represent myosin heads, including the heads attached and not attached to the myosin filaments. Although only nine oblique rods are depicted per myosin backbone per half sarcomere for simplicity in (a), actually about 300 heads exists as calculated below. Z and M planes are perpendicular to the filaments. Since the tension T is given in units of N/m^2, let us consider a flat cylinder between the planes Z and M, whose base is 1 m^2 wide and thickness is the half sarcomere length $s/2$, as indicated by C1 and C2. The upper Z plane is considered fixed, and thus the tension T is downward. Then the actin filaments in C1 exert upward force on myosin filaments balancing the tension T, while the myosin filaments in C2 exert upward force on actin filaments balancing T. In this way, each flat cylinder produces the tension T in the sliding-filament theory. Below we shall consider C1.

The number of myosin heads in C1 is denoted as $N_{\rm hs}$, whose numerical value can be obtained as follows. The edge of the rhombus unit cell is indicated as a in Fig. 61.5b. It is known that a varies depending on T but, as an approximation, a is set equal to 42 nm following [8]. Then the area of the unit cell is $a^2\sin 60° = 1528 \times 10^{-18}$ m^2. Microscopic photographs of muscle suggest that the ratio of sarcomere area in the base of C1 is not very far from 1, and the ratio is set as 0.9 as an approximation, following one study [8]. Then the number of myosin filaments in C1 is $0.9/(a^2\sin 60°) = 5.89 \times 10^{14}$ m^{-2}. As shown in Fig. 61.1e, the myosin projections (myosin heads) are arranged with spacing of about 14.3 nm on the actin filament with threefold rotation symmetry. The spacing is denoted as d and is set equal to 14.3 nm as in another study [8]. Because of the threefold rotation symmetry, the myosin filament has six myosin heads per d. The length of myosin filament minus that of the bare zone is about 1.43 μm. Thus the number of myosin heads on one myosin filament per half sarcomere is $6 \times (1.43 \times 10^{-6}/2)/14.3 \times 10^{-9} = 300$. Thus we have an approximate value of $N_{\rm hs}$ as

$$N_{\rm hs} = 300 \times 5.89 \times 10^{14}{\rm m}^{-2} = 1.76 \times 10^{17}{\rm m}^{-2} \qquad (61.3)$$

The symbol r is defined as the ratio of the number of myosin heads attached to an actin filament per total number of myosin heads at the same moment. Then the relation between the mean force p produced by one attached head and the tension T is given by

$$p = T/(rN_{\rm hs}) \qquad (61.4)$$

61.3.3 Thermodynamic Relationship

Combining Eqs. (61.1), (61.2), and (61.4) gives

$$D/r = e_{\rm A}N_{\rm hs}V/(W+H) \qquad (61.5)$$

This is the required thermodynamic relationship that any model based on the sliding-filament theory should satisfy.

If the units of the quantities in Eq. (61.5) are presented in parentheses, they are D(m), $e_{\rm A}$(J), $N_{\rm hs}$(1/m^2), V(1/s), and $(W+H)$(J/m^{3}s), so that the unit of the right-hand term is (J)(1/m^2)(1/s)(m^{3}s)/J = m, the same as the unit of D/r.

As T approaches to 0, $W = TV$ becomes negligible compared to H, and Eq. (61.5) becomes

$$D/r = e_{\rm A}N_{\rm hs}V/H \qquad (61.6)$$

Let us use $e_{\rm A} = 8.0 \times 10^{-20}$ J/molecule, $V_{\rm max} = 2.25$ (1/s) (V under no load) [9], $H = 35.2$ kW/m^2 at $T = 0$ at 0°C [10], as was done in Section 2.1 of Ref. 5. Then Eq. (61.6) gives

$$D/r = 900 \text{ nm, for } T = 0 \text{ at } 0°{\rm C} \qquad (61.7)$$

This value of D/r is large, but those of similar order of magnitude can be obtained from other experimental data as described in the next section.

61.3.4 Values of D/r Estimated from Literature Data [11]

Harada et al. [11] observed the motion of actin filaments on a glass strip covered by myosin molecules, and measured the velocity of the actin filament and rate of hydrolysis of ATP. They estimated from their data that D is larger than 60 nm at 30 and larger than 200 nm at 20°C. As mentioned by several authors, however, their method for estimating D seems too speculative. Nevertheless, the order of magnitude of D/r can be estimated from their data as follows.

According to Harada et al. [11], the mean sliding velocity of the actin filaments does not depend on the filament length. They determined the rate of hydrolysis of ATP by the Pi production rate per 1 nm of the actin filament. Here let us simplify their system by supposing the following model. Myosin molecules are arranged on a straight line with the mutual separation of d_{H} on the glass strip. The length of the line is more than 1 m. A straight actin filament of 1 m is on the myosin line and moves along it. Now the stress T is regarded as a friction force against the actin filament movement. Then relations similar to Eqs. (61.2), (61.4), and (61.5) can be derived. If the quantities concerning the experiment by Harada et al. are expressed with suffixes H, Eq. (61.5) becomes

$$D_{\mathrm{H}}/r_{\mathrm{H}} = e_{\mathrm{A}} N_{\mathrm{H}} V_{\mathrm{H}}/(H_{\mathrm{H}} + W_{\mathrm{H}}) \tag{61.8}$$

Harada et al. [11] determined the average distance between myosin molecules on the glass strip by electron microscope as about 12 nm. Hence we set

$$d_{\mathrm{H}} = 12 \text{ nm} \tag{61.9}$$

Since the length of the actin filament is 1 m and the myosin molecule is two-headed, we have

$$N_{\mathrm{H}} = 2/d_{\mathrm{H}} = 2/12 \times 10^{-9} = 0.17 \times 10^{9} \tag{61.10}$$

In Table 1 of the paper by Harada et al. [11], values of v(μm/s) and (pi/s per nm) are given. With our notations, V_{H} (m/s) = $v \times 10^{-6}$ and $H_{\mathrm{H}} + W_{\mathrm{H}}$ (J/s per m) = e_{A}(pi/s per nm)×10^9. Then Eq. (61.8) becomes

$$D_{\mathrm{H}}/r_{\mathrm{H}} \text{ (nm)} = 170v/(\text{Pi/s per nm}) \tag{61.11}$$

By using the values given in Table 1 of Harada et al. [11] and N_{H} in Eq. (61.10), we have

$$D_{\mathrm{H}}/r_{\mathrm{H}} = 850 \text{ nm} \quad \text{for actin filament at } 22°\text{C} \tag{61.12a}$$
$$D_{\mathrm{H}}/r_{\mathrm{H}} = 350 \text{ nm} \quad \text{for actin filament at } 30°\text{C} \tag{61.12b}$$
$$D_{\mathrm{H}}/r_{\mathrm{H}} = 1280 \text{ nm} \quad \text{For thin filament at } 22°\text{C} \tag{61.12c}$$

These values of $D_{\mathrm{H}}/r_{\mathrm{H}}$ are as large as D/r = 900 nm in Eq. (61.7).

61.4 DIFFICULTIES OF THE POWER STROKE MODEL

61.4.1 Difficulty Concerning Magnitude of r

According to Eq. (61.7), the order of magnitude of D/r is 900 nm for free shortening at 0°C. This value of 900 nm is derived from the sliding-filament theory according to the first law of thermodynamics irrespective of modeling on muscle contraction mechanism. Hence any model based on the sliding-filament theory should give this order of magnitude. In the power stroke model, the power stroke (or working stroke), which corresponds to D in our notation, is approximately 10 nm [12]. Then the relation D/r = 900 nm gives r as 0.011.

The stiffness of a muscle varies depending on the stress and is assumed to be a measure of r in the power stroke model [13]. According to one report [13], the ratio of the stiffness of the crossbridge at $T = 0$ to that at $T = T_0$ is about 0.35, where T_0 is the isometric tension (see Fig. 61.13, given later). Therefore, if $r = 0.011$ is for $T = 0$, the ratio r for $T = T_0$ becomes $r = 0.011/0.365 = 0.031$. This means that 3.1 % of all the myosin heads in muscle contribute to force production at the maximum. The value of 0.011 or 0.031 seems too small to be realistic. This is an essential difficulty of the power stroke model.

61.4.2 Values of r and D Estimated from Experimental Data

In the isometric state, Eq. (61.4) becomes $p_0 = T_0/(r_0 N_{\mathrm{hs}})$, where p_0, T_0 and r_0 are values of p, T and r in the isometric tetanus state. Then

$$r_0 = T_0/(N_{\mathrm{hs}} p_0) \tag{61.13}$$

$T_0 = 4.1 \times 10^5$ N/m^2 according to Edman [9] and $N_{\mathrm{hs}} = 1.76 \times 10^{17}$ m^{-2} by Eq. (61.3). The experimental results of one team [14] indicate that p_0 is close to 5.7 pN. We adopt this value in the following calculations:

$$p_0 = 5.7 \text{ pN} \tag{61.14}$$

Using these values, Eq. (61.13) gives

$$r_0 = 0.41, \text{ for } T = T_0 \tag{61.15}$$

X-Ray data are favorable to $r_0 = 0.41$. By X-ray diffraction study of the [1,0] and [1,1] equatorial reflections from a sartorius muscle, another team [15] estimated that about 80% of myosin heads migrate around the thin filament in isometric tetanus muscle. This percentage is higher (approximately 92–99%) according to one report [16]. Since these percentages are about twice r_0 = 41%, it seems reasonable to suppose

that approximately one of two heads of a myosin molecule attaches to actin filament and produces force while the other exists in the vicinity of the thin filament as nonattached relief.

In shortening muscles, several teams of investigators [16–19] observed that the intensity ratio of the [1,0] and [1,1] equatorial reflections increases only minimally as shortening velocity increases, indicating that the total number of myosin heads in the vicinity of the actin filament decreases only slightly. These experimental data strongly suggest that the ratio r in shortening muscles is about the same as r_0 in Eq. (61.15), and we incorporate $r = r_0$ in the following discussion:

$$r = 0.41, \text{ for any } T \tag{61.16}$$

This value of 0.41 is much larger than 0.011 or 0.031 of the power stroke model.

In the power stroke model, the constant r indicated by X-ray studies is explained by assuming that weakly attached crossbridges exist in addition to strongly attached crossbridges and that the muscle stiffness and the force are determined by the strongly attached crossbridges. This explanation implies that 1.1% or 3.1% of all myosin heads are strongly attached heads and produce tension while (41 – 1.1)% or (41 – 3.1)% are weakly attached heads. Such situation does not seem realistic if muscle is a machine of high efficiency.

By Eq. (61.16), Eq. (61.7) gives

$$D = 370 \text{ nm, for } T = 0 \text{ at } 0°\text{C} \tag{61.17}$$

This D value is large but estimated from the thermodynamic relationship and the experimental data regardless modeling of the muscle contraction mechanism. As mentioned in Section 61.4.1, the working stroke (D in our notation) is about 10 nm in the power stroke model. The value 370 nm is much larger than 10 nm, indicating need of a new model.

61.5 REQUIREMENTS FOR ANY MODELS BASED ON SLIDING-FILAMENT THEORY

Requirements that any models based on the sliding-filament theory should fulfill may be listed as follows.

1. Large D/r or D in shortening muscles. The value of $D/r = 900$ nm [Eq. (61.7)] for free shortening is derived solely from the sliding-filament theory and the first law of thermodynamics with macroscopic experimental data. Also the value of $D = 370$ nm [Eq. (61.17)] is strongly suggested by the experimental data as discussed in Section 61.4.2. These values are very large but are determined irrespective of modeling of the muscle contraction mechanism. Accordingly, any model based on the sliding-filament theory should give the order of magnitude of D/r or D.
2. Small D observed in experiments with single myosin molecule in vitro. One team [20] studied the movement and force generation produced by a single myosin head and found the movement during one ATP hydrolysis cycle to be about 4 nm. Another team [21] developed a new assay for direct manipulation of S-1, making visualization possible with a fluorescent label. Their results show that a myosin head moves along the actin filament with 5.3-nm steps, often producing displacement of 11– 30 nm for each ATP hydrolysis cycle.
3. Crossbridges independently produce force in the isometric tetanus state. As noted in Section 61.1, early history of muscle research is surveyed by A. Huxley [1]. Chapter III in Part II of Ref. 1 concerns experimental data by two investigators [22] and analysis of their data [23]. They [22] measured tension developed by isolated frog muscle fibers when stimulated at various degrees of stretch in the isometric tetanus state. Their length–tension curve indicates that there is a linear fall as length is increases above the optimum [11, Fig. 9]. This is what to be expected if the tension that the fiber is able to generate is directly proportional to the extent of overlap between thick and thin filaments in each sarcomere. Then it is reasonable to conclude that the myosin heads produce force independently of each other in the isometric tetanus state as discussed in [23].
4. Reasonable explanation should be given on the coupling between the force production and energy liberation by chemical reaction.
5. The model should explain major experimental data on muscle properties or behaviors.

61.6 CONSTRUCTION OF A NEW MODEL

61.6.1 Formation of Complex MA_3 by a Myosin Head and Three Actin Molecules

Let us consider interaction between an ATP-activated single myosin head and an actin filament by using distribution of potential wells for the head on the actin filament as shown in Fig. 61.6.

In Fig. 61.6a the activated myosin head is indicated as M, which sits at a position apart from the actin filament. The actin filament is represented by the periodic array of potential wells that correspond to the possible binding sites for M. As shown in Fig. 61.1f, an actin filament consists of two strands. The wells are arranged with the period L of actin strand

$$L = 5.46 \text{ nm} \tag{61.18}$$

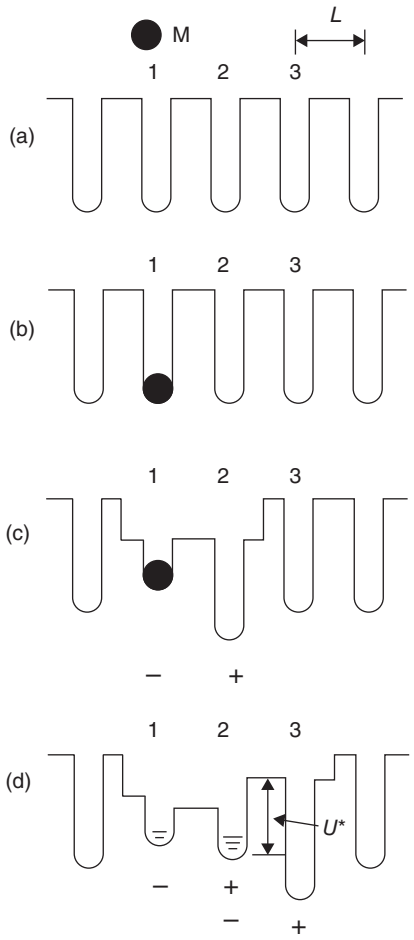

FIGURE 61.6 Diagram showing sequential changes in the potential of force acting on ATP-activated single myosin head M (subfragment 1) when M binds to an actin filament. The numbers 1, 2, and 3 are assigned to the potential wells at the binding sites of actin molecules on the same strand. (a) Periodic potential distribution when M is sitting at a position apart from the actin filament. (b) Just after M attaches to actin 1. (c) Molecules deform and potential distribution changes. (d) Final potential distribution. Generally M is statistically distributed in wells 1 and 2.

The helical structure of the actin filament will disturb the periodic potential arrangement, but its effect does not seem essential and is neglected here.

Two other teams [24, 25] studied the binding pattern of a myosin head to an actin filament by using tryptic digestion of myofibrils and measuring optical polarization and dichroism. One team [25] concluded that in the rigor rabbit psoas muscle each myosin head binds to two actin monomers in a thin filament, indicating the possibility that the myosin head firstly binds to one and then to two monomers in the actin filament. Figure 61.6b–d shows an example of possible mechanism of how such binding change occurs. Figure 61.6b shows the state at the moment M when attaches to actin 1. Attachment of the myosin head may cause large strain in actin molecules. Protein molecules are structurally polar. (Note, for instance, that G-actin has the permanent dipole moment of 600 Debyes [26].) Hence the actin filament is piezoelectric. Consequently, it is a possibility that the strain produces an electric polarization as symbolically indicated by the electric charges – in actin 1 and + in actin 2 in Fig. 61.6c. The myosin head is negatively charged and the Coulomb interaction between the head charge and the induced polarization charges raises the potential well for the head at actin molecule 1 and lower the well at actin 2 as shown in part (c) of Fig. 61.6. Also it is assumed that the change lowers the potential barrier between 1 and 2 (c), so that M can jump over the barrier as a result of the thermal fluctuation and is statistically distributed in the wells 1 and 2 as schematically drawn in (d). Then the head at well 2 will produce the polarization charge – in well 2 and + in well 3 similarly to the case of (c) but somewhat differently from (c), due to the different prehistory. The induced charges in this case are symbolically shown by small – and + in (d). The structural changes from (c) to (d) will be similar to that from (b) to (c) but somewhat different from (c) because of the different prehistory. The resultant potential distribution is supposed to be such as shown in (d). Presumably the myosin head bound to actin 1 and 2 is observed [24,25]. Figure 61.6d shows the potential barrier U^* that the myosin head M has to cross over to move from well 2 to 3. U^* will be discussed in Section 61.6.3.

61.6.2 Molecular Model for MA_3

Figure 61.7 illustrates the change of molecular structures associated with the change in potential distribution in Fig. 61.6. Figure 61.7a shows a myosin head just after attachment to actin filament (the shape is speculated), which corresponds to the state in (b). Then the potential changes occur from (b) to (c) and (d), causing the shift of the binding site of the head from (a) to (b) in Fig. 61.7. The shape of the head in (b) is depicted by referring to the shape in Fig. 6 of Ref. 27. It is assumed that the molecular deformation occurs mainly in the shadowed three actin molecules together with the head in Fig. 61.7b, associated with the potential variation in Fig. 61.6d. The shadowed complex in Fig. 61.7b is denoted as MA_3. Figure 61.7c is a model of Fig. 61.7b. The tilting angle of the neck domain relative to the vertical z axis is denoted as θ_{eq} in the case of a single myosin head.

61.6.3 Cooperative Interaction among Crossbridges

As mentioned regarding requirement 3 in Section 61.5, one can conclude that the myosin heads produce force independently of each other in the tetanus state. One team [23] extended this conclusion to the case of shortening muscle

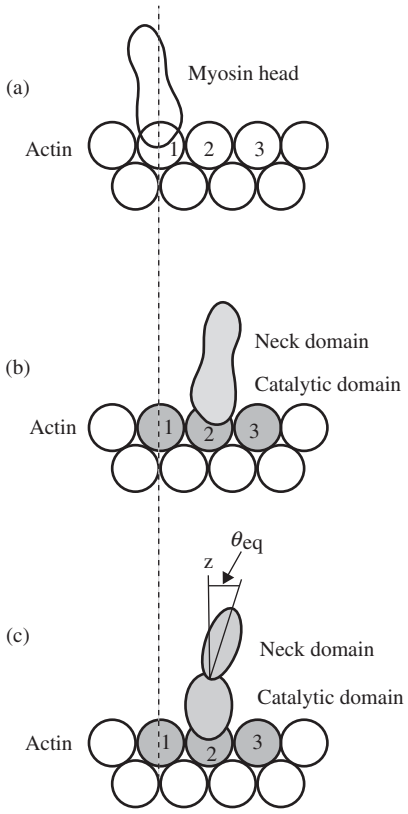

FIGURE 61.7 Formation of a complex MA_3 of myosin head and actin molecules. (a) Just after attachment of myosin head to actin molecule 1 corresponding to Fig. 61.6b. Molecules are not deformed yet. (b) The shadowed myosin head and actin molecules 1, 2, and 3 are deformed and the complex MA_3 is formed, corresponding to Fig. 61.6d. (c) Modeling of (b). The myosin head is represented as neck domain plus catalytic domain. The angle θ_{eq} is the bending angle of neck domain at equilibrium.

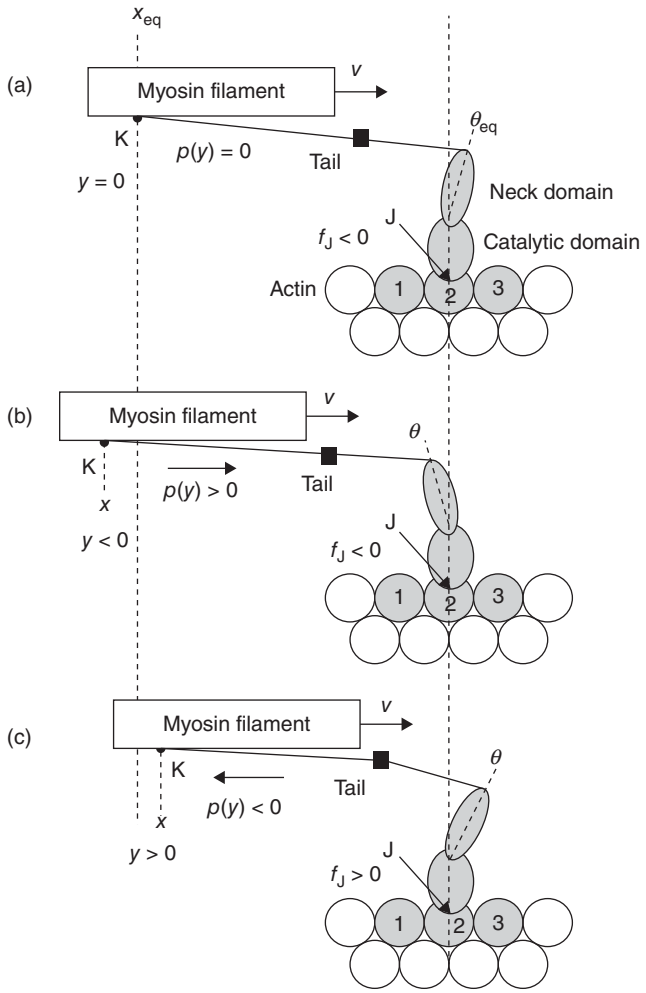

FIGURE 61.8 Three states (a), (b), and (c) of the MA_3 complex indicated by shadowing. Ends of the crossbridges are indicated as *J* and *K*. Ends *J* are set on the dotted line *z* and *K* at different positions referring to the dashed line x_{eq} in (a), (b), and (c). *y* represents shortening of the crossbridge. (a) The myosin head is at its equilibrium angle, θ_{eq} and $y = 0$. (b) The myosin head is pulling the myosin filament forward. The crossbridge is elongated and $y < 0$. (c) The myosin head is pushing the myosin filament backward. The crossbridge is shortened and $y > 0$.

and assumed that the myosin heads produce force independently of each other also in shortening muscles, and proposed an "independent force-generator theory." Construction of the power stroke model was based on this theory, as discussed in chapters following Chapter III in Part II of Ref. 1. It seems, however, too speculative to assume that myosin heads produce force independently of each other also in shortening muscles. The power stroke model encounters various difficulties as mentioned in Section 61.4. The difficulties, however, can be avoided by assuming cooperative interaction among crossbridges in shortening muscles as discussed elsewhere [5–7]. The cooperative interaction disappears in the isometric tetanus state [5–7] in accordance with the conclusion in another study [23]. The discussion in Refs. 5–7 is outlined below.

According to Eq. (61.16), 41% of the myosin heads are bound to actin filaments forming the complex MA_3 in shortening muscle. In Fig. 61.8, the complex MA_3 is shadowed and connected to a myosin filament by the thin bar denoted as tail, forming the crossbridge.

The right direction corresponds to the sliding direction of the myosin filament against the actin filament and is called *forward* and the left direction, *backward*. The end of the crossbridge at the myosin filament is indicated as *K* and the end at the actin filament, as *J*. The tail has bending freedom [5, Section 3.4], which is represented by one hinge depicted as a black square for simplicity. Figure 61.8 shows three states of the crossbridge, where the actin filaments are fixed at the same position and *J* are placed on the line *z*. In part (a), the tilting angle of the neck domain is equal to the

equilibrium angle θ_{eq}. The shortening of the crossbridge is defined in reference to the state at θ_{eq} and denoted as y. The force that the crossbridge exerts on the myosin filament is a function of y and denoted as $p(y)$. In (a), $y = 0$ and $p(y) = 0$. In (b), K is set to left from K in (a) and the neck domain tilts to left from θ_{eq}. The myosin filament is pulled forward [$p(y) > 0$]. The crossbridge is elongated ($y < 0$). The tail is straightened and the elastic force by the myosin head will be straightforwardly transmitted to the myosin filament. In (c), K is set to right from (a) so that the tail is shortened ($y > 0$), and the crossbridge pushes the myosin filament backward [$p(y) < 0$]. The tail is bent, and the effect of the backward force by the crossbridge will be weakly transmitted to the myosin filament.

The basic idea of theoretical treatments elsewhere [5,6] is outlined below. As shown in Fig. 61.6d, the myosin molecule has to cross over the potential barrier U^* to move from well 2 to well 3 in MA_3. The probability Q that the myosin head crosses over U^* is discussed based on Eyring theory of the rate process described in Ref. 28, as was done in another study [29]. (It should be noted that our model is quite different from the model discussed in Ref. 29, although Eyring theory is used during formulation in both models.) U^* and Q are functions of $p(y)$ and written as $U^*(y)$ and $Q(y)$. Then, as in Eq. (3-5-1) in Ref. 5, $Q(y)$ is given by

$$Q(y) = A \exp(-U^*(y)/kT) \tag{61.19}$$

Here, A is a constant, k is the Boltzmann constant, and T is the absolute temperature. In Ref. 5, $U^*(y)$ is expressed by $U^*(y) = U^*_0 - af_J(y)$ [5, Eq. (3-5-2)] and $f_J(y) = -p(y)$ [5, Eq. (3-4-2)], where U^*_0 and a are constants. Thus we have

$$U^*(y) = U^*_0 + ap(y) \tag{61.20}$$

Because of the bending freedom, the stiffness of the crossbridge (i.e., myosin head plus tail) depends on y. The stiffness is denoted as κ_f in the case shown in Fig. 61.8b, where the tail is straightened and $y < 0$. The stiffness is denoted as κ_b in part (c), where the tail is bent and $y > 0$. Following Eq. (3-4-6) in Ref. 5, $p(y)$ is approximately given by

$$p(y) = -k_f y, \quad \text{for } y < 0 \tag{61.21a}$$

$$p(y) = -k_b y, \quad \text{for } y > 0 \tag{61.21b}$$

Values of the stiffness are given by Eqs. (4-1-13) and (4-1-14) in Ref. 5:

$$k_f = 2.80 \text{ pN/nm} \tag{61.22a}$$

$$k_b = 0.26 \text{ pN/nm} \tag{61.22b}$$

Equation (61.22) indicates that the crossbridge is elastically nonlinear.

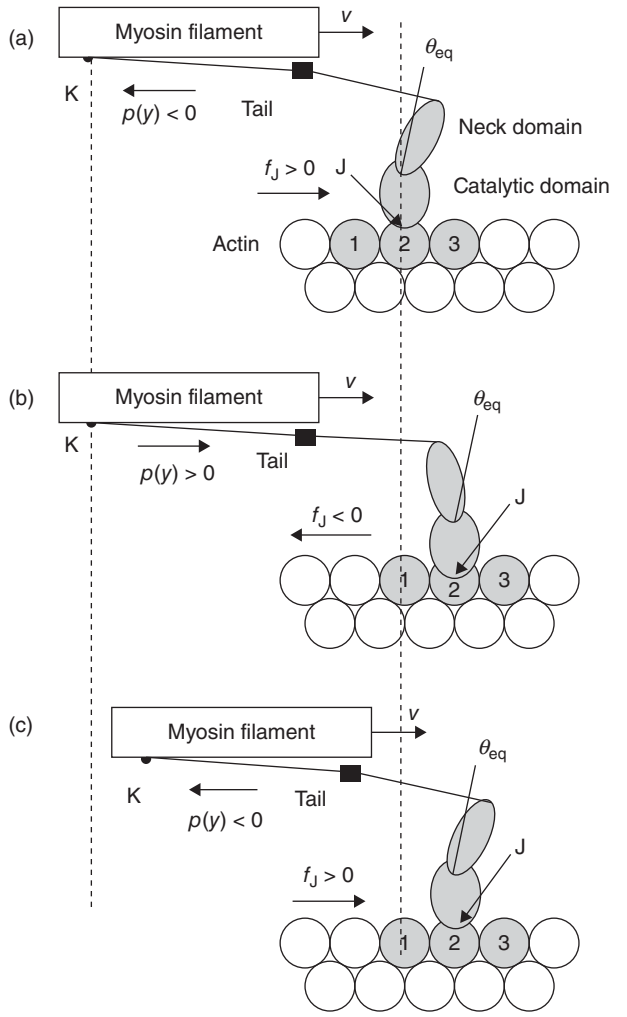

FIGURE 61.9 Step motion of complex MA_3 (shadowed) along an actin filament. (a) The neck domain tilts to the right from θ_{eq}. The myosin filament is pushing the neck domain forward and MA_3 is just before translation to the right position. (b) Just after the MA_3 has moved to the new position. The crossbridge is pulling the myosin filament forward. (c) The myosin filament moves to the right by the filment sliding and MA_3 is ready for translation to the right position.

We leave mathematical discussion based on these equations to Refs. 5 and 6, and explain only implication of the above equations here. Figure 61.9 illustrates what happens with the model during the filament sliding. Figure 61.9a shows the state that the neck domain tilts to right from the equilibrium angle θ_{eq} and pushes the myosin filament backward. The crossbridge is shortened, and thus $y > 0$, the stiffness is κ_b and $p(y) < 0$ by Eq. (61.21b). (The head corresponds to the weakly attached head in terms of the power stroke model since $\kappa_b < \kappa_f$.) When the myosin filament moves forward, $p(y)$ decreases and the potential barrier $U^*(y)$ decreases according to Eq. (61.20), so that the transition probability $Q(y)$ increases according to Eq.

(61.19). Let us denote the critical y at which the head most frequently crosses over U^* during filament sliding as y_c, and simplify the discussion by assuming that all the transitions crossing over U^* occur at y_c. If Fig. 61.9a shows the state at y_c, the head will cross over U^* in the next moment and will form a new complex MA_3 as shown in (b), where the neck domain tilts to the left from θ_{eq} and pulls the myosin filament forward. Now $y < 0$, $p(y) > 0$ [Eq. (61.21a)], and the stiffness is κ_f. (The head corresponds to the strongly attached head in term of the power stroke model since $\kappa_f > \kappa_b$.) $U^*(y)$ is large according to Eqs. (61.20), (61.21a), and (61.22a), and $Q(y)$ is small per Eqs. (61.19) and (61.20). Hence the head has practically no chance to cross over U^* and continually pulls the myosin filament forward. Then the myosin filament slides forward and the end of the crossbridge K moves forward from (b) to (c). The situation in (c) is identical to that in (a) except for binding actin mates, and the U^* transition occurs. Filament sliding takes place repeating such steps. The parameter y_c is a function of the tension as will be discussed in Section 61.7.2.

The filament sliding is a result of force production by all MA_3. On the other hand, the filament sliding induces the U^* transition of each MA_3 so that the MA_3 produces the force. Thus the force production of each crossbridge is enhanced by other crossbridges. In this sense, there is a mutual cooperation among crossbridges. Generally cooperative system is mathematically discussed by using a feedback loop that output of each element is affected by output of all elements in the system [e.g., 30, Section 22]. Equations (61.19)–(61.22) imply such a feedback loop.

As mentioned in Section 61.5, one research team [21] developed a new assay for direct manipulation of S-1, making visualization possible with a fluorescent label. Their results show that a myosin head moves along the actin filament in 5.3-nm steps, often producing displacement of 11–30 nm for each ATP hydrolysis cycle. In their experiment, the single myosin molecule has no partner of cooperation and the force on the head is close to 0 after the movement, corresponding to the case of practically zero $p(y)$ in the expression of $U^*(y) = U^*_0 + ap(y)$ [Eq. (61.20)]. Thus their results seem to indicate that U^*_0 is relatively large so that the probability for the myosin head to cross over U^* is small. Presumably, there was some fluctuation of the force depending on the experimental conditions, and D was observed as about 5.46 nm [Eq. (61.18)] a few times. This is an answer to requirement 2 in Section 61.5.

As mentioned in Section 61.3.4, Harada et al. [11] studied the motion of actin filaments on a glass strip covered by myosin molecules. They observed that the actin filaments longer than ~40 nm moved on the myosin-covered glass strip, and that the actin filaments of ~40 nm sometimes stopped the movement. It is plausible that usually two or three myosin heads attach to the moving actin filament of 40 nm and occasionally only one myosin head remains to attach to the actin filament so that there is no cooperatively working mate and the actin filament stops.

The change of the form of MA_3 from Fig. 61.9 (b) to (c) does not occur without the filament sliding. Thus the filament sliding is a necessary condition for the cooperative interaction among crossbridges. In the isometric tetanus state, there is no filament sliding and hence no cooperativity among crossbridges. Accordingly, crossbridges produce force independently in the isometric tetanus state as observed by several investigators [22, 23]. This is an answer to requirement 3 in Section 61.5.

61.6.4 Chemical Reactions and Energy Liberation Associated with Force Production

The authors of one study [31] proposed the chemical cycle associated with the force production in the power stroke model. In their scheme, dissociations of pi and ADP play the important role in force production. In our model, the way of energy flow and chemical reaction is quite different from theirs, and dissociations of pi and ADP do not play any important role in connection with force production.

The energy liberated by hydrolysis of one ATP molecule is denoted as e_A. The ATP-activated myosin head M in Figure 61.6a has e_A. A portion of e_A is used to form the complex MA_3 in Fig. 61.6d. The remains of e_A are used for the force production. The head detaches from the actin filament when e_A is exhausted. Each cycle of force generation is connected with the chemical reactions, which consist of dissociation from one actin molecule and binding to the neighboring actin molecule. Figure 61.10 illustrates the steps. On the right, a myosin head is depicted as a box with the energy G stored in it. On the left, an actin filament is depicted as a box with many shelves where the shelf A_i corresponds to ith actin molecule. The force f_J from the myosin filament to the head

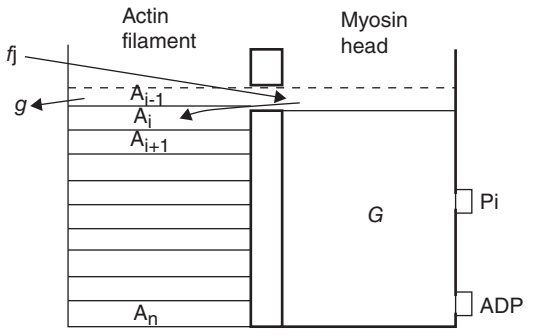

FIGURE 61.10 Energy flow and chemical reaction associated with the force production. Chemical reaction is a series of detachment from actin A_{i-1} and attachment to A_i. The fraction g of the free energy of a myosin head is used for force production at each chemical reaction. The energy stored in the myosin head after the ith step is denoted by G. The initial value of G is e_A given to the head by the ATP hydrolysis.

lowers the potential barrier U^* and lets the head dissociate from $A_{i\text{-}1}$ and bind to A_i. The myosin head produces force associated with this step. The level of G is lowered by g by the chemical reaction and the force generation. Energy liberation rate calculated on this scheme is in good agreement with experimental observation as shown later in Fig. 61.15. The step energy liberation seems to be related with thermal fluctuations as discussed in next subsection.

61.6.5 Role of Thermal Fluctuations

On the basis of Eyring theory with respect to the rate process described in Ref. 28, the probability Q for a myosin head to cross over U^* is given by $Q = A \exp(-U^*/kT)$ [Eq. (61.19)]. In most textbooks, Eyring theory is discussed in the case where a single material particle crosses over a potential barrier U^*. Then, the energy for the particle to cross over U^* is supplied by the thermal energy of the surroundings. In the case of a myosin head, however, the head has much internal freedom for structural and thermal fluctuation. Then it becomes possible for adiabatic fluctuation to occur in a limited timeframe in such a way that the decrease of structural fluctuation energy of the head is compensated by increase of the thermal fluctuation energy of constituent atoms, and vice versa. Thus the internal energy of the head can be used to excite the mode of motion of center of gravity of the head and to help the head cross over U^* in Fig. 61.6d. The difference between the potential energies at wells 2 and 3 in Fig. 61.6d is converted into the elastic energy of the crossbridge to be used to pull the myosin filament in the process from Fig. 61.9 (b) to (c). In this way the internal energy of the head originally supplied by ATP hydrolysis is used by parts to pull the myosin filament. The thermal fluctuation plays an important role for force production but it is not contradictory to the second law of thermodynamics because contribution from thermal fluctuation of surroundings to force production is zero as time average. This idea is similar to the model proposed by Huxley in 1957 [32] in the sense that the thermal energy plays an important role to produce force. In his model, however, it is assumed that thermal fluctuation having energy comparable to the ATP hydration energy e_A (about $21kT$ at 0°C) is excited to produce the power stroke. Then the probability for such excitation is approximately proportional to $\exp(-e_A/kT) = \exp(-21) = 7.6 \times 10^{-10}$, which seems too small to be realistic. In our model, a fraction of e_A is used in each cycle of force production and there is no such difficulty.

61.7 CHARACTERISTICS OF THE MODEL THAT ARE HELPFUL FOR NUMERICAL CALCULATIONS

Major experimental data can be explained based on the proposed model as demonstrated in the next section. In this section, factors that are very helpful for numerical calculations are mentioned, leaving details of the calculations to Refs. 5 and 6.

61.7.1 Relation between p and T

Combining Eqs. (61.4) and (61.16) gives

$$p/p_0 = T/T_0, \quad \text{for any } T \tag{61.23}$$

This relation means that we can obtain an expression of any quantity as a function of macroscopic parameter T/T_0 when we derive an expression of the quantity as a function of microscopic parameter p/p_0. This is a very useful relationship for numerical calculations.

61.7.2 Cyclic Force Generation and Parameter y_c

The shortening y of the crossbridge is defined in reference to Fig. 61.8. The parameter y_c is defined in Section 61.6.3 as a critical y at which the U^* transition occurs during the filament sliding. Since y is considered as the critical value y_c in Fig. 61.9a, the U^* transition occurs in next moment and the myosin head changes its partner actin molecules from (a) to (b) with shift of the crossbridge end J by $L = 5.46$ nm. Thus the crossbridge length increases by L and the shortening y changes from y_c to $y_c - L$. In the change from (b) to (c), the myosin filament moves forward by L and the molecular shape of MA_3 becomes the same as (a). Thus y changes from $y_c - L$ to y_c. In the steady filament sliding, y repeats the cycle from (a) to (b) to (c). Figure 61.11 illustrates the cycles on the y axis: y changes from y_c to $y_c - L$ by the U^* transition and from $y_c - L$ to y_c through filament sliding. In the steady sliding, y increases at the constant rate and thus y of all the crossbridges are distributed uniformly between

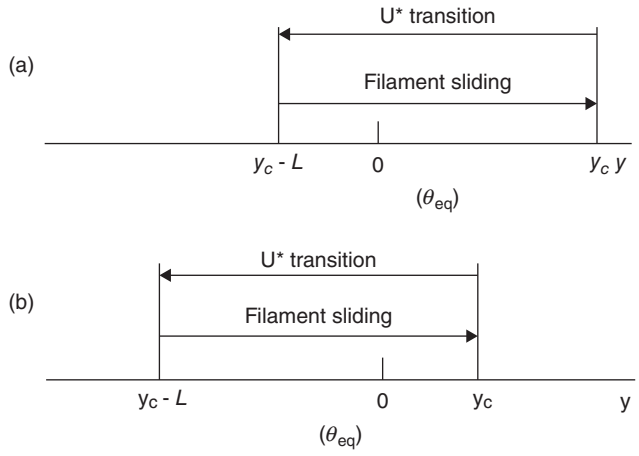

FIGURE 61.11 Cycle of variation of y. The filament sliding velocity is determined by y_c. (a) Fast filament sliding. (b) Slow filament sliding.

$y_c - L$ and y_c at any moment. Accordingly, the force p produced by a crossbridge during one cycle is given by integration of the force $p(y)$ from $y_c - L$ to y_c. Per Eq. (61.21), $p(y)$ is proportional to -y and thus p becomes small as y_c becomes large. Figure 61.9a shows the case of fast sliding for small p and (b) the case of slow sliding for large p.

The tension T is determined by p [Eq. 61.23)] and thus determined by y_c. The filament sliding velocity v is determined by the transition probability $Q(y_c)$ putting $y = y_c$ in Eqs.(61.19) and (61.20). Thus v can be calculated as a function of y_c. The parameter y_c is very useful to discuss also other quantities, as can be seen in Refs. 5 and 6.

61.8 COMPARISON OF CALCULATION RESULTS WITH EXPERIMENTAL DATA

Calculations are done on muscle properties or behaviors on the model proposed model in Refs. 5 and 6. This section illustrates how well the calculation results explain experimental observations. In Section 61.8.1, we comment on postulation in the calculations in Refs. 5 and 6, leaving the details of calculations to those studies [5, 6]. Section 61.8.2 discusses for steady filament sliding as discussed in Ref. 5. Section 61.8.3 covers transition phenomena discussed in Ref. 6.

61.8.1 Existence Probability of Myosin Molecule in Wells in MA_3

Figure 61.6d schematically shows distribution of the existence probability of myosin molecules in wells 1 and 2 in the MA_3 complex. In shortening muscle the myosin head in well 2 moves over the potential barrier U^* and produces force, while the head in well 1 does not directly contribute to force production. Hence, if the muscle is designed as an effective machine, the depth of well 2 will be made suitably deep so that the existence probability in well 2 becomes 1, as shown in Fig. 61.12a. The existence probability is affected also by the tension T. The crossbridges having $y < 0$ pull the myosin filament forward. Then, by reaction, the myosin filament pulls the myosin head of the crossbridge backward and tends to increase the existence probability of the head in well 2. Hence it is a possibility that the existence probability in well 1 become finite when T is large, as shown schematically in Fig. 61.12b.

In Ref. 5, calculations are based on the assumption that the existence probability in well 2 is 1 as shown in Fig. 61.12a. General behaviors of steady filament sliding are clearly explained on this assumption61., as illustrated in Section 8.2. There is, however, disagreement between the calculated result and the experimental data in the force–velocity relation for $T/T_0 > 0.66$ as shown later in Fig. 61.14.

In Ref. 6, finite probability is considered in well 1 as schematically shown in Fig. 61.12b, and the above-mentioned disagreement in the force–velocity relation becomes understandable. The transition phenomena are discussed in relation with the finite probability in well 1. Calculation results clearly explain various experimental data on the transition phenomena as illustrated in Section 61.8.3.

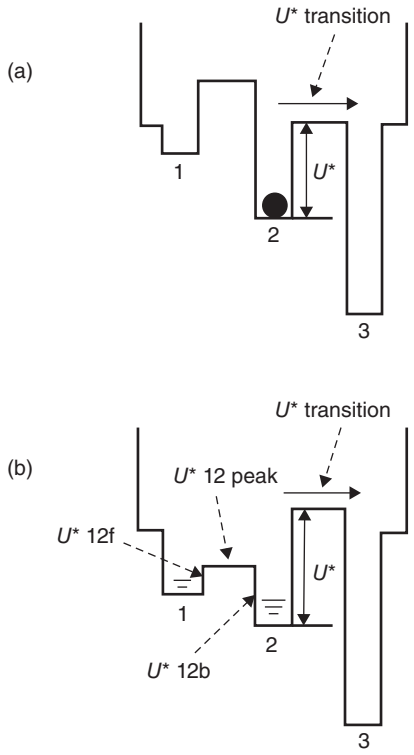

FIGURE 61.12 Existence probability of myosin head in wells of the MA_3 complex. (a) The case of $T < T_{dev}$. The black circle indicates that the myosin head exists solely in well 2. The force–velocity relation is Hill-type in this case. (b) The case of $T_{dev} < T < T_{0obs}$, where the existence probability of the myosin head becomes finite in wells 1, causing deviation of the force–velocity relation from Hill-type.

61.8.2 Steady Filament Sliding

This subsection introduces calculation results in Ref. 5 on muscle behaviors in steady filament sliding. Those calculations [5] are based on the scheme shown in Fig. 61.12a.

The ratio of the stiffness of the muscle at $T = 0$ to that at $T = T_0$ is about 0.35, where T_0 is the isometric tension [13]. This T dependence of stiffness was attributed to the variation of the number of the attached myosin heads in the power stroke model. In our model, the T dependence is explained in terms of the difference between the stiffness κ_f of the crossbridge having the straightened tail and κ_b related with the bent tail [see Eq. (61.22)]. Calculation is done on relative stiffness $S/S(T_0)$ as a function of T/T_0 in Section 4.1 of Ref. 5. Figure 61.13 shows that the calculation results reproduce the general feature of the experimental data.

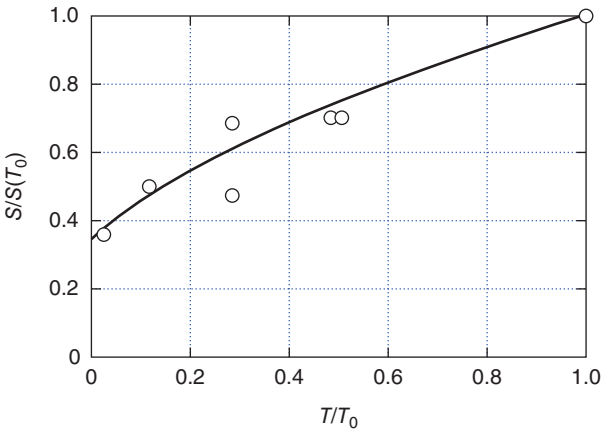

FIGURE 61.13 Relative stiffness $S/S(T_0)$ of muscle as a function of T/T_0, after Fig. 9 of Ref. 5. Open circles represent experimental data cited from Fig. 10B of the paper by Ford et al. [13]. Solid line indicates calculation results in Ref. 5. (Data from Mitsui et al. 2008 [5], Fig. 5 and Ford et al. 1985 [13], Fig. 10B.)

The filament sliding velocity v is calculated for a muscle of unit length as a function of T/T_0 in Section 4.2 of Ref. 5. The unit of v is converted to the value for half sarcomere (μm/s) by using the sarcomere length 2.10 μm reported by Edman [9]. Figure 61.14 shows the result by the curve in comparison with the experimental data given by Edman [9]. The curve coincides with the hyperbolic force–velocity relation reported by Hill [33], and is called *Hill-type curve below*.

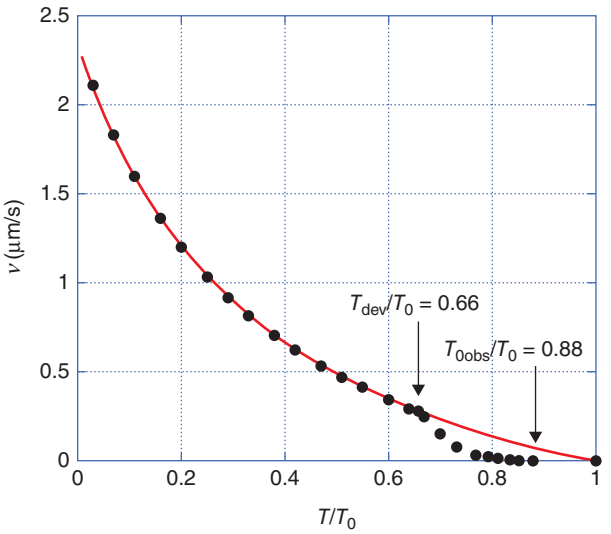

FIGURE 61.14 Force–velocity relation and definition of T_{dev} and T_{0obs}, after Fig. 11 of Ref. 5. The ordinate v is the filament sliding velocity per half sarcomere. The curve is after the calculation result in Ref. 5. Circles correspond to experimental results given in Fig. 6A of the paper by Edman [9]. (Data from Mitsui et al. 2008 [5], Fig. 11 and Edman 1988 [9], Fig. 6A.)

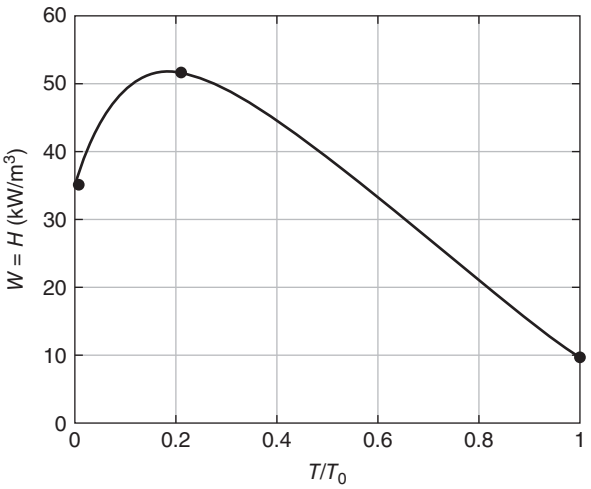

FIGURE 61.15 Energy liberation rate $W + H$ in contracting muscle as a function of T/T_0, after Fig. 12 of Ref. 5. Black circles represent experimental data by Homsher et al. [10]. Curve represents results of calculation [5]. (Data from Mitsui et al. 2008 [5], Fig. 12 and Homsher et al. 1984 [10].)

The distribution of data points, however, deviates from the red curve as the tension increases beyond $T_{dev}/T_0 = 0.66$. The origin of this deviation is discussed later with Fig. 61.18.

In Section 61.3.1, the rates of total energy liberation rate per unit volume of muscle are denoted as $W + H$. In Section 4.3 of Ref. 5, the expression for $W + H$ is derived and given as Eq. (4-3-13). The functional form of the expression is quite similar to the empirical equation given by Hill [34]. Figure 61.15 shows calculation result given in Ref. 5 in comparison with the experimental data.

Figure 61.16 shows the distance D over which a myosin head translates using $e_{A,}$ after Fig. 61.14 of Ref. 5. In the calculation there [5], Eqs. (61.3), (61.5), (61.16), and (61.23) are used with the values given by the curves in Figs. 61.14 and 61.15. Theb D becomes 370 nm for $T = 0$ as expected from Eq. (61.17).

Large values of D can be estimated also from the experiment by Harada et al. [11] mentioned in Section 61.3.4. They observed that most actin filaments shorter than about 40 nm dissociated from the myosin-coated surface, while longer ones remained bound to the surface. This fact suggests that two or three myosin heads are bound to an actin filament of 40 nm so that at least one of the myosin heads remains attached to the filament, although the others occasionally detach. In Section 61.3.4, the mean distance between neighboring myosin molecules d_H is set equal to 12 nm [Eq. (61.9)]. Then the mean number of the myosin heads that can bind to the actin filament of 40 nm is $2 \times 40/12 = 6.7$, considering the two-headed structure of myosin molecule. The ratio of the number of myosin heads attached to the actin filament is denoted as r_H. Then $6.7r_H = 2 \sim 3$. Thus

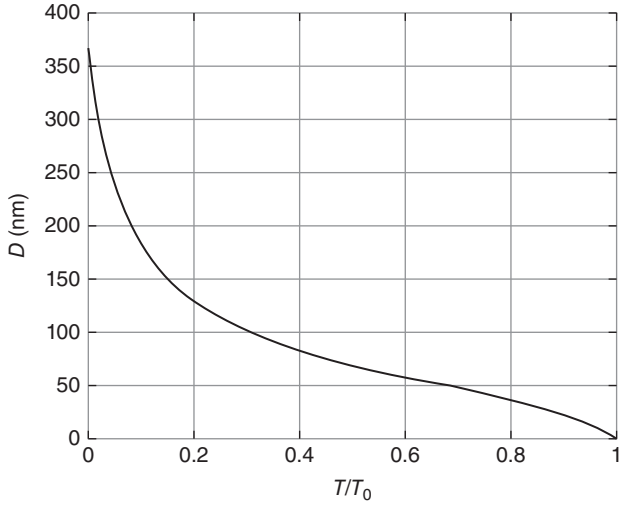

FIGURE 61.16 Calculated D as a function of T/T_0, after Fig. 14 of Ref. 5. D is the distance over which a myosin head translates using the ATP hydrolysis energy e_A. Temperature is about 0°C. (Data from Mitsui et al. 2008 [5], Fig. 14.)

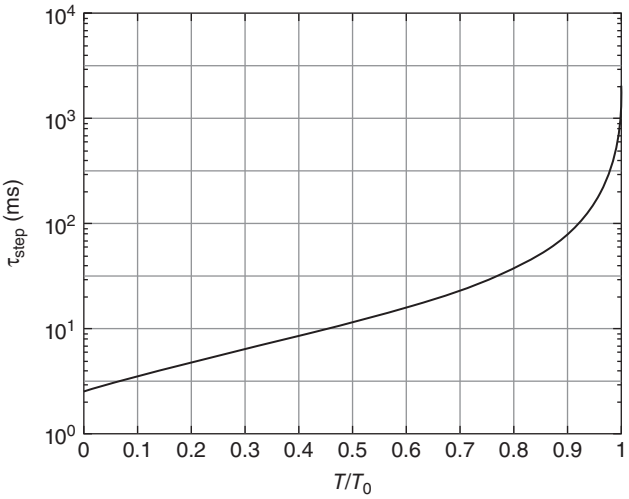

FIGURE 61.17 7 Mean time τ_{step} needed for occurrence of the U^* transition as a function of T/T_0, calculated by Eq. (61.24).

$r_H = 0.30 \sim 0.45$. By using values of $D/r_H = 850$, 350, 1280 nm in Eq. (61.12), we have $D = 260$–380, 110–160, and 380–580 nm at $T/T_0 = 0$. They are as large as 370 nm at $T/T_0 = 0$ in Fig. 61.16. Also Harada et al. [11] observed that an actin filament of about 40 nm sometimes stopped the motion. Presumably in this case only one myosin head remains attached to an actin filament so that there is no cooperatively working mate and the actin filament stops.

To discuss the transition phenomena in the next section, it is important to have an idea about mean time τ_{step} for occurrence of the U^* transition as a function of T/T_0. In the steady filament sliding, τ_{step} corresponds to the time in which a myosin head moves from one actin molecule to the neighboring one. Then τ_{step} is given by

$$\tau_{step} = L/v \tag{61.24}$$

Here $L = 5.46$ nm [Eq. (61.18)] is the distance between the centers of potential wells 2 and 3 in Fig. 61.6d, and v is the sliding velocity, which is given by the curve in Fig. 61.14. Values of τ_{step} calculated by Eq. (61.24) are shown as a function of the relative tension in Fig. 61.17, where τ_{step} is ~2 ms at $T/T_0 = 0$, increasing to ~10 ms at $T/T_0 = 0.5$, and increasing to >100 ms as T/T_0 increases. Hence the U^* transition is a relatively slow process and practically does not contribute to early processes in the transition phenomena, as will be discussed later concerning Fig. 61.20.

61.8.3 Transition Phenomena

Transient phenomena were studied by various workers. Especially, detailed studies were done on the isometric tension transient by Ford et al. [35] and on the isotonic velocity transient by Civan and Podolsky [36]. Calculations are done to explain the experimental data on these transition phenomena in Ref. 6. Results are introduced in this section.

Figure 61.14, on the force–velocity relation, shows that the experimental data deviate from the calculation result (the red curve) for $T/T_0 > T_{dev}/T_0 = 0.66$. The curve coincides with the hyperbolic force–velocity relation reported by Hill [33]. As mentioned in Section 61.8.1, finite existence probability is considered in well 1 as shown schematically in Fig. 61.12b to explain the deviation.

Section 7 of Ref. 6 discusses how U^* varies when the existence probability of the myosin head becomes finite in well 1 in the case of $T > T_{dev}$. A parameter $({y_c}^H - {y_c}^*)$ is derived to represent the structural modulation of MA_3 due to finite existence probability of the myosin head in well 1. As a result, $U^*(y) = {U^*}_0 + ap(y)$ [Eq. (61.20)] has an additional factor $c({y_c}^H - {y_c}^*)$:

$$U^*(y) = U^*0 + ap(y) + c\left(y_c^H - y_c^*\right) \tag{61.25}$$

Here, c is a constant. Calculated $({y_c}^H - {y_c}^*)$ is given as a function of T/T_0 by the curve in Fig. 61.18a. The filament sliding velocity v^* to be observed is given in relation with the Hill-type velocity v^H by

$$v^* = v^H \exp\left(-b_v \left(y_c^H - y_c^*\right)\right) \tag{61.26}$$

Calculation is done by setting

$$b_v = c/kT = 7.9\ (1/\text{nm}) \tag{61.27}$$

Obtained v^* is shown by the curve in Fig. 61.18b, which agrees well with the experimental data by Edman [9].

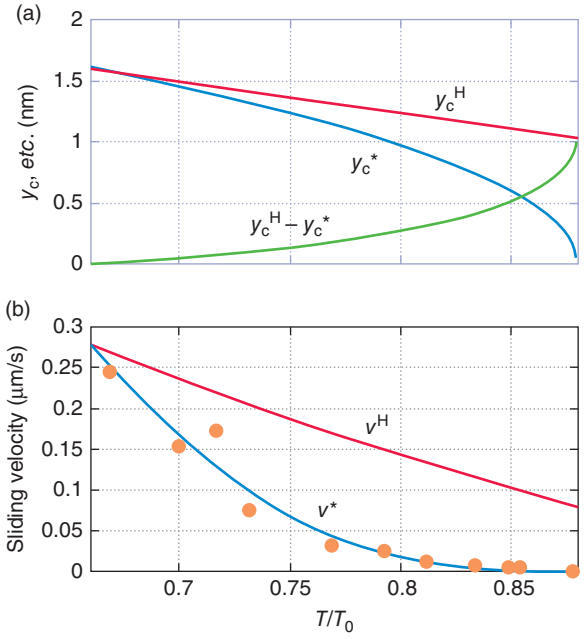

FIGURE 61.18 Deviation of the force–velocity relation from Hill-type, after Fig. 19 of Ref. 6. (a) The curve $y_c^H - y_c^*$ gives values of the same in Eq. (61.25). (b) Circles indicate experimental data of the sliding velocity per half sarcomere obtained referring to Fig. 3A of the paper by Edman [9]. Curve: v^H, the Hill-type filament sliding velocity, the same as the curve in Fig. 61.13. Curve: v^*, the velocity calculated by Eqs. (61.26) and (61.27). (Data from Mitsui and Ohshima [6], Fig. 19 and Edman 1988 [9], Fig. 3A.)

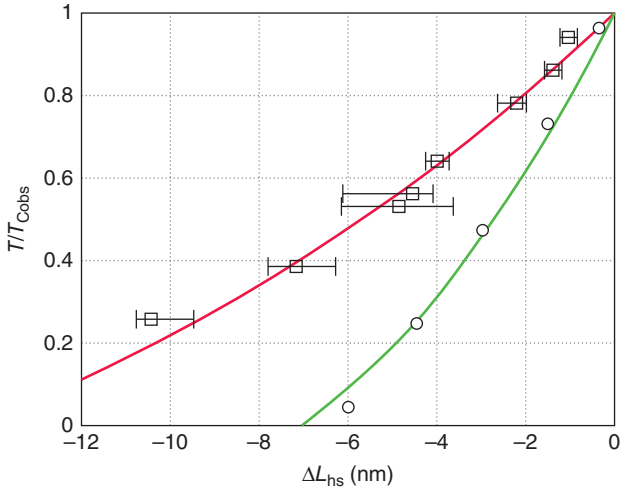

FIGURE 61.19 T/T_{0obs} versus ΔL_{hs} relations in the first phases in the transient phenomena, after Fig. 9 of Ref. 6. Circles indicate experimental data in the isometric tension transient cited from Fig. 13 of Ford et al. [35] Squares represent experimental data in the isotonic velocity transient obtained from Fig. 3 of Civan and Podolsky [36]. The error bar indicates error of readout from Fig. 3 of Ref. 36. The thin curve: T/T_{0obs} calculated for the first phase of the isometric tension transient in Ref. 6. The thick curve: ΔL_{hs} calculated for the first phase of the isotonic velocity transient in Ref. 6. (Data from Mitsui and Ohshima 2011 [6], Fig. 9; Ford et al. 1977 [35], Fig. 13; and Civan and Podolsky 1966 [36], Fig. 3.)

Huxley [37] divided the transient responses to the sudden reduction of length or of load into four phases. The first phase of the isometric tension transient is the step change of tension due to sudden length change. The first phase of the isotonic velocity transient is the step change of muscle length due to the sudden load change. The initial state in these changes is the isometric tetanus state, in which the existence probability of the myosin head is finite in well 1 as shown in Fig. 61.12b. Calculation is done assuming that the existence probability does not change during the first phases in Ref. 6.

Figure 61.19 shows calculation results reported in Section 4 of Ref. 6. Here the length change per half sarcomere is denoted as ΔL_{hs} in both transients and the relative tension is given by T/T_{0obs} (Fig. 61.14 for T_{0obs}). The experimental data by Ford et al. [35] are shown by circles for the isometric tension transient and the data by Civan and Podolsky [36] by squares for the isotonic velocity transient.

In the calculation Ref. 6, it is assumed that there is a time lag in length change of the thin filament against the length changes of crossbridge and the myosin filament, taking the results by Julian and Sollins [38] into account. Also it is assumed that extensibility ratios of the crossbridge, myosin filament and actin filament are 0.22, 0.26, and 0.52. These values roughly agree with the extensibility ratios 0.31, 0.27, and 0.42 estimated through X-ray diffraction [39]. Calculation is done by using the values of stiffness given by Eq. (61.22), which implies that the elasticity of crossbridge is largely nonlinear. The curvatures of the curves in Fig. 61.19 reflect the nonlinearity.

As mentioned above, the results shown in Fig. 61.19 are obtained assuming that the existence probability of the myosin head in well 1 of Fig. 61.12b does not change during the first phases. Thus the initial existence probability becomes unstable after the first phases. The complex muscle behaviors in the following phases are considered as the process that the existence probability in well 1 decreases toward a stable probability at the new state.

Ford et al. [35] studied in detail the relative tension T/T_{0obs} as functions of time t for various length change steps ΔL_{hs} after the first phase in the isometric tension transient. In Fig. 61.20, the green circles represent experimental data cited from Ref. 35, and the red curves show calculated values reported in Section 5 of Ref. 6. The curves are approximately in agreement with the experimental data. The curves become flat as t increases. Since the maximum t in the abscissa is 9 ms, the gap between the flat line and the line of $T/T_{0obs} = 1$ means that there is a very slow process of tension increase with time constant more than 9 ms. As shown in Fig. 61.17, the time τ_{step} needed for the U^* transition increases with T/T_0 and becomes more than 40 ms for $T/T_0 > 0.8$. In Fig. 61.20,

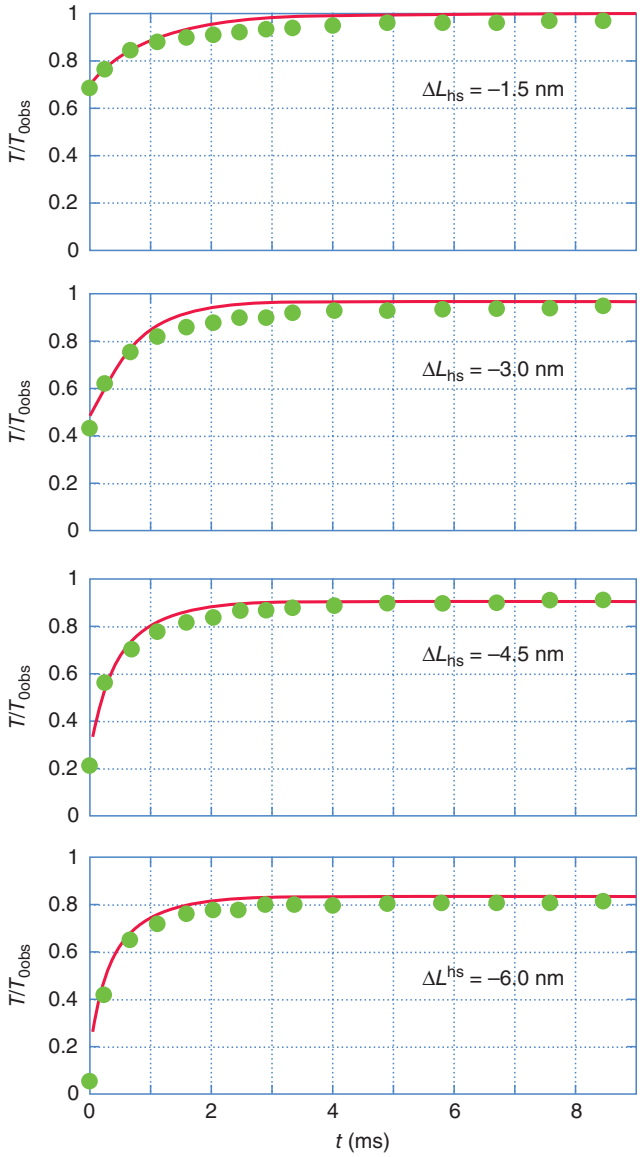

FIGURE 61.20 T/T_{0obs} as functions of time t for various length change steps ΔL_{hs} in the isometric tension transient, after Fig. 14 of Ref. 6. The origin of t is set as the moment that the first phase finishes. Circles indicate experimental data cited from Fig. 23 of Ford et al. [35]. Curves represent calculation results in Ref. 6. (Data from Mitsui and Ohshima 2011 [6], Fig. 14 and Ford et al. 1977 [35], Fig. 23.)

the flat parts appear for $T/T_0 > 0.8$. Accordingly, the U^* transition does not contributes to variation of T/T_{0obs} in the time range in Fig. 61.20.

Civan and Podolsky [36] studied in detail the timecourse of length change ΔL_{hs} after the first phase in the isotonic velocity change. In Fig. 61.21, green circles represent experimental data cited in Ref. 36. Red curves represent calculation results reported in Section 6 of Ref. 6, which show similar tendency as the experimental data.

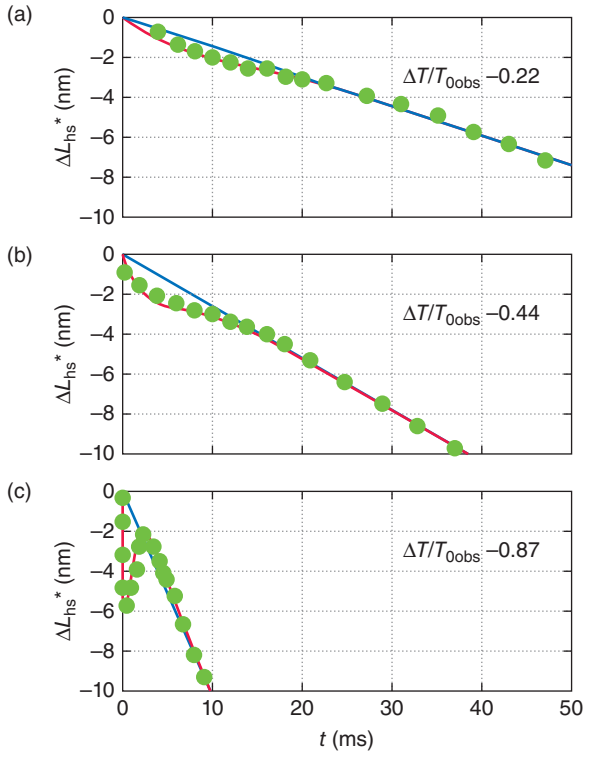

FIGURE 61.21 Length change $\Delta L'_{hs}$ versus t relations for three values of $\Delta T/T_{0obs} = (T_{0obs} - T)/T_{0obs}$, after Fig. 18 of Ref. 6. (a) $\Delta T/T_{0obs} = 0.22$; (b) $\Delta T/T_{0obs} = 0.44$; (c) $\Delta T/T_{0obs} = 0.87$. Data points are obtained from Fig. 3 of the paper by Civan and Podolsky [36]. Straight lines indicate steady filament sliding. Curves: $\Delta L_{hs}'$ calculation results in Ref. 6. (Data from Mitsui and Ohshima 2011 [6], Fig. 18 and Civan and Podolsky 1966 [36], Fig. 3.)

61.9 SUMMARY AND DISCUSSION

61.9.1 Requirements for Models

In Section 61.5, requirements for any models based on the sliding-filament theory are listed. They are discussed with the same item numbers below.

1. Large D/r or D in shortening muscles. Our model is constructed to give the large values of D/r as explained in Section 61.6. The value of r is estimated as 0.41 for any T [Eq. 61.16)], and calculated values of D become as large as shown in Fig. 61.16.
2. Small D observed in experiments with single myosin molecule in vitro. The myosin molecule has to cross over the potential barrier $U^*(y)$ to move from well 2 to well 3 in Fig. 61.12. In our model, U^*_0 is relatively large in the expression $U^*(y) = U^*_0 + apy$ [Eq. (61.20)], and the probability $Q(y) = A\exp(-U^*(y)/kT)$ [Eq. (61.19)] for the myosin head to cross over $U^*(y)$ is small when the force $p(y)$ on

the head is small. In two single-molecule experiments [20, 21], the single myosin molecule has no partner of cooperation and the force on the head $p(y)$ is close to 0, and thus $Q(y)$ is small and D is expected to be about L = 5.46 nm [Eq. (61.18)]. D may be a few times L since there may be some fluctuation of the force depending on the experimental conditions.

3. Crossbridges independently produces force in the isometric tetanus state. As mentioned at the end of Section 61.6.3, the filament sliding is a necessary condition in the cooperative interaction among crossbridges. Since there is no filament sliding in the isometric tetanus state, crossbridges produce force independently in the isometric tetanus state, in agreement with two observations [22, 23].
4. Reasonable explanation should be given to the coupling between the force production and energy liberation by chemical reaction. In our model, the ATP hydrolysis energy stored in a myosin molecule is used by fraction for force production as illustrated in Fig. 61.10. There are repeated chemical reactions between the myosin head and actin filament per the ATP energy. The myosin head has many modes of structural and thermal fluctuations, which makes the fractional use of the ATP energy possible as discussed in Section 61.6.5. This scheme clearly explains the energy liberation rate versus T/T_0 relation as shown in Fig. 61.15.
5. The model should explain major experimental data on muscle properties or behaviors.

   Figures 61.13–61.15 and 61.18–61.21 demonstrate good agreement between calculation results based on the model and the experimental data.

61.9.2 Discussion

It seems quite difficult for the power stroke model to fulfill requirement 1 as discussed in Section 61.4. In the power stroke model, the ATP hydrolysis energy e_A is used in one power stroke. This does not seem efficient use of e_A. As explained with Fig. 61.10, e_A is used in fraction in our model as is done in most biological systems. In the power stroke model, the actin filament is treated as a relatively passive element such as a ladder for a myosin head. In general, protein molecules play a more active role in biological systems.

Extensibility ratios of the crossbridge, myosin filament, and actin filament are assumed to be 0.22, 0.26, and 0.52 to obtain good agreement between the calculation results and experimental data in Fig. 61.19. These values are approximately in agreement with the extensibility ratios 0.31, 0.27, and 0.42 estimated through X-ray diffraction [39]. The ratio is assumed to be 1, 0, and 0 in the power stroke model [40].

Merits of the two-headed structure of myosin molecule are discussed in Section 5.2 in Ref. 5.

Cooperativity among myosin moleules is discussed with respect to cytoplasmic streaming in Characean algae in Section 5.3 of Ref. 5.

Presumably, one can get valuable information on the mechanism of myosin sliding on the actin filament by extending the ingenious experiment by Harada et al. [11], changing experimental parameters and using muscles of different kinds.

Our model has some similarity with the ratchet model [cf., e.g., 41]. In the ratchet model, however, concrete picture seems lacking on chemical reaction and energy liberation process during the force production as posed by requirement 4 in Section 61.5.

Chemical reaction and energy liberation process in our model are illustrated in Fig. 61.10.

As discussed in terms of Fig. 61.6, piezoelectric effect is important to construct the present model. In general, protein molecules are structurally polar, and hence any biological system should be treated as a system of four variables (stress, strain, electric field, and polarization) from the physical perspective, as mentioned also in the discussion on the flagellar rotary motion [42, Section 6.1].

NANOCARRIERS OF FUNCTIONAL MATERIALS FROM AMINO ACID SURFACTANTS

Geetha Baskar, S. Angayarkanny, and Asit Baran Mandal
CSIR–Central Leather Research Institute (CLRI), Adyar, Chennai 600 020, India

62.1 INTRODUCTION

Nanocarriers, which typically range within 1–100 nm in size, are excellent reservoirs and vehicles of functional materials. Because of their high surface area:volume ratio, nanocarriers provide incredible scope in the manipulation of structures at nanometer scale, and exhibit remarkable characteristics. They provide encapsulation of functional materials with retention of inherent characteristics. They act as smart vehicles and aid in site-specific delivery of functional materials [1–3]. Nanocarriers are emerging as promising materials in drug delivery systems for challenging diseases such as cancer [4]. The important characteristics of nanocarriers have implications on the economy, efficiency, and environment in terms of applied materials and industries. The "smart" nanocarriers, which exhibit characteristics in response to external stimuli such as temperature and pH, are in demand in various applications. In fact, nanocarriers have brought about revolutionary green approaches in various industries [5–7]. Nanocarriers occupy an intense area of research, and there is growing interest in designing nanocarriers to meet the increasing demand. Amphiphiles, simple and polymeric types, and nanoparticles from organic and inorganic polymers are the well-identified substrates that produce nanocarriers [8–11]. The substrates consist of regions that have large variations in polarity; for example, nonpolar core and polar shell structures are the most suitable architectures for nanocarriers. They enable stable dispersions in size ranging within a few nanometers of functional materials such as drugs. Here, in view of the small size of the dispersed structures and the density difference between the continuous and dispersed phases, the colloidal dispersions are stable. Some of the important physicochemical characteristics of the nanocarriers, the principles of which are drawn from emulsion-phase structures, play a significant role on the stability of the colloidal dispersions [12, 13].

The main focus in the field of nanocarriers is to develop low-cost simple methodology for the tailormade nanocarriers for cosmetics, diagnostic tools, and drugs [14] for which the self-assembled structures form one of the best options. Self-assembled structures such as micelles, vesicles, and liposomes, ranging with a few nanometers in size, are formed in solutions of low-molecular-weight surfactants, also known as *amphiphiles.* Macromolecules of molecular weight generally $\geq 10^4$ Da, also form self-aggregated structures such as polymeric micelles and polymerosomes, 5–100 nm in size. A pictorial representation of nanocarriers from self-assembled structures of simple and polymeric amphiphiles and the inorganic polymer nanoparticle is presented in Fig. 62.1.

It is essential to understand the fundamental aspects underlying the process of self-assembly and the formation of self-aggregated structures for the design of nanocarriers. With growing concern for energy and environment, there is an obvious demand for the design of high-performance nanocarriers derived from biodegradable resources. For this, the ideal source materials are proteins, peptides, amino acids, natural oils, and sugar. These surfactants from such natural sources are broadly classified as *biosurfactants*. The most popular application of nanocarriers from biosurfactants is in the field of drug delivery systems. They are being widely exploited in medicine from the context of diagnostics and targeted

delivery of drugs, as seen from literature reports [15]. Nanocarriers from polymeric nanopartilces are produced adopting template assisted strategy involving self-assembled structures of amino acid surfactants. By virtue of structures, nanocarriers facilitate the colloidal dispersions of drugs, and facilitate travel in the body fluid consisting of water as the major component, and targeted delivery of the drugs. They can be considered for potential applications that include herbicides, pesticide formulations, detergents, healthcare, cosmetics, paper, coal, textiles, ceramic processing, food industries, and/or processing [16–19].

In this chapter, a brief report of self-assembled structures of simple and polymeric amphiphiles, followed by an elaborate account of biosurfactants, especially those derived from amino acid derivatives, is presented. Applications of nanocarriers from amino acid surfactants, polypeptides, and polymers consisting of amino acid or peptide segments, especially in drug delivery, are discussed. The scope for producing nanocarriers from polymeric nanoparticles employing the self-assembled structures of simple and polymeric amino acids surfactants is also discussed.

62.2 SELF-ASSEMBLY AND AGGREGATED STRUCTURES

The self-assembly process eventually leading to formation of aggregated structures occurs in simple and polymeric amphiphiles. Amphiphiles are compounds consisting of hydrophilic and lipophilic or, in other words, hydrophobic groups. From the terminology, one can understand that

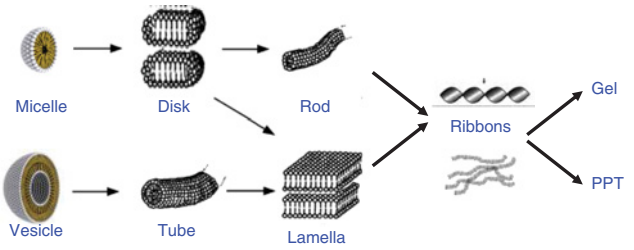

FIGURE 62.2 Intercoversion of self-aggregated structures.

hydrophilic groups are those having affinity for water and therefore are generally polar. Hydorphobic or lipophilic groups interact with air or nonpolar solvents. In water, amphiphiles self-assemble to form different structures such as micelles, vesicles, or gels [20–24]. Inverse micelles are formed in nonaqueous solvents as demonstrated in a report by Mandal et al. [25]. An excellent account of the hierarchy of self-aggregated structures in simple and polymeric amphiphiles was given by another team [26]. The interconversion of aggregated structures ultimately leading to formation of gel or precipitate from the simple assembled structures such as micelles is ilustrated in Fig. 62.2. The microstructure of self-organized assemblies on an infinitesimal scale underlies the comprehensive performance in various applications [27–31].

62.2.1 Self-Aggregated Structure Formation in Simple Amphiphiles

The molecular interactions due to electrostatic, hydrophobic, and van der Waals forces are the driving forces in the self-assembly. The chemical architecture of the surfactants plays a significant role in determining the formation of self-assembled structures [32–35]. On the basis of the charge carried by the polar group attached to the hydrophobic segment, surfactants are classified as anionic, cationic, nonionic, and/or zwitterionic; the details on the self-assembly in surfactants of different charge characteristics can be found in the work of Rosen [36]. Basically, the formation of self-assembled structure is governed by the packing parameter (p) that is dependent on the length of the hydrophobic group and the surface area of the headgroup/molecule at the interface [37]. A general understanding is that surfactants consisting of single headgroup and tailgroup prefer to organize as micelle assemblies and those with double tail and single head, as lamellae or vesicles. There are, of course, exceptions to these tendencies.

A typical micelle aggregate in water consists of the hydrophilic "head" regions in contact with the surrounding solvent and the hydrophobic “tail” regions in the micelle center. This type of micelle is known as a *normal-phase micelle* (oil-in-water micelle). Inverse micelles have headgroups at the center with the tails extending outward

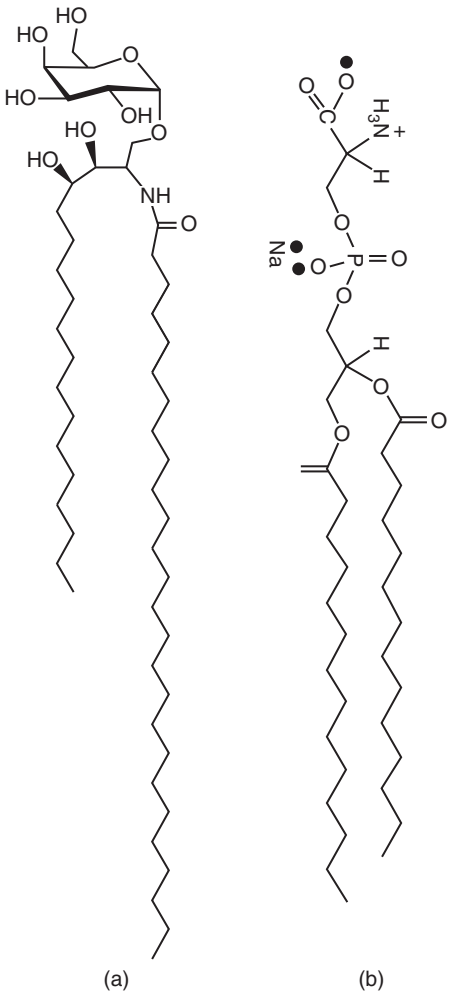

FIGURE 62.3 Structural representation of (a) glycolipid and (b) phospholipid.

(water-in-oil micelle). Figure 62.3 may be referred to for structures. Micelles are approximately spherical in shape. The chemical architecture and the microenvironment play a significant role in the formation of unusual micelle structures such as ellipsoids and cylindrical and inverse micelles. The size and shape of these assemblies depend on the chemical architectures of surfactants, and may vary with concentration, temperature, and solvent. In ionic surfactants it is possible to change the surfactant behavior from a hydrophilic to lipophilic compound. The transformations in solution structures from globular (spherical) to flexible rodlike micelle assemblies occur as a result of increase in concentration. The variations in temperature and number of ethylene oxide groups affect modulations in solution structures in nonionic surfactants from ethoxylated alcohols [38]. Vesicles consist of bilayer organization of the surfactant molecules in a spherical architecture. The important architecture requirement for the formation of bilayer is presence of double tail and single headgroup; classic examples are phospholipids and glycolipids (Fig. 62.3). By virtue of bilayer organization, vesicles exhibit extraordinary characteristics. They provide a waterpool inside the aggregates that facilitates encapsulation of polar functional compounds such as dyes and drugs. Vesicles exhibit excellent microfluidity and stability characteristics that are required in the design of stable nanocarriers. Cell membranes consist of vesicles and act as carriers transporting proteins and nucleic acids between cells [39].

The formation of vesicles or, in other words, bilayer structures from single-chain amphiphiles, attracts significant attention. The mechanism operating in the reversible transformation of structures varying between micelles and vesicles in phospholipids has been described [40]. Several strategies such as tuning the packing parameter, design of amphiphiles, and selection of external stimuli are adopted to form bilayer assemblies from single-chain amphiphiles [41–43]. The tuning of the intermolecular forces affords programmed transformations of aggregated structures. They are desirable in the design of smart materials [44, 45]. The formation of vesicles and micelle structures in mixtures of cationic and anionic surfactants [46], and fatty- acid soaps [47], has been demonstrated. Interestingly, these amphiphiles are preferred in view of reversible switching between micelles and vesicles.

62.2.2 Different Chemical Architectures in Surfactants

In low-molecular-weight surfactants, based on the chemical architecture, amphiphiles are classified as simple geminis and bola amphiphiles. Please note that low-molecular-weight surfactants are also referred as simple surfactants. In simple surfactants, as determined by the packing parameter, different structures such as micelles, vesicles, and membranes are formed.

Gemini surfactants are characterized by two hydrophilic and hydrophobic groups that are linked by the spacer group (Fig. 62.4). Thus, Geminis exhibit extraordinary surface activity and aggregation behavior. A review on geminis may be found in the literature [48,49]. In geminis, the modulation in aggregated structures is afforded through symmetric and asymmetric variations in the alkyl chain length and the spacer groups. In this way, different types of aggregated structures, namely, micelles, bilayers, vesicles, and membranes, could be generated. The optimization of electrostatic interaction

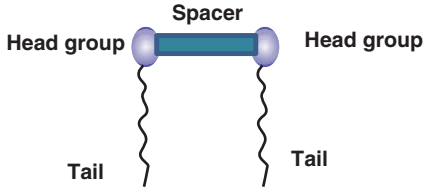

FIGURE 62.4 Chemical structural representation of gemini surfactant.

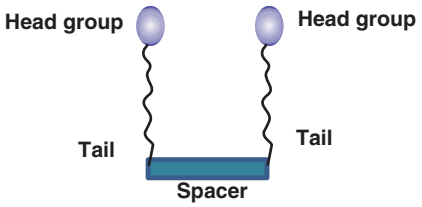

FIGURE 62.5 Chemical structural representation of bola amphiphile.

and the intramolecular hydrophobic association as dictated by the spacer groups, account for the formation of various types of aggregated structures. The structure–property correlation in geminis has been reviewed in the literature [50–52]. In view of the industrial significance, the popular cationic geminis with methylene spacer groups have been investigated in detail with respect to the adsorption and aggregation characteristics under various conditions [53–55].

Bola amphiphiles (also known as *bolaform surfactants*, *bolamphiphiles*, or *alpha–omega-type surfactants*) are amphiphilic molecules that have hydrophilic groups at both ends of a long hydrophobic hydrocarbon chain (Fig. 62.5) [56, 57] or, in other words, two surfactants connected at their tails. Compared to simple surfactants, the bola amphiphiles have higher solubility in water, which may be due to the introduction of a second headgroup. The second headgroup also induces an increase in the critical micelle concentration (cmc), and a decrease in aggregation number. The bola amphiphiles form self-aggregates such as spheres, cylinders, disks, and vesicles. Therefore, bola amphiphiles are considered as hydrophobic skeletons with two water-soluble headgroups on both ends [58–65]. Bolaform amphiphiles exhibit high thermal resistance and are identified in the cell membranes of thermophilic bacteria. The formation of controlled self-assembly by bolaamphiphiles has been understood according to the concepts of supraamphiphiles with noncovalent interactions [66–69].

62.3 POLYMERIC AMPHIPHILES

The concept of self-assembly in simple surfactants is extended to polymeric amphiphiles to generate self-assembled structures of remarkable stability and structural diversity [70–73]. The self-assembled structures such as micelles of low-molecular-weight surfactants are dynamic, as continuous exchange occurs between the aggregated and nonaggregated structures within them. On the contrary, in view of covalent bond force between the molecules in the aggregated structures and the entanglement of chains, the aggregated structures that from polymeric amphiphiles show extraordinary stability. Furthermore, they provide a large structural diversity due to variations in the chemical architectures and distribution of different segments, and exhibit smart behavior responding to external stimuli such as pH and temperature.

The hydrophilic-lipophilic balance (HLB) in polymeric amphiphiles is modified by adopting a simple method, through variation in ratio of chain length of different components. Polymeic amphiphiles are, in fact, recognized as one of the potential nanocarriers. One team has presented an excellent review on the polymer nanocarriers [74]. Polymeric amphiphiles form different aggregated structures determined by the hydrophilic lipophilic balance and the architectures.

62.3.1 Architectures and Formation of Self-Aggregated Structures in Polymeric Amphiphiles

Polymeric amphiphiles exhibit different architectures such as block, random, comblike, and brushlike, as determined by the chemical characteristics and distribution of the segments (Fig. 62.6). Polymeric amphiphiles with block copolymer architecture are synthesized by employing synthetic strategies such as cationic, anionic, atom transfer radical polymerization (ATRP), and reversible addition fragmentation chain transfer (RAFT) reactions. For example, pluronics, one of the best-known block copolymer amphiphiles, consist of hydrophilic and hydrophobic blocks derived from poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO), respectively. They form direct and indirect micelles depending on the HLB as determined by the PEO and PPO blocks, respectively, and also microenvironment as detailed in studies by Mandal et al. [75–78].

62.3.2 Self-Organisation in Graft Polymers and Other Polymeric Amphiphiles

Polymeric amphiphiles from graft polymers are popular, especially in view of simple synthetic methodologies. The

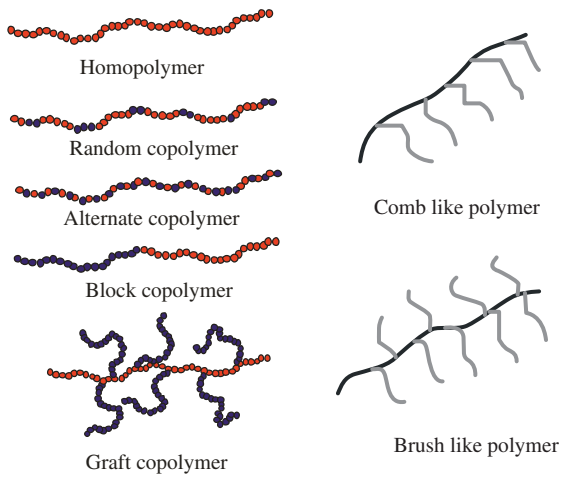

FIGURE 62.6 Pictorial representation of polymeric amphiphiles of different architectures (red, hydrophilic; blue, hydrophobic).

approaches are (1) grafting of preformed polymer onto suitable backbone through chemical reactions [typical examples are grafting amino-terminated poly(styrene) (PS) on the poly(acrylic acid) (PAA) backbone chain [79] and PAA-*g*-poly(*N*-isopropyl acrylamide) (PNIPAM) [80]] and (2) graft polymerization of a monomer on a suitable polymeric backbone through free-radical and ionic polymerization methods as in the case of cholestryl-grafted poly(propyl amino methacrylate) copolymers [81]. The structural architecture of polymeric amphiphiles and the microenvironment provided at different interfaces both dictate formation of self-assembled structures that vary among monolayers, vesicles, and micelles. The influence of structural features on the adsorption characteristics and scope for modulation of these characteristics through changes in chain architecture of the polymer, hydrophilic and hydrophobic chain length, introduction of spacer group [82], and additives are well documented in the literature [83]. The influence of polymer architecture on the behavior of polymers has also been well documented in a more recent report [84]. It is understood that secondary bond forces arising from H-bonding, electrostatic, and hydrophobic interactions control the formation of self-assembled structures. Water-soluble polymeric amphiphiles with comblike structures are in high demand from the perspectives of synthetic strategies and functional characteristics. They can generate functional latex that forms novel cross-linked structures [85]. They perform as effective steric stabilizers at the interface and could form stable colloidal dispersions or emulsion-phase structures. It is noteworthy that emulsion-phase structures are gaining popularity as templates in the generation of nanomaterials [86].

Water-dispersible ionic polymers with comblike architectures form different kinds of associated structures varying between polyelectrolytes to polysoaps. The predominance of electrostatic interaction promotes polyelectrolyte structures in aqueous medium, as shown for in polyacrylic and related acids [87], whereas polysoap structures resembling micelle-like nanostructures are promoted in polymers with long hydrocarbon sidechains, through hydrophobic association [88, 89]. The efficient use of comblike copolymers from acrylic acid and octadecyl acrylates in miniemulsion polymerization reactiond to produce poly(styrene) latex has been established [90].

Polymeric amphiphiles consisting of biodegradable segments drawn from biologically related and biocompatible species have been reported. Polymers consisting of sugars or steroids units provide rigid headgroups that can be functionalized using different reagents. For example, 2-amino-2-deoxy-D-glucopyranose, the building block of chitin [91], can be ionized specifically at the amino and hydroxyl terminals to form interesting starting materials for sugar- based surfactants. Several anionic, cationic, and nonionic 2-aminoglucose-based surfactants are known. Synthesis and solution properties of two new glucose-based series, namely, sodium methyl-2-acylamido-3-deoxy-6-*O*-sulfo-D-glucopyranosides, were recently studied. The chemical modification of self-aggregated structures of surface-active polymers or, in other words, polymerizable amphiphiles, is a promising approach to forming stabilized structures as reported [92, 93].

62.4 AMINO ACID SURFACTANTS

62.4.1 Highlights of Unique Characteristics of Amino Acid Surfactants

The biodegradability, facile green methodologies in the generation of amino acids, the chemical architecture consisting of chiral centers, functional groups such as carboxyl, amino groups that undergo facile chemical modifications, the wide structural diversity, and response to external stimuli like pH, all account for choice of amino acid surfactants as nanocarriers [94–100]. The superior properties of amino acid surfactants to form rods, fibers, and tubes as a result of one-dimensional growth of the aggregated structures have been comprehensively described in one review [101]. The structure–property correlation; the reversible manipulation of structures among micelles, vesicles, and fibers through change in pH and temperature; and the role of chirality in the aggregated structures have been demonstrated in the literature [102–105]. Simple, gemini, and bola amphiphiles that exhibit different chemical architectures can be designed from amino acids. They self-organize in presence of solvents to form different types of aggregated structures similar to those established through classic surfactants.

The most popular and well-known example of amino acid surfactants is the *N*-fatty acyl amino acid surfactant, known for quite a long time and derived from the renewable sources of amino acids and vegetable oils [106–110]. The widespread applications of these surfactants in pharmaceuticals, antimicrobial agents, food emulsifiers, and cleaning agents are well established [111]. There is an excellent scope for the synthesis of *N*-fatty acyl amino acids surfactants from leather waste and silkworm industries [112]. The ordered structures from amino acids, peptides, and proteins find diverse advanced applications [113].

62.4.2 Types of Amino Acid Surfactants

Amino acids belonging to different types (viz., acidic, basic, and neutral) form the starting materials for the synthesis of amino acid surfactants. Examples of some amino acids are glycine, alanine, leucine, valine, serine (neutral), aspartic acid, glutamic acid (acidic), proline, and lysine (basic) (see Table 62.1).

The chemical structures of amino acids facilitate the design of anionic, cationic, and zwitterionic surfactants

TABLE 62.1 Classification of Amino Acids

Characteristics	Amino acids
Hydrophilic, acidic	Aspartic acid, glutamic acid
Hydrophilic, basic	Lysine, arginine, and histidine
Hydrophilic, nonionic	Glycine, serine, cysteine, tyrosine, threonine, asparagin, and glutamine
Hydrophobic	Alanine, leucine, isoleucine, proline, phenyl alanine, tryptophan, methionine

through selective chemical modifications of the carboxyl and the amino groups. Furthermore, the side chain structures in the acidic, basic, and neutral amino acids play a significant role in the self-assembly process. Amino acid surfactants are versatile nanocarriers, and, in fact, it is possible to fine-tune the properties of the aggregates to suit almost every application. In these surfactants, the amino acids and long aliphatic chains have been combined with each other to generate three main structures: (1) linear or single-chain, (2) dimeric or gemini, and (3) glycerolipidlike structures. Linear structures consist of an amino acid bearing at least one hydrophobic tail derived from fatty acids, alcohols, or amines [114–117]. It is to be noted that single-chain lipo–amino acid surfactants exhibit diversity in structures with the common chiral centers, and therefore, afford nanocarriers with large variations in the characteristics [118–122]. The remarkable varieties of structures from lysine amino acids, in view of availability of one carboxyl group and two amino groups, have been studied in detail. Lysine-derived surfactants cover anionic, cationic, and nonionic types depending on chemical modification to form ester or amide linkage [123].

The disulfide amino acid cystine is one of the best starting amino acids for the synthesis of geminis. This amino acid, the major component of keratin present in hair, is known for the inherent characteristics to form fiberlike structures. Cationic geminis from *N* -alkyl derivatives and anionic, from fatty esters, from cysteine, exhibit superior aggregation behavior. Geminis derived from cystine dimethyl ester, cystamine dichydrochloride [124], and *N*- alkyl cystine esters [125] have been reported.

62.4.3 Self-Assembled Structure Formation in Amino Acid Surfactants

Amino acid amphiphiles, when dissolved in water, self-assemble to form various supramolecular assemblies that give rise to primary, secondary, and tertiary structures. The primary structure (angstrom to nanometer scale) is determined by the molecular level recognition of the aggregate. The secondary structure (nano- to micrometer scale) is defined as the morphology of the aggregates, that is, micelles, vesicles, fibers, ribbons, or sheets. They are directly influenced by the molecular structure. Secondary structures give rise to tertiary structures such as disks and fibers. The fibers could precipitate, or form gel depending on the electrostatic and H-bonding interactions [126].

The assembled structures of different morphology and the influence of chemical structural features, especially in the micellization process, are presented here to help the reader understand the spectacular self-assembling process of the amino acid amphiphiles.

The length of alkyl chain essentially controls the hydrophobic interaction. The influence of odd- and even-number carbons in the alkyl chain on the type of aggregated structures could be seen in the series of bolaamphiphiles. Shimizu and colleagues synthesized a new family of oligopeptide-based bolaamphiphiles, glycylglycine-, glycylglycylglycine-, sarcosylsarcosine-, L-prolyl-L-proline-, glycylsarcosylsarcosine-, and glycyl-L-prolyl-L-proline-based bolaamphiphiles with a dicarboxylic headgroup at each end [127]. It was observed that only sodium or potassium salts (acid soap) of the bola amphiphiles, with an even-number alkyl chain ($n = 6,8,10$), produced well-defined microtubes of 1–3 μm diameter with closed ends. All tubes encapsulated a number of vesicular assemblies inside the aqueous compartment. The odd-number alkyl chain surfactants form relatively stronger hydrogen bonds between amide groups and are not suitable for the formation of intralayer anion dimmers and hence microtubes. Nanoscale fibers with widths of 10–30 nm, via proton triggered self-assembly of bola amphiphiles consisting of L-valyl-L-valine moiety in water [127]. The dependence of pK_a on chain length in bola amphiphile was also demonstrated. On increasing chain length of the bola amphiphile from 6–10 carbon atoms, the pH for complete protonation of the bola amphiphile increased from 3.40 to 4.90. Similar alkyl-chain-length-dependent pK_a in amino- acid-based amphihiples was reported [128]. The alkyl-chain-length-dependent hydration and the micellisation process are demonstrated in the homologues series of anionic surfactants from alanine, namely, sodium-*N*-(alkyloxycarbonyl) alanine, varying alkyl chain as octyl, dodecyl, hexadecyl, and octadecyl. One team showed significant differences in the micellisation process of nonionic surfactants derived from lysine [129]. These amphiphiles consist of two different fatty-acid chains in the hydrophobic part and one or two polyoxyethylene methoxy–capped chains in the hydrophilic headgroup. It was shown that the asymmetry surfactants exhibit better surface activity and micellization characteristics. Another team demonstrated the effect of alkyl chain length on the conformation of aggregated structures in aqueous medium [130]. It was shown that the conformation adopted by two optically active cationic surfactants with different sidechains from phenylalanine and leucine was different in aqueous medium. Nuclear magnetic resonance (NMR) studies indicate that the phenyl ring is directed into the micellar core, while the isopropyl group is directed outward from the micellar

core. Interestingly, the area per molecule occupied by the surfactants at the air–water interface (43.6 $Å^2$ for and 54.6 $Å^2$) is similar to that of related cationic surfactants and the aggregation number is much smaller. The results are explained on the basis of probable influence of the size or homochiral nature of the head group in the packing of the micelle.

Another team demonstrated the effect of chain length in aqueous aggregation properties in diacyl lysine salts, wherein the alkyl chain length varied as $n = 5,7,9,11,13$. From X-ray studies, it was shown that the long alkyl chain favors a lamellar arrangement; intermediate-length, cubic bicontinuous structures; and the short derivative, a reverse hexagonal structure [131]. Another group demonstrated alkyl-chain-length-dependent tertiary structures in peptide oligomer surfactants [132]. It was shown that the oligomers exhibited conformation similar to β-poly(L-alanine) in the solid state, and the long acyl chains, induced a sheet structure due to H-bonding between the peptide skeleton. The stabilization of helical structure on micellization was established with respect to potassium salts of the related surfactants.

In the gemini surfactants from cystine, the octyl chain was established to be the optimum length of alkyl chain to form micelles in water. The introduction of decyl or dodecyl, in these gemins, confers lipophilic character. They show very low solubility in water at pH 7.0. The chemical architecture of octyl ester in cationic geminis from cystine favors tilted orientation at the interface and thereby favors elongated morphology and fibril-like structures [125]. The sidechain structure of amino acid plays a significant role on the microstructures of self-assembled structures, as established, for example, in the lauryl esters of tyrosine (LET) and phenyl alanine (LEP). The phenol OH in tyrosine favors packing in the polar shell in contrast to the phenyl ring of (LEP), in the core of the micelles [102, 103], and thereby impacts the dimensions of micellar core and thickness of the shell (Fig. 62.7).

The chiral structures of amino acid amphiphiles influence the aggregated structures and the micellization process as established [133] in proline surfactants. Amino acid amphiphiles also favor gel-like assemblies. The formation of a gel requires right primary, secondary, and tertiary

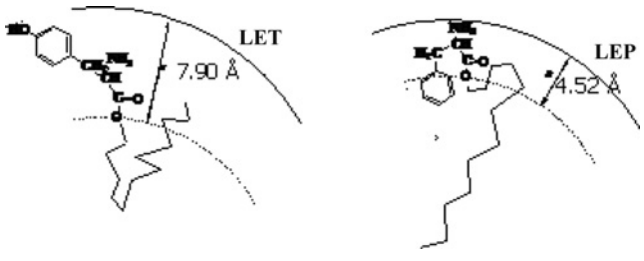

FIGURE 62.7 Conformation of amino acid surfactants from tyrosine (LET) and phenyl alanine (LEP): phenolic group of LET in the shell, thickness 7.90 Å, phenyl of LEP in the core, thickness, 4.52 Å.

structures. It is hypothesized that rodlike micelles are responsible for gelation. The example of low-molecular-weight organogelators could be found in serine-based amphiphiles [134]. Aromatic rings that provide π–π stacking provides more facile gelation process.

The formation of vesicles using mixtures of anionic and cationic surfactants is dictated by electrostatic interactions, the hydrophobic interactions between the alkyl chain of the ionic surfactants, and the type of counterions [135, 136]. Another team [137] studied the conditions for formation of vesicles in the mixture of lysine-derived anionic gemini and cationic single- chain surfactant from serine. The lysine-derived pseudoanionic gemini surfactant and cationic single-chain surfactant from serine of different chain lengths were studied in detail. It was demonstrated that the mixtures of these cationic and anionic surfactants formed vesicles when the overall charge of the vesicle was cationic.

The formation of vesicles and subsequent transformation into tubelike morphology by altering the composition was demonstrated in the mixtures of histidine-derived bolaamphiphile, 1,12-dihistidine diaminododecane (H_2D), and dodecyl trimethyl ammonium bromide (DTAB). Another team synthesized a cationic surfactant from arginine that formed a vesicle at a concentration as low as 0.005 mM and was subsequently transformed to ribbonlike morphology at a high concentration [138].

The maleyl derivatives of LET (MTH) and LEP (MPH) also showed sidechain- dependent self-aggregated structures. The sodium salts of MTH formed micelles in water as against MPH, vesicles [139]. These amphiphiles exhibit pH-responsive aggregated structures. MTH transforms from micelles to vesicles on reducing the pH as against MPH, from vesicles to large aggregates, leading to precipitates [140]. Another team [141] demonstrated formation of vesicles using single-chain valine-based surfactant, namely, *N*-(2-hydroxydodecyl)-L-valine, at pH∼13. They demonstrated that the surfactant exhibits stepwise aggregate formation. At low concentration, only spherical vesicles were formed, which partially transformed to tubular structures with an increase in concentration. It was shown that the tubelike structures have a packing parameter of $0.7 < P < 1$ whereas vesicles have a packing parameter in the $0.5 < P < 0.7$ region [141].

62.4.4 Polymeric Amphiphiles from Amino Acids

Poly(L-amino acid)s (PAAs) are biodegradable ionic polymers often employed for the design of nanocarriers. By virtue of hydrolysable peptide bonds, they can form polyelectrolyte complexes with DNA and hence have immense potential in theuraptics. They are involved in the synthesis of amphiphilic block copolymers that form self-assembled structures such as micelles or polymersomes. Polymerosomes have the unique property of encapsulation of hydrophilic components in the

aqueous cavities and hydrophobic molecules within their membranes. By suitable molecular design and the choice of environment, such as a solvent, the polymerosomes can be generated. Another team demonstrated that the polymeric amphiphile from amino acids segments and consisting of two hydrophilic segments linked through hydrophobic alkyl chain form vesicles in water and inversted micelles in toluene [142].

Synthetic PAA nanocarriers are usually obtained from the polymerization of *N*-carboxyanhydride (NCA) initiated by primary amino compounds. Poly(aspartate), poly(benzyl-L-glutamate) (PBLG), poly(L-lysine) (PLL), and poly(histidine) (PHis) are the best-known PAA nanocarriers. The hydrophilic blocks in the block copolymers from PAA are mainly PEG, heparin, hyaluronan, and polygalactose. [143]. The more hydrophilic molecules form nanosized micellar aggregates, molecules of intermediate hydrophobicity, polymeric vesicles, and the more hydrophobic variants, amorphous polymeric nanoparticles of 100–1000 nm in diameter. By strategic design through synthetic methodologies, it is possible to generate different aggregated structures from polymeric amphiphiles. The formation of controllable and versatile self-assembled nanostructures is demonstrated in the copolymers, for example, in glutamic acid derivatives [144].

Another team synthesized a series of pH-responsive random copolymer poly(l-glutamic acid-co-l-lysine) [P(Glu-co-Lys)] through the ring-opening polymerization (ROP) of γ-benzyl-l-glutamate *N*-carboxyanhydride (BLG-NCA) and 3-benzyloxycarbonyl-l-lysine *N*-carboxyanhydride (ZLys-NCA) and the subsequent deprotection. They were established to act as intelligent drug delivery systems for cancer therapy [145].

Another team designed a series of polyanionic nanocarriers based on biodegradable and biocompatible poly(aspartic acid)s for oral administration. Adopting a series of synthetic methodologies, partially esterified poly(aspartic acids), which afford an amphiphilic polyanion, poly(sodium aspartate-g-hexadecyl aspartate) (Na-PASP-g-C-16-PASP), was produced [146].

Another team synthesized a series of PCL-pluronic-PCL-biodegradable block copolymers by ring-opening polymerization of ε-caprolactone (ε-CL) initiated by pluronic (PEG–PPG–PEG) macromonomer. The self-assembled structures from these block polymers were employed as hydrophobic drug carriers [147]. The gel–sol transition temperature range could be altered in these polymer according to practical applications, which would be very useful as injectable drug delivery system.

Amino acid sidechain-based block polymeric amphiphiles were developed as smart nanocarriers and as vehicles for both drugs and genes [148]. Here, the amino acids, l-phenyl alanine and l-alanine containing vinyl monomers, were polymerized via reversible addition fragmentation chain transfer (RAFT) process in the presence of monomethoxy poly(ethylene glycol)-based macrochain transfer agents (mPEGn-CTA) [148].

Poly(ethylene glycol) (PEG2000) polymers containing one or two amine residues are linked to α-lipoamino acids (LAA) to produce mono- and homo-disubstituted PEG–LAA conjugates as new materials. The PEF-LAA congugates provide dual functions, and form vesicles with different surface properties [149].

Another team reported novel PEGtide dendrons of generations 1 through 5 (G1.0–5.0) containing alternating discrete poly(ethylene glycol) (dPEG) and amino acid/peptide moieties. The dendrons were modified with mannose derivatives to establish the targeting utility of the nanocarriers [150]. Selected examples of polymeric amphiphiles from amino acids derivatives are listed in Table 62.2.

62.5 POLYMERIC NANOCARRIERS IN PHARMACEUTICAL AND OTHER APPLICATIONS

In a recent review one team investigated the drug delivery of polymeric amphiphiles from amino acids [143]. Amino acid containing polymeric amphiphile such as 7-carboxymethoxy coumarin monoend-functionalized methoxy poly(ethylene glycol) (mPEG-Lys-DCOU) micelles have been established as promising carriers for antitumor drug delivery [155]. By ring-opening polymerization reaction, disulfide-linked block copolymers of methoxy poly(ethylene glycol) (mPEG) and

TABLE 62.2 Selected Examples of Nanocarriers from Polymers with Amino Acid Sidechains

Serial No.	Amino acid	Nanocarrier	Ref.
1	L-Lysine	(a) Poly(l-glutamic acid-*co*-l-lysine)	148
		(b) [P(Glu-*co*-Lys)], poly(ε-benzyloxycarbonyl-L-lysine),	151
2	Arginine	(a) Polyarginine,	152
4	Aspartic acid	Poly(sodium aspartate-*g*-hexadecyl aspartate)	146
6	L-Aspargine	(a) Poly(asparagine) grafted with octadecylamine (PAsn-*g*-C18)	153
		(b) Poly-l-asparagine	154
7	l-Phenylalanine and l-alanine	Poly(ethylene glycol)-*b*-poly(Boc-l-phenyl alanine/alanine amino acids methacryloyloxyethyl ester)	148

poly(ε-benzyloxycarbonyl-L-lysine) (PZLL) were synthesized. They showed excellent hemocompatibilities, and cell and tissue compatibilities, and hence potential drug delivery systems. The enhancement in the effectiveness of the drug was established in the poly(amino acid) amphiphiles modified with immunomodulatory agent.

A novel transepidermal drug carrier system was produced from phospholipids and amphiphilc poly(amino acid)s grafted with alkyl amines [153]. Novel poly-l-asparagine (PASN) nanocapsules were found to act as potential anticancer drug delivery systems. PASN nanocapsules showed sizes of around 170–200 nm and negative zeta-potential values (around −20 to −40 mV). The nanocapsules enabled a high level of encapsulation and efficiency of the anticancer drug. Another team established the superior properties of nanocarriers from poly-L-asparagine (PASN) nanocapsules, as the anticancer-targeted drug delivery system [154]. Smart block copolymers containing a poly(ε-caprolactone) (PCL) hydrophobic block with a poly(triethylene glycol) block that were copolymerized with an amino acid-functionalized monomer have been synthesized. The block copolymers formed micellar structures in aqueous solutions. The polymer that was functionalized with 6-aminocaproic acid (ACA) possessed pH-sensitive phase transitions at mildly acidic pH and body temperature. Doxorubicin-loaded micelles formed from these polymers were stable at blood pH (∼7.4) and showed increased drug release at acidic pH.

A series of pH-responsive random copolymer poly(l-glutamic acid-*co*-L-lysine) [P(Glu-*co*-Lys)] were synthesized through the ring-opening polymerization (ROP). Critical aggregation concentration and transmission electronmicroscopy measurements indicated that the P(Glu-*co*-Lys)s could self-assemble into aggregates. The surface charge of P(Glu-*co*-Lys) aggregates was greatly affected by the pH of the solutions and L-glutamic acid/L-lysine ratio. These polymer nanoparticles are smart and exhibit characteristics as determined by the surface charge. The charge reversal and the toxicity characteristics of these nanoparticles were established in presence of the anticancer drug cisplatin [143].

The design and development of water-dispersible, pH-responsive peptides that mimic shell cross-linked magnetic nanocarriers (PMNCs) using a facile soft chemical approach has been reported. These nanocarriers have an average size of ∼10 nm, are resistant to protein adsorption in physiological medium, and transform from a negatively charged to a positively charged form in the acidic environment [156].

62.5.1 Polymeric Nanoparticles

Nanoparticles (NPs) are solid colloidal systems composed of the dispersion of functional materials, such as drugs [157]. Organic and inorganic polymers are the best-known substrates and are generally described as polymeric nanoparticles. The engineering of self-aggregated structures of amphiphiles with polymer nanoparticles is one of the most promising approaches in the design of high-performance nanocarriers from nanoparticles. Here, the self-assembled structures provide dual functions of acting as templates and surface modifiers. The synthetic methodologies determine the morphopolgy, varying between nanospheres and nanocapsules of the nanoparticles, and control the dispersion properties. To elaborate, in nanospheres, the functional material-like drug is dispersed in the polymeric chain. On the contrary, in nanocapsules, the drug solubilized inside the pool of water inside is surrounded by the polymeric chain membranes and thereby acts as more efficient reservoirs of functional materials [158]. The functional materials show enhanced dispersion properties in the colloids of nanoparticles. Furthermore, the polymer nanoparticles are versatile structures, providing scope for modifications of the surface structures and compositions, and hence, high-efficiency nanocarriers [159–173].

62.5.2 Amino Acid Templates for Synthesis of Nanoparticles

The self-assembled structures of amino acids are employed as templates in the design of polymer nanoparticles. Here, the emulsion-phase structures as determined by the organization of the amino acids and their derivatives at the liquid–liquid interface enable the templates to produce nanoparticles of desired size, morphology, and microstructures. It is noteworthy to mention here that emulsion-phase structures find remarkable potential in design of advanced materials, formulations, and controlled polymerization reactions. The surfactants employed in the emulsions act as templates and also surface modifiers, and thereby provide scope for the design of high-performance nanocarriers. The preparation of silica nanoparticles employing the self-aggregated structures from amino acid surfactants as templates has been established [174]. The scope for the design of silica spheres of size 12–23 nm, with well-ordered structures, from tetraethoxysilicate (TEOS) employing the well-known Stober method using L-lysine was shown [175]. By the same procedure, hollow silica spheres were prepared using the amino acid surfactant, lauryl ester of tyrosine. The maleamic acid derivatives of glycine perform as cosurfactant for SDS micelles, and afford polymer nanoparticles by the emulsion template methodology [176, 177]. The micelle structures of amino acid surfactants, LET and LEP, showed extraordinary emulsification characteristics for industrially significant monomers such as styrene and butyl acrylate, and this property was utilized to produce polymeric nanoparticle dispersions [178]. The micelle templates of these surfactants enabled polymerization under controlled conditions and formed nanoparticles of poly(styrene) homopolymer and copolymer with low polydispersity index in the molecular weight and size distribution. The significance of micellar structures and the emulsion phases, as

determined by the chemical architecture of the surfactant, has been established. The polymer nanoparticle–coated micelle assemblies of LET act as potential nanocarriers for the model solid lipid stearyl alcohol [178].

62.6 SUMMARY

Nanocarriers are promising materials and, in fact, have potential to revolutionize various industries. Among various substrates, amphiphiles derived from simple and polymeric surfactants are clearly identified as the potential substrates for the nanocarriers. The growing demand for environment conservation necessitates the ecofriendly source materials for amphiphiles. Among various sources, amino acids offer one of the best choices in view of several unique characteristics such as ease of production through chemical and biochemical pathways, facile chemical modifications of carboxyl, amino and sidechain reactive groups in their structures, biodegradability, and nontoxicity. Further, amino acids, in combination with other natural sources such as lipids, can form lipoamino acids. Amino acids can form an integral part of the macromolecules as mainchain as in proteins or sidechain, as in synthetic polymers. The diversity in structures is offered by simple low-molecular-weight amino acid surfactants and the polymers consisting of amino acid segments and thereby facilitate surface modifications, binding, and site-specific delivery of functional materials such as drugs, dyes, and lubricants. With these extraordinary features, nanocarriers directly impact the economy, the prime factor of various industries. By virtue of their small size, ranging within 1–100 nm, and their high aspect ratio, nanocarriers facilitate the encapsulation and design of nanomaterials. The principles and the fundamental aspects of the self-assembly process in simple and polymeric amphiphiles, the science and technology of emulsions, all underlie the design of new series of nanocarriers. Current and future research in the area of nanocarriers, especially those from amino acid surfactants, embrace the multidisciplinary areas of synthetic and physical chemistry, biology, and physics. Nanocarriers are expected to emerge as indispensable materials in a wide range of photonics, catalysts, and diagnostic tools.

SYNTHESES OF METALLIC NANOCOLLOIDS AND THE QUENCHING ABILITIES OF REACTIVE OXYGEN SPECIES

YUKIHIDE SHIRAISHI AND NAOKI TOSHIMA

Department of Applied Chemistry, Tokyo University of Science Yamaguchi, Sanyo Onoda-shi, Yamaguchi 756-0884, Japan

63.1 INTRODUCTION

Recently much attention has been paid to metallic nanocolloids, important building blocks of nanostructures to achieve nanotechnology, which has been demonstrated by the US government as one of the most important technologies of this century. *Metallic nanocolloids* are defined as the dispersed state of fine metallic particles ranging in size from 1 nm to 1 μm [1–3]. Metallic nanocolloids such as nanoparticles are now creating a new class of materials different from either conventional bulk materials or atoms, providing one of the smallest building blocks of matter. Metallic nanocolloids have various properties based on high surface area and quantum size effects, and are promising as catalysts. Many preparation methods have been proposed, and detailed characterizations have been carried out on various preparations of metallic c nanocolloids. Here we focus on the synthesis of monometallic and bimetallic nanocolloids, which are mainly stabilized by polymers, and the application to reactive oxygen species (ROS) scavengers.

Addition of water-soluble natural or synthetic polymers [4, 5], surfactants [6], and organic ligands [7, 8] can stabilize the colloidal dispersion of metals as well. These stabilizers are called *protective colloids* or *surrounding ligand*. In this case, the surrounding ligand can be absorbed on the surface of metallic nanocolloids, and steric repulsion between the surrounding ligand stabilizes the metallic nanocolloids. Figure 63.1 depicts a schematic stabilization structure of a metallic colloid by soluble polymers in an aqueous solution. Stabilizing polymers can be adsorbed on the surface of hydrophobic metallic nanocolloids. Hydrophobic "train" segments are directly adsorbed on the surface of solid metal, and hydrophilic "loop" or "tail" segments are spread out into the hydrophilic solvent. The diameter d of core metallic nanocolloids can be easily measured by transmission electron microscopy. The thickness δ of surrounding ligand or the total diameter D including the surrounding ligand can be measured by various methods depending on the nature of the surrounding ligand. In solution, the hydrodynamic radius provides $D/2$. When the hydrodynamic radius is large enough, it can be measured by a light-scattering method. However, when the hydrodynamic radius is small, it can still be measured by a Taylor dispersion method if the size is homogeneous or uniform enough [9]. When the surrounding ligand is composed of soluble polymers, the direct measurement of D is not so easy. The thickness δ was proposed to be measured by the amount of polymers adsorbed on the surface of metallic nanocolloids [10]. Because it is not easy to measure D in solution, measurement using scanning tunnel microscopy (STM) was performed in the dry state [11].

Recently much attention has focused on polymer-protected metallic nanocolloids as nanocolloids based on rapid improvement of analytical technology on fine materials. Such nanocolloids, defined by a diameter of 1–10 nm and a narrow size distribution, are creating a new category of materials, which is different from either conventional

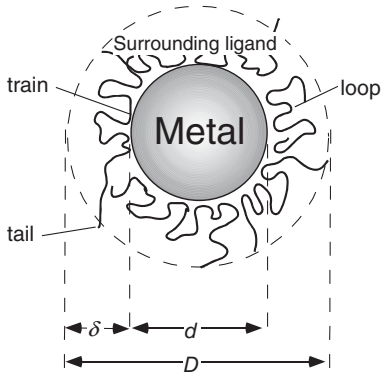

FIGURE 63.1 Structure model of polymer-protected metallic nanocolloids.

bulk materials or atoms, the smallest units of matter. Much attention has focused on their special properties in physical, biological, and chemical fields. The quantum size effect [12] is a major problem for physicists. Gold nanocolloids, for example, are interesting as materials of nonlinear optics for third harmonic generation. In the biological field, gold nanocolloids have been used for labeling specific positions of cells for observation by transmission electron micrography (TEM). Silver nanocolloids are very popular for detection of specific proteins in electrophoresis.

The most intensive investigations of applications of metallic nanocolloids are focused on catalyses. Many reports have been published on the application to catalysts [13]. Since some noble metallic nanocolloids are reducing catalysts, they may be usable as antioxidants, which reduce reactive oxygen species (ROS) in a living body. However, there are only a few studies reporting antioxidant effects of gold nanocolloids [14–16]. Typical ROS in animals, including human beings, are superoxide anion radicals, hydrogen peroxide, and hydroxyl radicals produced in normal metabolic process [17]. The dominant pathway to generate ROS is the mitochondrial electron transport chain, by which 98% oxygen inhaled by animals is reduced to water for energy production. In the electron transport process, a small number of electrons leak out and react with oxygen to generate superoxide anion radicals [18]. The superoxide anion radical is reduced to hydrogen peroxide by superoxide dismutase (SOD), and subsequently hydrogen peroxide crosses the mitochondrial membranes and diffuses inside and even outside of cells. The hydroxyl radical is generated from superoxide anion radical and hydrogen peroxide by Haber–Weiss and Fenton reactions, respectively. These ROS oxidize biomolecules found in the body such as nucleic acids, proteins, and lipids. There are many defensive systems against oxidative stress in the body. As the first defence, ROS are reduced by antioxidant enzymes such as SOD, catalase, and glutathione peroxidase as well as endogenous and exogenous small molecules, including glutathione and vitamins C and E. When biomolecules are oxidized, they are repaired or replaced by biological protective systems. Nevertheless, biomolecules are irreversible and gradually become oxidized, and oxidized biomolecules accumulate over long time periods and impair biological functions, eventually leading to aging and age-related diseases [19].

In this chapter we would like to present a preparation procedure and characteristic aspects of monometallic and bimetallic nanocolloids, and then show special structures and application to ROS scavengers of the metallic nanocolloids as examples.

63.2 MONOMETALLIC NANOCOLLOIDS

63.2.1 Preparation of Monometallic Nanocolloids

Monometallic nanocolloids can be prepared by two distinct methods: (1) by subdivision of bulk metals (a physical method) and (2) by growth of particles starting from metal atoms, which are obtained from molecular or ionic precursors (a chemical method). The latter preparative method (method 2) is more suitable for obtaining small and uniform nanocolloids than is method 1. In method 2, control of atom aggregation is the most important step in controlling the size and uniformity of the monometallic nanocolloids.

Faraday found that the addition of gelatin to gold nanocolloids protected them from the aggregation [20]. Another team advanced this idea and used synthetic polymers, such as poly(vinyl alcohol), as a surrounding ligand for platinum and palladium nanocolloids and applied them to catalysts [21,22]. Another group of researchers introduced gold and platinum nanocolloids, produced by citrate reduction, for use as supported catalysts [23, 24]. Ligands and polymers, with some affinity for metals, are often used as stabilizers of metallic nanocolloids. These substances also control both the reduction rate of metal ions and the aggregation process of metal atoms. Preparation of polymer-stabilized nanocolloids by a chemical method involves two processes: reduction of metal ions to 0-valence atoms and coordination of the stabilizing polymer to monometallic nanocolloids.

One of the most reproducible methods for preparation of monometallic nanocolloids is alcohol reduction of precious metal ions in alcohol–water in the presence of water-soluble polymers such as poly(*N*-vinyl-2-pyrrolidone) (PVP) [25]. The precious-metal ions form complexes with polymers at first. The metal ions can be reduced by alcohol to produce polymer–metal atom complexes accompanying aldehyde formation from alcohol. Other chemical reductants, such as hydrazine, molecular hydrogen, glycol, and sodium borohydride, can be used instead of alcohol. Energy, such as photoenergy, X-ray and γ-ray energy, electron beams, microwaves, ultrasonic waves, and electrolysis, can also be used in solution in the presence of stabilizers to break the

bond or reduce the metal ions to 0-valence metal atoms resulting in monometallic nanocolloids.

63.2.2 Characterization of Metallic Nanocolloids

Metallic nanocolloids can be characterized as follows.

1. *Ultraviolet and Visible Adsorption Spectroscopy*. The color change is a convenient and useful method to identify the chemical change from the solution of metal ions to the dispersion of metallic nanocolloids. The dispersions of Au, Ag, and Cu nanocolloids have a reddish yellow color because of their plasmon absorption, the peak position of which varies depending on the particle size and the extent of coagulation.
2. *Transmission Electron Microscopy (TEM).* This is the most reliable method for measuring the size and shape of metallic nanocolloids. The average size is usually calculated by counting the sizes of ~200 particles. High-resolution TEM can provide information not only on particle size and shape but also on the crystalline structure of metallic nanocolloids. When energy-disperse X-ray microanalysis (EDS) is used in conjunction with TEM, elemental information of metallic nanocolloids can be obtained. The localized elemental information is acquired by energy-loss spectroscopy in conjunction with energy-filtering TEM.
3. *X-Ray Photoelectron Spectroscopy*. This methhod is used to obtain information on the state of metal, such as the oxidation state of metal on the surface. Metal on the surface is often oxidized by air. So the 0-valence of surface metal must be confirmed by using X-ray photoelectron spectroscopy.
4. *X-Ray Diffraction*. For monometallic nanocolloids, X-ray diffraction can provide information on the phase changes depending on the particle size. X-ray diffraction can determine whether the bimetallic nanocolloids are composed of the mixtures of two kinds of monometallic nanocolloids or of single bimetallic nanocolloids in which two elements are included in one particle.

63.2.3 Application to Reactive Oxygen Species (ROS) Scavengers by Monometallic Nanocolloids

Noble metal is often used as ROS scavengers. Cyclodextrin (CyD)-protected noble metallic nanocolloids were prepared by photoreduction method. Figure 63.2 shows a transmission electron micrograph and the corresponding histogram indicating the particle size distributions of γCyD-protected Pt nanocolloids. The most γCyD-protected Pt nanocolloids were distributed in the range of 1–4 nm, suggesting that the size of CyD-protected Pt nanocolloids is homogeneous. The

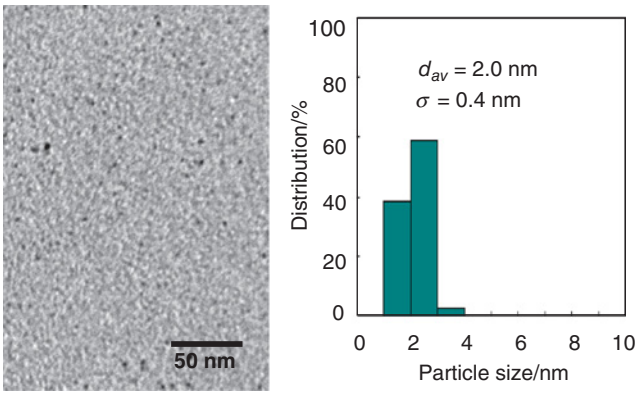

FIGURE 63.2 Transmission electron micrographs and particle size distribution histograms of γCyD-protected Pt nanocolloids (d_{av} = average diameter; σ = standard deviation).

average diameters of γCyD-protected Pt nanocolloids are 2.0 nm, with a narrow size distribution.

γCyD-protected noble metallic nanocolloids were applied to the catalyst for quenching of reactive oxygen species. Figure 63.3 exhibits UV–Vis absorption spectra of an aqueous solution of hydrogen peroxide in the absence and presence of γCyD-Pt nanocolloids. Table 63.1 summarizes the quenching ability of hydrogen peroxide by γCyD-protected noble metallic nanocolloids. The γCyD-protected Pt, Pd, and Au nanocolloids quenched 65%, 13%, and 3%, respectively, of hydrogen peroxide. Kajita et al. reported the quenching ability of hydrogen peroxide by Pt-black and pectin-protected Pt nanocolloids, as shown in Fig. 63.4 [26]. The Pt-black, which was composed of relatively larger particles (the average diameter of 100 nm) and their aggregates, did not quench hydrogen peroxide at all. The high catalytic activity of

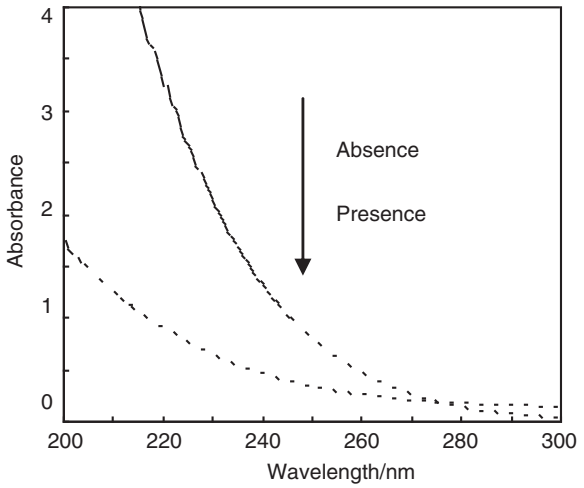

FIGURE 63.3 UV–Vis absorption spectra of an aqueous solution of hydrogen peroxide in the absence and presence of γCyD-Pt nanocolloids.

TABLE 63.1 Quenching ability of hydrogen peroxide by γCyD-protected noble metallic nanocolloids.

Nanocolloids	H_2O_2 removal ratio (%)
γCyD-Au	3.0
γCyD-Pd	13
γCyD-Pt	65

γCyD-Pt nanocolloids may be due to the effect of surface area. On the other hand, the pectin-protected Pt nanocolloids with average diameters in the range of 4.7 nm have higher catalytic activity (residual ratio 17%, removal ratio 83%) than that of γCyD-Pt nanocolloids. Polymers that weakly coordinate to the surface of metallic nanocolloids at many points are especially effective for stabilizing the metallic nanocolloid catalyst [27]. In the process of catalytic reaction, when the substrate is added to the reaction mixture, a weakly coordinating polymer can be easily replaced in part with the substrate molecule, resulting in the reaction of substrates on the surface of metallic nanocolloids. Strongly coordinating organic ligands cannot be easily replaced by substrate molecules, making it difficult for the substrate to make the catalytic reaction proceed on the surface of metal nanocolloids. This kind of reversible capping of the polymer on the metal surface cannot occur in organic ligands with low molecular weight, although organic ligands or ionic species play an important role to control the shape of metallic nanocolloids [28].

63.3 BIMETALLIC NANOCOLLOIDS

63.3.1 Preparation of Bimetallic Nanocolloids

Bimetallic nanocolloids, in which each particle contains two metal elements, are very important and interesting in terms of catalysis of metallic nanocolloids because catalytic performance is very often affected by the addition of another element to the metal. In addition, the structure of bimetallic nanocolloids is strongly related to catalytic performance. Polymer-protected bimetallic nanocolloids have been prepared by simultaneous reduction of two corresponding metal ions with refluxing alcohol in the presence of PVP. For example, PVP-protected Pt-core/Pd-shell bimetallic nanocolloids can be prepared by refluxing the alcohol/water (1/1, v/v) mixed solution of palladium(II) chloride and hexachloroplatinic(IV) acid in the presence of PVP at about 90–95°C for 1 h [29]. The special structure has been proposed on the basis of extended X-ray absorption fine structure (EXAFS) analyses [30]. The PVP-protected Pt-core/Pd-shell model for Pt/Pd (1/4, mole ratio) is shown in Fig. 63.5, where 13 platinum atoms are preferentially located in the central part (core) of the bimetallic nanocolloids, and where 42 palladium atoms surround the core forming a shell with an atomic layer. The formation process of core–shell structure may be due to orders of reduction potential of metal ions and coordination ability of the protective polymer to reduced atoms.

Au/Pd, Au/Pt, and Pt/Rh bimetallic nanocolloids have been prepared by the same method [31]. One team prepared Ag/Pd bimetallic nanocolloids by photoreduction of silver(I) bis(oxalato)palladate(II) in water [32]. Ag/Pt bimetallic nanocolloids were obtained by sodium tetrahydroborate reduction of silver(I) bis(oxalato)platinate(II) in ethylene glycol [33]. Colloidal dispersions Au/Ag bimetallic nanocolloids were prepared by γ-irradiation of the mixed solution for study of electrochemical reaction [34].

The inverted core/shell, for example, Pd-core/Pt-shell-structured bimetallic nanocolloids, are difficult to synthesize. Addition of platinum(IV) ions to palladium nanocolloids resulted in a redox reaction to form platinum nanocolloids and palladium(II) ions. In order to avoid this unfavorable reaction, the colloidal dispersions of palladium cores were treated with hydrogen and then solutions of the second element, platinum(II) ions, were slowly added to the dispersions. This novel method, based on sacrificial hydrogen strategy,

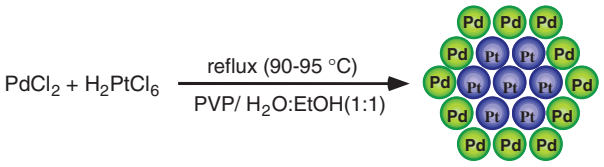

FIGURE 63.5 Schematic illustration of formation of Pt-core/Pd-shell bimetallic nanocolloids.

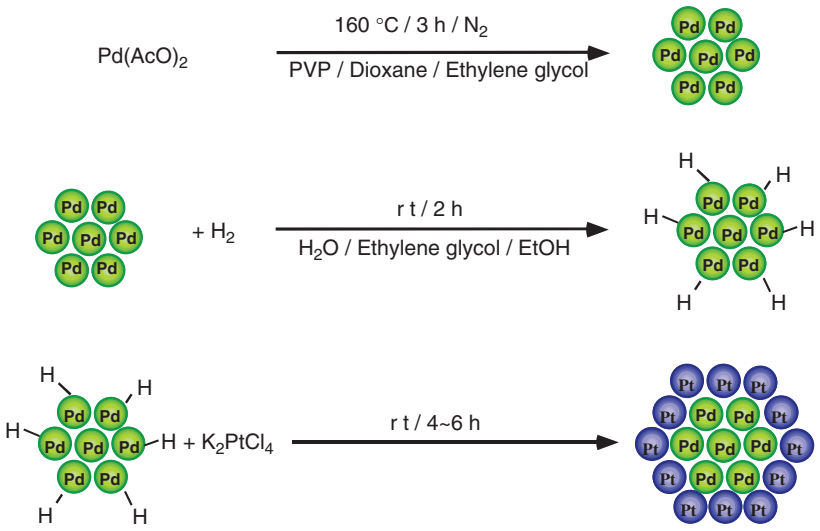

FIGURE 63.6 Schematic illustration of formation of Pd-core/Pt-shell bimetallic nanocolloids.

gave the inverted core—shell-structured bimetallic nanocolloids as shown in Fig. 63.6. The PVP-protected Pd-core/Pt-shell structure was confirmed by FT-IR spectrum of adsorbed carbon monoxide [35].

Reduction of two different precious-metal ions by UV irradiation in the presence of Poly(γ-cyclodextrin) (PγCyD) gave a colloidal dispersion of so-called core–shell-structured bimetallic nanocolloids. In the case of Au and Pt ions, the colloidal dispersions of bimetallic nanocolloids with an Au-core/Pt-shell structure are produced. PγCyD- protected Au/Pt bimetallic nanocolloids were applied to the catalyst for quenching of hydrogen peroxide [36].

63.3.2 Application to ROS Species Scavengers by Bimetallic Nanocolloids

Figure 63.7 exhibits the relationship between catalytic activity and the metal composition of PγCyD-protected Au-core/Pt-shell bimetallic nanocolloids. Since gold have low activity and platinum have high activity for the quenching of hydrogen peroxide, PγCyD-protected Au-core/Pt-shell bimetallic nanocolloids were assumed to exhibit activities somewhere between the corresponding monometallic nanocolloids. PγCyD-protected Au-core/Pt-shell (1/4) bimetallic nanocolloids show higher catalytic activity than do the monometallic nanocolloids. Previous reports had shown that platinum nanocolloids containing a certain amount of additional other metals such as gold and palladium exhibit higher catalytic activity in hydrogen evolution and hydrogenation than do platinum monometallic nanocolloids [37]. In the series of the PVP-protected Au/Pt bimetallic nanocolloids, the relation between catalytic activity and Pt content is expressed by a sigmoidal curve. High catalytic activity was achieved at the position of 40% Au and 60% Pt. The same tendency was observed on PγCyD-protected Au-core/Pt-shell bimetallic nanocolloids. The high catalytic activity can be explained by an electronic effect of neighboring Au on the surface Pt.

On the other hand, the next question is how the catalytic activity of Pt-core/Au-shell (inverted core/shell) structured bimetallic nanocolloids is. Figure 63.7 also depicts the relationship between the metal composition and the catalytic activity of PγCyD-protected Pt-core/Au-shell bimetallic nanocolloids for the quenching of hydrogen peroxide.

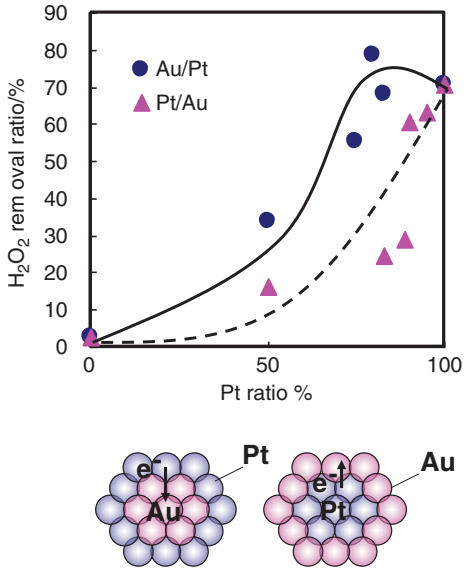

FIGURE 63.7 Plots of quenching activity of hydrogen peroxide versus the metal composition of PγCyD-protected Au-core/Pt-shell and Pt-core/Au-shell bimetallic nanocolloids.

Since gold has low activity and platinum has high activity for the quenching of hydrogen peroxide as described above, PγCyD-protected Pt-core/Au-shell bimetallic nanocolloids were believed to possess the activities just between the two corresponding monometallic nanocolloids. However, the catalytic activities of PγCyD-protected Pt-core/Au-shell bimetallic nanocolloids are lower than those expected at a molar ratio of <100 mol% of Pt. The transition of catalytic activity from the linear correlation can be explained by an electronic effect of the neighboring Au on the surface Pt. When the Pt core particles is covered mostly by Au atoms, the number of surface Pt atoms decreases, resulting in decrease of the catalytic activity.

ACKNOWLEDGMENTS

The authors thank not only all the coauthors of the cited references but also the coworkers who have worked with them, especially Miss M. Hashimura and Miss M. Nakao for their wide-ranging contributions to the present work. 64.1 INTRODUCTION

The motivation for biointerface science stems from the urgent need to increase the understanding of interactions between biomolecules and surfaces. The behavior of complex macromolecular systems at material interfaces are important in the fields of biology, biotechnology, diagnostics, and medicine. Molecularly designed interfaces, colloidal and/or nanoparticle interfaces has been the subject of various authors from the 1857. Faraday reported the formation of deep red solutions of colloidal gold by reduction of an aqueous solution of chloroaurate using phosphorus in a two-phase system. He investigated the optical properties of thin films prepared from dried colloidal solutions and observed reversible color changes of the films upon mechanical compression [1]. Topics of interest include, but are not limited to neural interfaces, cells in engineered microenvironments and regenerative medicine, computational and modeling approaches to biointerfaces, membranes and membrane-based biosensing, peptides, carbohydrates, and DNA at biointerfaces. The interfaces are omnipresent in Nature and can be used broadly as ideal means for the self-assembly of nanoparticles. The chemistry of nanosized and colloidal metal particles in terms of their physicochemical properties in solution has come a long way, and their importance in various fields of chemistry and physics are unlimited [2–10]. The reason for using colloidal metal solutions was to apply these materials as catalysts for free-radical reactions initiated by light or ionizing radiation. In these reactions, electrons are transferred across the particle–solution interface similar to electrode reactions in electrochemistry. The small particles are therefore referred to as *microelectrodes*. Various theories have been applied for the preparation and characterization of small particles [11–15]. In colloid preparation, the hydrated electrons and reducing organic radicals that are generated in the radiolysis of aqueous solutions reduce dissolved metal ions, thus producing unusual valence states.

One team of researchers [16] observed an absorption at 310 nm after application of a 0.1-μs pulse of high-energy electrons to a 10^{-4} mol dm^{-3} solution of silver sulfate and attributed it to the free silver atom produced in the reaction for the first time

$$Ag^{+} + e^{-}_{aq} \longrightarrow Ag^{0} \qquad (64.1)$$

which subsequently coalesce to form larger particles [6]. Most studies on the surface chemistry of metal particles have been performed with silver, because the position and shape of the plasmon absorption band of this metal is strongly influenced by chemical modification to the surface. Whereas these changes can be used as sensitive indicators for the occurrence of an interaction between the metal particles and a dissolved substrate, the changes themselves are not yet understood in detail [6]. The silver atom formed in the reaction in Eq. (64.1) reacts rapidly with an Ag^{+} ion to yield Ag^{2+} [Eq. (64.2)], and the Ag^{2+} ions dimerize [Eq. (64.3)]. $Ag_4{}^{2+}$ undergoes

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.

further reaction to yield larger aggregates until Ag_8 is formed in solution [17–19]:

$$Ag^+ + Ag^0 \longrightarrow Ag_2^+ \quad (64.2)$$

$$2Ag_2^+ \longrightarrow Ag_4^{2+} \quad (64.3)$$

$$2Ag_4^{2+} \longrightarrow Ag^+ + Ag_7^{3+} \quad (64.4)$$

$$2Ag_7^{3+} \longrightarrow Ag_8 + 6Ag^+ \quad (64.5)$$

$$2Ag_7^{3+} \longrightarrow Ag_9^+ + 5Ag^+ \quad (64.6)$$

In absence of a stabilizing polymer, the rate constants for reactions (64.5) and (64.6) are 8×10^9 and 2.6×10^9 mol^{-1} dm^3 s^{-1}, respectively [6]. In absence of a polyanion, the growth stops at the stage of $Ag_4{}^{2+}$ [20]. The cluster $Ag_6{}^{4+}$ and other highly charged silver clusters have been detected in zeolites. In aqueous solution, the stabilizing effect, exerted by the anionic charges in a zeolite cage, is not present. It has been established that exposure of zeolite-stabilized $Ag_6{}^{n+}$ clusters to water results in fragmentation [21]. For the gold reduction, reaction can be summarized as follows:

$$AuCl_4^- + 3e^- \longrightarrow Au^0 + 4Cl^- \quad (64.7)$$

Metal nanoparticles (monometallic and bimetallic) have exhibited their diversity and potential applications in, for instance, information technology, optoelectronics, sensing, biocatalyst and plasmonics [22–28]. There has been a great deal of efforts applied to the development of new methodologies for preparing a range of metal nanoparticles having uniform sizes and aspect ratios; such approaches include the use of rigid and soft templates, seed mediated growth, polymers, and surfactants and co-surfactants for crystal growth of nanomaterials [29–32].

Amino acids (the basic structural units of proteins; facilitate a wide range of physiological functions) are biologically important substances whose activities depend largely on their redox behavior. Amino acids are known to provide different coordination sites: at the N, O, and S centers that can coordinate with silver ions and with metallic nanoparticles. Amino acids play a significant role in the preparation of advanced nanomaterials of silver. It has been recognized that amino and carboxyl functional groups of amino acids undergo chemical transformations while the side chain remains intact. Another team [33] reported that the sidechain –OH group of tyrosine residues and –COOH groups of aspartic acid and/or glutamic acid residues are responsible for the reduction of Ag^+ ions and for the anisotropic growth of silver nanocrystals into nanoplates, respectively. The process of silver nanoplates formation was kinetically controlled and depending on the ratio of –COOH groups to tyrosine per peptide molecule and silver surface. Different-shaped and different-sized Au–Ag nanocomposites from gold nanorods in presence of various amino acids such as arginine, cysteine, glycine, glutamate, glutamine, histidine, lysine, and methionine have been synthesized [34]. The –SH group of cysteine was responsible for the formation of quantum dots of silver [35]. Extensive research in finely dispersed metallic particles has clearly established that size, combination, and internal structure strongly affect their properties in both dispersed and condensed states [36]. Numerous methods have been used for the preparation of ultrasmall metal nanoparticles, such as molecular beam epitaxy [37], chemical vapor deposition [38], reduction by ionizing radiation [6], thermal decomposition in organic solvents [39], chemical or photoreduction in reverse micelles [40], and chemical reduction with [41] or without stabilizing polymers [42]. The colors of the silver colloidal sols vary depending on the method of preparation and the state of aggregation. Silver nanocrystallities, mostly hydrosols, are widely studied because of their applicability in surface-enhanced Raman scattering [43–45] and their use in the photographic process [46]. Prolate spheroids and bispherical particles are particularly effective in surface-enhanced Raman scattering [47, 48].

The main objective of this chapter is to summarize the role of amino acid sidechains that influence morphology of nanoparticles and their implications in cellular uptake. In a biological medium, nanoparticles may interact with biomolecules such as carbohydrates, proteins, nucleic acids, lipids, and even biological metabolites because of their nanosize and large surface-to-mass ratio. Of particular importance is the adsorption of amino acids on the nanoparticle surface. Controlling size and shape simultaneously remains an extremely difficult task, since the outcome of these syntheses is generally determined by a number of factors and is only partially characterized by the interplay of kinetics and thermodynamics. This difficulty increases when silver nanoparticles with a controlled size and shape must be synthesized by green chemistry. Sulfur-containing amino acids have three possible reactions and/or coordination sites: at the S, O, and N centers. Sulfur has been established as the most susceptible element to gain electrons from the oxidizing agents. In methionine [2-amino-4-(methylthio)butanoic acid], the reactive site is partially blocked by a methyl (–CH_3) group. Recognizing the importance of amino acids in the synthesis of silver nanomaterials as reducing and nucleophilic reagents, we have chosen to discuss the role of amino acids, especially methionine in this chapter.

64.2 ROLE OF SIDECHAIN

The chemical literature contains abundant reports aimed at clarifying the role of α- amino acids in the synthesis of different-shaped/-sized silver–gold nanocomposites and their nanoparticles [49–54]. One team of investigators [50] reported the surface chemistry of gold colloids in presence

of different amino acids (neutral, acidic, and basic) and suggested that basic sidechain of amino acids (glutamine, arginine, lysine, histidine, cysteine, methionine, and tyrosine) can act as cross-linking agent for pairs of gold particles, whereas the amino acids with nonpolar (alanine) and acidic sidechains (aspartic and glutamic acids) produced no change in the spectra of gold nanoparticles. These investigators also suggested the connection between gold nanoparticles via amino acids, in the absence/presence of glutaraldehyde as a molecular "bridge," over a wide range of pH values.

Lysine, a basic sidechain amino acid, has been used in the synthesis of gold nanowires [50]. Length of the nanowires (5 nm and length varying from 80 to 200 nm) might be controlled at a specific pH (∼8.4–9.5) and at a constant molar ratio of gold and lysine.

The key factor for the formation of linear nanowires is believed to be a subtle attractive (cross-linking) force, provided by the basic sidechain of lysine. Gold nanoplates (with thicknesses of <30 nm) have been synthesized in large quantities using aspartate-mediated reduction of gold salt [55], suggesting that specific interactions between the amino acid and the crystal lattice structure alter the surface distribution with amino acid concentrations and reduction processes.

The reaction pathways and the final oxidation products depend on the experimental conditions and the nature of the amino acid sidechain. Aromatic sidechain amino acids were oxidized more rapidly than the alkyl sidechain amino acids [56, 57]. Amino acids are known to provide different coordination sites at the N, O, and S centers that can coordinate with a variety of metal ions. Sulfur has been established as the most susceptible element to gain electrons from oxidizing agents [58]. The reactions of silver and gold ions with sulfur-containing amino acids (methionine and cysteine) have been investigated for several reasons [50,53,54]. Methionine has rich applications in redox and surface chemistry as a reductant and a stabilizer [59]. The literature describing the preparation of silver nanoparticles is especially broad, since classical colloid methods are combined with modern nanotechnology leading to many procedures for particle preparation, control of particle size, and surface modification. Silver nanoparticles have been the subject of great interest for decades because of their use in catalysis, photography, photonics, electronics, labeling, imaging, sensing, and surface-enhanced Raman scattering. Silver nanoparticles capped with various stabilizers (surfactants or polymers) have been widely studied [60–64]. Silver atoms that are reduced from silver ions by ascorbate deposit onto the surfaces of the gold nanoparticles to form dumbbell-shaped silver–gold nanoparticles whose morphologies differ depending on the pH and the concentration of silver ions and glycine. By controlling the value of pH as well as the amount of glycine in the growth solutions, I-shaped, dumbbell-shaped, and/or peanut-shaped gold core/gold–silver shell nanoparticles from gold nanoparticles seeds can be achieved [65]. Glycine, used to control the pH of the solutions, also plays a role in controlling the reduction of silver and gold ions. In the presence of high concentrations of glycine, AgCl and AgBr do not precipitate, mainly because of the formation of glycine–silver complexes. These investigators also pointed out that the as-prepared silver and gold nanoparticles were stable for >3 months in glycine solution after removal of CTAB; this result suggests that glycine acts as a capping agent that stabilizes the silver–gold nanoparticles. The silver and gold nanoparticles having different morphologies (shape, size, and the size distribution) prepared simply by controlling the nature of the amino acid species and its concentration, the pH, and the incubation time were summarized in Table 64.1. Functionalized nanoparticles were conjugated with protein molecules through electrostatic attraction between the surface-terminated negatively charged carboxylate groups of glutamic acid and the positively charged amino groups of the protein [70].

The reduction of $HAuCl_4$ by acidic amino acid (i.e., glutamic acid) occurred through the transfer of electrons from the $-NH_2$ group to the Au^{3+} ion leading to the formation of Au^0. This metallic gold then nucleates and grows to form gold nanoparticles, and is subsequently capped and stabilized by the amino acid. The amino group of the amino acid is oxidized to a positive radical, due to the transfer of an electron from the amine to the gold ion. The visible spectrum of the resulting gold nanoparticles showed one sharp peak. The shape of the spectra markedly changed from sharp to much broader, indicating that aggregation of the gold nanoparticles occurred by increasing the concentration of glutamic acid. The color of the colloidal solutions changed from reddish, dark red, to blue. The change in color of colloidal gold solutions from red to blue as a consequence of aggregation is a well-understood phenomenon. Glutamic acid acted as a reducing as well as stabilizing and/or capping agent in the synthesis of silver and gold nanoparticles, which might be due to the association and adsorption of acidic sidechain ($HOOCCH_2CH_2$-) onto the surfaces of metal nanoparticles [67,70].

64.3 MECHANISM IN THE FORMATION OF SILVER NANOPARTICLES

When $AgNO_3$ is allowed to react with methionine in presence of CTAB and sodium hydroxide, a yellow color appears as the reaction proceeds, indicating the formation of silver nanoparticles. To confirm the nature of the yellow color and determine the size of the nanoparticles, spectra of the resulting color were recorded by using a Spectronic 21D spectrophotometer. Spectrophotometric and transmission electron microscopic (TEM) measurements were carried out using a JEOL, JEM-1011 model, operating at 300 kV, respectively. For the TEM, samples were prepared by placing

TABLE 64.1 Effects of Sidechain on Morphologies of Silver and Gold Nanoparticles

Sidechain	Color of sol	Morphology; media	Ref.
Silver Nanoparticles

a drop of silver sol in a carbon-coated standard copper grid (300 mesh) and allowing the solvent to evaporate. The reaction mixture containing the required concentrations of Ag^+ ions, CTAB and H_2O (for dilution) was thermally equilibrated at room temperature (30°C) and this was added in a glass-stoppered two-necked flask fitted with a spiral double-walled condenser to check evaporation. The reactions were started after the addition of measured amount of methionine and NaOH solutions, preequilibrated at the same temperatures. The reaction volume was 50 cm^3 throughout. The formation of yellow color (progress of reaction) was followed by measuring the absorbance at 550 nm (neither reactants nor products showed any absorbance at this wavelength) on the Spectronic 21D spectrophotometer. A control dynamic pH meter fitted with a combination electrode was used to measure the pH of the working solutions. The apparent first-order rate constants were calculated from the slopes of the plots of ln $(a/(1-a))$ versus time, where $a = A_t/A_\alpha$ and A_t and A_α are the absorbance at time t and α, respectively. Duplicate runs gave rate constants that were reproducible to within 5%.

The effect of $[OH^-]$ [range $(0.0–3.0) \times 10^{-4}$ mol dm^{-3}] was studied at constant $[Ag^+] = 10.0 \times 10^{-4}$ mol dm^{-3}, $[CTAB] = 8.0 \times 10^{-4}$ mol dm^{-3} and [methionine] = 10.0×10^{-4} mol dm^{-3}. The spectra of yellow color silver sol formation as a function of [NaOH] are depicted graphically in Fig. 64.1. The most characteristic part of the silver sol is the sharp surface plasmon resonance band observable at ~400 nm. The spectra of silver sol cover the whole visible region of the spectrum and is yellow-brown in color. The shape of the spectra gives information about the size, shape, the size distribution and the surface properties of the metal particles. The nature of the spectra was unsymmetric, indicating the presence of aggregated particles (polydispersity). The plots of log(absorbance) versus log(wavelength) are linear (Fig. 64.2). It is well known that the yellow color is due to the formation of colloidal silver particles in the spectrum, which be due mainly to the scattering of light (Rayleigh's law). Thus, we may safely conclude that the available data are consistent with the formation of colloidal silver nanosized particles under the present experimental conditions. The absorbance of the silver sol increases with

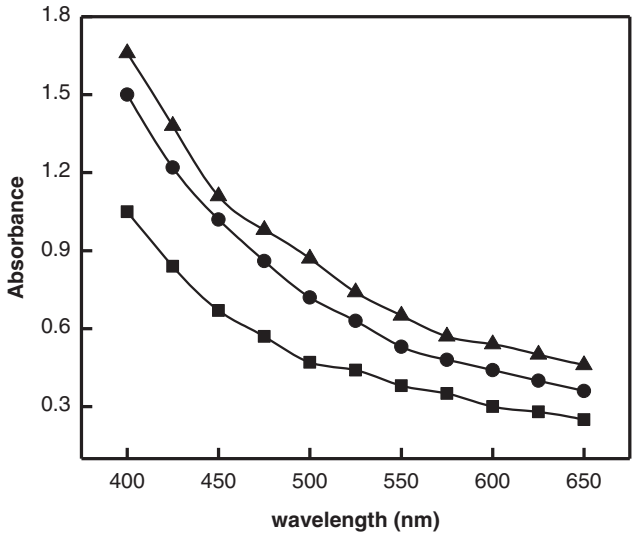

FIGURE 64.1 Spectra of silver nanoparticles. Reaction conditions: [methionine] = 10.0×10^{-4} mol dm^{-3}; $[Ag^+] = 10.0 \times 10^{-4}$ mol dm^{-3}; $[CTAB] = 8.0 \times 10^{-4}$ mol dm^{-3}; $[OH^-]$ = 2.0 (■), 8.0 (•) and 20.0×10^{-4} mol dm^{-3} (▲).

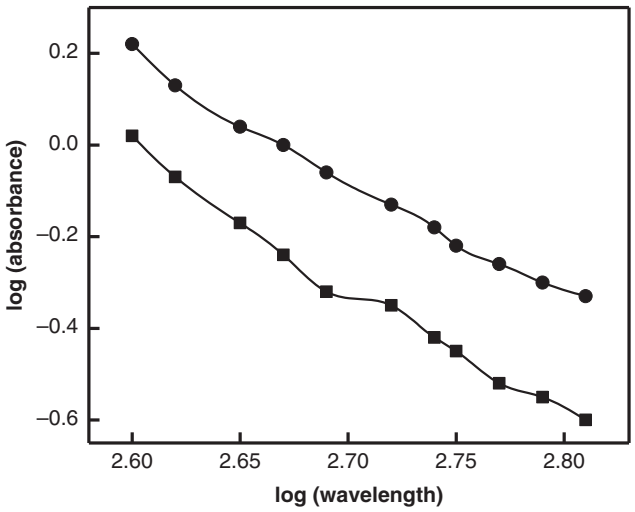

FIGURE 64.2 Plots of log(absorbance) versus log(wavelength) to the yellow color silver sol for the data in Fig. 64.1((■) and (•)).

increasing [OH^-] until it reaches a maximum, after which it decreases. These observations are summarized in Fig. 64.3 as an absorbance–[OH^-] profile. The increase/decrease behavior (hypochromic shift) of absorbance after a definite time interval (30 min) may be explained in terms of adsorption of OH^- onto the positive surface of metallic silver particles electrostatically, which, in turn, increases the Fermi level of particles. The nucleophiles and neutral stabilizing polymers have a strong effect on the plasmon absorption band of silver and/or metal nanometer particles and donate the electron density to the particles via lone pairs of electrons.

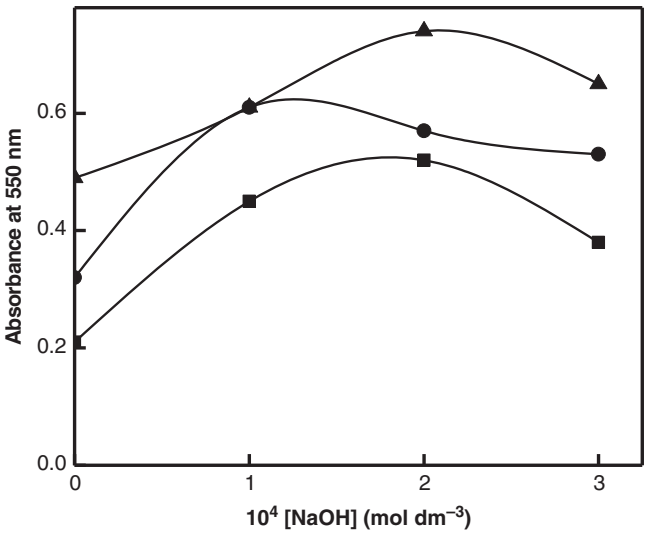

FIGURE 64.3 Plot showing the effect of [NAOH] on absorbance of silver nanoparticle formation after 30 min of mixing of silver(I) and methionine. Reaction conditions: [methionine] = 10.0×10^{-4} mol dm^{-3}; [Ag^+] = 10.0×10^{-4} mol dm^{-3}; [CTAB]= 8.0×10^{-4} mol dm^{-3}; [OH^-] = 2.0 (■), 8.0 (•) and 20.0×10^{-4} mol dm^{-3} (▲).

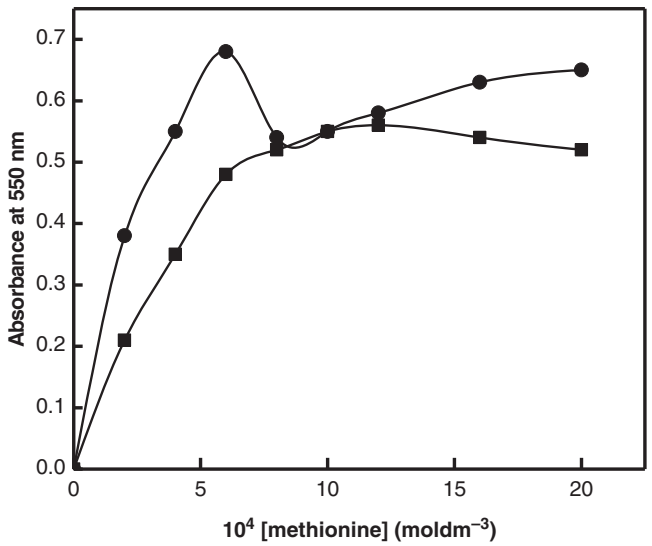

FIGURE 64.4 Plot showing the effect of [methionine] on the absorbance of silver nanoparticles formation after 30 min of mixing of silver(I) and methionine in absence (■) and presence (•) of [OH^-] (= 2.0×10^{-4} mol dm^{-3}). Reaction conditions: [Ag^+] = 10.0×10^{-4} mol dm^{-3}; [CTAB] = 8.0×10^{-4} mol dm^{-3}.

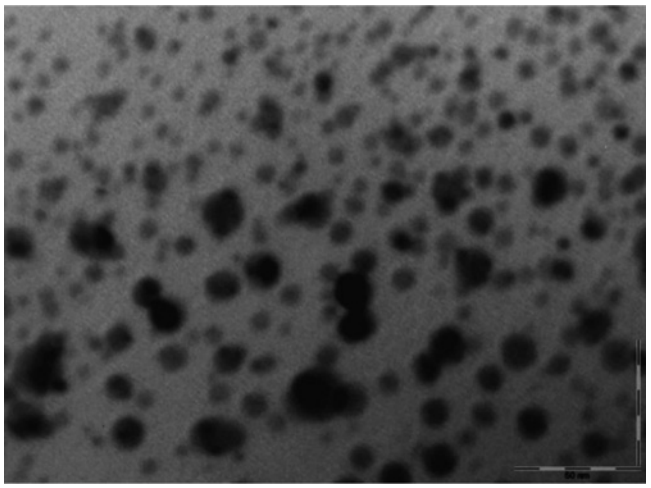
The effect of [methionine] on the silver sol formation was investigated at different methionine concentrations (2.0×10^{-4} to 20.0×10^{-4} mol dm^{-3}) at constant [CTAB] = 8.0×10^{-4} mol dm^{-3}, [Ag^+] = 10.0×10^{-4} mol dm^{-3} in absence and presence of [NaOH] (= 3.0×10^{-4} mol dm^{-3}) and temperature = 25°C. For a specific reaction time (viz., 30 min), the absorbance first increased until it reached a maximum, and then decreased with [methionine] (Fig. 64.4). Therefore, methionine also acts as a stabilizer. The presence of the $–NH_2$ group is responsible for the adsorption of



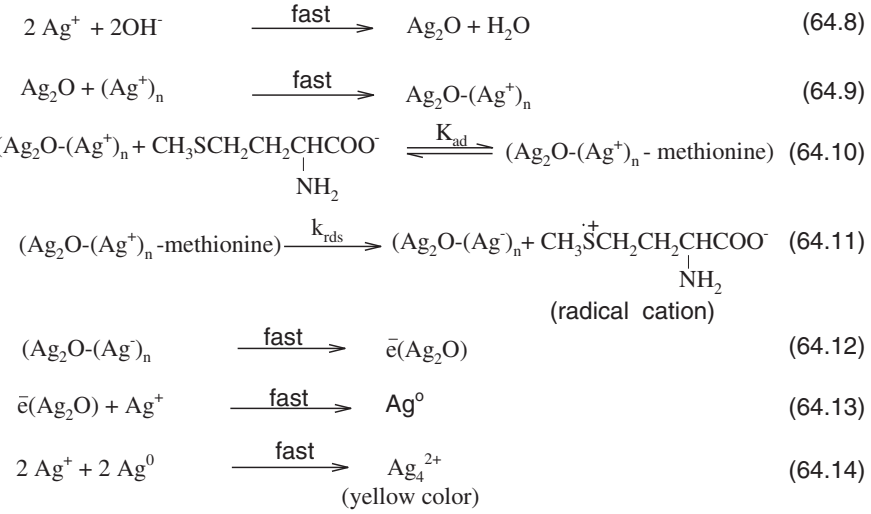


FIGURE 64.5 TEM images of silver nanoparticles. Reaction conditions: [methionine] = 10.0×10^{-4} mol dm^{-3}; [Ag^+] = 10.0×10^{-4} mol dm^{-3}; [CTAB] = 8.0×10^{-4} mol dm^{-3}; [OH^-] = 2.0×10^{-4} mol dm^{-3}.

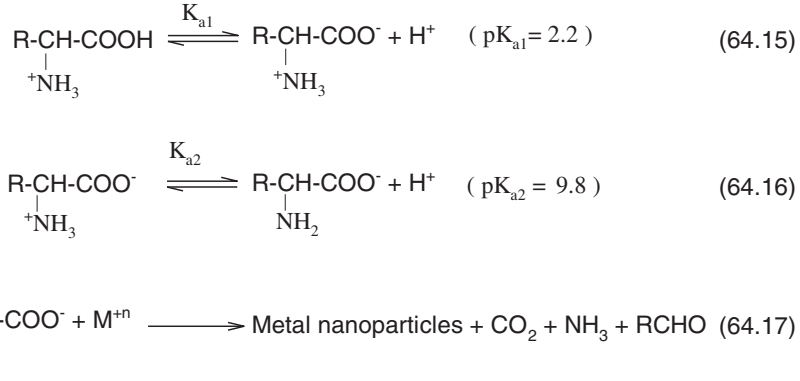
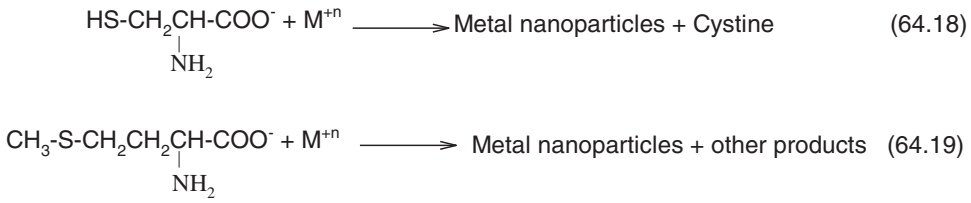


Scheme 64.1 Reduction of Ag^+ ions by mehtionine in basic medium.

methionine on the surface of silver particles, which easily donates the lone pairs of electrons, leading to the formation of stable water-soluble nanosized silver particles. The most interesting features of the present observations are the formation of yellow-color silver sol in presence of NaOH. The experimental finding is that the colorless reaction mixture became purple in absence of NaOH; instead of yellow, which is the characteristic of nanosized monodispersed silver particles. Hydroxide ions play a crucial role in the formation of silver nanoparticles (the hydroxide ions is known to have a catalytic effect on the formation of silver sols, providing a significant change in the reactivity of Ag^+ ions, thus allowing initiation of the electron transfer from reductant to Ag^+ ions, which in turn, prevents a fast corrosion of the very small silver particles at early stages of the reaction).

To evaluate the order with respect to [silver(I)], the measurements were made by recording the changes in the intensity of the plasmon absorption band at 550 nm. The reaction rate remains constant with an increase in [silver(I)] ($k_{obs} = 2.5 \pm 0.5 \times 10^{-4}$ s^{-1} at [silver(I)] = 1.0, 2.0, 4.0, 6.0, 8.0,10.0, and 12.0×10^{-4} mol dm^{-3}) at constant [methionine] (10.0×10^{-4} mol dm^{-3}), [CTAB] (8.0×10^{-4} mol dm^{-3}), indicating the first-order dependence on $[Ag^+]$.



In order to determine the shape, size, and size distribution of silver nanoparticles, the TEM images were also determined by TEM. Figure 64.5 shows a TEM image of silver sol at a constant $[Ag^+]$ / [CTAB] ratio of 1.0. In agreement with the UV–Vis spectrophotometric observations, the TEM pictures reveal silvernanoparticles are aggregated and roughly spherical with a rather similar diameter of 20 nm. On

where R = H, CH_3, $HOOCCH_2$ and $HOOC(CH_2)_2$ for glycine, alanine, aspartic acid and glutamic acid

$M^{+n} = Ag^+$ and Au^{3+}

Scheme 64.2 Formation of silver and gold metal nanoparticles by amino acids.

Scheme 64.3 Formation of silver and gold metal nanoparticles by sulfur-containing amino acids.

the basis of the above results and discussion, the mechanism shown in Scheme 64.1 is proposed for the reduction of Ag^+ ions by methionine in presence of OH^- ions.

Scheme 64.1, Eqs. (64.8) and (64.9) represent the fast formation of colloidal Ag_2O and adsorption of Ag^+ from solution onto the surface of Ag_2O particles, respectively. The next step is the adsorption of methionine onto the surface of colloidal Ag_2O-$(Ag^+)_n$ particles [Eq. (64.10)] through the lone pair electrons of S and N atoms of methionine. In Eq. (64.11), one-step one-electron transfer occurs from the S atom to the Ag^+ ions. Silver ions adsorbed on the surface of Ag_2O are then reduced via reaction with the delocalized electrons [Eqs. (64.12) and (64.13)]. It is well known that various species such as Ag_2^+, Ag_3^{2+}, Ag_4^{2+}, $Ag_{8,}$ Ag^+, or Ag_9^+ and Ag_6^{4+} exist in aqueous solution and in zeolites. Out of these species, only Ag_4^{2+} can be stabilized for a long time in presence of a polyanion even under air and growth stops at the stage of this species. Under our experimental conditions of working solutions, the yellow color of the silver sol is due to the formation of Ag_4^{2+}. The participation of amino acid sidechain in the formation of metal nanoparticles is summarized in Schemes 64.2 and 64.3 for nonpolar or polar sidechains and sulfur-containing amino acids, respectively.

NANOGEL, AN INTERNALLY NETWORKED POLY(AMINO ACID) NANOPARTICLE FOR pH-RESPONSIVE DELIVERY

Jong-Duk Kim and Chan Woo Park

Department of Chemical and Biomolecular Engineering, KAIST, 291 Daehak-ro, Yuseung-gu, Daejeon, Republic of Korea

65.1 INTRODUCTION

Nanogels are internally networked hydrophilic polymeric nanoparticles in nanoscale dimensions (i.e., <100 nm) [1], having hydrogel-like properties. Nanogels imbibe water when they are located in an aqueous environment, unlike dense nanospheres. Also, nanogels have high mechanical stability due to cross-linking, and their environment-sensitive swelling/deswelling can be observed likewise in hydrogel. In particular, the high surface area and small particle size enable nanogels to show faster swelling or deswelling in response to stimuli (pH, temperature, ions, light, etc.) compared to microgels [2].

Nanogels have several advantages in drug delivery system due to their affinity to water, high colloidal stability, inertness in blood and internal domains, as well as reduced drug degradation and toxicity [3]. The nanoscale size with narrow size distribution [4] also leads a delivery of oligonucleotides into the brain [5] and a rapid response to biological pH conditions. The surface functionalized nanogels are very useful for delivery of drugs to various diseases such as cancer or central nervous system via the blood–brain barrier [6].

In most physiological processes pH, is well controlled, and any deviation of pH can reflect systemic pathologies. For example, the extracellular pH of most tumors and inflamed and wound tissues is acidic (5.8–7.2), which is different from neutral normal tissue [7,8]. As the hydrostatic pressure builds up inside of tumors, the interior pH decreases as a result of the low oxygen concentration and high lactic acid concentration. Further, hydrolytic enzymes in lysosomes drop the interior pH to 4.5–5.0, and at Golgi complex to 6.4. Such pH differences between normal and pathological tissues, and endosomes as well as lysosome, would promote an excellent opportunity to explore a site-specific drug delivery from the pH-responsive nanogels.

65.1.1 pH Sensitivity of Nanogels

The pH sensitivity of nanogel is usually attributed to the functional groups of sidechains. For example, the polymer networks containing acidic groups (–COOH, $–SO_3H$), such as poly(acrylic acid) and poly(aspartic acid) (PAsp), are deprotonated and swell at neutral and basic pH. On the other hand, nanogels having basic groups ($–NH_2$), such as poly($_L$-lysine) (PLys), swell at acidic pH. In an environment where nanogel is ionized, the density of charged groups increases by a generation of mobile counterions inside of gels, and enhances swelling of gels due to electrostatic repulsion. In fact, the deionization of acidic or basic groups decreases both the charge density and the content of mobile counterions within nanogels, and the gel phase becomes compact, less hydrophilic, and enters a collapsed phase. Interestingly, this phase transition is highly nonlinear and occurs in narrow pH ranges near pK_a or pK_b of ionizable groups. Therefore, transition conditions could be modified by changing the chemical nature [9] or the structure of nanogels [10, 11]. Figure 65.1 shows the change in size, surface charge, or chemical nature induced by a pH change. As pH increases or decreases, the size of nanogels may be changed as a result of the collapsed networks, or the density of cross-links may be reduced by

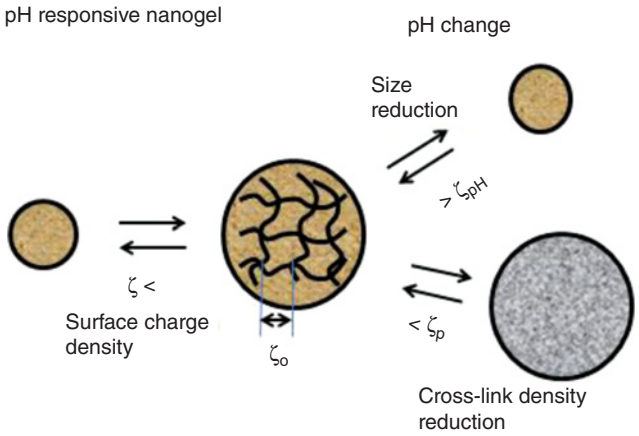

FIGURE 65.1 Dynamic change of nanogels in response to stimuli.

the chemical degradation or ζ-potential of surface decreases by reduction.

The preparation methods of nanogels can be divided into four groups:

1. The physical cross-linking or self-assembly of polymers [12]. The principles of the physically noncovalent cross-linking includes the ionic interaction, the polyelectrolyte complexation (coacervation), and the self-assembly of hydrophobically modified polymers.
2. The chemical cross-linking by the addition or radical polymerization of monomers in a homogeneous phase or in a micro- or nanoscale heterogeneous environment [13, 14].
3. The cross-linking of preformed polymers as well-defined building blocks.
4. The template-assisted nanofabrication of nanogel particle, including photolithography, micromolding, and microfluidics [15].

65.1.2 Modified Poly(amino acid)s

Poly(amino acid)s, polymerized from natural or synthetic amino acids, may be used in biomedical applications because of their biocompatibility, biodegradability, nontoxicity, and in vivo stability [16]. The diversity of amino acid monomers may influence the various properties of hydrophobicity, polarity, and stimuli responsive property. For these reasons, poly(amino acid)s are regarded as good materials for stimulus-responsive drug carriers. The pH-responsive core–shell poly(amino acid) nanogels were prepared from copolymers having reactive poly(succinimide) blocks that can be converted into poly(amino acid)s [17]. The preparation method of pH-responsive nanogels should be a high-throughput method that does not require the use of surfactants, emulsions, or expensive coupling agents. The chemically cross-linked nanogels can be synthesized from reactive amphiphilic diblock or graft copolymers as presented in Fig. 65.2.

FIGURE 65.2 Types of copolymers.

Amphiphilic copolymers form diverse nanostructures such as spherical and tubular micelles, vesicles, and lamellae through the spontaneous self-assembly in a selective solvent [18]. Additionally, the diverse morphology of self-aggregates that are prepared from reactive amphiphilic polymer can provide various nanogel architectures. Figure 65.3 illustrates nanogel architectures, including sphere, hairy shell, core–shell, and hollow shell. The favored morphologies of amphiphilic polymers depend on the hydrophilic/hydrophobic ratio, molecular geometry, concentration, temperature, solvent, and force balance such as the degree of stretching of core-forming blocks, intercorona chain interactions, and interfacial energy between the micelle core and the solvent. These polymeric nanostructures are thermodynamically and kinetically more stable than the surfactant systems. In particuar, the polymer vesicles of a layer have become a subject of special interest, because they can entrap hydrophilic molecules within their aqueous cavity [19, 20].

In this chapter, we address the various synthesis strategies of poly(amino acid) nanogels with respect to physicochemical cross-linking. Also, the structure and physical property analysis by small-angle neutron scattering (SANS),

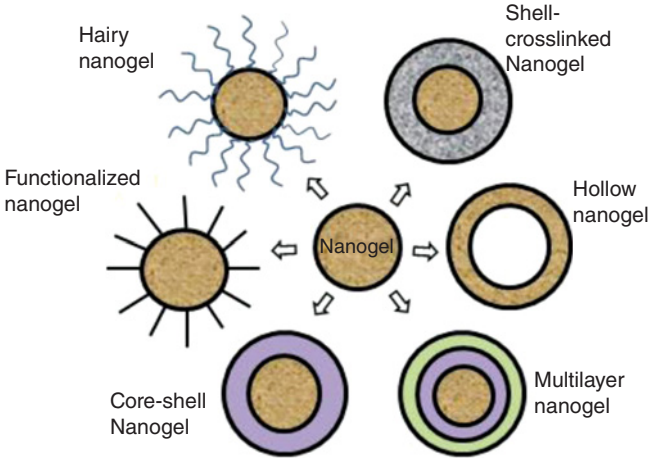

FIGURE 65.3 Diverse structure of nanogels.

pH-responsive behaviors, and their potentials as drug delivery carriers are comprehensively discussed.

65.2 PREPARATION OF POLY(AMINO ACID) NANOGELS

Poly(amino acid) nanogels can be prepared from physical or chemical cross-linking reactions of as-synthesized poly(amino acid)s or prepolymers for poly(amino acid)s.

The copolymers of poly(amino acid)s are typically synthesized from the ring-opening polymerization (ROP) of *N*-carboxyanhydride (NCA) of amino acids using nucleophiles and aprotic bases [i.e., aminopoly(ethylene glycol) (PEG-amine)] [21]. The polymerization of NCAs can provids high molecular weight and relatively narrow polydispersity of poly(amino acid)s [22].

On the other hand, a reactive poly(succinimide) (PSI) can be employed as reactive polymer blocks to be converted to poly(amino acid)s. The acid-catalyzed polycondensation of L-aspartic acid produces the PSI [23]. Amphiphilic graft poly(amino acid)s have been prepared from ring-opening reaction of the PSI backbone with hydrophobic nucleophiles such as alkyl amines [24]. Also, PSI can be converted into diverse poly(amino acid)s including poly(L-aspartic acid) (PAsp), and poly(L-asparagine) (PAsn), poly(aspartamide), by hydrolysis or an aminolysis reaction in NaOH, NH_4OH, and ethanolamine solution.

Because of the diversity of amino acids, the ionizable groups and reactive side groups of poly(amino acid)s can be modulated by the selection of monomers, thereby poly(amino acid)s can be designed to be appropriate for the physically or chemical cross-linking reaction.

65.2.1 Physical Association

The physically associated nanogels have been widely studied. In general, multivalent ions, charged protein, surfactants, DNA, and RNA have been employed as ionic cross-linkers to form an ionic linkage with oppositely charged polyelectrolyte polymers. Such a polyionic interaction generates a stable self-assembled nanostructure, and the charged biomolecules (proteins and nucleotides) are participated in the physical aggregation; in this way, biomolecules can be stabilized within nanogels for drug delivery applications.

Negatively charged nucleotides, DNA and RNA, can induce a polyionic complexation with cationic poly(amino acid)s and produce nanogels. One team of investigators prepared cationic *N*-(2-aminoethyl)-2-aminoethyl group–grafted PEG-*b*-poly(aspartic acid) backbone, denoted as PEG-*b*-P[Asp(DET)] [25]. The nanogels were synthesized from aminolysis reaction of PEG-*b*-poly(*β*-bezyl-L-asparate) (PEG-*b*-PBLA) with diethylenetriamine [25]. Here, the amine/phosphate (N/P) ratio and pH of the aqueous solution play a crucial role in the nanogel preparation process. Protonation states differ depending on the chemical structure of polycation and pH. In fact, the complexation of PEG-P[Asp(DET)] with DNA was more efficient at pH 5 than at pH 7.4, and also at the higher N/P ratio than at the lower N/P ratio. The prepared poly(amino acid)-based nanogels show higher biocompatibility than do poly(ethyleneimine)-based nanocomplexes with DNA.

Similarly, ribozyme-entrapped nanogels (∼100 nm) can be prepared from the complexation of cationic PEG-*b*-PLys with negatively charged ribozyme molecules, and PLys of having high positive charges contributes to form small nanogels [26].

Physically aggregated nanogels can also be utilized as templates for further chemical cross-linking to improve the stability of nanogels. Another team [27] prepared pyridyldithiopropionyl (PDP) group conjugated PEG-*b*-PLys by reaction of amine groups on PLys with the *N*-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP). The removal of mercaptopyridine groups from PDP groups generated free thiol groups on PEG-*b*-PLys by oxidation reaction. After the physical complexation of the polymer with DNA, free thiol groups could form disulfide cross-links by the self-oxidation reaction during dialysis [27].

65.2.2 Chemical Cross-Linking of Poly(amino acid)s

Physical cross-linking by ionic association or complexation could successfully prepare nanogels, and chemical cross-linking is believed to be more stable than the physically associated nanogels. The chemical cross-linking uses the formation of a covalent bond in the process of chemically joining two or more molecules with specific functional groups (primary amines, sulfhydryls, etc.). In a direct polymerization, the size of macrogels can also be reduced by increase of the cross-linker concentration or initiator concentration [28]. For water-soluble polymers grafted with vinyl groups, the size of nanogels can be controlled using nano- or microemulsion in the presence of surfactants or PEGylated macromers, namely, the oil-in-water emulsion method for poly(ethylene glycol)-*cl*-polyethyleneimine nanogels [29] or the free-radical precipitation polymerization of poly(*N*-isopropylacrylamide) (pNIPAm) [30].

Since the nanogels of UV-induced cross-linked polymer were first developed [31], various cross-linking methods were introduced, including radiation-induced cross-linking [32], reaction with bifunctional cross-linker [33], and click cross-linking [34]. For example, the shell cross-link of polystyrene-*b*-poly(acrylic acid) was accomplished by cross-linking of carboxylic groups with diamine via the carbodiimide coupling method [33]. Since amine has strong reactivity with carboxylic acids, activated esters [35], and isocyanates [36], the amidation with carboxylic acid forms a stable and pH-responsive cross-linked network [37].

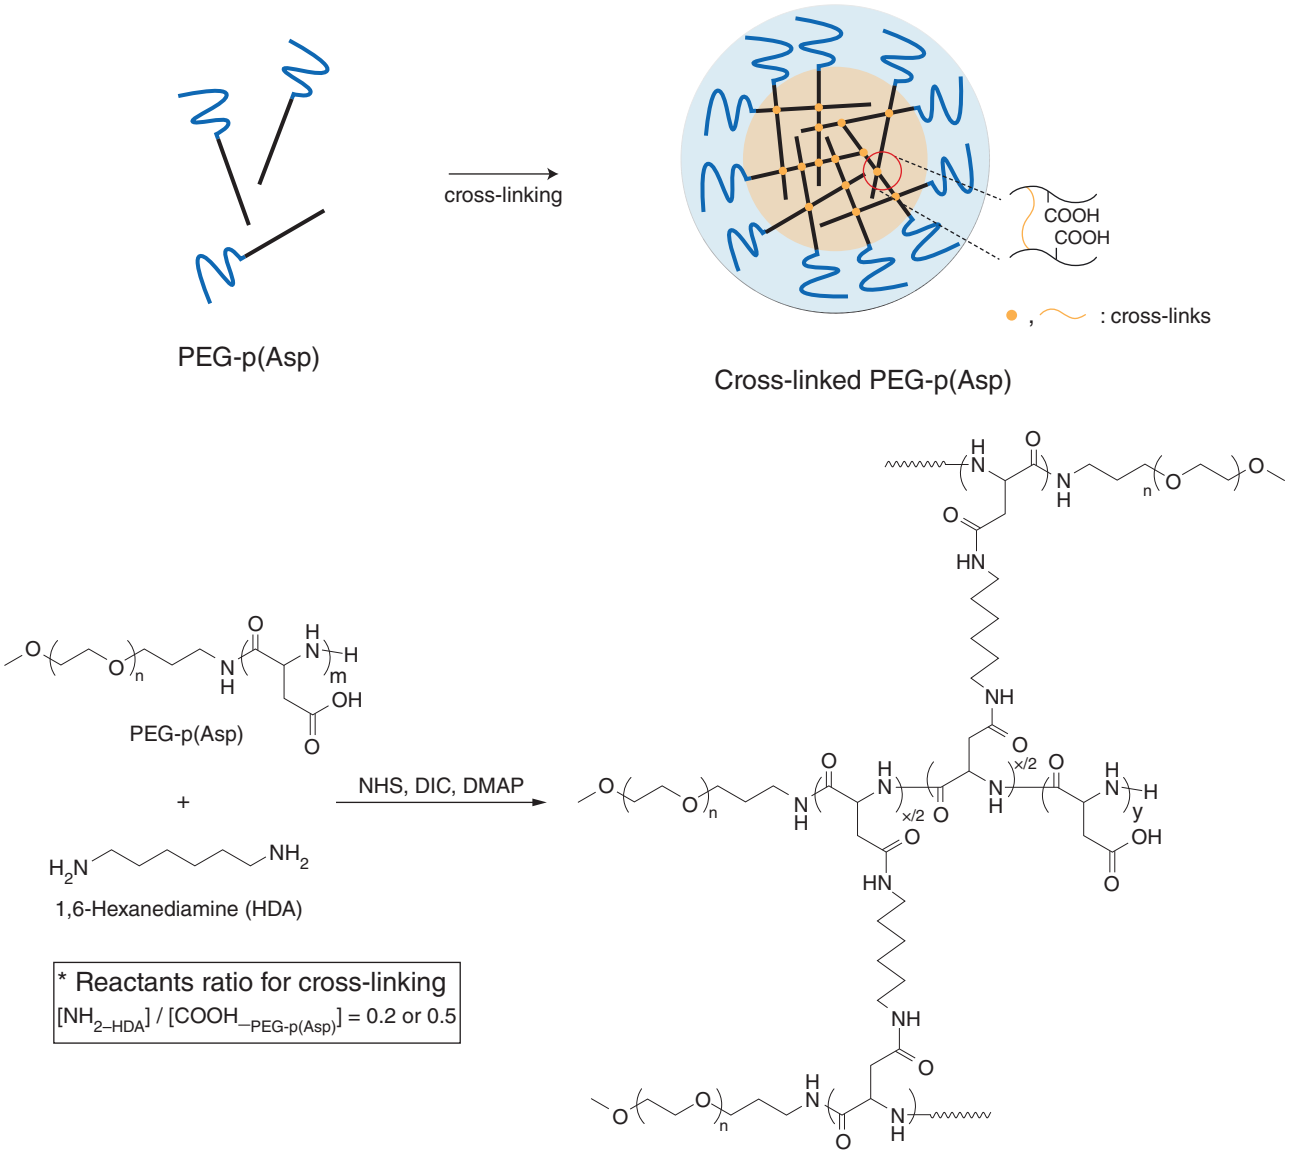

FIGURE 65.4 Preparation of PEG-PAsp nanogels by carbodiimide coupling reaction [38].

65.2.2.1 Coupling Reactions. The preparation of chemically cross-linked poly(amino acid)s have been attempted by cross-linking of reactive groups of poly(amino acid)s, carboxylates or amines, with the use of coupling agents.

Figure 65.4 illustrates the cross-linking method of the PEG-*b*-PAsp which is prepared from hydrolysis of PEG-*b*-PBLA [38]. The carboxylates of PAsp groups were cross-linked with hexamethylenediamines (HDA) by the coupling reaction of carbodiimide in DMSO. When the carboxyl groups of PAsp were reacted with 50% of HDA, PEG-PAsp nanogels can be successfully prepared with a high yield of 80%. The NMR and GPC analyses indicated that a total of 11 block copolymers were cross-linked in each nanogel, which has 253 of Asp units. Similarly, the PAsp inner shells of PEG-*b*-PAsp-*b*-poly(L-phenylalanine) (PEG-*b*-PAsp-*b*-PPhe) self-aggregates were also cross-linked with diamine cross-linkers by carbodiimide chemistry [39].

Despite this success, the cross-link of poly(amino acid)s with coupling agents is not desirable because of the high cost of coupling agents. In addition, the synthesis of PEG-*b*-poly(amino acid)s from NCA monomers requires the application of toxic phosgene-based chemistry.

65.2.2.2 Cross-Linkable Block Copolymer. Another approach for cross-linked nanogels employs a cross-linkable amphiphilic block copolymer of PEG-PSI. The hydrophobic succinimide in PSI backbone can react with nucleophiles such as primary and secondary amines; therefore, PSI is directly cross-linked by diamines. Also, the PSI can turn into

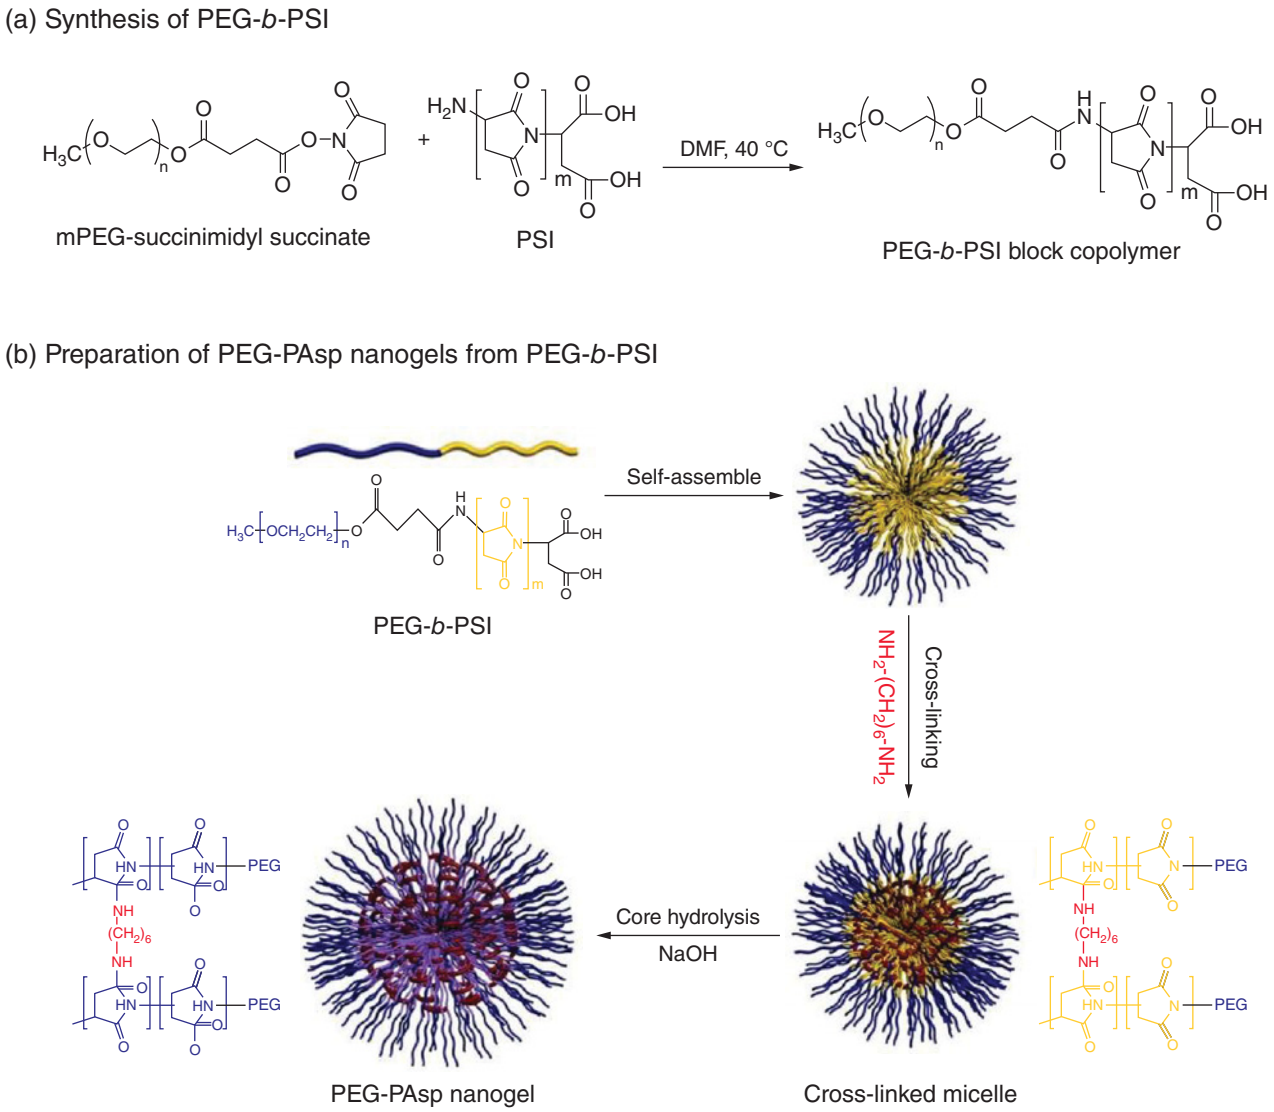

FIGURE 65.5 (a) Synthetic scheme of PEG-*b*-PSI block copolymer; (b) preparation method of PEG-PAsp nanogels from the PEG-*b*-PSI [17, 40].

diverse poly(amino acid)s, including poly(L-aspartic acid) (PAsp), and poly(L-asparagine) (PAsn), poly(aspartamide), by hydrolysis or an aminolysis reaction in NaOH, NH_4OH, and ethanolamine solution.

Figure 65.5 shows the amphiphilic cross-linkable PEG-*b*-PSI and core-hydrolyzed nanogel [17, 40]. In Fig. 65.5a, mPEG–succinimidyl succinate reacts with PSI in *N,N*-dimethyl formamide by the amidation reaction of the ester linkage in mPEG-succinimidyl succinate with a primary amine of PSI. Since PEG-*b*-PSI consists of hydrophilic PEG and hydrophobic PSI, the diblock copolymer has a surface-active property, and the PEG-*b*-PSI forms micelle structures stabilized by the PEG hairy shell with the hydrophobic PSI core in an aqueous solution. The diameter of the PEG-*b*-PSI self-aggregates is generally smaller than 100 nm.

The cross-linked nanostructure of PEG-PSI can be fabricated by adding diamine, hexamethylenediamine, to the micellar solution of PEG-*b*-PSI. As diamine diffuses into the PSI core, amine groups react with succinimide units, and induce cross-linked networks within the PSI core region of self-aggregates.

The degree of cross-link of nanogels, namely, the mole percentage of PSI groups that interconnected by diamine, can be controlled through adjustment of the feed mole of diamine. The degree of cross-links can be analyzed by monitoring the increment of nitrogen atoms after the cross-linking reaction by element analysis, because nitrogen atoms increase with cross-links. After the cross-linking with 5%, 50%, and 100% (1.1-fold excess of amine was added for 100% cross-linking) of diamines to succinimide units, the calculated degrees of

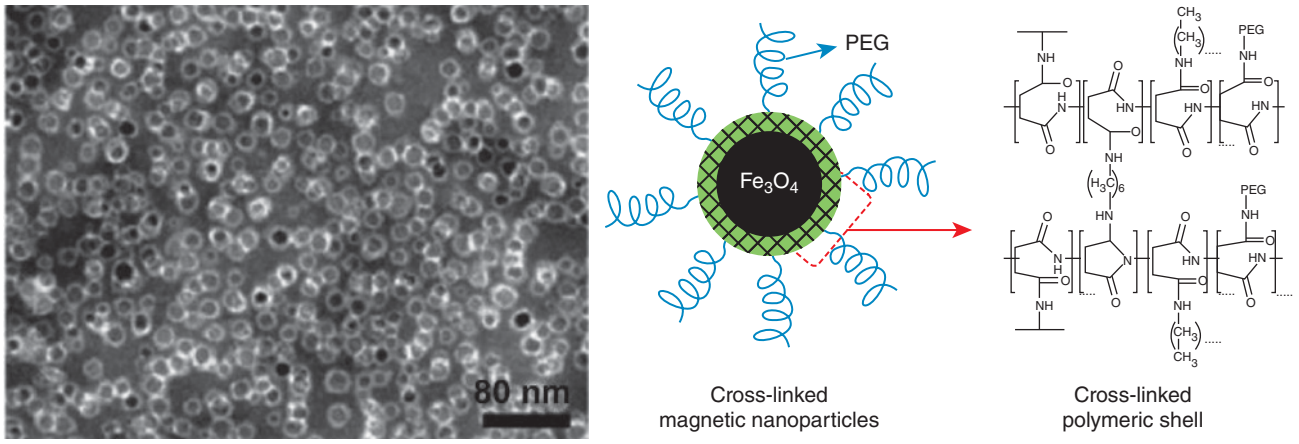

FIGURE 65.6 Nanogel-coated magnetic nanoparticles prepared from PSI-*g*-PEG [43].

cross-links were found to be 2.7%, 26%, and 66%, respectively. Hereafter, these will be denoted as Nanogels 5, 50, and 100, respectively, for the targeted degrees of cross-links.

The fully hydrophilic nanogel can be obtained when the hydrophobic PSI core is converted into hydrophilic poly(amino acid)s [17]. After cross-linking, the residual SI units are converted into the hydrophilic and negatively charged backbone of aspartic acid (Asp) by a hydrolysis reaction in NaOH solution [41]. Therefore, the cross-linked PAsp nanogels with hairy PEG were obtained by cross-linking the core of PEG-*b*-PSI aggregates. If the internal structures of diblock polymer aggregates are not chemically cross-linked, the copolymer cannot maintain the particle structure because of the high water solubility of both PEG and PAsp. In this microscopic analysis, however, the PEG-PAsp nanogels maintained their spherical structure after the hydrolysis of the partially cross-linked hydrophobic core.

65.2.2.3 Cross-Linkable Graft Copolymer. Along with block copolymer systems, graft copolymer systems have also been studied for nanogel preparations. Among various polymer systems, PSI has been widely studied for the graft polymers of poly(amino acid)s. As PSI can react with amine-containing molecules, the desired molecules with amine groups can be simply grafted by an aminolysis reaction. Therefore, any multifunctional polymer system can be readily prepared by multiple grafts in a single PSI backbone. As sidechains, any of long polymers, small molecules (alkyls, lipids, cholesterol), and nanoparticles has been used to prepare the graft copolymers [24]. Instead of covalent bonding, the noncovalent interactions such as ionic interactions, π–π interactions, and hydrogen bonding can also be introduced to PSI as graft groups [42].

The properties of graft copolymers can also be controlled by the chemical composition of backbone and grafts. Thus, the chemical nature can be defined with the graft density, such as the degree of substitution (DS) by the number of sidechains in a polymer backbone and the length of sidechain as the degree of polymerization (DP) of a branch.

To take advantage of the graft polymer system, one team of investigators developed cross-linkable PSI-*g*-PEG as shown in Fig. 65.6 [43, 44]. The amphiphilic copolymer of PSI-*g*-PEG-C_{12} was synthesized from subsequent aminolysis reaction of PSI with PEG-amine and dodecyl amine. The hydrophobic alkyl group was employed to coat hydrophobic iron oxide nanoparticles by the hydrophobic interaction in aqueous solution, and the nanoparticles coated with PSI inner shell with hairy PEG outer shell were obtained. The PSI inner shell was successfully cross-linked by adding hexamethylenediamine. To determine whether HMD reacts with two succinimide units without generation of dangling cross-linkers on PSI, X-ray photoelectron spectroscopy (XPS) analysis was carried out. The generation of amide peak at 399.4 eV was observed as a result of the successful cross-linking, while the free amine (NH_2) peak at 397.1 eV did not appear in the XPS spectrum. Thus, the reaction of only one side of diamine with PSI is negligible in the PSI-diamine cross-links.

65.2.3 Morphology of Nanogels Prepared from Amphiphilic Polymers

The advantage of PSI-based prepolymer of poly(amino acid)s is that the amphiphilic property of the copolymer is easily adjusted; therefore, the diverse morphology of nanogels can be generated in a derivative family. Amphiphilic polymers of the same building blocks could form not only spherical assemblies but also cylindrical and tubular aggregates, vesicles, disks, or lamellar structures by self-assembly in a selective solvent, and also the favored morphology can be obtained with the variation of hydrophilic/hydrophobic ratio, chemical nature, and external design factors such as concentration, temperature, and solvent [18].

The amphiphilc property, especially hydrophilic/hydrophobic ratio, of PEG-*b*-PSI can be modulated by

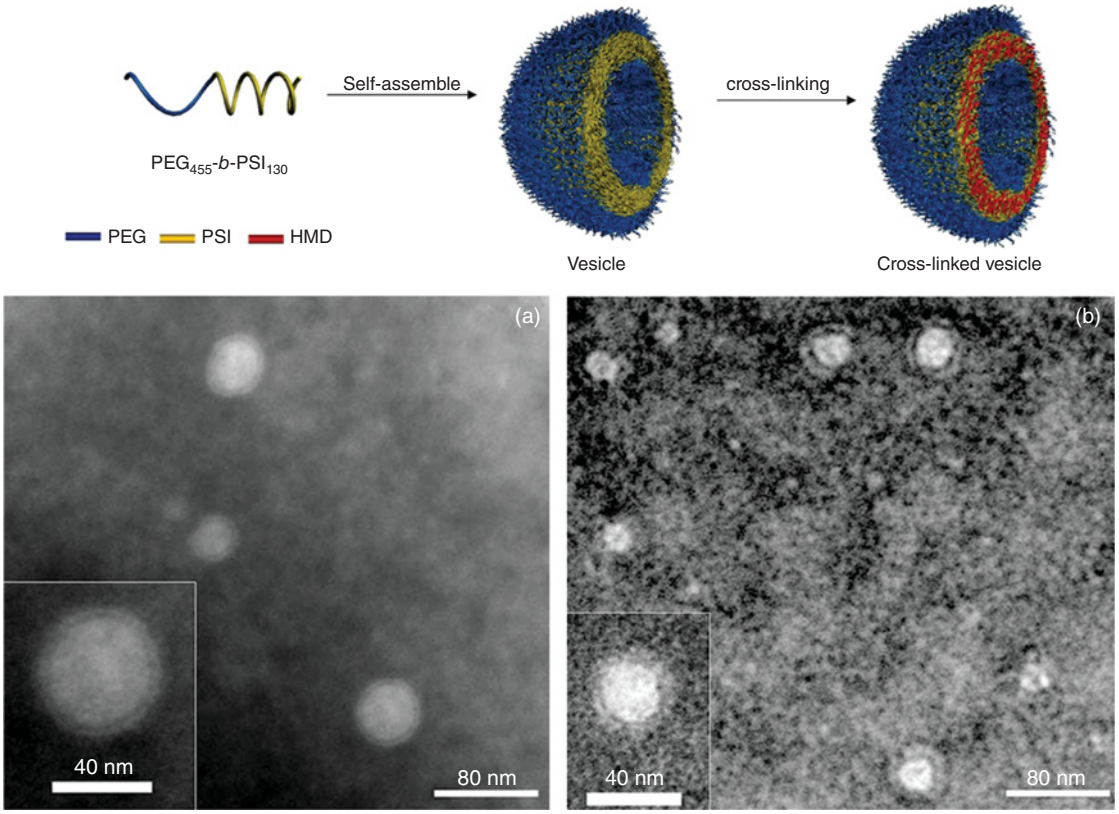

FIGURE 65.7 TEM images of the (a) PEG20k-PSI vesicle and (b) cross-linked vesicle [40].

adjusting the block length of PEG and PSI. When the molecular weight for PEG of PEG-*b*-PSI is reduced from 30 to 20 kDa, the morphology of self-aggregates changes from spherical micelles to vesicles whose diameter is 74.9 ± 18.3 nm in Fig. 65.7 [17]. Generally, the self-assembled morphology of diblock copolymers transforms from sphere, cylinder, to vesicle as increasing the weight fraction of hydrophobic moieties or decreasing the molecular weight of PEG blocks [18]. As were the spherical nanogels of PEG-*b*-PSI, the vesicle nanogels can also be fabricated by adding hexamethylenediamine to the PEG-PSI vesicle solution [17]. The 43.3% of cross-linking can be achieved at 1:2 molar ratio of amine groups and succinimide. After cross-linking, the hollow structure of vesicular nanogels remained undisturbed.

The hydrophilic/hydrophobic ratio of graft polymers can be controlled by changing the degree of substitution (DS) and degree of polymerization (DP) of sidechains. In the case of PSI-*g*-PEG, the polymers became hydrophobic with decrease in the molecular weight of PEG grafts (DP) and the number of PEG branches (DS) on PSI backbone. Further, the additional grafts of hydrophobic alkyl chains can modulate the hydrophilic/hydrophobic ratio [43, 44]. The PSI-*g*-PEG:C_{12} showed that structure changes from sphere to cylinder with increases in the grafted alkyl chains.

65.3 STRUCTURE AND CHARACTERISTICS OF NANOGEL

65.3.1 Shape and Size

Nanogels are swellable in a good solvent, and their shape architectures will vary with monomers and polymer solubility, reactivity of cross-linkers, and reaction temperature [45]. Nanogels are generally prepared in a specific size, having size distribution (polydispersity) [46, 47] and with the architectures of core–shell [48], hollow [49], or nonspherical, di- or trimeric structures as shown in Fig. 65.3 [50].

65.3.1.1 Hairy Shell. The "hairy nano-/microgels," as a cross-linked core surrounded by covalently grafted polymer chains (hairs), are synthesized by radical cross-linking polymerization [51, 52]. On the other hand, hydrophobic cores of partially cross-linked PEG-*b*-PSI micelles can be chemically converted into hydrophilic PAsp and to form PEG–PAsp nanogels (Fig. 65.5). So far, the direct chemical conversion methods have rarely been reported [53]. The nanogels consisting of a hydrophilic anionic PAsp core exhibit not only the high water uptake but also pH-responsive swelling and drug release behavior. In a macromonomer approach, PEGylated microgels in heterogeneous conditions in the presence of

stabilizing macromonomers also can provide the hairy structure [54, 55].

65.3.1.2 Sphere, Core–Shell, Hollow Gels. Hollow nanogels, which are also called *nanocapsules*, can encapsulate payloads, such as drugs, dyes, inks, and DNA [56]. Spherical nanogels are designed to avoid the formation of long-range networks in the prepolymer cross-linking as well as the formation of noncovalent microgel [46, 57, 58]. Cross-linking reactions can be carried out on preformed colloidal self-assemblies of synthetic or natural polymers, and "free radical cross-linking copolymerization" of monovinylic monomers with cross-linkers [59]. Most core–shell hydrogel particles are synthesized by two-step radical polymerization. First, the core is prepared by (co)polymerization in the presence of a bifunctional monomer as a cross-linker. Then, a second monomer is added for the shell synthesis (seed and growth process), but there is no chemical linking between the core and the shell, only a low interpenetration of chains at the interface exists as in hollow nanogels.

Alternatively, the diblock or graft copolymer with hydrophilic and hydrophobic groups can be dissolved in water to form a self-assembly of vesicle type, and cross-linkers can be placed into the vesicle layer for cross-linking. This structure is different from the shell cross-link hollow particle, because both sides of the shell have hydrophilic corona and the hydrophobic chains of shell may be bilayered or interdigitized as they become a thin layer.

65.3.2 Internal Structure

Figure 65.8 illustrates a model nanogel having the hairy shell or core–shell structure. The volume ratios between the core and the shell (giving access to the thickness of the shell) and the cross-linking density of the shell, were studied by dynamic light scattering (DLS) and small angle neutron scattering (SANS) [60].

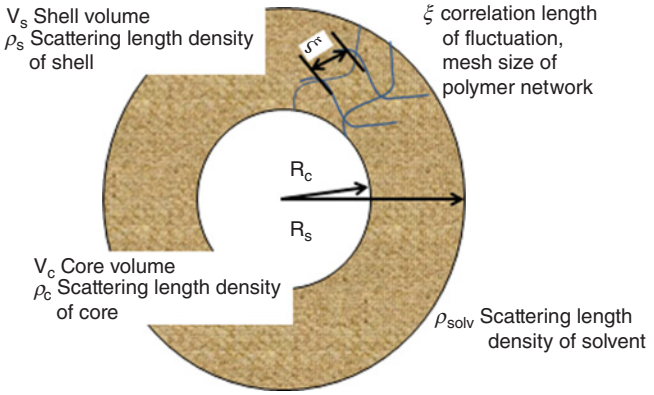

FIGURE 65.8 Core–shell nanogel model.

65.3.2.1 SANS Model for Nanogels. The small-angle neutron scattering (SANS) technique can probe macromolecular and microstructures of micelles, polymers, protein, and many other materials. The SANS technique is also utilized to analyze the structure and physical properties of nanogels. A model equation for core–shell nanogels, which have PEG shells and cross-linked PAsp cores, has been suggested [17]. The model function is designed to include the two independent major contributions of scattering intensity, with both intensities derived from the isolated core–shell particles and the fluctuation of the cross-linked network shown in Fig. 65.8. The total scattering intensity $I(q)$ measured for the nanogel particle solution can be modeled as

$$I(q) = I_{\text{particle}}(q) + I_{\text{fluct}}(q) + bkg \tag{65.1}$$

where $I_{\text{particle}}(q)$ is the scattered intensity that arises from a homogeneous core–shell structure, $I_{\text{fluct}}(q)$ are the dynamic fluctuations of networks in nanogels $[I_{\text{fluct}}(q)]$, and bkg denotes the residual incoherent scattering [61].

In a dilute particle system, the interparticle interference becomes negligible, and the scattering intensity of particles can be expressed as $I_{\text{particle}}(q) = n_{\text{p}}P(q)$, where n_{p} is the number density of particles and $P(q)$ is the particle form factor. Here, the particle form factor of the polydisperse core–shell model is employed, and the spherical core–shell model can be expressed as

$$\begin{aligned} P_{\text{core–shell}}(q) = {} & [3V_{\text{c}}(\rho_{\text{c}} - \rho_{\text{s}})j_1(qR_{\text{c}})/qR_{\text{c}} \\ & + 3V_{\text{s}}(\rho_{\text{s}} - \rho_{\text{solv}})j_1(qR_{\text{s}})/qR_{\text{s}}]^2 \\ & j_1(x) = (\sin x - x\cos x)/x^2 \end{aligned} \tag{65.2}$$

where V_{c} and V_{s} are the volume of the core and shell, respectively; R_{c} and R_{s} are the radius of the core and shell, respectively; and ρ_{c}, ρ_{s}, and ρ_{solv} are the scattering length density (SLD) values of the core, shell, and solvent, respectively. In modeling the distribution of the core size, the particle form factor is normalized with the width parameter of the Schulz distribution [62].

Unlike the solid core–shell structure, nanogel is swellable in water, and the swelling of core and shell of nanogel leads to change in the ρ_{c} and ρ_{s} values depending on the swelling degree. Consequently, the SLD values of nanogel core and shell can be expressed as

$$\rho_{\text{c}} = \varphi_{\text{CL-PAsp}} \times \rho_{\text{CL-PAsp}} + \varphi_{\text{D2O}} \times \rho_{\text{D2O}} \qquad (0 \le r \le R_{\text{c}}) \tag{65.3}$$

$$\rho_{\text{s}} = \varphi_{\text{PEG}} \times \rho_{\text{PEG}} + \varphi_{\text{D2O}} \times \rho_{\text{D2O}} \qquad (R_{\text{c}} \le r \le R_{\text{s}}) \tag{65.4}$$

$\varphi_{\text{CL-PAsp}}$, φ_{PEG} and φ_{D2O} are the volume fractions of cross-linked PAsp, PEG, and D_2O, respectively [17].

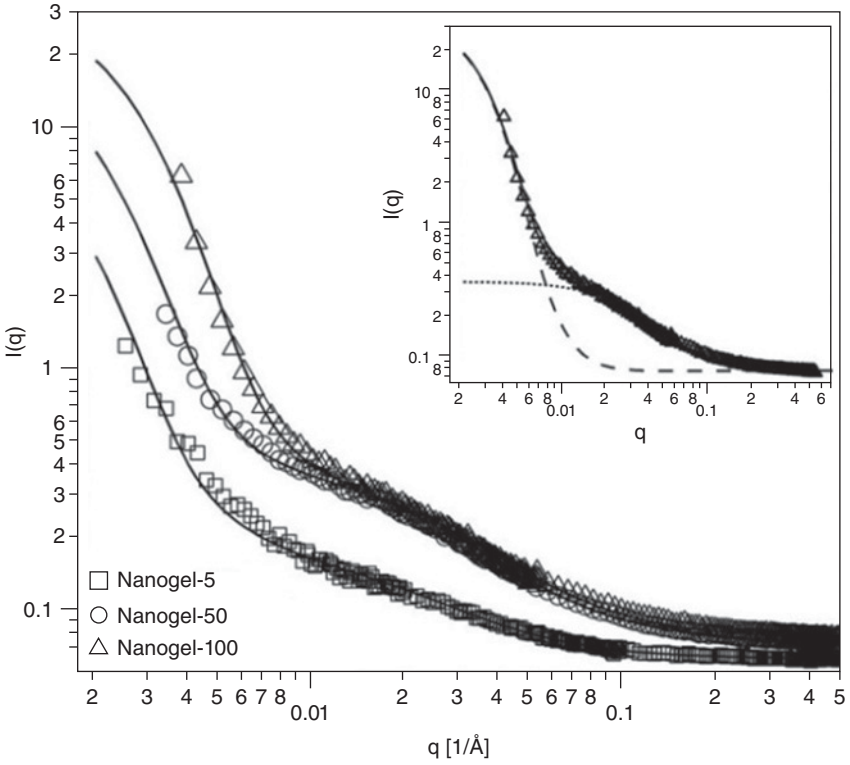

FIGURE 65.9 SANS scattering profile of PEG-PAsp nanogels. The solid lines represent the fitting results. The inset shows the contribution of $I_{\text{particle}}(q)$ (dashed line) and $I_{\text{fluct}}(q)$ (dotted line) [17].

Along with the change in SLD values in core and shell by swelling of the network, the scattering arises from the dynamical fluctuation of the polymer network in solvent is also important in the SANS analysis of nanogels. For this reason, the $I_{\text{fluct}}(q)$ in Eq. (65.1) is essential to describe the scattering from the polymer network [63]. The Lorentzian function that describes the ensemble average of correlations in the polymer network is used as the $I_{\text{fluct}}(q)$ term by [64]

$$I_{\text{fluct}}(q) = I_{\text{fluct}}(0)/(1 + \xi^2 q^2) \tag{65.5}$$

where $I_{\text{fluct}}(0)$ is the intensity at $q = 0$ and ξ is the correlation length of the fluctuation, which is related to the mesh size of networks [17, 65].

65.3.2.2 SANS Analyses of Nanogels. The SANS measurements and model-fitting analyses allow the better understanding of the structure and swelling behavior of nanogels. Figure 65.9 shows the SANS scattering profiles of PEG-PAsp nanogels in D_2O, and the inset shows the two distinct scattering intensities of $I_{\text{particle}}(q)$ and $I_{\text{fluct}}(q)$ [17]. The scattering from the isolated particles, $I_{\text{particle}}(q)$, is dominant in the low-q region (dashed line), whereas the scattering that arises from the fluctuation of the network, $I_{\text{fluct}}(q)$, is dominant in the high-q region (dotted line). Also, the SANS analysis showed that the scattering intensity of the PEG-PAsp nanogels decreases as approximately q^{-4} in the low-q region by following the classical Porod's law, and thus, this behavior is attributed to the scattering from a particle surface.

The model-fitting results for Nanogels 5, 50, and 100 provide various types of information on nanogel structures in aqueous solvent. Table 65.1 shows that the average particle size decreases as the degree of cross-link increases. The

TABLE 65.1 Parameters Obtained from Fitting Analysis of SANS Data

Parameter	Nanogel 5	Nanogel 50	Nanogel 100
R_{SANS} (nm) [a]	65.9	55.0	47.7
R_{DLS} (nm) [b]	67.6	57.4	44.5
R_c (nm)	57.1	45.7	37.1
δ_{shell} (nm) [c]	8.8	9.3	10.6
ρ_{core} ($\times 10^{10}$ cm^{-2})	6.22	5.94	5.38
ρ_{shell} ($\times 10^{10}$ cm^{-2})	5.79	5.58	5.25
ξ (Å)	43	40.6	37.2
$\varphi_{\text{CL-PAsp}}$	0.032	0.096	0.210
φ_{PEG}	0.098	0.135	0.193
Q_v^{core} [d]	31.25	10.42	4.76

[c] Thickness of the PEG shell.
[d] Q_v^{core}=(swollen volume of core)/(polymer volume in core).
Source: Ref. 17.

higher degree of cross-linking provides the smaller mesh size of network, and the lower ability of nanogels to swell. Similarly, the core size of PEG-PAsp nanogels decreases with the degree of cross-link. When the degree of cross-link increases from 2.7% to 66%, the core size decreases from 57.1 to 37.1 nm. Therefore, this indicates that the cross-linking would particularly affect the swelling of the core.

On the other hand, the thickness of hairy PEG shell is independent of the cross-link density. In fact, the thickness of PEG shells is in the range of 8.8–10.6 nm depending on the molecular weight of PEG.

The mesh size of a polymer network in nanogel, which is related to the correlation length (ξ) of the Lorenzian function, also can be obtained from SANS analysis. One team of researchers proved that ξ of a poly(*N*-isopropylacrylamide) (pNIPAm) microgel decreases as the cross-link density of microgel increases [64]. Similarly, the ξ values of the PEG–PAsp nanogels decrease as the degrees of cross-link increase (Table 65.1) [17]. Thus, it is believed that the mesh size of the hydrogel network decreases as the degree of cross-link increases.

65.3.3 Swelling of Nanogel

The smart or responsive nanogel particles retain their volume and morphology change in response to a stimuli such as pH, temperature, and ionic strength. The dimensions of nanogels depend on the solubility of both monomers and polymers [66]. The solvent properties change the interfacial energies and the mechanism of a particle formation.

The volume fractions of polymer and water can be calculated using Eqs. (65.3) and (65.4) with SANS analysis data [17]. Swelling of the polymer network reduces the volume or weight fraction of polymer in nanogels to extremely low levels, and increases those of water molecules. In general, less-cross-linked hydrogels may exhibit significantly higher water uptake than do the more highly cross-linked hydrogels. For Nanogels 5, 50, and 100, the volume fractions in core (φ_c) of PEG-PAsp nanogels increases from 0.032 to 0.210 when the degree of cross-linking increases from 2.7% to 66%. If the swelling ratio of the core ($Q_v{}^{core}$) is defined by the ratio of the swelled volume to the polymer volume of the core, this indicates that the less-cross-linked nanogel can imbibe water approximately 30 times greater than the polymer volume of the core. The swelling ratio of the core ($Q_v{}^{core}$) could be calculated from $Q_v{}^{core} = 1/\varphi_{CL\text{-}PAsp}$, and was assumed to be 31.25 when the degree of cross-link was 2.7% [17]. Compared to the hydrogels, the cross-linked nanogels prepared here are less swellable. In general, maximum swelling ratio values of bulk PAsp hydrogels, when cross-linked by various diamines, can be in range of 90–280 g g^{-1} depending on the cross-linking agents (measured in deionized water, with 5 mol% cross-linkers used) [67]. During the cross-linking process, the polymer concentration as well as the amount of cross-linking agent is important for determining the mesh size of network, which is related to the swelling property of hydrogels. The nanogel system prepared from cross-linked polymer micelles have the highly confined geometry during the cross-linking reaction and less local water pocket; therefore, the nanogel system may show a relatively low swelling ratio.

65.4 pH-RESPONSIVE NANOGELS

65.4.1 pH-Sensitive Property of Nanogels

Nanogels can be designed to swell or deswell in response to stimuli such as temperature, pH, redox, or multiple stimuli [68]. In particular, a small variation in pH can change the ionization degree of the polyelectrolyte chain, and thus, suffice to induce the swelling of nanogels [69]. Therefore, a change in external pH can alter the ionic interaction, hydrogen bonding, and hydrophobic interaction, resulting in a reversible microphase separation or self-organization phenomenon. Thus, the active drug release from a delivery system can be triggered by physiological pH environments. Such pH-triggered delivery systems can be achieved by (1) incorporation of a pH-responsive moiety to the polymer structure, (2) cross-linking with pH-labile cross-linkers, and (3) chemical conjugation of pH-liable linkage between polymers and drugs.

Also the pH-responsive nanogel with a pH-dependent charge conversion can be used as a possible anticancer drug carrier. The transition from a negatively charged to a positively charged form in slightly acidic environments enhances the cellular uptake of nanogels and the efficiency of drug release in killing cancer cells. Positively charged nanoparticles show a higher affinity for negatively charged cell membranes to be readily internalized by the cells. In contrast, negatively charged carriers have a high potential for protein resistance, exhibiting prolonged circulation in vivo [70].

The PEG-PAsp nanogels have shown pH-responsive swelling/shrinking behavior based on the ionization/deionization of the polyanionic PAsp. The hydrodynamic diameters of PEG-PAsp nanogels, which are prepared from the cross-linking of PEG-*b*-PSI, ranged from 80 to 130 nm at pH 7, while the diameters were significantly reduced to 75–90 nm at pH 2 (Fig. 65.10) [17]. Furthermore, the pH-responsive swelling/shrinking of nanogels can be observed by AFM. Nanogel showed a smaller size at pH 2 compared to that at pH 7 even after drying ((Fig. 65.10). Similarly, PEG-PAsp nanogels, prepared by the cross-linking of PEG-PAsp with coupling agents, showed the swelling (>40 nm) and shrinking (< 20 nm) behavior depending on the surrounding pH [38].

The pH-responsive degradable nanogels can be prepared by employing pH-degradable polymers or pH-labile

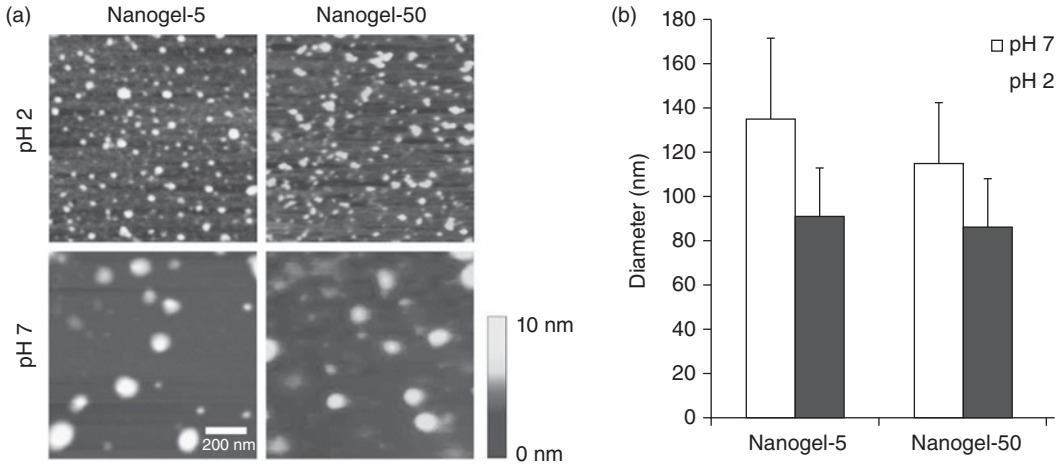

FIGURE 65.10 (a) AFM images of PEG-PAsp nanogels dried on mica at pH 2 and 7; (b) hydrodynamic diameters of the nanogel at pH 2 and 7 [17].

cross-linkers. One team developed ketal cross-linked nanogels of poly(amino acid)s by cross-linking PAsp groups of PEG-*b*-PAsp-*b*-PPhe aggeregates with ketal-containing diamines in the presence of carbodiimide coupling agents [39]. The ketal cross-link can be cleaved by hydrolysis, with the reaction rate increasing under acidic conditions. From hydrolysis kinetics, the hydrolysis half-life of ketal cross-links would be estimated as 0.7 h at pH 5.0 but 52 h at pH 7.4, which is 74-fold faster at the endosomal pH than at nomal plasma.

65.4.2 pH-Responsive Release of Payloads from Nanogels

The pH-responsive nanogels hold great promise as drug carriers for the delivery of hydrophilic drugs via pH-controlled drug release at target sites. The pH-sensitive hydrogel, whose volume can change by swelling and shrinking, can control the release of payload depending on the pH. Polycationic polymer-based nanogels show facilitated drug release at acidic pH, while polyanioic polymer nanogels, such as poly(methacrylic acid-*g*-poly(ethylene glycol)) P(MAA-*g*-EG), show slow release at acidic pH. The nanoparticles of P(MAA-*g*-EG) shrinks at an acidic condition due to the deionization below pK_a 4.5, and the nanoparticles can entrap drugs stably in the stomach when they are applied orally.

Insulin-drug-loaded PEG-PAsp nanogels can be produced by a simple postincubation of nanogels in an insulin solution, and a loading efficiency of ≤40% can be achieved. The pH-responsive release of insulin from nanogels was monitored in buffer solutions of pH 2 and 7.4; the release profiles are shown in Fig. 65.11. At pH 7.4, the insulin release was completed within 48 h, whereas 50% of the drugs were released at pH 2 within 48 h, due to the shrinkage of nanogels. The release behavior of drug carriers can be analyzed by employing a power-law equation, and the initial slope of log(released amount %)–log(t) plot, defined as the diffusional exponent (n), is closely related to the drug transport mechanism. The diffusional exponents for nanogels at pH 7.4 and 2 were found to be 0.78 and 0.66, respectively [17]. The results imply that the drug release from the PEG-PAsp nanogel is the anomalous transport system, which is a combination of Fickian diffusion and polymer relaxation by swelling. However, the n value is close to 1 at pH 7.4 because the drug release by swelling becomes dominant.

On the other hand, the utilization of ionic interactions between ionized drugs and nanogels is another approach for drug loading in nanogels [38]. An amino group of doxorubicin (DOX), an anticancer drug, forms an ionic bond with a carboxylic acid group of PEG-PAsp nanogel, and DOX can be entrapped in nanogels up to 27%. The DOX-loaded nanogels also displayed a pH-responsive shrinking at

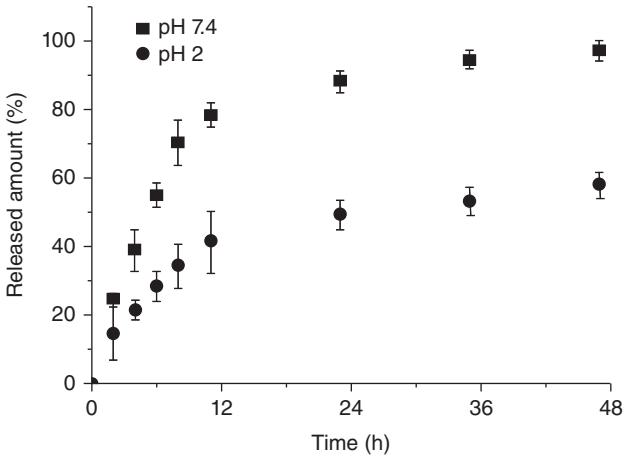

FIGURE 65.11 rh-insulin release profile from PEG-PAsp nanogel in pH 2 and pH 7.4 buffer solutions [17].

acidic pH due to free carboxylates. Furthermore, nanogels showed accelerated DOX release at pH 5 compared to that at pH 7.4. This is attributed to the ionic interaction between DOX and Asp, which becomes weaker as the carboxyl groups are deionized in acidic pH.

Also, the pH-labile bond of cross-links and drug conjugation provides pH-responsive drug release from nanogel networks. The DOX-loaded ketal cross-linked nanocarrier showed the minimized drug release at pH 7.4, whereas the release was accelerated at pH 5, due to the hydrolysis of cross-linkers and destabilization of the carrier [39]. On the other hand, the drug conjugation by an acid-labile hydrazone linker was also realized by the reaction of hydrazide group of PEG-*b*-poly(aspartate hydrazide) with the carbonyl group of DOX [71]. The hydrazone bond is typically stable at a neutral pH and degradable in acidic environments, and thus the conjugated drugs release at acidic pH. For this reason, the accelerated drug release was observed at pH 5.0 by 1.78–3.91-fold with respect to pH 7.4.

65.5 CONCLUSIONS

Nanogels have the distinctive properties of not only hydrogel-like behavior but also advantageous properties of nanoparticles. Nanogels can be prepared by ionic cross-linking or chemical cross-linking of functional groups on poly(amino acid)s. The physical and chemical properties of poly(amino acid)s can be readily modulated from the selection of amino acid monomers. Furthermore, the poly(amino acid) nanogels can have a stimulus-responsive property, especially pH sensitivity, which originates from ionizable polymer backbone, and stimulus-labile cross-link or drug conjugation. The stimulus-responsive destabilization or swelling/deswelling of nanogels induces the release of payloads from nanogels at a specific target site. Since poly(amino acid)s have great biocompatibility and biodegradability, the poly(amino acid)-based stimulus-responsive nanogels have great potential as smart drug delivery carriers. The development of new chemical technologies for multifunctional nanogel synthesis, such as diagnostics, sensing, imaging, and active targeting of tumors, is expected to open up new opportunities for their clinical applications.

STRATEGIES OF METAL NANOPARTICLES FOR NANOBIOLOGY

DAISUKE MATSUKUMA AND HIDENORI OTSUKA
Faculty of Science Division I, Department of Applied Chemistry, Tokyo University of Science

66.1 INTRODUCTION

With the development of science and technology, numerous scientific phenomena have been investigated in microscopic dimensions. The pertinent scientific issue has progressed from big to small. The quantum invention of analytical methods such as an electron microscope helped investigators examine phenomena in the regime of nanometer. Because of the electronic confinement of nanosized objects, their chemical and optical properties are significantly different from those of larger objects. As we look at lifeforms in smaller and smaller dimensions, we end up with biological objects, which are involved in fundamental life processes. The key molecules in biology such as DNA, enzymes, receptors, antigens, antibodies, and oxygen carriers can be included in the dimension of nanometers. Thus, all fundamental processes in biology are taking place in the dimension of 1–100 nm. Molecular self-organization around nanoparticles based on surface science can be used as probes for understanding fundamental life processes. The coupling of surface science and molecular biology has given birth to a new subject called *nanobiology*, which symbolizes a path-breaking evolution in the progress of biology. This new subject is able to reveal many fundamental secrets of lifeforms that are yet to be discovered.

The science of nanobiology has progressed significantly and can be grouped into several disciplines of life science such as cellular biology, genomics, proteomics, oncology, immunology, diagnosis, and targeted drug delivery. The idea of creating the hybrid systems of inorganic nanoparticles with biological moieties has helped solve several technical difficulties in medical and biosciences. Using nanomaterials, instead of conventional materials, in life science applications has increased efficiency while decreasing cost. Thus, the hybridization of nanotechnology and biotechnology has laid the ground for many novel methodologies, which are capable of solving several technical difficulties in bioanalysis. The ideas and innovations of nanoiology can be extended to the frontiers of biotechnology. In this chapter, we highlight the currently employed metal nanoparticles and their bioconjugation strategies for nanobiology.

66.2 METAL NANOPARTICLES

Unlike bulk materials, metal nanoparticles have characteristic physical, chemical, electronic, electrical, mechanical, magnetic, thermal, dielectric, optical, and biological properties [1–4]. Decreasing the dimension of nanoparticles has a pronounced effect on the physical properties that significantly differ from those of the bulk material. These physical properties are caused by their large surface atom, large surface energy, spatial confinement, and reduced imperfections. Obviously, metal nanoparticles are considered as building blocks of the next generation of optoelectronics, electronics, and various chemical and biochemical sensors [5–8]. In fact, a number of significant technologies such as catalysis, electronics, high-density information storage, photoluminescence devices, targeted drug delivery, and enzyme immobilization have been applied in various disciplines (Fig. 66.1);

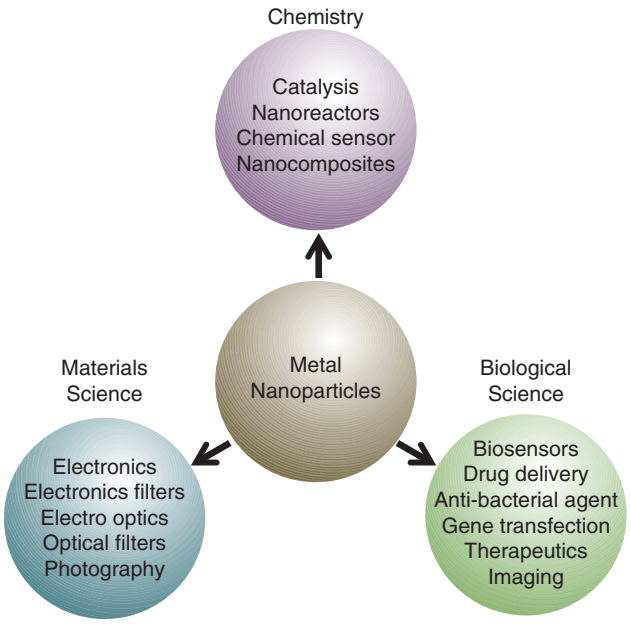

FIGURE 66.1 Significant applications of nanoparticles in various disciplines.

there have been many efforts to synthesize nanoparticles with different functionalities [9].

66.2.1 Basic Key Aspects of Metal Nanoparticles for Nanobiology

The key point for the fabrication of metal nanoparticles for biological applications is related to its mode of usage. It is applied orally or directly injected into the blood. For example, the drug delivery vehicle should be chemically stable at the locations to which it is transported. Thus, key aspects in biological applications are (1) lack of cytotoxicity, (2) absence of side effects, (3) chemical stability at transported locations, and (4) targeted drug delivery.

66.2.2 Noble Metal Nanoparticle

Generally, several types of noble nanomaterials such as nanoparticles, nanorods, metal nanoshells, and nanocages, made from gold and silver, are used for biological applications. For example, nanoshells constitute a novel class of optically tunable nanoparticles that consist of a dielectric core surrounded by a thin gold shell [10,11]. Antibodies can be immobilized to the gold surface of nanoshells. The gold surfaces of nanoshells are considered to be biocompatible, and polymers such as poly(ethylene glycol) (PEG) may be attached to nanoshell surfaces to further enhance biocompatibility and improve circulation in the bloodstream [12]. Silver [13] and gold [14] nanoparticles are used as intracellular surface-enhanced Raman scattering (SERS) probes. The advantages of noble metal nanoparticles are listed as (1) ideal immunolabels for transmission electron microscopy, (2) efficient contrast agents for optical microscopy, (3) powerful SERS probes, (4) inert to physiological conditions, (5) effective biocompatibility, and (6) ideal vehicles for immobilization of biomolecules.

Since 2005, biological delivery applications utilizing gold nanoparticles as inert, nontoxic, and biocompatible vehicles have been extensively studied and reviewed [15,16]. Modification with biomolecules such as oligonucleotide, peptide/protein, carbohydrate, and lipid has provided not only dispersive stabilization for nanoparticles under physiological conditions but also efficient transport of biomacromolecules with minimal cytotoxicity. In fact, gold nanoparticles with monolayers generated by biomolecules can address various delivery issues such as endosomal escape and specific targeting without conjugation of additional moieties. For example, endosomal trapping can be avoided by using a cell-penetrating peptide-based coating on the nanoparticle surface [17].

In addition, a critical requirement in molecular cell biology is the local mapping of specific biomolecules in cells and tissues. Immunofluorescent labeling is the standard approach, but fluorescence-based imaging is limited in spatial resolution by the wavelength of light. Hence, the application of transmission electron microscopy (TEM) in conjunction with immunolabeling has proved to be advantageous for high-resolution structural studies [18]. The prevalent strategy for immunolocalization via TEM is to employ antibodies conjugated with gold nanoparticles of various dimensions [19].

66.2.3 Quantum Dots

Quantum dots are small (<10-nm) inorganic nanocrystals that possess unique luminescent properties. Their fluorescence emission is stable and can be tuned by varying the particle size or composition. Quantum dots are generally composed of atoms from II–VI or III–V elements in the periodic table and are defined as particles with physical dimensions smaller than the exciton Bohr radius [20]. This size leads to a quantum confinement effect, which endows nanocrystals with unique optical and electronic properties. Semiconductor nanocrystals can be capped with inert oxides or sulfides and can be attached to a biomolecule with a specific function. The salient features of semiconductor nanocrystals are (1) size-tunable emission (from the UV to the IR) of quantum dots, (2) narrow spectral linewidths, (3) high luminescence, (4) continuous absorption profiles, (5) stability against photobleaching, and (6) ideal immunolabels for in vitro and in vivo fluorescent imaging.

One group of researchers reported that in vivo targeting by using semiconductor quantum dots has proved to be highly feasible [21]. It was found that ZnS-capped CdSe quantum

dots coated with a lung-targeting peptide accumulate in the lungs of mice after injection, whereas two other peptides specifically direct quantum dots to blood vessels or lymphatic vessels in tumors. It was also seen that on adding PEG to the quantum dot, coating prevents the nonselective accumulation of quantum dots in reticuloendothelial tissues. These results encourage the construction of more complex nanostructures with capabilities such as disease sensing and drug delivery. ZnS-capped CdSe quantum dots emitting in the green and the red (550 nm and 625 nm fluorescence maxima, respectively) were coated with peptides by using a thiol exchange reaction. These peptide-coated quantum dots were injected into the tail vein of a mouse and allowed to circulate for a given time. Then each dot was frozen, sectioned, and examined under an inverted fluorescent microscope or confocal microscope. The use of peptides to target drug-carrying nanostructures such as those composed of dendrimers or stabilized drug nanocrystals is also possible.

66.2.4 Magnetic Nanoparticles

The phenomenon of magnetism has received significant attention in life sciences and medical sciences. The magnetic particles in nanoscales can be synthesized by various methods, including soft chemical methods such as coprecipitation of hydroxides [22], hydrothermal synthesis [23], sol–gel transformation, and ball milling [24]. More recently, microbial synthesis of nanoparticles has been developed as a green chemistry approach that consists in interconnecting nanotechnology and microbial biotechnology. Intracellular ferrimagnetic nanocrystals of greigite (Fe_3S_4) magnetite (Fe_3O_4) have been found in magnetotactic bacteria [25]. These ferrimagnetic nanocrystals are aligned in a linear fashion in the intracellular part called *magnetosome*, which helps the bacteria in its alignment and motion parallel to the geomagnetic field. A variety of remarkable applications in biology such as biosensors, magnetic resonance imaging, drug delivery, and magnetic fluid hyperthermia can be attained by the synergy of magnetic nanocrystals and biomolecules. Magnetic nanocrystals are size-compatible, sufficiently competent to interrelate with biological entities, detectable in an applied magnetic field, and capable of conveying energy from an alternating magnetic field. Magnetic nanomaterials have various applications such as proteomics, molecular cell biology, medical science, analytical biochemistry, clinical diagnostics, microbiology, immunology, biotechnology, and targeted drug delivery.

66.3 BIOCONJUGATION OF METAL NANOPARTICLES FOR NANOBIOLOGY

Accurate and sensitive detection of water-soluble bioanalytes such as toxins, carbohydrates, ionic species, and various biomolecules including DNA, proteins, and peptides is one of scientific goals with implications in healthcare and industrial applications [26]. The interaction of a target molecule with a protein receptor in a biological recognition process is often associated with a change in the protein conformation as a response to the binding event. Many scientists focus on the design and development of recognition-based sensing assemblies that can account for such changes through signal transduction in a medium of interest.

These observations and methods lead us to the key issue concerning the fabrication of nanobiological hybrid systems. First, we have to consider about inorganic nanoparticles in aqueous medium. These nanoparticles have an either positive or negative charge on their surfaces depending on the synthetic methodology adopted for their preparation. A majority of biomolecules have electrostatic charge due to the presence of acidic and basic functional (amino) groups. Thus electrostatic self-assembly of biomolecules around the nanoparticle can be used to fabricate nanobiological hybrid systems.

Another protocol used for the fabrication of assemblies is the immobilization of biomolecules on the surface of inorganic nanoparticles by using covalent bonding with the aid of an anchor molecule. Both the methodologies can be used depending on the requirement of the desired application. The tactics used in the construction of nanoprobes for a specific purpose can be adopted from the logic of bioconjugation. This means that we are utilizing the principle of molecular interactions in the construction of nanoprobes. Immobilization of the molecular conjugate of the target molecule on the nanoparticle surface is the most efficient protocol. For example, antibody–nanoparticle hybrid systems can be used for the detection of antigens and vice versa. Such nanoprobes are now commercially available on the market. The kind of nanoprobes used for optical microscopy depends on the nature of the inorganic nanoparticles. For instance, semiconductor quantum dots are used for confocal fluorescence microscopy of biological samples, while noble metal nanoparticles are used for transmission electron microscopy of biological samples. Among the metal nanoparticles, gold nanoparticles are widely used because of their unique properties such as strong optical absorption, chemical inertness, and ease of surface functionalization.

Inorganic nanoparticles such as noble metal nanoparticles, magnetic metal oxide nanoparticles, and semiconductor nanocrystals are used for bioconjugation. They are further utilized in different analytical applications. In normal protocols, an antibody of biologically important molecule is immobilized on the surface of the nanoparticle, which, in turn, is used for applications such as molecular detection, targeted drug delivery, and biological imaging. Sensing studies utilizing fluorescence resonance energy transfer (FRET) between a fluorescent donor molecule bound to the target and an acceptor attached to a receptor protein have been widely used to study receptor–ligand interactions and

changes in protein conformation on binding to a target analyte [27]. FRET has also been used to study changes in the solution conditions (temperature, pH conditions, etc.). FRET is extremely sensitive to the separation distance between the donor and acceptor, and is ideal for probing such biological phenomena. For example, one team [28] used luminescent CdSe-ZnS core–shell quantum dots as energy donors in FRET assays. The interface of biological systems and inorganic nanomaterials has recently attracted widespread interest in biology and medicine. Nanoparticles are believed to have potential as novel intravascular probes for both diagnostic (e.g., imaging) and therapeutic purposes (e.g., drug delivery) [29].

66.4 SURFACE MODIFICATION OF METAL NANOPARTICLES BY FUNCTIONAL POLYMERS

As mentioned above, conjugation with biomolecules on nanoparticle surface is an effective tool because of the specific interaction between biomolecules and the target objective. On the other hand, this is a very important issue with respect to the disposition of nanoparticles under the existence of many substances in physiological conditions. Thus, surface modification of nanoparticles to yield nonfouling properties is also required to avoid the aggregation and/or uptake by the mononuclear phagocytes system [30]. The enhanced permeability and retention (EPR) effect is the best example of this aspect and observed to be universal in solid tumors. Nanosized objects (including liposomes, nanoparticles, and macromolecular drugs) with long circulation times leak preferentially into tumor tissue through a leaky tumor vasculature and then are retained in the tumor to reduced lymphatic drainage.

In this case, functional polymers have proved very useful, and have been extensively studied. Polymer-assisted or polymer template synthesis of metal nanoparticles have received substantial attention because of very low concentrations of homopolymer and block copolymers capable of stabilizing nanoparticles effectively by steric stabilization, and the possibility of controlling the size, morphology of nanoparticles by varying the polymer/metal salt ratio. Moreover, the use of polymers containing appropriate functional groups serves as both reducing and stabilizing (capping) agent, and offers to prepare novel metal–polymer nanocomposites.

66.4.1 Natural Polymer Coating of Nanoparticles

Because of their nontoxic and biocompatible nature, natural polymers have always been the first choice of material scientists for synthesis of their composites with metal nanoparticles. In fact, coating with natural polymers ultimately improves the colloidal stability, oxidation resistance, mechanical stability, and functionalization characteristics of the composite systems. For example, chitosan, derived from chitin by partial deacetylation is a natural polymer with polycationic properties in dilute acidic solutions, enabling electrostatic attraction toward the negatively charged gold nanoparticle surfaces. Addition of aliquots of chitosan solution to gold colloidal solution results in a chitosan-capped gold nanoparticle dispersion–composite system [31]. Nanoparticles of ferromagnetic character (e.g., magnetite, maghemite) have been embedded into natural polymers such as chitosan for the purpose of wastewater treatment and medicinal/biotechnological applications (e.g., separation of microorganisms, extracorporal blood detoxification and targeted drug delivery) [32]. The magnetite nanoparticles including in chitosan microspheres are prepared by a suspension crosslinking technique [33]. The magnetite nanoparticles are prepared by coprecipitation of ferrous and ferric salts in alkaline medium, and the resulting product is mixed into acidified solution of chitosan, followed by addition of the cross-linker, glutaraldehyde. This suspension is now added dropwise into dispersion medium, which is composed of mineral oil, petroleum ether, and emulsifier. The magnetic chitosan microspheres, so produced, are collected with the help of magnet.

A few formulations based on superparamagentic nanoparticles coated by dextran polymer are being approved by the Food and Drug Administration (FDA, USA) for clinical imaging applications, and some of them are under clinic investigations. Recent reviews provide outstanding information about the magnetic nanoparticle formulations to a number of clinical applications [34,35]. These reviews suggest that superparamagnetic iron oxide nanoparticles coated with or incorporated in the biodegradable polymers can serve as contrasting agents as well as targeted delivery applications. Gum arabic or gum acacia (GA) is widely known as natural polysaccharide. A few recent studies indicate that gum acacia is extensively useful as a stabilizer, as well as reducing agent for nanoparticles synthesis [36]. The acacia polymer can produce 5–10-nm silver nanoparticles with good dispersion property over a long period of time. The reduction capacity of the acacia polymer progresses with higher amounts of polymer.

66.4.2 Synthetic Polymer Coating of Nanoparticles

Coating of nanoparticles with biocompatible synthetic polymers is a promising approach to generating core–corona particles for biomedical applications [37]. A survey of the more recent literature shows that indeed many different polymers have been used, for example, to stabilize gold colloids in aqueous media. Among these are Nafion 117 [38], poly(ethylene glycol) (PEG) [37], poly(vinyl alcohol) (PVA) [39], polyphosphate [40], polyacrylate [41,42], poly(ethylene imine) (PEI) [43], poly(*N*-vinylpyrrolidone) (PVP) [44], and poly(methyl methacrylate) (PMMA) [45].

These polymers have to provide solubility in the desired medium (mainly aqueous media) and at the same time bond to the metal colloids.

PEG is one of the most efficient dispersants, and has proved to be effective in suppressing the opsonization process because of its ability to prevent protein adsorption [37,46–50]. This feature is particularly interesting for particles that are intended for intravenous injections, because their half-life in blood circulation will be extended. This is usually so-called PEGylation of surfaces. To consider several parameters, the concept of PEGylation is also applied to biomolecules such as protein and antibody. To obtain an optimum protein activity by the PEGylation, estimation of the appropriate molecular weight of PEG can be based on the size of the given protein and the desired in vivo half-life increase. The selection of the activated PEGylating agent and the coupling method are less straightforward. To ensure a high retention of biomolecules by polymer coupling tethered to those amino acids, it is necessary to retain the biological function. The conjugated polymer should avoid the shielding of amino acid sequences to recognize the specific biological interaction. Consequently, a case-by-case approach is necessary to achieve the desired outcomes [51].

One team reported that surface PEGylation of gold particles by CH_3O–PEG–SH significantly improved their dispersion stability in aqueous milieu due to steric repulsion effects of tethered PEG strands [52]. Yet, the CH_3O–PEGylated nanoparticles possess no reactive groups to further immobilize ligand molecules. Thus, a system possessing both sufficient colloidal stability and biofunctionality is strongly desired to construct quantitative bioassays using gold nanoparticles [53,54]. Another group of researchers reported a facile route to functionalize PEGylated gold nanoparticles, having a potential utility for colloidal sensor systems [37], by the use of newly designed heterobifunctional PEG derivatives. That strategy to synthesize various types of heterobifunctional PEGs is based on the ring-opening polymerization of ethylene oxide using a metal alkoxide initiator with a protected functional group. Other researchers have reported the synthesis of heterobifunctional PEG containing both mercapto and acetal terminal groups (α-acetal-ω-mercapto-PEG, acetal-PEG-SH) [55–60]. The acetal moiety can readily be transformed into a reactive aldehyde group by simple treatment with dilute acid. An aldehyde-functionalized PEGylation of gold nanoparticles using this acetal-PEG-SH was successfully achieved, and the obtained gold nanoparticles expressed high dispersion stability, particularly in physiological condition. Furthermore, appreciable aldehyde reactivity to immobilize ligand molecules on the PEG coronas additionally impart them sensitivity and selectivity because of their nonfouling properties. As a model ligand, lactose was successfully introduced in the distal end of PEG chain to induce lectin-mediated quantitative and reversible association of gold nanoparticles under physiologically relevant conditions, producing a concomitant color change (Fig. 66.2) [61].

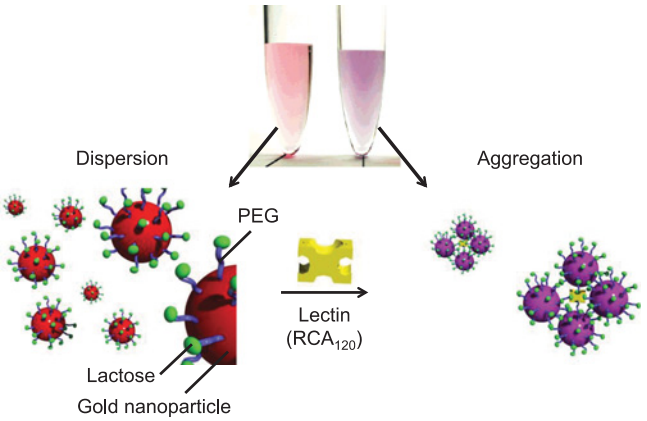

FIGURE 66.2 Schematic representation of the aggregation–dispersion behavior of lactose-modified gold nanoparticles by the addition of RCA_{120} lectin with change in color from red to purple [60].

66.4.3 Structural Regulated Copolymer for Coating Agent

The great advantage of synthetic polymers contrasted with natural polymers is the regulation of their primary structure. Amphiphilic block copolymers are versatile materials being explored for applications in medical, cosmetic, environmental, and industrial fields. The more recent developments of different synthetic techniques and the availability of numerous types of core and corona blocks with varying properties have provided a wide range of block copolymers [62]. In typical micellar applications, these copolymers are composed of a hydrophobic core block and a hydrophilic corona block. Under appropriate conditions, these amphiphilic copolymers can produce different aggregates of a wide range of shapes and sizes (especially spheres, rods, and vesicles) [63–71]. These aggregates can serve as versatile delivery vehicles for both hydrophobic and hydrophilic agents [72–82]. Block copolymers can provide nanoscale environments of varying and tunable shape, dimensions, mobility, local polarity, concentration, and reactivity. Reagents can be loaded into and react with functional polymers. The nanoscale domains formed by block copolymers can provide loci for the growth of metal and inorganic nanoparticles [83,84], while the block architecture can facilitate both the modification of the nanoparticle surface and the long-range positioning of nanoparticles [85–88].

Another group of coworkers successfully prepared the extremely high density PEG brush surface (~0.7 chains/nm^2) compared with other general methods (~0.3 chains/nm^2) [89–91]. The most peculiar aspect of the fabrication of the high-density PEG brush is the applyication of comb- and block-type copolymer (PEG-*co*-Py, PEG-*b*-Py), which is composed of a PEG segment as the hydrophilic part and a pyridine segment as the hydrophobic part [89,92–94] (Fig. 66.3). It is known that pyridine shows a high

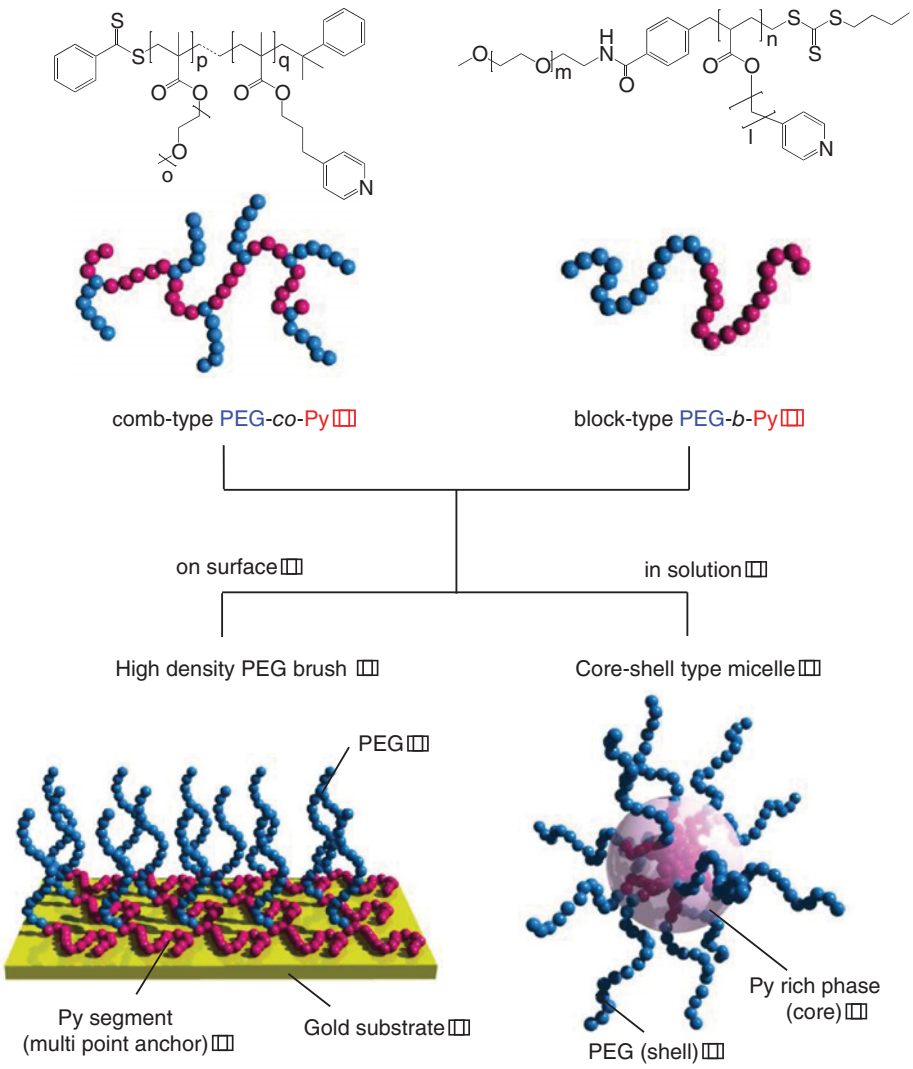

FIGURE 66.3 Chemical structure and schematic illustration of amphiphilic copolymers consisting PEG and polymerized pyridine on surface and in solution [91–93].

affinity to various metal surfaces. Thus, polymerized pyridine segment acts as the multipoint anchor to a metal surface. It is important that copolymer shows the phase-separated conformation in aqueous media, leading to the multipoint anchoring to provide exothermic enthalpy by adsorption compensating for entropy loss by crowding chain formation. This high-density PEG surface shows the specific features: excellent oil-repellent property based on their hydrophilicity, the molecule barrier property depending on the molecular weight of analytes such as biological protein, even at low molecule weight (myoglobin; MW = 17,600, R_g = ~2 nm) based on the exclusion volume effect of PEG, and the antioxidation activity in an oxidant environment likely in vivo. Moreover, when PEG-*co*-Py-modified gold nanoparticles are exposed to high salt concentration (1 M NaCl), they show long-term dispersion stability compered with PEG-SH modification [92].

66.5 REDUCING POLYMERS ACT AS DISPERSANTS FOR NANOPARTICLES

Nanotechnology research is emerging as cutting-edge technology interdisciplinary with physics, chemistry, biology, materials science, and medicine. Nanoparticles are usually 10–100 nm in each spatial dimension and are commonly synthesized using two strategies: top–down and bottom–up. In the top–down approach, the bulk materials are gradually broken down to nanosized materials, whereas in bottom–up approach, atoms or molecules are assembled in molecular structures in the nanometer range. The bottom–up approach is commonly used for chemical and biological synthesis of nanoparticles, and also for regulation of size and shape of nanoparticles. Obtaining monodispersed nanoparticles of different sizes and shapes has been a challenge in nanotechnology. The development of simple and versatile methods for the

preparation of nanoparticles in a size- and shape-controlled manner has attracted significant attention [95].

As mentioned above, nontoxicity of nanoparticles is of consequence for nanobiology. Although various physical and chemical methods are extensively used to produce monodispersed nanoparticles, the stability and the use of toxic chemicals is the subject of paramount concern. The use of toxic chemicals on the surface of nanoparticles and nonpolar solvents in the synthesis procedure limits their applications in clinical fields. Therefore, development of clean, biocompatible, nontoxic, and ecofriendly methods for nanoparticles synthesis deserves merit.

On the basis of these observations, a substitute method for one-step polymer-mediated synthesis has been developed [96]. If we use a polymer with reducing capacity as both the reducing agent and the stabilizer, covering the nanoparticles immediately after they are synthesized, then highly stabilized nanoparticles can be produced and the limitations mentioned above can be avoided as well [97]. This one-step method introduces no more reducing agents into the reaction system except for the polymer, so the product tends to be of high purity. Besides, by adjusting the polymer structure, reaction temperature, reactant ratio, and reacting time, it is possible to control the shape and size of metal nanoparticles. According to some previous experiments, metal nanoparticles synthesized this way are surprisingly stable and homogeneous. Although this one-phase process has only recently been proposed, much wider application can be forecast for future because of the low cost and relatively high efficiency of this method. As many more varieties of polymers are being used as the dual-functional reductant and stabilizer, metal nanoparticles with different dimensions, morphologies, structures, and optical properties are likely to be easily synthesized according to our needs. Therefore, potential applications of polymer-coated nanocomposites can be quite promising in future therapeutic applications and biomolecular manipulations, including detection, drug transfer, and genetic engineering. These newer production methods of metal nanoparticles based on polymer science and material science are also evolving to improve the nanobiology.

66.6 CONCLUSION

An overlap of nanotechnology, biotechnology, and bioinformatics has resulted in the advent of a new technology called *nanobiotechnology*, which is defined as a field that applies the principles of nanotechnology and bioinformatics to probe and modify biological systems or to apply the principles of life sciences and surface sciences to develop novel devices and systems for biocatalysis. Since 2005 or so, this technology has reached a level that has enabled it to develop probes for understanding the intracellular and intercellular biological process, novel targeted labels for biological systems, and efficient nanoparticle-based immunoassays for the detection of biomarkers at extremely low concentrations and preconcentration probes for selectively adsorbing the analyte from crude samples. Nanobiotechnology has a high potential for catering to societal needs, and can be used in common applications such as clinical assay and medical diagnosis, and can provide cheaper and more efficient solutions.

ON-CHIP ELECTROPHORESIS FOR EVALUATING ZETA-POTENTIAL OF NANOLIPOSOMES

Takanori Akagi and Takanori Ichiki
Department of Bioengineering, Graduate School of Engineering, University of Tokyo

67.1 INTRODUCTION

Liposomes are artificially prepared vesicles composed of a lipid bilayer and are widely used in various fields such as pharmacy, medicine, cosmetics, and the food industry. In recent years, extensive study has been carried out toward their application in drug delivery systems (DDSs), where liposomes are used as smart carriers of encapsulated drugs to disease sites. As a step toward realizing future applications such as DDSs, in which nanoliposomes will be utilized in a more sophisticated manner, the accurate characterization of nanoparticles is becoming increasingly important [1, 2].

The zeta-potential is one of the major physical properties of liposomes that determines the behavior in liquid. As for a liposomal DDS, it appreciably improves the physical stability and dispersibility of liposomes in the blood as well as the interaction of such vesicles with living bodies. Hence, the zeta-potential of liposomes has essential significance in correlation with nanoliposome application. Conventionally, laser Doppler electrophoresis has been the most widely used method for measuring the zeta-potential of nanoparticles [3]. However, it usually measures the intensity and wavelength shift of light scattered by a particle ensemble and cannot be used to evaluate the zeta-potential of individual nanoparticles in principle. Therefore, it is difficult to obtain an accurate zeta-potential distribution for nanoliposomes. Recently, we developed an Electrophoretic mobility (EPM) measurement system for individual nanoliposomes and applied it to comprehensively study the zeta-potential distribution of nanoliposomes [4].

67.2 NANOLIPOSOME PREPARATION

The materials used for the preparation of liposomes were 1,2-dilauroyl-*sn*-glycero-3 (DLPC) as the neutral lipid, L-α-phosphatidylserine (PS) as the anionic lipid, and cholesterol (chol) (Avanti Polar Lipids, Inc., AL, USA). The lipid mixture at an appropriate molar ratio dissolved in chloroform was deposited on a vial by evaporating the organic solvent, and the dried lipid film was then hydrated with phosphate-buffered saline (PBS) (pH=7.4), (GIBCO) containing 50 mM calcein (Kanto Chemical), a fluorescent dye encapsulated in liposomes for imaging. The mixture was incubated at 353 K for 2 h and then vortexed for 5 s. During the preparation, calcein (0.2 mM) was encapsulated in liposomes to enable fluorescent imaging. Subsequently, the liposomes were extruded through a polycarbonate membrane (pore size 50, 200, 400, and 1000 nm) to tailor their sizes [5]. The size distribution of liposomes extruded through different membrane pore sizes was measured using a Zetasizer nano ZS (Malvarn) by dynamic light scattering, and the average EPM of liposomes extruded through 50 nm pore size was measured by laser Doppler electrophoresis to investigate the effect of the composition ratio of the negatively charged PS lipid (Figs. 67.1 and 67.2).

67.3 ZETA-POTENTIAL MEASUREMENT SYSTEM

Figure 67.3 shows a schematic diagram of the on-chip zeta-potential measurement system. The system comprised a microcapillary electrophoresis (μCE) chip, a pair of platinum electrodes, a high-voltage dc power supply [HVL-1.1P(A), Matsusada Precision Inc., Japan], a 488-nm laser source (50 mW, 85-BCD-030-053, Melles Griot, USA), an inverted microscope (Ti-U, Nikon, Japan), and an EM-CCD camera (iXon3 897, Andor, UK). The details of μCE chip fabrication were described elsewhere [6]. Briefly, a chip made of poly(dimethylsiloxane) (PDMS) was fabricated by soft lithography. It was equipped with a microfluidic channel (length 1 cm; width 100 μm; height 50 μm) with reservoir tanks on both ends. To suppress nonspecific adsorption and electroosmotic flow, the inner surface of the microchannel was coated with 2-methacryloyloxyethylphosphorylcholine (MPC) polymer.

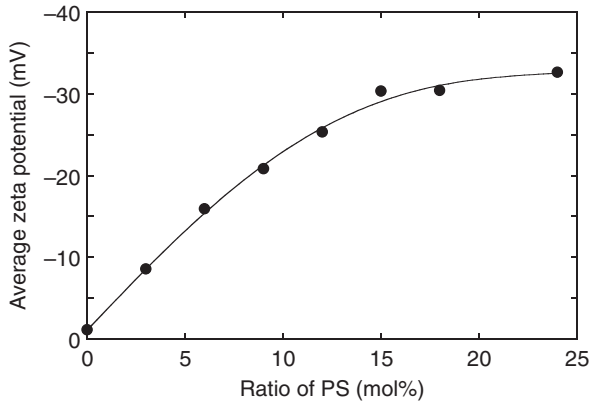

FIGURE 67.2 Average EPM of liposome measured by the PALS method as a function of lipid (PS) composition ratio.

The electrodes used to apply voltage were placed in the reservoir tanks of the μCE chip mounted on the inverted microscope. Fluorescence from individual liposomes excited by laser light was detected using an EM-CCD camera, which enabled the sensitive imaging of individual nanoliposomes.

67.4 CALCULATION OF ZETA-POTENTIAL OF LIPOSOMES

Liposomes suspended in PBS (pH=7.4, ionic strength 0.16) were introduced into the flow channel of the μCE chip, and the electrophoretic migration of liposomes was recorded while an electric field of 100 V/cm was being applied. Since the measured velocity of the migrating liposomes includes the electroosmosis velocity weakly observed in the microchannel, the true EPM of the liposomes was calculated using

$$\mu_{ep} = (U_{em} - U_{eo})/E \tag{67.1}$$

where μ_{ep} is the true EPM, U_{em} is the apparent electrophoretic velocity, U_{eo} is the electroosmotic flow velocity, and E is the electric field strength (V/cm). Electroosmosis velocity was measured by suspending charge-free beads of 500 nm diameter (Otsuka Electronics) in the electrophoresis buffer in the control experiment. According to the Henry equation, the EPM at low zeta-potentials (< 25 mV) can alternatively be given by

$$\mu_{ep} = \frac{\varepsilon_r \varepsilon_0 \zeta}{\eta} f(\kappa R) \tag{67.2}$$

where, ζ is the zeta-potential, η is the viscosity coefficient of the buffer solution, ε_r and ε_0 are the relative permeability of the solution and the permeability of vacuum, and $f(\kappa R)$ is Henry's function, in which κ, the Debye–Hückel parameter, is the reciprocal of the electric double-layer thickness, and R is the radius of the particle. Since the thickness of the electric double-layer in our experiments was approximately 0.8 nm, when R is a few hundreds of nanometers ($\kappa R \gg 1$), Henry's function is approximately 1.5; therefore, Smoluchowski approximation is applicable. However, for more accurate evaluation of Henry's function for a smaller R ($R < 100$ nm), we used the following formula derived by Ohshima to evaluate $f(\kappa R)$, which results in relative errors within 1% [7]:

$$f(\kappa R) = \frac{2}{3}\left[1 + \frac{1}{2[1 + 2.5/\{\kappa R(1 + 2\exp(-\kappa R))\}]^3}\right] \tag{67.3}$$

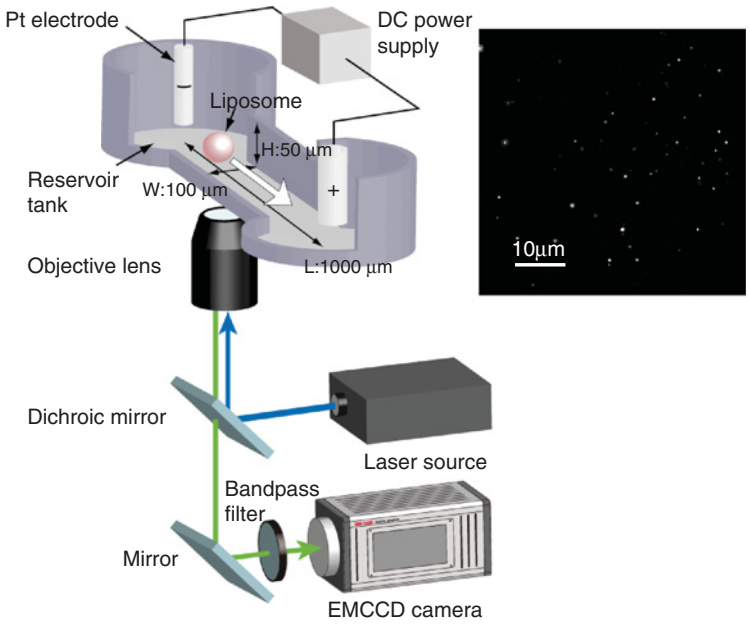

FIGURE 67.3 Schematic diagram of on-chip zeta-potential measurement system for nanoliposomes (left). Fluorescence microscopy image of nanoliposomes (extruded through filters with 50 nm pore size) in microchannel (right).

67.5 CAPILLARY ELECTROPHORESIS OF LIPOSOMES

Individual liposomes of different sizes were measured by on-chip electrophoresis. The sensitive fluorescence imaging system employed in this study enabled the direct observation of the electrophoretic migration of individual nanoliposomes. The histograms in Fig. 67.4 show the zeta-potential of liposomes prepared by extrusion through polycarbonate membranes with pore sizes of (a) 50 nm, (b) 100 nm, (c) 200 nm, (d) 400 nm, and (e) 1000 nm. Interestingly, although the averages are almost the same regardless of particle size, the apparent broadening of the zeta potential distribution was observed for the case of (a) 50 nm. In fact, the nanoliposomes extruded with a pore size of 50 nm showed a standard deviation approximately twofold that of the liposomes extruded with a pore size of 1000 nm.

From these data, we plotted the relationship between the average liposomal diameter and the standard deviation of EPM in Fig. 67.5 (solid circles) and found a size-dependent

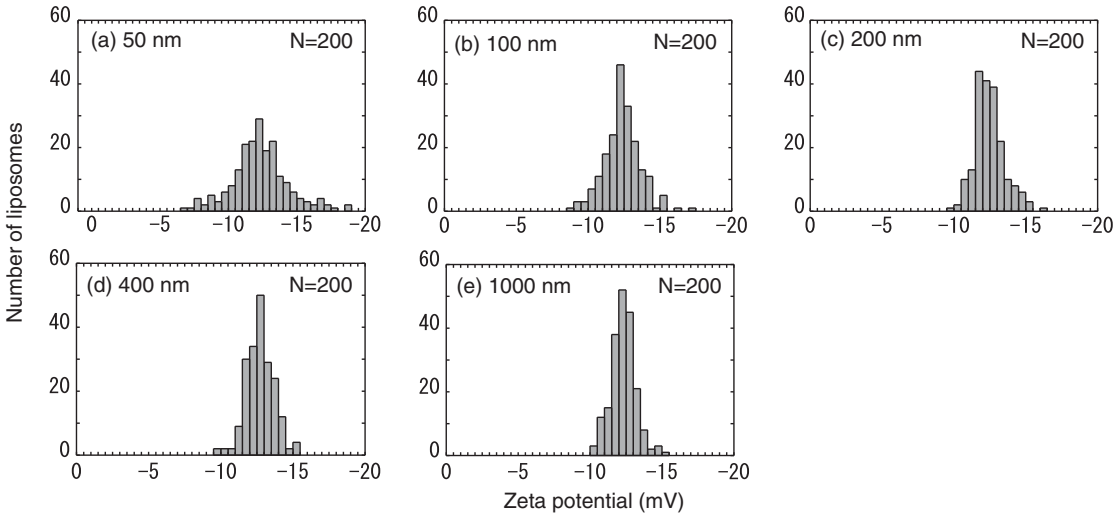

FIGURE 67.4 Zeta-potential distribution of liposomes of different sizes. The liposomes were extruded through membranes with pore sizes of (a) 50 nm, (b) 100 nm, (c) 200 nm, (d) 400 nm, and (e) 1000 nm. The liposomes were composed of DLPC:PS:Chol at molar ratio 5.55:0.45:4.00.

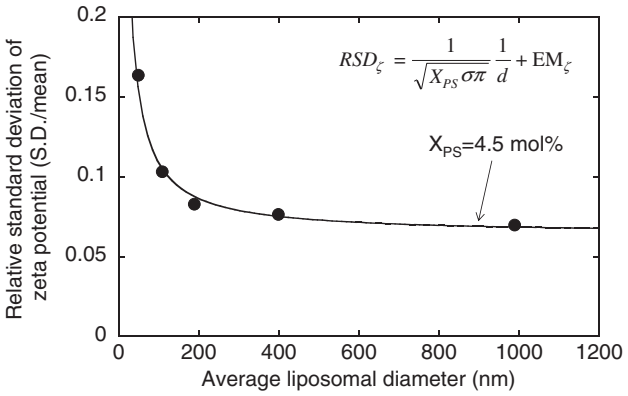

FIGURE 67.5 Relationship between average liposomal diameter and relative standard deviation of zeta-potential. Closed circles show experimental data. The solid line is a fitted curve obtained using the inverse curve given by Eq. (67.4). The curve was fitted by least-squares approximation using the experimental value of 4.5 mol% for the nominal composition of PS molecules, X_{PS}. The best-fit values of σ and EM_ζ are 0.41 nm^{-2} and 0.064, respectively.

broadening of the EPM distribution of nanoliposomes. We will now discuss the theoretical prediction of the zeta-potential distribution, considering this statistical fluctuation of anionic lipid PS molecules. Since the relative standard deviation of the zeta-potential RSD_ζ of nanoliposomes is expected to be the sum of the inherent deviation formulated above and other error margins EM_ζ that do not depend on liposomal diameter, it is expressed by the following equation and is inversely proportional to liposomal diameter:

$$RSD_\zeta = \frac{1}{\sqrt{X_{PS}\sigma\pi}}\frac{1}{d} + EM_\zeta \qquad (67.4)$$

Here, X_{PS} is the molar ratio of PS, d is the liposomal diameter, and σ is the surface density of lipid molecules. The solid line is the curve fitted using the inverse function given by Eq. (67.4). The curve was fitted by least-squares approximation using the experimental value of 4.5 mol% for the nominal composition of PS molecules, X_{PS}. From this curve fitting, σ and EM_ζ are obtained as 0.41 nm^{-2} and 0.064, respectively.

67.6 CONCLUSION

The zeta-potential measurement system that combines on-chip μCE with sensitive fluorescence imaging using an EM-CCD camera was developed to evaluate the electrokinetic behavior of individual nanoparticles, and was applied to a comprehensive study of the zeta-potential distribution of ternary-component nanoliposomes.

PHASE SEPARATION IN PHOSPHOLIPID BILAYERS INDUCED BY CHOLESTEROL

Nobutake Tamai, Masaki Goto, and Hitoshi Matsuki
Department of Life System, Institute of Technology and Science, The University of Tokushima, Tokushima, Japan

68.1 INTRODUCTION

Phospholipids are amphiphiles and self-assemble in the presence of excess water to form molecular aggregates of closed bilayer membranes, which are generally called *vesicles* or *liposomes*. Phospholipid vesicles provide the structural basis of biological membranes, or biomembranes, and therefore, various types of artificial phospholipid vesicles have long been used as models of the biomembranes to investigate their physicochemical properties and fundamental structure.

Dipalmitoylphosphatidylcholine (C16PC) is one of the phospholipid species that have most frequently been used in model membrane studies [1], and the structure and properties of the C16PC bilayer have been thoroughly investigated using various physical techniques, such as X-ray diffraction [2,3], differential scanning calorimetry (DSC) [4,5], nuclear magnetic resonance (NMR) [6], fluorescence spectroscopy [7, 8], and density measurements [9, 10]. It is well known that the C16PC bilayer exhibits several types of structural changes (i.e., phase transitions) with the variation in its surrounding conditions; for example, it undergoes the transition from the lamellar gel ($L_\beta{}'$) phase to the ripple gel ($P_\beta{}'$) phase (i.e., pretransition) and subsequently the transition from the $P_\beta{}'$ phase to the liquid–crystalline (L_α) phase (i.e., main transition) with the rise in temperature. Now we have ample information about the bilayer phase behavior of various kinds of phospholipids [11], which provides a deeper understanding of how the variation in the chemical structure of the constituent phospholipid molecules alters the bilayer phase behavior.

As a recent trend in model membrane studies, use of multicomponent phospholipid bilayer membranes containing cholesterol has increased [12, 13]. This recent trend is not due simply to the fact that cholesterol is a major component of animal cell membranes but is largely due to the proposal of a new concept that describes the structure and functions of the cell membrane [14]. According to this concept, there exist microdomains composed of specific kinds of phospholipids and cholesterol (i.e., *lipid rafts*) within the cell membrane, and signaling membrane molecules are localized in the microdomains. This means that the microdomains are essentially relevant to biological functions of the cell membrane, such as protein sorting [14] and signal transduction [15]. As a result, the significance of cholesterol within the cell membrane is highlighted as one of the key components directly related to the formation of the microdomains within the membrane. To state this boldly, a cholesterol-containing multicomponent phospholipid bilayer is preferable as a more "realistic" model of the biomembrane.

To date, a large number of basic studies have been performed to investigate the biophysical and biochemical properties of cholesterol-containing phospholipid bilayers, and many of the outcomes from those model membrane studies underpin the lipid raft concept. For example, the domain formation, which is a significant characteristic of the lipid raft concept, can be rationalized by the fact that cholesterol incorporated into a phospholipid bilayer has a propensity to induce phase separation within the bilayer. In fact, some relatively recent studies using various visualization techniques [16–18] have demonstrated the formation of domains due to

the heterogeneous distribution of the constituent lipids within cholesterol-containing ternary model membranes. However, the physical and chemical origin of the heterogeneous distribution induced by cholesterol has not been completely elucidated yet. This means that further basic studies are still needed to obtain a full understanding of the cholesterol effect on the lateral organization of the phospholipid bilayer.

A compositional phase diagram of a cholesterol-containing binary bilayer (i.e., temperature (T)–cholesterol mole fraction (X_{ch}) phase diagram) provides a strong basis for studying the lateral organization of the binary bilayer. It also provides useful information about the cholesterol–phospholipid interaction within the bilayer in terms of thermodynamics, because in general the shape of the compositional phase diagram of a binary system is influenced by the affinity (or miscibility) between the two components. We have recently reported on the T–X_{ch} phase diagrams for the cholesterol-containing binary bilayers of a series of linear saturated diacylphosphatidylcholines (CnPCs) with different acyl chain length n (n = 14–18) [19–21] and also proposed a molecular picture of the distribution of cholesterol within the CnPC–cholesterol binary bilayers that can be deduced from the phase diagrams by taking several known effects of cholesterol into account. In this chapter, we describe the effect of cholesterol on the lateral organization of the CnPC bilayers on the basis of these recent studies and also discuss how the thermodynamic features of the phase diagrams are influenced by the variation in the acyl-chain length of the host PC molecule. In addition, we also give a brief overview of the historical background of the model membrane studies on the phase behavior of phospholipid–cholesterol binary bilayers to review previous studies on this subject and also a simple explanation of solid–liquid phase equilibria for binary mixtures.

68.2 HISTORICAL BACKGROUND

The physical and chemical properties and structure of cholesterol-containing phospholipid model membranes have been studied for almost 50 years. Especially in the first two decades, many such fundamental studies focused on the characterization of the molecular properties of cholesterol and phospholipids within the bilayer, and a wide variety of the experimental techniques were used in those studies, such as NMR [22–28], electron paramagnetic resonance (EPR) [29–32], X-ray or neutron scattering [33–36], DSC [32, 33,37–39], fluorescence techniques [40–42] and freeze fracture electron microscopy [42–45]. These earlier studies provided the physicochemical basis necessary for understanding the behavior of cholesterol within the bilayer at the molecular level, which revealed several key features of the cholesterol-containing phospholipid bilayer. For example, cholesterol decreases the membrane fluidity (i.e., lateral diffusion of lipid molecules within the bilayer) above the main transition temperature, whereas it increases the fluidity below that temperature. Another significant feature is that the orientational order of the phospholipid hydrocarbon chains is enhanced by the presence of cholesterol above the main transition temperature. Some review articles [46,47] are also helpful in reviewing earlier studies on this subject. From the viewpoint of phase behavior, these features can be interpreted as signifying that cholesterol has a propensity to induce an "intermediate" state between the gel and the L_α states and thereby to stabilize the bilayer structure on the whole.

On the other hand, earlier attempts to elucidate how cholesterol affects the lateral organization of the phospholipid bilayer do not seem to have been successful. For this purpose, considerable efforts were made to determine the phase diagram of the cholesterol-containing binary bilayer, but the phase diagrams reported in earlier studies [32,41,42,48] were not sufficiently consistent with one another to give a unified picture explaining the cholesterol effect on the lateral organization of the bilayer successfully. A major reason for this is the experimental difficulty in determining the transition temperatures accurately for a phospholipid–cholesterol binary bilayer with relatively higher cholesterol content, because the thermotropic bilayer phase transitions tend to be obscured with increasing content of cholesterol in the binary bilayer owing to the abovementioned propensity of cholesterol to induce an intermediate state.

A breakthrough was achieved by Ipsen et al. [49], who predicted the phase boundaries of the binary bilayer of C16PC and cholesterol by theoretical calculation based on a thermodynamic and a simple microscopic model. Although the phase diagram they presented was not experimental, it could explain several major cholesterol effects that had been already known, and it also indicated several significant features of the thermotropic phase behavior of the phospholipid–cholesterol binary bilayer, most of which are universally accepted today. For example, they identified the phase state of the binary bilayer with a higher cholesterol content ($X_{ch} > \sim 0.3$) as a third phase that was distinguishable from the solid ordered (S_o) phase, including the L_β' and the P_β' phase, and the liquid disordered (L_d) phase like the L_α phase. This third phase was termed *liquid ordered* (L_o) *phase* by taking into account the characteristics of this phase, namely, higher conformational order of the acyl chains and relatively faster lateral diffusion. In addition, they revealed that there is a two-phase region due to the miscibility gap between the L_d and L_o phases in an intermediate cholesterol composition region of the phase diagram, which means that the incorporation of the corresponding amount of cholesterol induces phase separation. Today, this cholesterol-induced phase separation is considered to be a physicochemical basis for rationalizing the formation of the microdomains within the biomembrane. A few years later, Vist and Davis [50] reported an experimental phase diagram of the perdeuterated

C16PC (d_{62}-C16PC)–cholesterol binary bilayer determined by means of ^{2}H NMR and DSC. Their experimental phase diagram was qualitatively very similar to their theoretical phase diagram. This qualitative agreement between the theoretical prediction and the experimental result strongly supported the validity of the theoretical consideration by Ipsen et al. [49], and at the same time, enhanced the reliability of the experimental phase diagram. For this reason, these theoretical and experimental phase diagrams were widely accepted as among the most reliable phase diagrams for the cholesterol-containing binary bilayer.

After that, numerous compositional phase diagrams of cholesterol-containing binary bilayers were reported for various kinds of phospholipid, such as dimyristoyl-PC (C14PC) [51] and unsaturated PCs [52]. It is interesting that most of them indicated some common features regarding the effect of cholesterol on the bilayer phase behavior; for example, the L_o phase is formed at higher cholesterol compositions and the two-phase state consisting of the L_o phases and the L_d (or S_o) phase is observed at intermediate cholesterol compositions above (or below) the main-transition temperature. A more recent review [53] is very helpful in considering these common features, where many of the phase diagrams that have so far been reported for various kinds of cholesterol-containing binary bilayers are collected together to compare and contrast those obtained by different experimental techniques. On the other hand, it has been also pointed out in this review that there is incomplete agreement between different determinations of the phase diagrams for the same binary bilayer. In fact, several dissimilar phase diagrams of the C16PC–cholesterol binary bilayer [54–56] have so far been reported even after that of the same system given by Vist and Davis [50] was widely accepted. This implies that the phase behavior of the cholesterol-containing binary bilayer has not been completely elucidated yet and that there are still some issues that need to be investigated for the complete elucidation.

One of those issues is how the thermotropic phase behavior of cholesterol-containing binary bilayers is affected by the variation in the chemical structure of the constituent phospholipid molecule. In order to clarify this, systematic investigations for binary bilayers of various phospholipids with cholesterol are indispensable. Another group has systematically studied the effect of cholesterol on the thermotropic bilayer phase transitions of various kinds of phospholipids [57–61] by means of high-sensitivity DSC and Fourier transform infrared spectroscopy (FT-IR) in detail. Their extensive studies have clearly revealed how the effects of cholesterol on thermodynamic properties of the bilayer phase transitions (e.g., transition temperatures and transition enthalpies) depend on the chemical structure of the host phospholipid and also found that those cholesterol effects can be classified into two types in terms of whether the effect is dependent on or independent of the acyl chain lengths of the host phospholipid molecules. Their studies, however, did not show how thermodynamic features of the phase diagram of the cholesterol-containing binary bilayers change with variations in the chemical structure of the constituent phospholipid, because the main aim of their studies was not to construct the phase diagrams. To our knowledge, the only study that has addressed this issue is that of Huang et al. [54] (see also Ref. 62), who investigated the phase behavior of cholesterol-containing binary bilayers of C16PC, distearoyl-PC (C18PC), and diarachidoyl-PC (C20PC) by means of solid-state NMR and high-sensitivity DSC to construct the phase diagrams of those binary bilayers excluding the C20PC–cholesterol binary bilayer. Although their phase diagram of the C16PC–cholesterol binary bilayer is essentially different from that of the same binary bilayer given by Vist and Davis [50], it can be directly compared to their own result for the C18PC–cholesterol binary bilayer to deduce what effect the difference in the acyl chain length has on the phase behavior of those binary bilayers. This means, as was emphasized in their paper, that examination of just one lipid species, such as C16PC, is insufficient and that a variety of phospholipids must be sampled to determine the overall trend.

It should be also mentioned that although some cholesterol effects directly related to the lateral organization of the binary bilayer and the distribution of cholesterol within the binary bilayer (e.g., condensation effect and the formation of cholesterol–phospholipid complexes [30,37,39,46,63–70]) have been well known, it has not been fully clarified how relevant this type of cholesterol effects are to the overall phase behavior of cholesterol-containing binary bilayers. This may be due to the fact that quantitative features of the phase diagram have been regarded as comparatively less significant while the qualitative similarities, as described above, were often emphasized, although those cholesterol effects are expected to be reflected in quantitative features of the phase diagram, especially with respect to the cholesterol composition. In order to clarify this relevance, therefore, it is important to determine quantitative characteristics of the phase behavior of the binary bilayers on the basis of the phase diagram.

68.3 SOLID–LIQUID PHASE DIAGRAMS OF BINARY MIXTURES

A solid–liquid phase diagram for a binary mixture is very useful for understanding the melting/freezing behavior of the mixture. It also helps us to predict the microscopic structure of the mixture in the solid state. We will briefly explain the significant features of typical solid–liquid phase diagrams of binary mixtures, along with the terminology, in terms of thermodynamics of the solid–liquid phase equilibria.

Figure 68.1a depicts the liquid–solid phase diagram of an ideal binary mixture of components A and B, which are

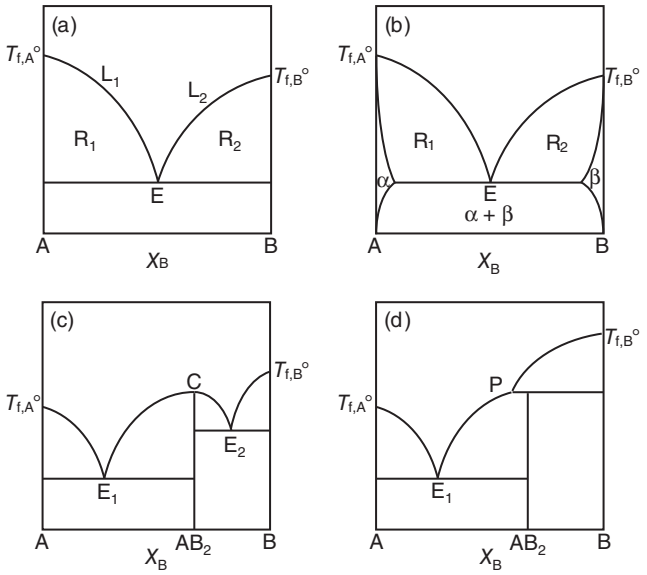

FIGURE 68.1 Typical solid–liquid phase diagrams for various types of binary mixtures: (a) a eutectic ideal binary mixture; (b) a eutectic binary mixture where the two components of A and B are partially miscible in a solid state; (c) a binary mixture that exhibits congruent melting behavior; (d) a binary mixture that exhibits incongruent melting behavior.

completely miscible in all proportions in the liquid phase (i.e., perfect solution) and completely immiscible in the solid state. The phase boundary labeled L_1 (or L_2) is the freezing-point–depression curve of A (or B) due to B (or A), given by the following relation between $T_{f,A}$ and X_B (for L_1):

$$\ln\left(1 - X_B\right) = \frac{\Delta H^\circ_{fus,A}}{R}\left(\frac{1}{T_{f,A}} - \frac{1}{T^\circ_{f,A}}\right) \qquad (68.1)$$

Here, X, ΔH_{fus}, T_f, and R are mole fraction, molar enthalpy of fusion, freezing-point temperature, and the gas constant, respectively. The superscript ° and the subscripts A and B denote quantities for pure substances and for components A and B, respectively. When a liquid solution of A and B with a given composition is cooled to $T_{f,A}$ (or $T_{f,B}$), pure solid A (or B) begins to freeze out, giving a two-phase region (i.e., region R_1 or R_2) in which pure solid A (or B) and a liquid solution coexist in equilibrium. Therefore, L_1 (or L_2) is a phase boundary that separates a liquid phase and a solid-containing phase and is called *liquidus*. The two liquidus lines L_1 and L_2 intersect at point *E*. This characteristic point is called a *eutectic point*. Below the eutectic temperature, both components exist as pure solids A and B independent of the composition, which means that the region below the horizontal line passing through the eutectic point corresponds to a two-phase region in which pure solids A and B coexist in equilibrium.

When components A and B are partially miscible in the solid state, the phase diagram of the binary mixture resembles Fig. 68.1b, in which there are three different solid-phase regions, each of which is labeled α, β, or α + β. The α and β phases correspond to solid solutions of B in A and of *A* in *B*, respectively. The α + β region corresponds to the two-phase region in which the saturated solid solutions of B in A and of A in B coexist in equilibrium. The boundaries that separate these three different solid phases are called *solvus*, and the boundary between α and the R_1 region, as well as that between β and the R_2 region, is called *solidus*. The presence of solidus and solvus lines in a binary phase diagram signifies that both components are partially miscible in the solid phase.

As is often the case with binary alloys and hydrated crystals, the two components A and B interact to produce a solid compound with a certain stoichiometry in the mixture. As typical examples, Figure 68.1c,d shows the compositional phase diagrams of the binary mixtures where the solid compound of AB_2 is formed. The common feature of these phase diagrams is that there is an isopleth (i.e., a vertical line) at $X_B = 0.67$, corresponding to the stoichiometric composition of AB_2, in each diagram. In the case of Figure 68.1c, when solid compound AB_2 is heated, it melts at the temperature of point C to give a liquid solution of A and B with the mixing composition equal to the stoichiometric composition of AB_2 (i.e., $X_B = 0.67$). This means that point C is the melting point of solid AB_2 and is called a *congruent melting point* in general. The overall melting/freezing behavior can be easily understood by regarding the phase diagram of Fig. 68.1c as consisting of two simple eutectic diagrams of A–AB_2 and AB_2–B mixtures adjacent to each other. When the melting point of pure solid B is much higher than that of solid compound AB_2, the freezing-point–depression curve of B (curve BE_2) no longer intersects the right-hand freezing-point–depression curve of AB_2 (curve CE_2), yielding a phase diagram of the type shown in Fig. 68.1d. In this diagram, the eutectic point between AB_2 and B and the congruent melting point disappear, and instead a new characteristic point (point P) occurs. This point is called a *peritectic point*. In this case, when solid AB_2 is heated, it begins to melt at the same temperature as that of point P to produce a liquid solution of A and B, and at the same time, pure solid B, which can coexist with the liquid solution in equilibrium, is also formed. The mixing composition of the resulting liquid solution is given by the composition of point P, which is obviously not equal to the stoichiometric composition of AB_2. For this reason, point P is also called an *incongruent melting point*. Qualitatively, the phase diagram of this type is not difficult to understand, because it is essentially the same as the congruent-melting type phase diagram (Fig. 68.1c) except that the increase in the melting temperature of pure solid B elevated the eutectic line between AB_2 and B along with the two-phase region between liquid solution and pure solid B in Fig. 68.1c, and as a result, eliminates

the right-hand two-phase region between AB_2 and liquid solution.

68.4 PHASE TRANSITIONS OF C*n*PC–CHOLESTEROL BINARY BILAYERS

In our studies, DSC and fluorescence spectroscopy using Prodan [6-propionyl-2-(dimethylamino)naphthalene] as a probe were utilized to determine the transition temperatures of a series of C*n*PC–cholesterol binary bilayers. DSC has often been used in many previous studies on the thermotropic phase behavior of phospholipid bilayers because of its high sensitivity to energetic thermotropic events such as conformational changes of the acyl chains of phospholipid molecules. On the other hand, Prodan is a polarity-sensitive fluorescent probe [71] and has a good potential as a membrane probe for investigating surface properties of phospholipid bilayers [72–84]. The emission spectrum of Prodan changes sensitively in response to the variation in the microenvironmental polarity around the probe molecule, and the bilayer phase transition can be detected from the spectral change. It has been also reported that the Prodan fluorescence technique is adequately applicable to cholesterol-containing phospholipid binary bilayers [78,81]. Thus, the combined use of these two complementary techniques enables us to investigate the phase transitions of the C*n*PC–cholesterol binary bilayers in detail from different aspects.

68.4.1 Prodan Fluorescence Spectra of Pure and Cholesterol-Containing C*n*PC Bilayers

Figure 68.2a shows the Prodan fluorescence spectra obtained for the pure C16PC bilayer at different temperatures ranging from 20°C to 55°C. It can be seen from these spectra that every spectrum has a unique local emission maximum, and that the wavelength at the maximum (λ_{max}) tends to shift toward higher wavelengths as the temperature is elevated. This spectral change is attributable to the thermotropic phase transitions (i.e., pretransition and main transition) of the C16PC bilayer, which can be clearly understood from the temperature dependence of λ_{max}, shown in Fig. 68.2b. The λ_{max} value changes from ~440 nm to a slightly higher wavelength around 34°C and sharply increases to nearly 490 nm at ~42°C. These temperatures are almost equal to those of the pretransition and main transition of the C16PC bilayer [4, 5]. Our previous study [27] has shown that there is a positive correlation between the λ_{max} value and the polarity of the solvent in which Prodan is dissolved. In addition, it is well known that the polarity inside the phospholipid bilayer membrane steeply decreases with the bilayer depth from the surface to the midplane along the longer axis of the constituent phospholipid molecule, as depicted by the zone model given by Okamura and Nakahara [85]. Taking these facts into account, the λ_{max} change with the bilayer phase transition is considered to be due to the relocation of the Prodan molecules in the bilayer depth direction caused by the change in the bilayer packing state at the transition. A similar λ_{max} change is observed for other C*n*PC bilayers, although the magnitude of the λ_{max} shift at the pretransition tends to be smaller as the acyl chain length becomes shorter. This can be roughly interpreted as follows: λ_{max} values of approximately 440 and 490 nm in the Prodan fluorescence spectra signify an ordered and a disordered membrane state, respectively.

There is another way to characterize the variation in the Prodan fluorescence spectra with the bilayer transitions. Since the wavelengths of 440 and 490 nm are characteristic wavelengths, the fluorescence intensities at those wavelengths, namely F_{440} and F_{490}, can be used as measures of the order of the bilayer packing state. Figure 68.2c

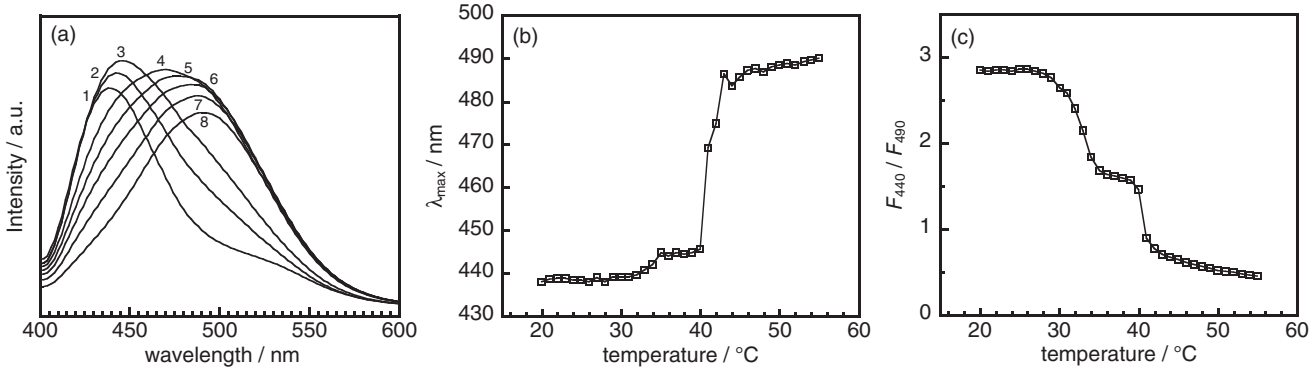

FIGURE 68.2 (a) Emission spectra of Prodan in C16PC bilayer at various temperatures: (1) 27.9°C, (2) 33.9°C, (3) 39.9°C, (4) 40.9°C, (5) 41.9°C, (6) 43.9°C, (7) 47.9°C, (8) 54.9°C. (b) Temperature dependence of wavelength at the maximum emission (λ_{max}) for C16PC bilayer. (c) Temperature dependence of ratio of the intensity at 440 nm (F_{440}) to that at 490 nm (F_{490}), namely, F_{440}/F_{490}, for C16PC bilayer.

shows the temperature dependence of the ratio, F_{440}/F_{490}, for the C16PC bilayer. This temperature dependence curve clearly shows two stepwise decreases in the intensity ratio of F_{440}/F_{490} with increasing temperature, which are consistent with the stepwise increases in λ_{max} with increasing temperature. As evident from the consistency, the decreases in F_{440}/F_{490} at a lower and a higher temperature are attributed to the pretransition and the main transition, respectively. Especially, the stepwise change corresponding to the pretransition can be more clearly seen in the temperature dependence curve of F_{440}/F_{490} than in that of λ_{max}. Therefore, the combined use of these two types of the temperature dependence curves allows us to determine the pre- and the main-transition temperatures of the C*n*PC bilayers with more reliability. Note that the intensity ratio F_{440}/F_{490} is too simple to use as a parameter to quantify membrane properties. Generalized polarization (GP) or three-wavelength GP (3wGP), which has been introduced by Parasassi et al. [77, 78], is more suitable as a quantitative parameter. As long as these intensity-based parameters are used only for the purpose of determining the transition temperatures, however, it should make no significant difference in the results what type of intensity-based parameter is used.

Figure 68.3 shows the temperature dependence curves of λ_{max} and F_{440}/F_{490} for the C16PC–cholesterol binary bilayers with different cholesterol compositions (X_{ch}). It can be seen that there is an overall tendency in the temperature dependence curves of λ_{max}: the temperature at which the λ_{max} reaches close to 490 nm moves to higher temperatures as X_{ch} increases, and at the same time, the λ_{max} shift to 490 nm itself becomes a gradual increase occurring in a finite temperature range. An obvious tendency can be seen also in the temperature dependence curves of F_{440}/F_{490}, which corresponds well to the above tendency in those of λ_{max}: the decrease in F_{440}/F_{490} with temperature also becomes gentle progressively with increasing X_{ch}. These tendencies suggest that in the C16PC–cholesterol binary bilayers, the conversion from an ordered state to a disordered state is not a discontinuous change like a first-order phase transition, but rather a continuous transformation process occurring over a finite temperature range. This means that two temperatures, namely, an onset and a completion temperature, can be defined to characterize this process of the conversion in the cholesterol-containing bilayers, whereas the conversion can be characterized by a single temperature (i.e., the main transition temperature) for the pure C16PC bilayer. Similar overall tendencies are also observed for the C*n*PC–cholesterol binary bilayers (n = 14,15,17), which suggests that, similarly, the conversion from the ordered state to the disordered state in these binary bilayers changes from a discontinuous transition to a continuous transformation process by the presence of cholesterol. The thermodynamic origin of the continuous process is explained later on the basis of the compositional phase diagram. On the other hand, the C18PC–cholesterol

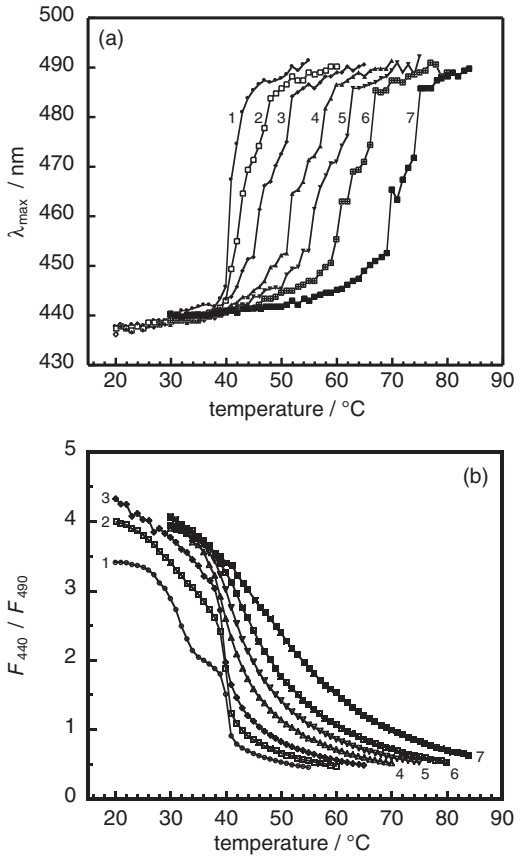

FIGURE 68.3 Temperature dependence of (a) wavelength at the maximum emission (λ_{max}) and (b) ratio of the intensity at 440 nm (F_{440}) to that at 490 nm (F_{490}), specifically, F_{440}/F_{490}, for C16PC–cholesterol binary bilayers at different cholesterol compositions (X_{ch}): (1) X_{ch} = 0.01, (2) 0.05, (3) 0.10, (4) 0.15, (5) 0.19, (6) 0.24, (7) 0.31.

binary bilayer exhibits very slightly different behavior: as X_{ch} increases, initially the temperature range of the process becomes wider, but it becomes narrow once around X_{ch} = 0.1 and then it becomes wider again with increasing X_{ch}. As seen from the phase diagram later, this shrinking of the temperature range around X_{ch} = 0.1 can be interpreted as attributable to the presence of a eutectic point around that cholesterol composition.

68.4.2 Characterization of Phase Transitions of C*n*PC–Cholesterol Binary Bilayers by DSC

Figure 68.4 shows the DSC thermograms of the pure C16PC and the C16PC–cholesterol binary bilayers with different cholesterol compositions. Two endothermic peaks are clearly seen in the thermogram of the pure C16PC bilayer (curve 1), and a small endothermic peak at 34.5°C and a large sharp one at 41.6 °C arise from the pretransition and the main transition, respectively. When cholesterol is incorporated into

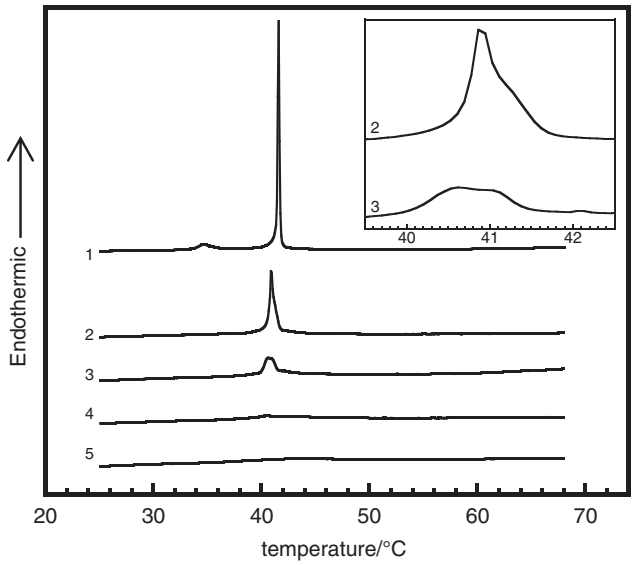

FIGURE 68.4 DSC thermograms of C16PC–cholesterol binary bilayers at different cholesterol compositions (X_{ch}): (1) $X_{ch} = 0$, (2) 0.07, (3) 0.14, (4) 0.20, (5) 0.30. The magnified view of the endothermic peaks of thermograms 2 and 3 are shown in the inset. Each thermogram is vertically shifted appropriately to avoid overlapping one another.

the C16PC bilayer, the endothermic peak of the pretransition becomes smaller with increasing X_{ch} and eventually undetectable above $X_{ch} = 0.08$. This indicates that the pretransition is abolished when the mole fraction of cholesterol within the binary bilayer exceeds at least 0.08. The X_{ch} value at which the pretransition is abolished is slightly different depending on the acyl-chain length n: $X_{ch} = 0.03$–0.035 for C18PC and $X_{ch} = 0.05$–0.06 for C14PC, C15PC and C17PC. The main transition is also affected by the presence of cholesterol within the binary bilayer, which is reflected in the variation in the shape and the size of the endothermic peak with increasing X_{ch}. As X_{ch} increases, the endothermic peak of the main transition gradually increases in width but steeply decreases in height, and as a whole, it becomes smaller. In the case of the C16PC–cholesterol binary bilayer, as seen from Fig. 68.4 (curve 2), the main transition peak is obviously asymmetric at $X_{ch} = 0.07$, signifying that the endothermic peak is composed of at least two component peaks with different heights and widths. At $X_{ch} = 0.14$ (curve 3), the heights of the two component peaks become apparently almost comparable, and only the broad peak remains above $X_{ch} = \sim 0.20$ (curve 4). This broad peak also becomes progressively smaller and markedly broader with further increases in X_{ch} (curve 5) and finally undetectable above $X_{ch} = 0.35$. Qualitatively, the other C*n*PC–cholesterol binary bilayers ($n = 14,15,17,18$) exhibit similar X_{ch}-dependent behavior with respect to the variation in the endothermic peak of the main transition, although there seems to be a tendency for the asymmetry of the main transition peak to become less noticeable in appearance as the acyl chain length becomes longer. Quantitatively, on the other hand, there is a definite difference in the X_{ch} value at which the main transition becomes undetectable as a peak: it can be detected even at $X_{ch} = 0.45$ for the C18PC–cholesterol binary bilayer whereas it becomes undetectable above $X_{ch} = 0.35$ for the remaining C*n*PC–cholesterol binary bilayers ($n = 14$–17).

The main transition temperature T_m and the enthalpy change with the main transition ΔH_m can be determined as the temperature at the peak maximum and as the peak area from the baseline, respectively. The half width of the endothermic peak $\Delta T_{1/2}$, defined as the so-called full width at half height, is also an important property relating to the cooperativity of the transition [86]. Figure 68.5 shows the X_{ch} dependence of ΔH_m, T_m and $\Delta T_{1/2}$ for all the C*n*PC–cholesterol binary bilayers ($n = 14$–18). As seen from Fig. 68.5a, the ΔH_m value decreases almost linearly with increasing X_{ch} and becomes zero at $X_{ch} = 0.45$–0.50 for the C18PC–cholesterol binary bilayer and at $X_{ch} = 0.30$–0.35 for the remaining C*n*PC–cholesterol binary bilayers ($n = 14$–17). As described in Section 68.2, earlier studies established that when cholesterol is incorporated into a phospholipid bilayer it suppresses the thermally induced *trans–gauche* conformational change in the hydrocarbon chains (i.e., chain melting) of the constituent phospholipid molecules with which it interacts. Therefore, the almost linear decrease in ΔH_m with X_{ch} indicates that the population of the C*n*PC molecules that still undergo the chain melting (i.e., main transition) decreases nearly in proportion to the amount of cholesterol incorporated into the bilayer. Furthermore, the fact that ΔH_m becomes zero at $X_{ch} = 0.45$–0.50 (C18PC) or at $X_{ch} = 0.30$–0.35 (C*n*PCs, $n = 14$–17) suggests that no constituent C*n*PC molecules undergo the chain melting in the binary bilayer above $X_{ch} = 0.50$ or 0.35. Conversely speaking, that amount of cholesterol is enough to suppress the *trans–gauche* conformational change in the acyl chains of all the constituent C*n*PC molecules. The difference in those X_{ch} values is discussed in the following section.

The X_{ch} dependence of T_m (Fig. 68.5b) shows that the main transition temperature decreases slightly with increasing X_{ch} in the relatively low X_{ch} region. This tendency is common to all the C*n*PC–cholesterol binary bilayers ($n = 14$–18). The solid lines in Fig. 68.5b represent the freezing-point–depression curves calculated by applying Eq. (68.1). Note that X_B, $\Delta H^\circ_{fus,A}$, $T^\circ_{f,A}$, and $T_{f,A}$ in Eq. (68.1) need to be replaced by X_{ch}, ΔH_m(at $X_{ch} = 0$), T_m(at $X_{ch} = 0$), and T_m, respectively. As described above, Eq. (68.1) is based on the simple thermodynamic concept of solid–liquid phase equilibrium of an ideal binary mixture, and thus assumes several thermodynamically ideal conditions for simplification: (1) the two components are perfectly immiscible in a solid state, (2) the binary mixture behaves as an ideal dilute solution in

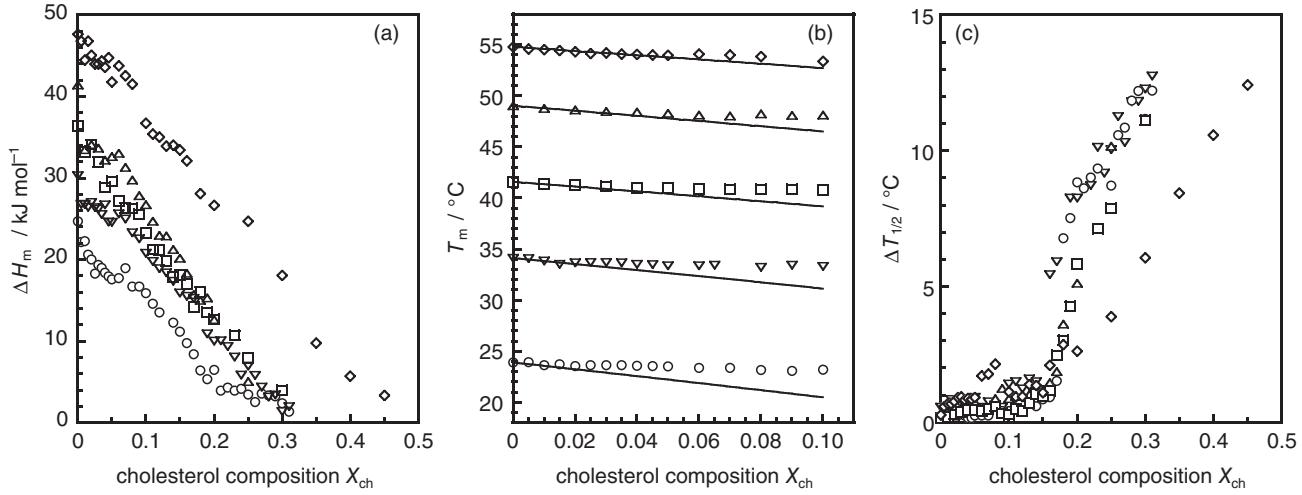

FIGURE 68.5 Cholesterol composition (X_{ch}) dependence of (a) enthalpy change with main transition (ΔH_m), (b) main transition temperature (T_m), and (c) peak width at half height ($\Delta T_{1/2}$) for C*n*PC–cholesterol binary bilayers (n = 14–18): (○) C14PC–cholesterol, (▽) C15PC–cholesterol, (□) C16PC–cholesterol, (△) C17PC–cholesterol, (◇) C18PC–cholesterol binary bilayer. In panel (b), solid lines represent the results of the calculation using the general thermodynamic relation of Eq. (68.1).

a liquid state, and (3) the molar enthalpy of fusion of the solvent in solution is invariant and equal to that of the pure solvent. As seen from Fig. 68.5b, the agreement between the experimental result and the calculated curve is recognized in a very dilute region for all the C*n*PC–cholesterol binary bilayers (n = 14–18). Therefore, these binary bilayers can be regarded as thermodynamically ideal binary mixtures in this dilute region; that is, the C*n*PC and the cholesterol molecules are almost completely immiscible in the P_β' phase while they are almost ideally miscible in the L_α phase. It is also interesting that there is a tendency concerning this dilute region; it extends to higher compositions with an increase in the acyl chain length [$X_{ch} \leq \sim 0.01$ (C14PC), $\leq \sim 0.02$ (C15PC and C16PC), $\leq \sim 0.03$ (C17PC), and $\leq \sim 0.04$ (C18PC)]. This may suggest that the miscibility of cholesterol and C*n*PC in the gel state becomes lower as the acyl chain of the host C*n*PC molecule becomes longer. On the other hand, when X_{ch} exceeds the upper limit of the dilute region, the experimental values begin to deviate from the calculated curve, which may be indicative that cholesterol becomes partially miscible with the C*n*PC bilayers even in the gel phase.

The X_{ch} dependence of $\Delta T_{1/2}$, as shown in Fig. 68.5c, suggests the possible existence of a threshold-like cholesterol composition around $X_{ch} = 0.15$ for all the C*n*PC–cholesterol binary bilayers (n = 14–18). The dependence changes drastically around this composition: the variation in $\Delta T_{1/2}$ with X_{ch} is relatively small in the X_{ch} region below ~0.15, whereas the $\Delta T_{1/2}$ value increases steeply with increasing X_{ch} in the X_{ch} region above ~0.15. The remarkable increase in $\Delta T_{1/2}$ in the higher X_{ch} region is consistent with the results of the Prodan fluorescence measurements; that is, the temperature range where the gradual increase in λ_{max} from 440 to 490 nm is observed becomes noticeably wider with increasing X_{ch} in the X_{ch} region above ~0.15. Therefore, it is reasonable to regard this X_{ch} of ~0.15 as a characteristic cholesterol composition related to some change in the phase behavior of these binary bilayers. Taking into account the fact that the reciprocal of $\Delta T_{1/2}$ is generally related to the cooperativity of the transition, the marked increase in $\Delta T_{1/2}$ in the X_{ch} region above ~0.15 indicates that the intermolecular cooperation when the chain melting occurs is considerably reduced in this X_{ch} region. It is discussed later on the basis of the compositional phase diagram what kind of change in the phase behavior causes the marked reduction in the intermolecular cooperation, but it is interesting that the change commonly occurs at almost the same composition in all the binary bilayers independent of the acyl chain length.

It may be useful to compare the above DSC results with several previous results. The DSC study by McMullen et al. [57] is one of the most systematic studies performed for a homologous series of C*n*PCs (n = 13–21). They have demonstrated that the endothermic peak is composed of a sharp and a broad component and also that the broad component remains until $X_{ch} = \sim 0.50$ while the sharp component fades out in the X_{ch} range between 0.20 and 0.25. In addition, their results showed that the $\Delta T_{1/2}$ value of the broad component increases steeply with increasing cholesterol composition above $X_{ch} = \sim 0.15$ for the C14PC– and the C16PC–cholesterol binary bilayer. Another team [54] also reported that the main transition of the C16PC–cholesterol

binary bilayer is eliminated at $X_{ch} = \sim 0.50$ while those of the C18PC– and the C20PC–cholesterol binary bilayer are not eliminated at the same X_{ch}. Our DSC results are qualitatively consistent with these previous results: the asymmetry of the endothermic peak becomes noticeable in the intermediate X_{ch} region and the $\Delta T_{1/2}$ value increases steeply with increasing X_{ch} in the X_{ch} region above ~0.15. On the other hand, quantitatively, they are not always in agreement with those previous calorimetric studies. With respect to the abolition of the main transition, the X_{ch} values estimated from Fig. 68.5a for these binary bilayers are overall lower than the values reported in those studies. This disagreement is presumably due to the uncertainty in accurately identifying the endothermic peak at higher X_{ch}. It is extremely difficult to determine the onset and the completion temperature accurately without any ambiguity for a broad endothermic peak with small height, especially when the peak height is small as compared to the variation or instability in the baseline. At least, the X_{ch} value estimated from our DSC results for the C16PC–cholesterol binary bilayer is supported by several recent studies using different techniques [87–89] that provide experimental evidence indicating that the homogeneous L_o phase is formed in the C16PC–cholesterol binary system above $X_{ch} = 0.33$.

68.5 PHASE DIAGRAMS OF C*n*PC–CHOLESTEROL BINARY BILAYERS

Figure 68.6 shows possible T–X_{ch} phase diagrams of all the C*n*PC–cholesterol binary bilayers (n = 14–18) constructed on the basis of the experimental results from the Prodan fluorescence and DSC measurements. In appearance, these phase diagrams resembles a typical solid–liquid phase diagram for a binary mixture that exhibits incongruent melting behavior, and this provides the information about important features of the phase behavior of these binary bilayers. First, it can be inferred from the shapes of the phase boundaries that cholesterol and these C*n*PCs are, on the whole, immiscible within the bilayer membranes below the eutectic temperature. Note that this never means the perfect immiscibility as assumed in Eq. (68.1). In fact, a noticeable increase in T_m with X_{ch} is observed in a higher X_{ch} region (X_{ch} > ca. 0.25) for the C*n*PC–cholesterol binary bilayers (n = 14–16). This increase in T_m is considered to correspond to the solidus line on each phase diagram. As described in a previous section, solidus and solvus lines appear in a solid–liquid phase diagram of a binary mixture that can form a homogeneous solid phase like a solid solution within a limited temperature range, whereas no solidus and no solvus lines exist on the solid–liquid phase

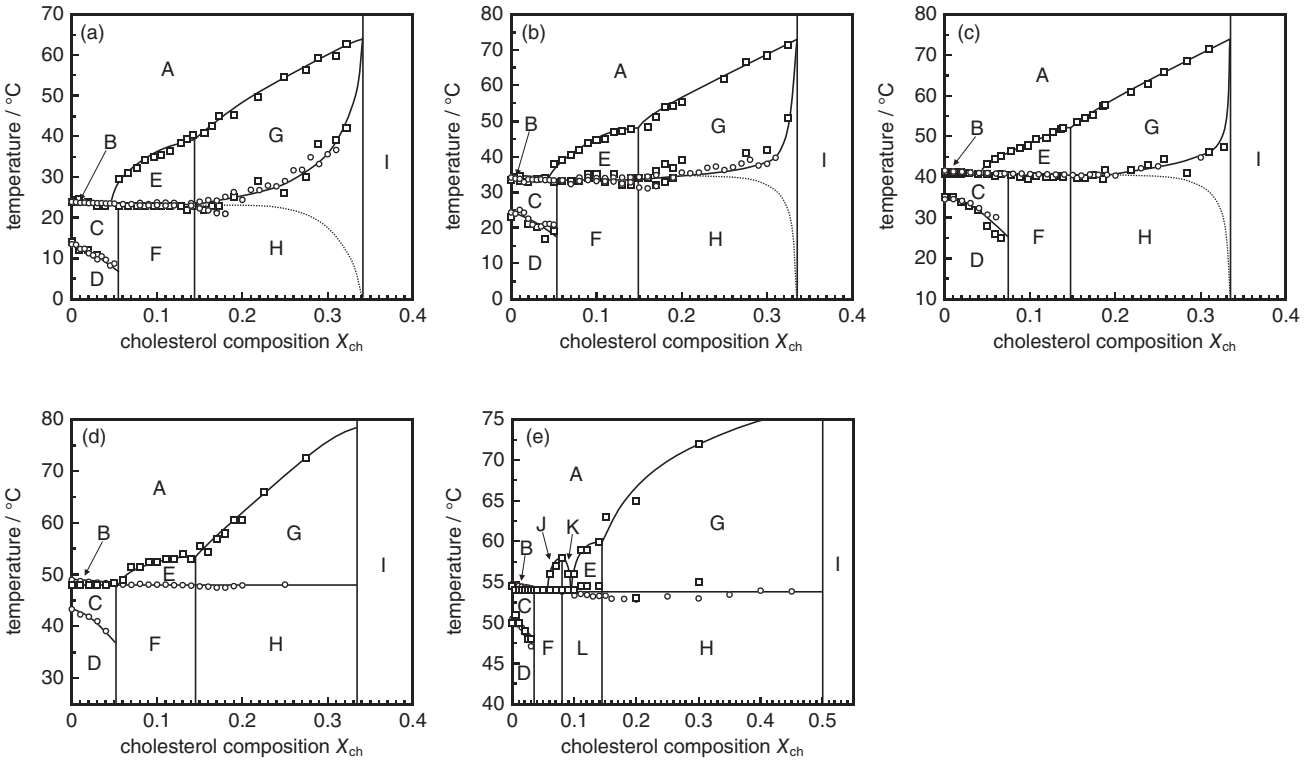

FIGURE 68.6 Temperature (T)–cholesterol composition (X_{ch}) phase diagrams of (a) C14PC–cholesterol, (b) C15PC–cholesterol, (c) C16PC–cholesterol, (d) C17PC–cholesterol, and (e) C18PC–cholesterol binary bilayer, all of which are constructed on the basis of the data from Prodan fluorescence (□) and DSC (○) measurements. See text for phase assignments.

diagram of the ideal binary mixture. Therefore, this increase in T_m can be interpreted as an indication of partial miscibility between the phase structures formed in the higher X_{ch} region in the C*n*PC–cholesterol binary bilayers ($n = 14$–16). On the other hand, such increase in T_m in the higher X_{ch} region is not clearly observed for the C17PC– and the C18PC–cholesterol binary bilayers, suggesting that in the case of these binary bilayers the phase structures formed in the higher X_{ch} region are almost immiscible with each other. Furthermore, it can be seen that there is a tendency among the variations in T_m of the respective binary bilayers: the increase in T_m in the higher X_{ch} region tends to be less noticeable as the acyl chain length of the host C*n*PC molecule increases, suggesting that the partial miscibility between the phase structures formed in the higher X_{ch} region tends to be lower as the acyl chain length increases. This is very interesting because this tendency is consistent with the tendency regarding the miscibility between C*n*PC and cholesterol deduced from the consideration on the decrease in T_m in the low-X_{ch} region.

Another feature of our phase diagram is that there is a characteristic point at $X_{ch} = \sim 0.15$ in each phase diagram. This point can be regarded as a point thermodynamically equivalent to the peritectic point on the basis of the fact that the phase diagrams of these C*n*PC–cholesterol binary bilayers are similar in shape to a typical solid–liquid phase diagram containing a peritectic point. In general, a peritectic point occurs as a result of incongruent melting, and as described in a previous section, this type of melting behavior is usually observed for such binary systems where the two components react to produce a solid compound with a specific stoichiometry that is stable in a solid state but unstable in a liquid state. The stoichiometry of the solid compound is also reflected in the compositional phase diagram; that is, an isopleth (i.e., a vertical line) always appears at the composition corresponding to the stoichiometry on the phase diagram. Taking this thermodynamic generalization into account, the presence of a peritectic point in our T–X_{ch} phase diagrams for all these C*n*PC–cholesterol binary bilayers ($n = 14$–18) suggests that a cholesterol molecule interacts with several C*n*PC molecules within the bilayer membrane to form a complex, or a molecular cluster, which is relatively stable below T_m but rather unstable above T_m. The stoichiometry of this complex can be presumed to be 1:6 (cholesterol:C*n*PC, $X_{ch} = 0.143$) independent of the acyl chain length, because the isopleth corresponding to the formation of this complex can be drawn at $X_{ch} = 0.15$ in our T–X_{ch} phase diagrams of all these binary bilayers on the basis of the X_{ch} dependence of $\Delta T_{1/2}$ (Fig. 68.5c). As described above, the dependence changes drastically around $X_{ch} = 0.15$, which suggests that this composition can be regarded as a threshold indicative of some drastic change in the phase behavior of the binary bilayer.

It is also a suggestive feature of our phase diagram that two or three other isopleths are drawn at characteristic X_{ch} in addition to that at $X_{ch} = 0.15$. The isopleths at the lowest and the highest X_{ch} on each phase diagram are relevant to the abolition of the pretransition and main transition, respectively. Although all these isopleths do not always signify the formation of complexes of cholesterol and C*n*PC, the concept of the complex formation is useful to estimate the average properties of the binary bilayers and to understand the X_{ch}-dependent phase behavior. Furthermore, the X_{ch}-dependent phase behavior can be linked with the distribution of cholesterol within the binary bilayer by applying the so-called *superlattice view* [90–92]. According to this view, cholesterol molecules tend to be distributed regularly within the binary bilayer and the distribution is well represented schematically by a typical hexagonal lattice. In fact, it has been reported as evidence for the regular distribution [93–102] that there are discontinuous changes in some measurable properties of the cholesterol-containing binary bilayers at specific cholesterol compositions. Figure 68.7 shows the schematic illustrations of several possible types of regular distributions of cholesterol within the binary bilayer using the hexagonal lattice, where an open circle and a closed circle on a lattice point represent a C*n*PC and a cholesterol molecule, respectively. Here, it should be noted that in the original superlattice model, either a cholesterol molecule or an acyl chain of a phospholipid molecule is assigned to a lattice point. However, we use simpler geometry (i.e., one molecule to one site) taking into account the fact that the cross-sectional areas of a fully extended hydrocarbon chain, a cholesterol molecule and a C*n*PC molecule have been roughly estimated at 0.20, 0.40, and 0.55–0.70 nm^2 (depending on X_{ch}) on insoluble monolayers or mixed monolayers, respectively [65, 66,103, 104]. The fundamental unit shown in Fig. 68.7a, for example, is composed of a cholesterol molecule and 30 C*n*PC molecules within the next-next-next-nearest-neighbor sites around the cholesterol molecule [i.e., Unit (1:30)], and when the binary bilayer is entirely occupied with only fundamental units of this type, the X_{ch} value is equal to 0.032. Similarly, the fundamental units shown in (b) and (c) of Fig. 68.7 are composed, respectively, of a cholesterol molecule and its surrounding 18 C*n*PC molecules [i.e., Unit (1:18)] and of a cholesterol and its 12 surrounding C*n*PC molecules [i.e., Unit (1:12)], and these units correspond to the X_{ch} values of 0.053 and 0.077, respectively. These X_{ch} values of 0.032, 0.053, and 0.077 are very close to the experimentally determined X_{ch} values of the abolition of the pretransition, respectively, for the C18PC–cholesterol binary bilayer (i.e., $X_{ch} = 0.03$–0.035), for the C14PC–, C15PC–, and C17PC–cholesterol binary bilayers (i.e., $X_{ch} = 0.05$–0.06) and for the C16PC–cholesterol binary bilayer (i.e., $X_{ch} = 0.07$–0.08). The abolition of the pretransition of the C*n*PC bilayer by the incorporation of cholesterol is generally attributed to the conversion of both L_β' and P_β' phases into an L_β-like phase induced by the presence of cholesterol, where the orientation of the acyl chains of the C*n*PC molecules is more perpendicular to the bilayer surface [57]. Therefore, this cholesterol effect of inducing such

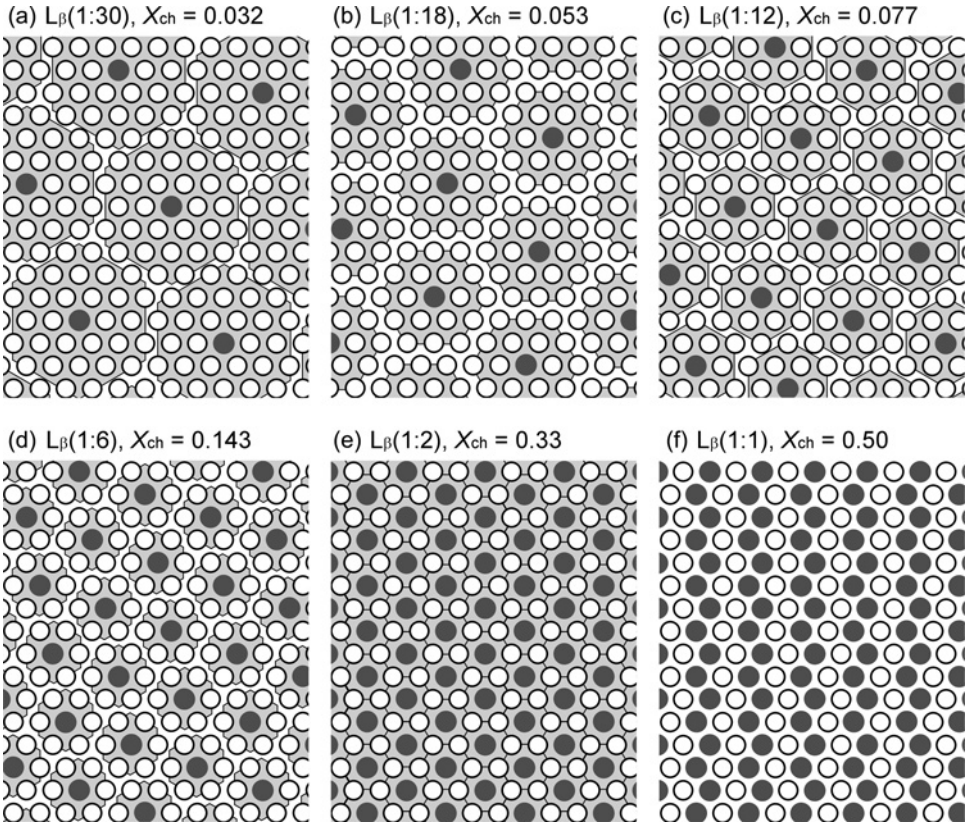

FIGURE 68.7 Schematic illustration of various types of regular distribution of cholesterol in binary bilayers based on hexagonal lattice model. A closed circle and an open circle represent a cholesterol and a C*n*PC molecule, respectively. A fundamental unit is indicated as a dark shaded area around a cholesterol molecule in each panel: (a) L_β (1:30) state ($X_{ch} = 0.032$) composed of only one unit [Unit (1:30)]; (b) L_β (1:18) state ($X_{ch} = 0.053$) composed of only unit [Unit (1:18)]; (c) L_β (1:12) state ($X_{ch} = 0.077$) composed of only one unit [Unit (1:12)]; (d) L_β (1:6) state ($X_{ch} = 0.143$) composed of only one unit [Unit (1:6)]; (e) L_o state ($X_{ch} = 0.333$) composed of only one unit [Unit (1:2)]; (f) L_o state in C18PC–cholesterol binary bilayer ($X_{ch} = 0.50$).

perpendicular orientation is presumed to propagate, on average, over the 30 C*n*PC molecules around a cholesterol molecule in the case of the C18PC–cholesterol binary bilayer, over the 18 C*n*PC molecules around a cholesterol molecule in the case of the C14PC–, C15PC–, and C17PC–cholesterol binary bilayers and over the 12 C*n*PC molecules around a cholesterol molecule in the case of the C16PC–cholesterol binary bilayer. Hereafter, we use the notation of L_β (1:*p*) to represent those gel states of the binary bilayers composed only of Units (1:*p*), as shown in Fig. 68.7. Note that all the L_β (1:*p*) phases with different *p* values given in Fig. 68.7 are regarded as thermodynamically different phases in respect of the interaction between the C*n*PC and cholesterol molecules, although the acyl chains of all the constituent C*n*PC molecules are oriented perpendicular to the bilayer surface in any L_β (1:*p*) phase.

Figure 68.7 also gives the schematic illustrations of three different types of distributions of cholesterol within the binary bilayer. Two of these three types correspond to other types of regular distributions, each of which is based on Unit (1:6) and Unit (1:2), as shown in (d) and (e) of Fig. 68.7, respectively. The other represents a distribution state of the binary bilayer composed of the 1:1 complexes of cholesterol and C*n*PC (Fig. 68.7f), and does not correspond, in a strict sense, to the superlattice. However, it can be regarded as virtually equivalent to a type of regular distribution, because an ample amount of cholesterol molecules are distributed almost homogeneously all over the binary bilayer. As apparent from the stoichiometry, Unit (1:6) is in accordance with the 1:6 complex of cholesterol and C*n*PCs deduced from the presence of a peritectic point on all the phase diagrams shown in Fig. 68.6, which means that the formation of the 1:6 complex does not conflict with the superlattice view. In this state, the orientation of the hydrocarbon chains of all the C*n*PC molecules within the binary bilayer is expected to be still perpendicular to the bilayer surface. Taking this into

account, we denote this phase state of the C*n*PC–cholesterol binary bilayer as L_β (1:6). As described above, this L_β (1:6) phase is a thermodynamically distinct phase from the other L_β (1:*p*) phases in terms of the molecular interaction between cholesterol and C*n*PC. As for Unit (1:2), it is obvious that the X_{ch} value becomes 0.33 when the binary bilayer is occupied entirely with this type of fundamental units. This X_{ch} value of 0.33 is very close to the experimental X_{ch} value for the abolition of the main transition of all the C*n*PC–cholesterol binary bilayers except the C18PC–cholesterol binary bilayer. The abolition of the main transition is generally considered to be due to the complete formation of the L_o phase within the binary bilayer membrane. Therefore, the L_o phase is presumed to be a homogeneous state composed by Units (1:2) as illustrated in Fig. 68.7e, where the thermally induced *trans–gauche* conformational changes in the acyl chains of all the C*n*PC molecules are completely suppressed by the cholesterol–C*n*PC interaction. In the C18PC–cholesterol binary bilayer, on the other hand, the main transition persists to $X_{ch} = 0.50$. Therefore, it can be said that the L_o phase formed in the C18PC–cholesterol binary bilayer corresponds to the homogeneous state where the 1:1-complexes of cholesterol and C18PC are distributed uniformly over the binary bilayer.

The above consideration of the X_{ch}-dependent phase behavior of a series of C*n*PC–cholesterol binary bilayers and the distribution of cholesterol within the binary bilayer may be somewhat speculative, but it is supported by several recent studies on the effects of cholesterol on the structure and properties of phospholipid bilayers. For example, other authors [105] have reported that the formation of the complexes containing large numbers of molecules in the binary bilayer is rationalized by the thermodynamic calculation based on the extended condensed complex model. Another team [106] also reported that the formation of complexes of cholesterol and constituent phospholipids is indicated by the disagreement between the calculated and the experimental values of the ratio of the translational diffusion coefficient to the rotational diffusion coefficient. Finally, the phase assignments based on the above consideration are given below. For the phase diagrams of the C14PC–, C15PC–, and C17PC–cholesterol binary bilayers, each of the areas labeled A to I in the phase diagram shown in Fig. 68.6 is assigned as follows: (A) L_d phase, (B) $L_d + P_\beta'$, (C) $P_\beta' + L_\beta$ (1:18), (D) $L_\beta' + L_\beta$ (1:18), (E) $L_d + L_\beta$ (1:6), (F) L_β (1:18) + L_β (1:6), (G) $L_d + L_o$, (H) L_β (1:6) + L_o, and (I) L_o. The same assignment is applicable to the phase diagram of the C16PC–cholesterol binary bilayer by replacing L_β (1:18) with L_β (1:12). In addition, it is also applicable to that of the C18PC–cholesterol binary bilayer except for the following: (C) $P_\beta' + L_\beta$ (1:30), (D) $L_\beta' + L_\beta$ (1:30), (F) L_β (1:30) + L_β (1:12), (J) $L_d + L_\beta$ (1:12), (K) $L_d + L_\beta$ (1:12), and (L) L_β (1:12) + L_β (1:6). Regarding the gel-phase structure, an X-ray diffraction study [107] has revealed that the periodically undulated structure (i.e., ripple structure) is observed for the C14PC– and the C16PC–cholesterol binary bilayers, and most part of the gel phase region in their phase diagram has been identified as P_β or P_β' phase on the basis of those structural data. However, such ripple structure can be also formed in the L_β'- L_β coexisting state.

68.6 ACYL CHAIN LENGTH DEPENDENCE OF CHARACTERISTIC CHOLESTEROL COMPOSITIONS

In the previous section, we described the X_{ch}-dependent phase behavior of a series of C*n*PC–cholesterol binary bilayers ($n = 14$–18) in connection with the distribution of cholesterol within the binary bilayer deduced from several characteristic X_{ch} values observed on the T–X_{ch} phase diagrams by applying the superlattice view. In this section, we discuss how the cholesterol effect on such X_{ch}-dependent phase behavior is affected by the variation in the acyl chain length *n* of the host C*n*PC molecules. First, we would like to briefly mention the miscibility of cholesterol and these C*n*PCs in the binary bilayer. As described above, our phase diagrams suggest that there is a qualitative tendency that the miscibility between them becomes slightly lower as the acyl chain length increases. This may be attributed to the fact that the van der Waals interaction between the acyl chains of the adjacent C*n*PC molecules in the bilayer becomes stronger with an increase in the acyl chain length, because in general two components in a binary mixture tend to separate out when the molecular interaction between the same species becomes stronger.

Figure 68.8 shows the acyl chain length dependence of the two characteristic X_{ch} values: one is the X_{ch} at which

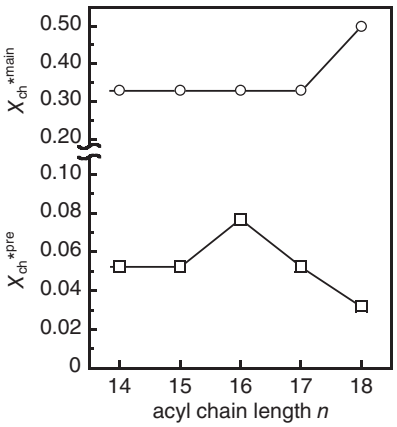

FIGURE 68.8 Acyl chain length (*n*) dependence of X_{ch}^{*main} (○), specifically, the cholesterol composition at which the main transition is abolished, and of X_{ch}^{*pre} (□), that is, the cholesterol composition at which the pretransition is abolished.

the main transition is abolished (X_{ch}^{*main}) and the other is the X_{ch} at which the pretransition is abolished (X_{ch}^{*pre}). As seen from the figure, the X_{ch}^{*main} value is constant at ca. 0.33 independent of n for $n = 14$–17, whereas it increases to ca. 0.50 at $n = 18$. As described above, this X_{ch}^{*main} value of ca. 0.33 for CnPC ($n = 14$–17) is surely low as compared to those from previous calorimetric studies [54,57], but the n-dependence of X_{ch}^{*main} shown in Fig. 68.8 is partly consistent with the tendency observed in each of those previous calorimetric studies; the constant X_{ch}^{*main} value for $n = 14$–17 is consistent with the results in Ref. 57, and the increase in X_{ch}^{*main} at $n = 18$ is consistent with the results in Ref. 54. Furthermore, this n-dependence of X_{ch}^{*main} can be successfully explained by the view proposed in Ref. 57. According to that view, there is no marked dependence on the acyl chain length of the host CnPC molecule in the effect of cholesterol on the thermotropic bilayer phase behavior of CnPCs with few exceptions, and the exceptions arise chiefly from the mismatch in the effective length of the hydrophobic region between cholesterol and CnPC in the bilayer. Taking into account the fact that this hydrophobic mismatch is minimized at $n = 17$ [57], the increase in X_{ch}^{*main} to ~0.50 at $n = 18$ can be interpreted as due to the reversal of the hydrophobic mismatch. Thus, in the case of CnPC with shorter acyl chains ($n \leq 17$), it is expected that the acyl chains of the CnPC molecules around a cholesterol molecules tend to be forcibly extended to minimize the hydrophobic mismatch, and consequently, the incorporation of the relatively small amount of cholesterol (i.e., at lower X_{ch}) can induce the homogeneous L_o phase within the entire binary bilayer. On the other hand, for $n \geq 18$, as has been discussed in Ref. 54, the hydrophobic mismatch can create a free volume in the middle of the bilayer, which is energetically unfavorable. This could contribute negatively to the complete suppression of the melting of the acyl chains, because the ends of the acyl chains would tend to have a kink to minimize the unfavorable effect of the voids. As a result, the relatively large amount of cholesterol is required to abolish the main transition of the bilayer of CnPC with longer acyl chains ($n \geq 18$).

As for X_{ch}^{*pre}, it is understandable that the acyl chain length dependence is biphasic: X_{ch}^{*pre} increases with an increase in the acyl chain length up to $n = 16$, whereas it decreases with an increase in the acyl chain length for $n \geq 16$. As described above, the abolition of the pretransition by the incorporation of cholesterol is thought to be due to the induction of an L_β-like orientation. Therefore, the biphasic n dependence of X_{ch}^{*pre} suggests that there are at least two antagonistic acyl-chain-length-dependent factors involved in the process of the induction of the L_β-like orientation: a factor that accelerates the induction of the L_β-like orientation when the acyl chains of the host CnPC molecule increase in length and the other one that promotes it when they decrease in length. Although the molecular mechanism of the induction of the L_β-like orientation by cholesterol has not yet been fully revealed, we currently speculate as follows. Van der Waals interaction is one of the most dominant interaction acting between the neighboring phospholipid molecules in the bilayer and tends to be stronger as the acyl chains becomes longer. The stronger van der Waals interaction is expected to facilitate wider propagation of the cholesterol effect of inducing the L_β-like orientation, and as a result, a smaller amount of cholesterol is required to induce the L_β-like orientation within the entire binary bilayer as the acyl chain length increases. This means that the pretransition is abolished completely at a lower X_{ch} as the acyl chain length increases. Second, we should also take the hydrophobic mismatch into account as an essential factor. In fact, the n value of 16, at which X_{ch}^{*pre} reaches maximum, is very close to that for the minimum hydrophobic mismatch (i.e., $n = 17$). The bilayer of CnPC with shorter acyl chains ($n < 17$) does not have a sufficient thickness of hydrophobic core to accommodate the cholesterol molecule, and thus, the cholesterol molecules are expected to be relatively forced out toward the bilayer surface as compared with those in the bilayer of CnPC with longer acyl chains ($n \geq 17$). This relative protrusion of the cholesterol molecule will inevitably become greater with a decrease in the acyl chain length for $n < 17$, which can interfere with repulsive interaction between the adjacent choline headgroups of the host CnPC molecules. The weakening of the repulsion will contribute to wider propagation of the cholesterol effect of inducing the L_β-like orientation. As a result, the hydrophobic mismatch for $n < 17$ can also cause the reduction in the amount of cholesterol needed to induce the L_β-like orientation within the entire binary bilayer. This can be the other factor that accelerates the induction of the L_β-like orientation as the acyl chain length decreases.

Finally, we mention a third characteristic X_{ch} value of 0.14. This X_{ch} value is relevant to the 1:6 complex of cholesterol and CnPCs, and the formation of this type of complex is common to all the CnPC–cholesterol binary bilayers ($n = 14$–18). This means that there is no definite n dependence in this characteristic X_{ch}. In addition, as seen from the T–X_{ch} phase diagrams shown in Fig.68.6, the L_o phase begins to be formed within the binary bilayers at this composition; that is, this characteristic X_{ch} corresponds to the minimum composition for the formation of the L_o phase. As far as we know, there have been no reports discussing the minimum composition for the formation of the L_o phase in connection with the molecular structure of constituent phospholipids. At present, we do not fully understand the physical and chemical origins of the formation of the 1:6 complexes within the binary bilayers regardless of the acyl chain length, as well as how relevant those origins are to the minimum composition for the formation of the L_o phase, but this result will support the applicability of the superlattice view based on the hexagonal lattice for all these binary bilayers.

68.7 SUMMARY

In this chapter, we described the phase behavior of the cholesterol-containing binary bilayers of a homologous series of C*n*PCs (n = 14–18) on the basis of the T–X_{ch} phase diagrams constructed by means of Prodan fluorescence and DSC. Our phase diagrams exhibited several significant features of the thermotropic phase behavior of these binary bilayers. First, the presence of a peculiar point like a peritectic point at $X_{ch} = \sim 0.15$ was indicated for all these binary bilayers. This finding indicates that these binary bilayers commonly exhibit peritecticlike melting behavior with the formation of 1:6 complexes of cholesterol and C*n*PCs, and not simple eutectic melting behavior, regardless of the acyl chain length. This characteristic X_{ch} was also found to correspond to the minimum composition for the formation of the L_o phase within the binary bilayer. Second, two more significant X_{ch}, in addition to this characteristic X_{ch} of 0.15, were seen in each phase diagram: the X_{ch} at which the main transition is abolished (i.e., ${X_{ch}}^{*main}$) and the X_{ch} at which the pretransition is abolished (i.e., ${X_{ch}}^{*pre}$). Although these characteristic X_{ch} values do not always suggest the formation of molecular complexes, they could be well explained by applying the concept of the complex formation based on the superlattice view (i.e., regular distribution of cholesterol within the binary bilayer). The distribution states of cholesterol and C*n*PC molecules at those characteristic X_{ch} were successfully represented by schematic illustrations using the hexagonal lattice, in each of which a single type of fundamental unit is contained depending on the X_{ch} value [e.g., Unit (1:30) for X_{ch} = 0.032, Unit (1:18) for 0.053, Unit (1:12) for 0.077]. These illustrations are also applicable to explain the two-phase coexisting state at an intermediate X_{ch}. Third, it was suggested from the change in the shape of the phase boundaries with the acyl chain length of the host C*n*PC molecule that there is a qualitative tendency for the miscibility cholesterol and C*n*PC to become slightly lower as the acyl chain length increases. This is presumably due to the fact that the van der Waals interaction between the acyl chains of adjacent C*n*PC molecules becomes stronger as the acyl chain length increases.

We also considered the acyl chain length dependence of ${X_{ch}}^{*main}$ and ${X_{ch}}^{*pre}$ in this chapter. The ${X_{ch}}^{*main}$ value was almost constant at 0.33 for n = 14–17, whereas it increased to ~0.50 at n = 18. This increase in ${X_{ch}}^{*main}$ at n = 18 can be explained in terms of the mismatch in the effective length of the hydrophobic region between the cholesterol and the C*n*PC molecule. As for ${X_{ch}}^{*pre}$, on the other hand, biphasic acyl chain length dependence was seen: it increased with an increase in the acyl chain length for $n \leq 16$, whereas it decreased with an increase in the acyl chain length for $n \geq 16$. Since the abolition of the pretransition is generally considered to be due to the induction of more perpendicular orientation of the acyl chains with respect to the bilayer surface (i.e., L_β-like orientation), this biphasic acyl chain length dependence suggests that there are at least two antagonistic acyl-chain-length-dependent factors involved in the process of the induction of the L_β-like orientation. A possible explanation for this is as follows. Increasing van der Waals interaction would contribute to wider propagation of the cholesterol effect of inducing the L_β-like orientation, which results in a decrease in ${X_{ch}}^{*pre}$ with an increase in acyl chain length. On the other hand, the location of the cholesterol molecule in the direction of bilayer depth is expected to move nearer to the bilayer surface as a result of the mismatch in the effective length of the hydrophobic region as the acyl chain length decreases for $n < 17$. This would weaken the repulsion between the neighboring choline headgroups, and this repulsion weakening would also contribute to wider prevalence of the cholesterol effect. As a result, ${X_{ch}}^{*pre}$ decreases with a decrease in the acyl chain length for $n < 17$.

69.1 INTRODUCTION

Various studies have been carried out to address structures and phase behavior of amphiphiles in aqueous solutions [1–3]. This interest is due to the vital role played by amphiphiles in industry as well as in biophysics, biotechnology, and pharmacology [4,5]. An amphiphilic molecule consists of two parts: solvent-loving (solvophilic/hydrophilic, in the context of water as solvent) and solvent-repelling (solvophobic/hydrophobic) parts. The sizes of both parts, as well as their shape and the hydrophilic–hydrophobic balance (HHB) [2,6], determine their self-assembly and ensuing fascinating physical properties. The presence of discrete hydrophilic and hydrophobic parts is, however, a prerequisite for self-assembly. The aggregates formed by the amphiphiles are commonly known as *micelles*, which are primarily the result of hydrophobic interactions [7]. The mean size of these aggregates (or micelles) is 1–100 nm. Micelles are dynamic as amphiphile monomers can exchange between the micelles and bulk phase. The threshold concentration at which the aggregates form [the so-called critical micelle concentration (cmc)], and the size, shape, and nature of the aggregates depend on the solution conditions as well as the nature of the amphiphile. The cmc values of nonionic amphiphiles are usually lower than those of ionic ones because of the absence of charge in the former ones. Similarly, block copolymers and triblock polymers also form aggregates, called *polymeric micelles*. Their size varies between 20 and 50 nm and they are relatively more stable than the surfactant micelles.

On the basis of their structure, the amphiphilic molecules may be classified into the following four categories: (1) flexible chain compounds (surfactants, etc.), (2) aromatic or heterocyclic ring or fused structures (dyes, drugs, etc.), (3) alicyclic compounds (bile salts, etc.), and (4) macromolecules (polymers, proteins, etc.) [8]. On the basis of studies of different features of molecular structure that influence the association pattern of amphiphiles, one researcher [8, 9] suggested that a high degree of flexibility and distinct polar and nonpolar parts are the necessary requirements of micellization. Rigid ring structures such as those found in cationic dyes and purines/pyrimidines result in face-to-face stacking in a continuous association pattern. In cationic dyes, the charge is delocalized in the ring system, and in purines/pyrimidines the structure is not flexible. Structures of amphiphilic drugs are intermediate to these two groups; although they have aromatic/heteroaromatic rings in their hydrophobic parts, they also have flexibility/rigidity in the molecules; and their charge is normally localized at a terminal group of a sidechain. These drugs belong to the families of phenothiazine and benzodiazepine tranquilizers, analgesics, peptide and nonpeptide antibiotics, tricyclic antidepressants, antihistamines, anticholinergics, β-blockers, local anesthetics, and nonsteroidal anti-inflammatory drugs [10–13]. Their aggregation is dependent on concentration, temperature, and pH. Some of these drugs form micelle-like aggregates; others associate by continuous stacking [14] with small aggregation numbers [10,15]. Their site of action is usually the plasma membrane. Even if their target is intracellular, they first interact with plasma membrane, resulting in various effects that have been studied in detail using a variety of spectroscopic [viz., electron paramagnetic resonance (EPR), nuclear magnetic resonance (NMR), fluorescence, Fourier transform infrared, circular dichroism (CD)] and biophysical [viz., X-ray and neutron diffraction, differential

scanning calorimetry (DSC), titration calorimetry, monolayer] techniques.

Undoubtedly, there are numerous drugs in the market (and every day new therapeutic agents are identified and/or synthesized), but the successful development of the field of pharmaceutics has been hampered by the requirement of a drug delivery system (DDS) for their safe delivery to the site of action. In addition to the solubility enhancement of the newly developed therapeutic agents (as they are hydrophobic, almost 50% are never marketed mainly because of their solubility, and hence, bioavailability problems), the properties of the many currently existing drugs could be improved with the use of an effective DDS. Hence, to increase their bioavailability and to protect them from degradation (hydrolysis and enzymatic decomposition), these drugs must be administered with carriers in the form of micelles (surfactant/ polymeric), liposomes, niosomes, cyclodextrin inclusion complexes, liquid crystalline phase, microemulsions, and self-emulsifying drug delivery systems [16–22]. In this context micelles and mixed micelles show great promise as DDSs as these systems are easy to prepare, have a long shelf life, and have low toxicity [23], and, above all, the size of such DDSs as well as drug loading can be tuned according to the need.

Another type of drug carrier is the biosurfactants, the bile acid salts [24]. Bile salts, when mixed with AMT or ADP, decrease the cmc of the drug–bile salt mixtures [25,26]. Here also a very small amount of bile salts is needed, because of their comparatively greater contribution in mixed micelles.

It is well documented that the presence of surfactants in DDS could change the physicochemical properties of drugs, such as their aqueous solubility [27], stability [28], bioactivity [29], skin penetration [30], and bioavailability. In general, nonionic surfactants (due to their low cmc values, better stability, biocompatibility, minimum binding to proteins, and extremely low hemolytic activity [31]) are considered as better DDSs than ionic surfactants [32]. However, ionic surfactants with positive charge (cationics) are considered as more efficient membrane permeation enhancers than anionic or nonionic ones, although cytotoxicity of cationics is more than that of the other two types [33, 34]. Among cationics, alkylammonium bromide gemini surfactants are known to efficiently modulate the order of bioavailability [35].

Recently, there has been increased interest in the development of drug delivery systems with improved properties and effectiveness as well as reduced side effects of drugs. The aim of any DDS is to (1) increase the solubility and stability of drugs in vivo, (2) improve bioavailability, and (3) reduce side effects. Various DDSs have been developed depending on the route of administration, which is selected on the basis of biological properties of therapeutic agent as well as on the pathological condition being approached. Development of pharmaceutical formulations is a complex and time-consuming process involving the application of various aspects of physical chemistry, microbiology, and engineering [36, 37]. The process requires an in-depth understanding of the physicochemical properties of the drug (e.g., stability toward degradation), its detailed thermodynamic solubility data, and the solution properties of the final formulation. The capability of a drug solution to micellize or self-aggregate along with the effect of excipients on this phenomenon imparts product design [3,38] and is an important parameter to reckon with [3].

69.2 DRUG-DDS INTERACTIONS: EFFECT OF TEMPERATURE ON SOLUTION

A common observation for a solution of nonionic surfactants/polymers (and ionic surfactants under special conditions [39–43]) is that, on heating, the solution (at a well-defined temperature range) starts to scatter light strongly; it becomes cloudy. The isotropic solution region is bordered, at higher temperatures, by a lower consolute curve, above which there is a phase separation into one surfactant-rich solution and one surfactant-poor solution (Fig. 69.1). The onset of phase separation is manifested by a cloudiness of the solutions accompanied by strong scattering of light due to critical fluctuations. At cloud point (CP) a single isotropic micellar phase spontaneously turns cloudy and, on standing, separates into two phases—one very small in volume composed almost totally of surfactant with a small amount of water, referred to as the *surfactant-rich phase*, and another aqueous phase containing a concentration of surfactant close to cmc (referred to as *surfactant-poor*). The process of clouding is reversible, and when the temperature falls below the CP, the two phases merge to form a clear solution. The phase-to-volume ratio, that is, the ratio of the volume of the aqueous phase to that of the surfactant coacervate phase following the phase separation step, can be very high in such systems ($\leq$1:0.007) [44].

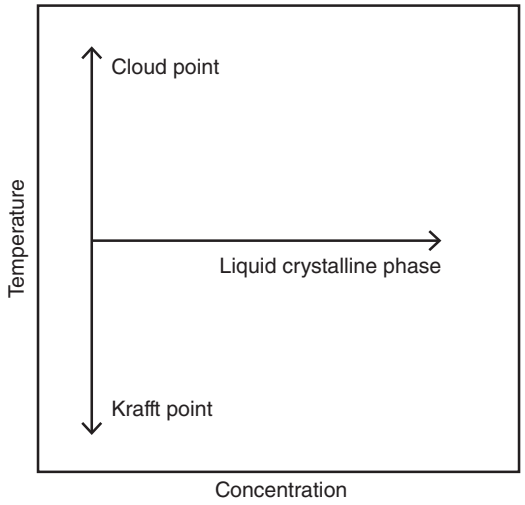

FIGURE 69.1 Schematic temperature–concentration phase diagram showing the types of aggregates encountered by moving away from the micellar region.

From simple thermodynamics, the primary reason for the CP behavior of nonionic surfactants is that the water around a polyoxyethylene chain (of amphiphiles) is more structured than bulk water; it has a lower enthalpy and entropy than bulk water. Existence of CP implies that the heat of mixing of the polyoxyethylene chain with water below the CP is exothermic. As the temperature increases, the hydration shells of two neighboring chains overlap, water is forced to leave these shells, and both the enthalpy and entropy of the system increase. At elevated temperature, the entropy gain in this destructuring of water is high enough to overcome the repulsive enthalpy contribution and the loss in entropy due to increased concentration—at this stage phase separation occurs.

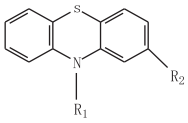
It has been shown [45, 46] that few mixed nonionic and ionic surfactant solutions show preclouding; solutions first become faintly turbid and then fully clouded at a higher temperature. This phenomenon is generally called a *double cloud point* or an *apparent cloud point* [47]. Maclay [47] was the first to report it in 1956. A solution containing a nonionic surfactant and a small amount of an ionic surfactant will contain both charged and uncharged aggregates, with the former incorporating one or more ionic species. As the temperature is raised, these micelles coalesce to form large bodies of either two uncharged micelles or a charged micelle and an uncharged micelle. Two charged micelles could not be expected to coalesce because of mutual repulsion. This process results in aggregates that are all charged and therefore do not coalesce further, constituting a relatively stable suspension. The size of such aggregates is dictated by the relative proportions of the two types of surfactants and, hence, the resulting suspension will be colloidal only for certain compositions. These solutions correspond to the ones that undergo preclouding.

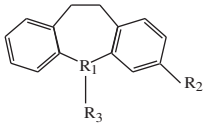
Reports in the literature reveal that phase separation can also occur in cyclodextrin- containing solutions, in reverse micellar systems, and in microemulsions [48–50].

Some nonionic surfactants, including dimethyldecylphosphine oxide, dimethyldodecylphosphine oxide, dimethyloleylamine oxide, tetraoxyethylene decyl ether, and pentaoxyethylene decyl ether, show a different type of clouding [51–53]. The phase-separated solutions again mix at higher temperatures of around 170–300°C, and the temperature – concentration phase diagram is a closed-loop type.

The CP depends strongly on both the polyoxyethylene chain length and hydrophobe size, although the effect of the hydrophobe size is marginal. It also depends on micellar size, which varies with the structure and nature of surfactant. A high micellar aggregation number is found to be equivalent to a high degree of polymerization of a polymer and thus gives a low cloud point.

The mechanism of phase separation is not fully understood yet. Some authors have discussed it in terms of an increase in the micellar aggregation number with the increase in temperature [54, 55]. One group of investigators [56–58] explained their SANS and viscosity results on nonionic surfactants through micellar growth. They found that with increase in temperature, spherical micelles change to rod-shaped ones that become so large that the solution becomes visibly turbid. However, the large scattering cross section in SANS results could be due to long-range concentration fluctuations, and some researchers have suggested change in micellar interactions, which changes from repulsive to attractive when temperature is increased [47,59,60]. Another team [61, 62] interpreted their SANS and light-scattering results by assuming attractive interactions among micelles with increasing temperature; the shape of micelles remained spherical throughout. The fact that addition of salts in nonionic surfactants increases the CP also supports the role of attractive interactions in producing CP.





Some other authors attributed this phenomenon to the dehydration of polyoxyethylene chains as the temperature is increased [63–65]. This dehydration is thought to be induced by the conformational change of the surfactant chains with increase in temperature [66, 67]. Also, with increasing temperature, the dielectric constant of water decreases, making it a poor solvent for the hydrophilic parts of the surfactants. Another team [68] studied the solution behavior of thermoresponsive polymer using differential scanning calorimetry (DSC) and found that the bound water plays an important role in its phase separation process.

Attempts have also been made to apply Flory–Huggins theory for polymer solutions [69–72]. Rupert [72] also interpreted the phase separation as a result of change in balance between the hydrophilic and hydrophobic interactions among micelles as well as with surroundings. Hence, any factor that can change this balance can change the CP of the systems also.

Another point that is still unclear is the nature of micellar solutions. In the low- concentration region the solution contains micelles, but at very high concentrations micelles cannot persist [73]. In micellar solutions above CP, it is usually stated in the literature that in surfactant-rich areas no micelles are present as the surfactants are segregated from the aqueous phase. However, there are many reports that provide evidence for the existence of different structures such as micelles, lamellae, or hexagonal structures [74, 75]. At temperatures high above the CP, the dilute phase becomes increasingly dilute and the concentrated phase may become nonmicellar [73].

Amphiphilic drugs of the families of tricyclic antidepressants and phenothiazines, like surfactants, also undergo phase separation. Drugs of these families are chemically similar (see Table 69.1), containing a planar tricyclic ring system as a hydrophobic part and a short alkylamine part as hydrophilic portion. The pK_a values of these drugs range between 9.1 and 9.5 [76–80]. The nature and charge of these drugs are pH-dependent. At low pH values the N atom of amine acquires a positive charge, whereas at high pH values it becomes neutral.

TABLE 69.1 Amphiphilic Drugs Used and Their Basic Properties

Class	Name of drug	Abbreviation used in text	Structure	CP (°C)	Ref.
Phenothiazine					
	Promazine HCl	PMZ	$R_1 = -CH_2CH_2CH_2N(CH_3)_2$; $R_2 = H$	33 at 50 mM and pH = 6.7	122
	Chlorpromazine HCl	CPZ	$R_1 = -CH_2CH_2CH_2N(CH_3)_2$; $R_2 = Cl$	38 at 50 mM and pH = 6.7	90
	Promethazine HCl	PMT	$R = -CH_2CH(CH_3)N(CH_3)_2$; $R_2 = H$	26 at 50 mM and pH = 6.7	118
Tricyclic antidepressant					
	Imipramine HCl	IMP	$R_1 = N$; $R_2 = H$; $R_3 = CH_3–CH_2–CH_2–N(CH_3)_2$	49 at 100 mM and pH = 6.7	138
	Clomipramine HCl	CLP	$R_1 = N$; $R_2 = Cl$; $R_3 = CH_2–CH_2–CH_2–N(CH_3)_2$	32 at 50 mM and pH = 6.25	95
	Amitriptyline HCl	AMT	$R_1 = C$; $R_2 = H$; $R_3 = >CH–CH_2–CH_2–N(CH_3)_2$	25 at 50 mM and pH = 6.7	107
	Nortriptyline HCl	NOT	$R_1 = C$; $R_2 = H$; $R_3 = >CH–CH_2–CH_2–NH(CH_3)$	45 at 30 mM and pH= 7.07	119

The preceding discussion pertaining to mechanism of clouding in pure (or almost pure) systems is given as a prelude to the CPs observed in drug systems. Here, too, the phenomenon is related to hydration/dehydration of the entities, as well as their charge, concentration, size and shape, and other properties. In developing liquid formulations of these drugs, their CPs can be the key parameter as the normal body temperature is 12° above ambient. Phase separation of drug formulation under elevated temperatures such as in steam sterilization of parenteral product often leads to content heterogeneity. In the case of dispersed dosage forms, phase separation can result in physical instability. If the CP of pure drug is above room temperature, it may be close to physiological temperature. Also, it may change because of the presence of other components of the formulation (the pharmaceutical excipients). Human blood plasma has a pH close to 7.4. In some diseases pH may increase or decrease [81], which can also induce phase separation in the drug formulation administered during this time. All these points indicate that the effect of solution properties (effect of pH, buffer) of those additives that may be found in the body and of different pharmaceutical excipients on the clouding phenomenon in drug solutions is crucial in the rational design of more effective DDSs. Pharmaceutical excipients are the constituents of a drug formulation that are added in order to increase the stability, solubility, or bioavailability of the formulation. These are also used as preservatives and flavorings. Although they do not produce a medical effect, they cannot be considered as inert, as they can alter the physical properties of drugs, as can cmc and CP. Because clouding is concentration-dependent, it is essential to have a knowledge of clouding behavior of drugs under varying conditions of concentration, pH, and presence of additives. As the literature on the phase separation phenomenon in amphiphilic drugs is scarce, this chapter mainly summarizes the work done by our group on four antidepressants (AMT, NOT, IMP, CLP) and three phenothiazines (PMT, PMZ, CPZ) (for abbreviations, see Table 69.1). The experimental results shown in the figures are for PMT (50 mM). The CP values of pure drugs in SP buffer at the concentration used are listed in Table 69.1.

69.2.1 Effect of pH/Concentration

As per the requirement within a 24-h period, the body pH changes from a weak acid to a weak base. The question is then how pH may affect the phase behavior of a drug. One team [82, 83] observed a CP of ∼50°C for aqueous solution of 200 mM of AMT ($pK_a = 9.4$). They used sodium phosphate (SP) buffer and varied its concentration to see its effect on CP in terms of AMT. In yet another article, AMT concentration was varied at two SP concentrations of 10 mM and 500 mM [84]. They found an increase in CP with increase in drug and buffer concentrations. Also, the increase was less sensitive to drug concentration at higher SP concentration.

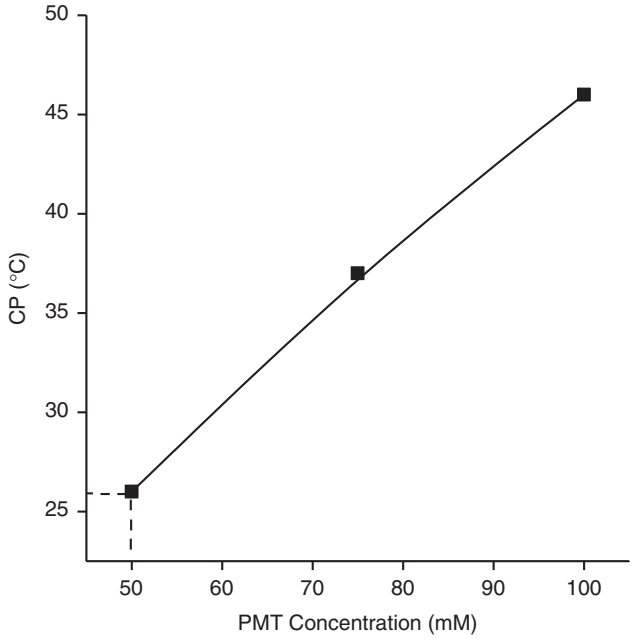


FIGURE 69.2 Effect of drug concentration on CP of PMT solution, prepared in 10 mM sodium phosphate buffer (pH = 6.7). Symbols depict the experimental points, and solid lines are drawn to guide the eye. (The same applies to all subsequent figures in which the various effects are shown.)

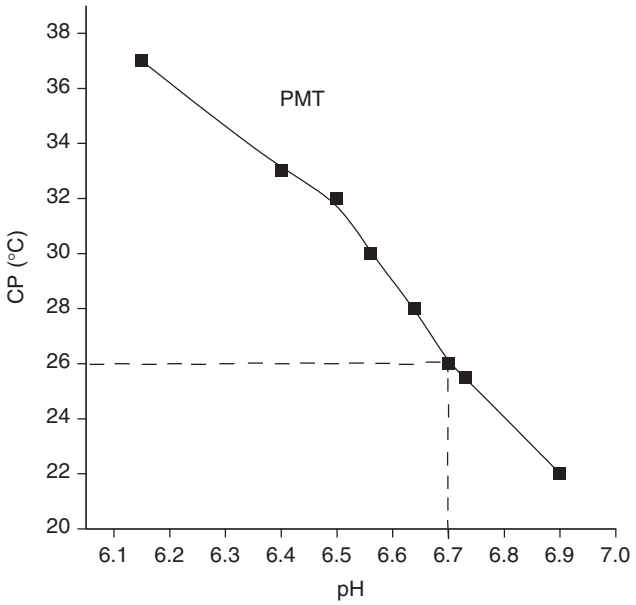

FIGURE 69.3 Effect of pH on CP of 50 mM PMT solution, prepared in 10 mM sodium phosphate buffer.

In these studies, pH was maintained at 6.7. At this pH most of the drug molecules would be in cationic form. They explained that excess of phosphate ions reduces the repulsion among drug headgroups and CP remains more or less constant. Kabir-ud-Din and coworkers fixed the concentration of buffer at 10 mM and varied the pH to observe the changes in the CP of the drug solutions. For all drugs the CP decreased with the increase in pH (Fig. 69.2). As stated above, charge of drug molecule is pH-dependent, and with increase in pH, an increasing number of molecules become neutral. This decreases the electrostatic repulsions experienced by the molecules at low pH values, and the molecules may come closer to each other. This also reduces the space among the headgroups [85], and CP decreases. An increase in the drug concentration increases the number of micelles. As drug monomers are positively charged, high drug concentration means more charged entities in the solutions (either micelles or monomers). This increases interparticle electrostatic repulsion (effect opposite to that of pH increase), and hence the CP increases (Fig. 69.3).

69.2.2 Effect of Electrolytes

Human muscles and neurons are activated by electrolyte activity between extracellular fluid or interstitial fluid, and intracellular fluid (fluid inside and outside or between cells). Sodium is concentrated in extracellular fluid and potassium, in intracellular fluid. Electrolytes may change the CP in any direction depending on their nature and concentration. Addition of electrolytes produces ions that can be classified into Hofmeister series [86] according to their size and other solution properties; ions on the right side of this series are known as *water structure breakers* or *chaotropes*, whereas ions on the left side are known as *water structure makers* or *kosmotropes* [87]. Alternatively, ions can also be classified on the basis of their adsorption/desorption ability [88]. Ions affect the CP by forming complexes with amphiphiles. Other authors [89] who studied the effect of sodium halides and alkali chlorides on the CP of 100 mM AMT (pH = 6.7), found that CP increases with the increase in salt concentration. The research group of Kabir-ud-Din also used inorganic salts to study their effect on CP of drugs [90–95]. The CP increased in the order: NaF < NaCl < NaBr and LiBr < NaBr < KBr (Fig. 69.4). F^-, Cl^-, and Br^- are counterions for the cationic drug micelles and directly interact with them. Although they decrease the charge of the drug micelles, at the same time, they increase the hydration of the micelles (as these ions are highly hydrated). The trend of CP increase is opposite to the hydrated size of the ion; hydrated radii of these ions increase in the order $Br^- < Cl^- < F^-$ [96]. Interaction of F^- with the drug micelles increases the micelle hydration more than with the addition of Cl^- or Br^-, and hence CP increase is sharper in presence of F^-. Results of UV–visible spectroscopy also support the above explanation: absorbance of Sudan III in drug–salt systems increased more with NaBr as compared to NaF. Because of its small hydrated size, Br^- could interact more strongly with the micelles and reduce the repulsions more than F^-. This results in micellar

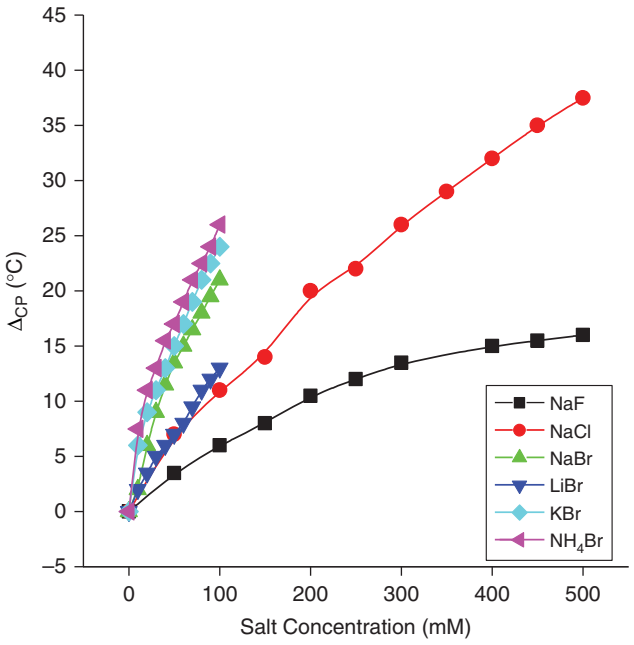

FIGURE 69.4 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of electrolyte concentration.

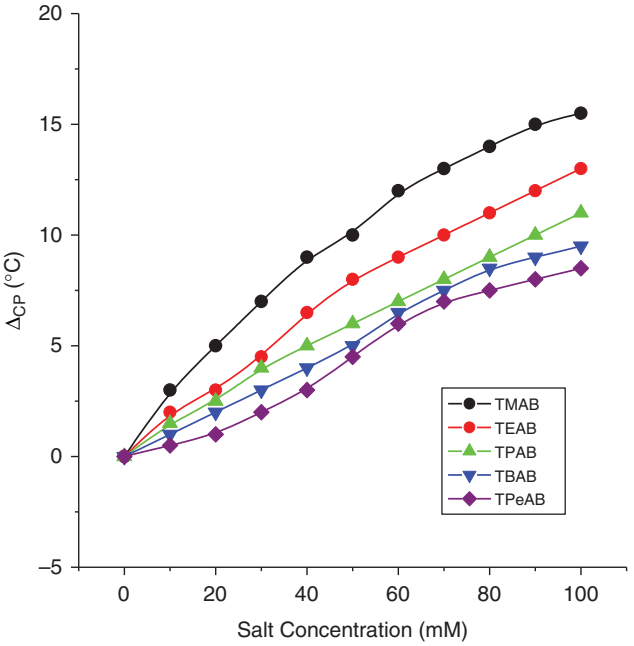

FIGURE 69.5 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of quaternary ammonium salt concentration.

growth and more dye solubilized in these micelles, resulting in increase in the absorbance [94, 95].

Coions also affect the CP in the same way, although their line of action is different [90–95] (Fig. 69.4). These ions (Li^+, Na^+, K^+) affect the micelle hydration indirectly as they remain in the aqueous phase and decrease the availability of water to the micelles according to their hydrated radii. The larger the hydrated radius, the more water an ion pulls from the micelles. These cations affect the solvent structure, too; Li^+ and Na^+ ions exhibit stronger interactions with water molecules than with water itself and, hence, behave as water structure makers, while K^+ ion exhibits weaker interactions with water and acts as water structure breaker. Therefore, CP increase is slower with Li^+ than with K^+ (Na^+ is intermediate). The results also indicate that cations are less effective in changing the CP (as the difference in CP of solutions with K^+ and Na^+ is not significant). This is consistent with the Schulze–Hardy [97] rule, namely, that the main effect of the valence of the ion oppositely charged to the colloid is on the stability of the colloid.

Addition of quaternary ammonium bromides also increases the CP (Fig. 69.5); CP increase is greater with short alkyl chain salt [90–92,94,95]. The order of increase is as follows: tetramethylammonium bromide (TMAB) > tetraethylammonium bromide (TEAB) > tetrapropylammonium bromide (TPAB) > tetrabutylammonium bromide (TBAB) > tetrapentylammonium bromide (TPeAB). The salt cations contain alkyl chains and are water structure makers. As their chain length increases, their hydrophobicity also increases and TBA/TPeA are almost nonhydrated ions. Short-chain salts adsorb to the drug molecules, while long-chain ones form mixed micelles. Their adsorption/mixed micelle formation predominates over their water-structure-forming ability [98], and they increase the CP. Also, these salts increase the micelle hydration; the least hydrated salt is least effective in increasing the CP.

69.2.3 Effect of Urea/Thiourea

Urea ($H_2N—C—NH_2$) is a protein decomposition product that is being produced continuously in the human body in large quantities. This nitrogeneous waste is removed from the body to avoid toxicity. Urea is known to affect the micelles in two different ways depending on its concentration [99]. To explain the behavior of urea, two mechanisms have been proposed [100–102]. In one mechanism urea replaces water in the hydration shells of the solutes. As urea is thought to interact directly with the micelles, this mechanism is known as a *direct mechanism*. In the other one, urea affects the water structure and indirectly affects the micelles. This mechanism is, hence, known as an *indirect mechanism*. Urea is generally considered as a water structure breaker (following indirect mechanism) [103, 104]. However, molecular

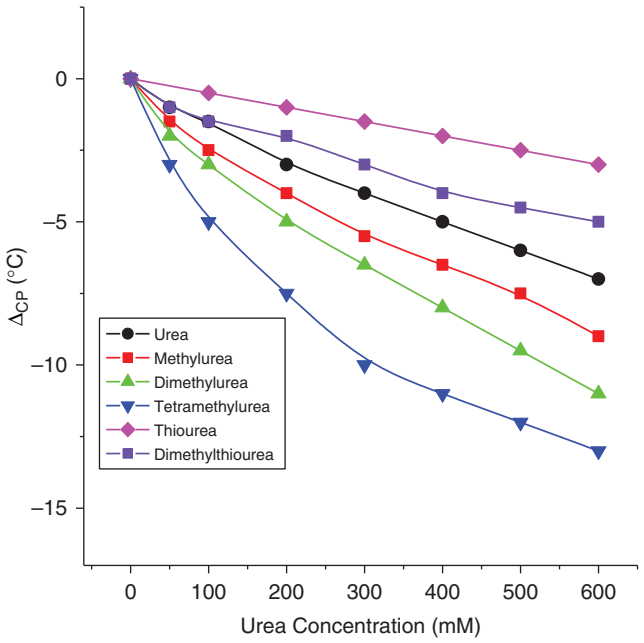

FIGURE 69.6 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of urea/thiourea concentration.

dynamic studies indicate that there is only a small difference in the properties of water present in the solvation region of urea and those of bulk water [105, 106], which supports direct mechanism. In fact, urea follows both mechanisms depending on its concentration. In drug systems, urea decreases the CP [84,91,92,107–110] (Fig. 69.6). In these systems urea follows a direct mechanism. It replaces water molecules from the headgroup region and dehydrates micelles. One team [111] also explained their results of *n*-dodecylhexadecylethylene–urea systems by a direct mechanism. Alkylureas also decrease the CP; the rate of decrease is higher with a greater number of alkyl groups in the molecule. This again confirms the theory that urea in drug systems follows the direct mechanism as the addition of methyl groups increases the size of urea molecules and replaces more water from the hydrophilic region of the micelles.

Thiourea, on the other hand, increases the CP. Thiourea is considered as a better water structure breaker [112]. If we assume that urea follows an indirect mechanism and decreases the CP, then CP should decrease more with the addition of thiourea. However, opposite behavior is observed with thiourea. This is due to the difference in the nature of >C=O and >C=S bonds. As O atoms are more electronegative than S atoms, the electrons around S atoms will be delocalized and hence it would act as Lewis acid. An S atom in thiourea would behave as a positive center, and its addition would increase repulsions in the micellar system and CP would increase.

69.2.4 Effect of Alcohols

Alcohol is absorbed through the stomach or small intestine directly into the bloodstream, travels through the body, reaches every organ, and distributes throughout the water in the human body. The body immediately begins to try to get rid of the alcohol. Alcohol can change brain chemistry and become lethal in high doses. Alcohol molecules are slightly amphiphilic in nature as they possess a hydrophilic OH group and an alkyl chain. Their amphiphilicity depends on the length of their alkyl chain. Such molecules affect the structural and dynamic properties of micelles in two different ways: either by interacting with micelles or by changing the solvent properties [113]. Short-chain alcohols are hydrophilic molecules, while long-chain alcohols are hydrophobic in nature. Short- and medium-chain alcohols decrease the aggregation and size of surfactant micelles, whereas long-chain ones increase the aggregation number [114, 115]. Micelles even disappear when short-chain alcohols are added in large quantities [116]. They modify the properties of the solvent [117], and a mixed "water + alcohol" system would be a better solvent for amphiphilic monomers. The CP of drug solutions either remains unaffected or increases slightly [108,118–122] (Fig. 69.7). Pentanol and higher alcohols affect the CP strongly. Long-chain alcohols, because of the presence of long alkyl chains, solubilize in the micelles by forming mixed micelles and affect the micellar properties. The OH group of such alcohols intercalates between the charged headgroups [123], reducing the

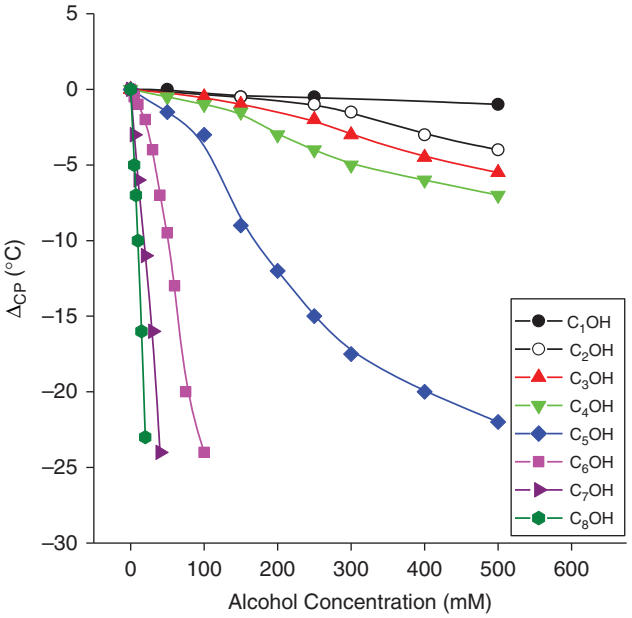

FIGURE 69.7 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of alcohol (*n*-alkanols) concentration.

electrostatic repulsions, and results in compact micelles with a small headgroup area (a_0). Also, their hydrocarbon chains interact with the hydrophobic part and increase the hydrophobic interactions. This increases the volume of hydrophobic part (v_c) without affecting the length of hydrocarbon chain (l_c). Both these factors result in large and compact micelles (with high values of Mitchell–Ninham parameter [124], $R_p = v_c/a_0 l_c$). This compactness decreases the micelle hydration, and CP decreases. As the chain length of alcohol increases, hydrophobic volume or v_c also increases, which results in increase in the R_p value. A high R_p value ($^1/_3 \leq R_p \leq {}^1/_2$) indicates larger micelles with low hydration. Therefore, octanol and decanol decrease CP very sharply. The effect of change in position of OH of the alcohol molecules on the CP of 200 mM AMT has been studied [83] by taking three pentanol isomers. The authors [83] observed that CP increases in all the three systems; only the magnitude of increase was different for the three isomers. At a given alcohol concentration, 1-pentanol increased the CP most, while 3-pentanol was least effective. They explained this on the basis of the length of alcohol molecule. 2-Pentanol has chain length equal to that of butanol, and its effect is also equal to that of butanol. The CP with 3-pentanol was lower than the CP with either butanol or 2-pentanol.

Ethane-diol and propane-1,2-diol were found to be ineffective in changing the CP (Fig. 69.8) as these diols are highly hydrophilic and completely miscible with water. Allyl alcohol and cyclopentanol decreased the CP at high

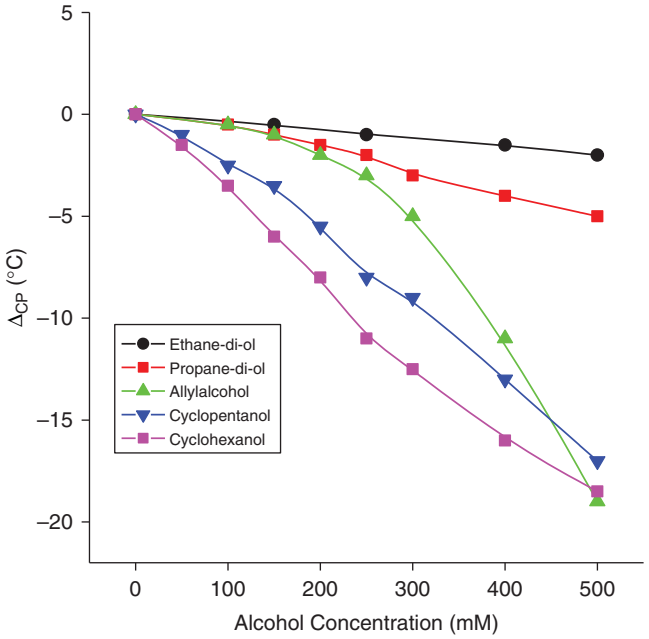

FIGURE 69.8 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of alcohol (diols and cyclanols) concentration.

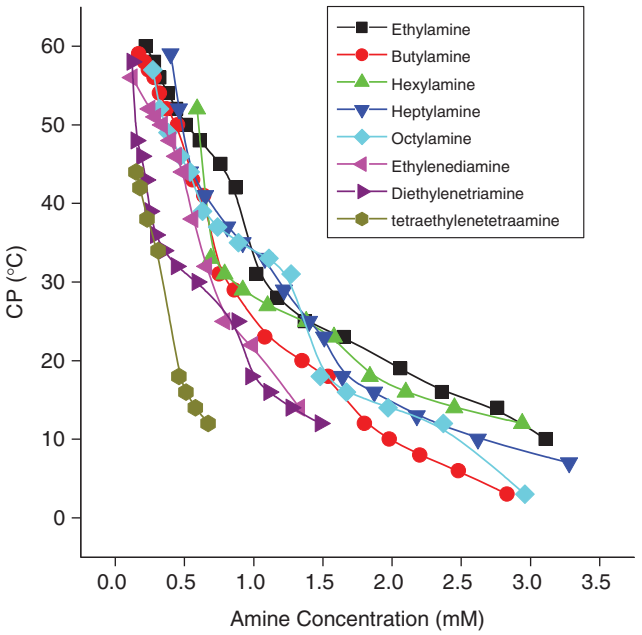

FIGURE 69.9 Variation of CP of 50 mM aqueous AMT solutions as a function of amine concentration.

concentrations, whereas cyclohexanol decreased it from the very beginning. Among these three, cyclohexanol is most hydrophobic and hence replaces more water from the micellar headgroup region [125].

69.2.5 Effect of Amines

Amines, like alcohols, are also slightly amphiphilic molecules. Blood and saliva contain amines and polyamines [126–129]. Stimulated mixed saliva contains lysine and arginine in ranges from 4 to 15 and 33 to 100 μg/mL, respectively [129], while stimulated parotid saliva contains even higher concentrations of these amines [129]. Other polyamines are also reported in saliva [126,127,130]. As shown in Fig. 69.9, 50 mM aqueous solutions of AMT exhibit CP with the addition of amines [131], which decreases with concentration. Amines, because of the presence of NH_2 group, hydrolyze on the surface of micelles [132]. Ethylenediamine, diethylenetriamine. and tetraethylenepentamine also decrease the CP of AMT solution. Nitrogen atom of amines forms hydrogen bond with the water molecules and decreases the CP. However, as solutions with amines are in water (without buffer), we cannot compare their results with those for alcohols.

69.2.6 Effect of Amino Acids

The role of amino acids is pivotal both as building blocks of proteins and as intermediates in metabolism. Outside proteins, they perform critical roles in processes such as neurotransmitter transport and biosynthesis. All amino acids

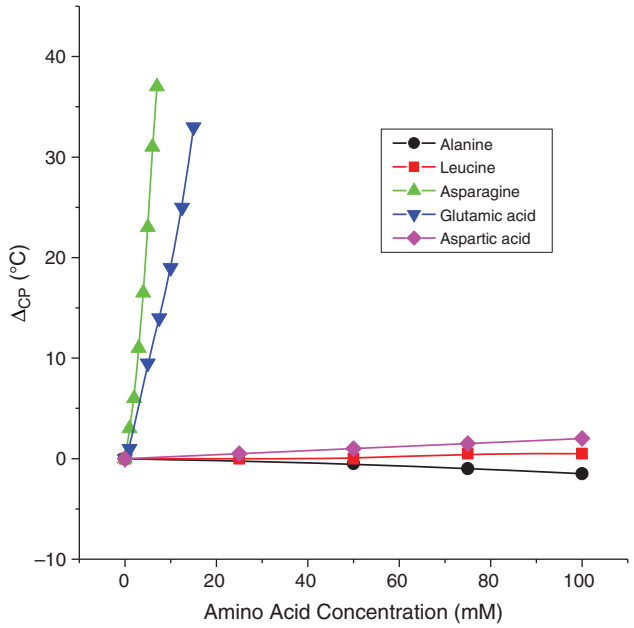

FIGURE 69.10 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of amino acid concentration.

have similar functional groups but different sidechains, and their behavior in changing the CP of drug systems was found to be dependent on the nature of sidechains [107, 108,118,120–122] (Figs. 69.10 and 69.11). Acidic amino acids (aspartic acid, glutamic acid) carry negatively charged sidechains, and their interactions with micelles would increase the micelle hydration; hence CP increases sharply. Uncharged polar (glycine, serine, asparagine) and nonpolar amino acids (alanine, leucine, threonine, proline, methionine, phenylalanine) either remain in the bulk or partition in micellar interior and do not affect the CP. Basic amino acids (lysine, arginine, histidine) decreased the CP by replacing water from the headgroup region. Hydrochloride salts (histidine.HCl, histidine methylester.2HCl, lysine.HCl, arginine.HCl) have a positive charge, and on interacting with the micelles they increased the repulsions among headgroups, resulting in loose micelles. This increased the hydration of micelles as well as the CP.

69.2.7 Effect of Sugars

Sugars work as fuel for the body by providing the required energy for sustenance. Blood sugar is transported through the bloodstream to all the body cells. Sugars decrease the CP of drug solutions [107, 108,118–122] (Fig. 69.12), although the mechanism is different from that in long-chain alcohols. Sugars act as kosmotropes [133] and shift the equilibrium

$$nH_2O \rightleftharpoons (H_2O)_n$$

to the right. Thus they decrease the availability of water to the drug micelles, thereby decreasing the hydration of the

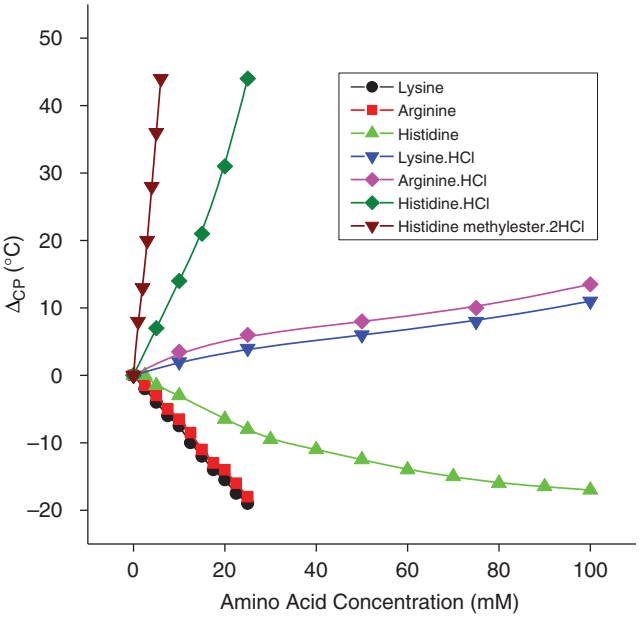

FIGURE 69.11 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of amino acid concentration.

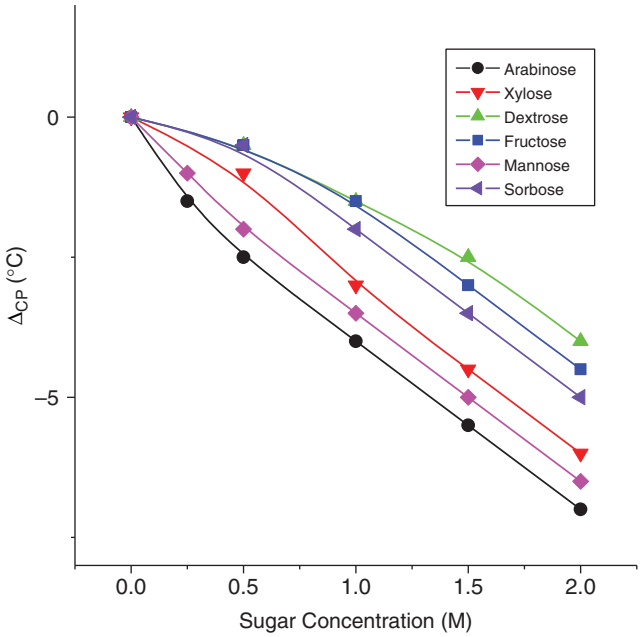

FIGURE 69.12 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of sugar concentration.

micelles and, as a result, CP decreases. This decrease in hydration increases the repulsion among drug headgroups, and micellar size decreases. This is confirmed by the dye solubilization experiments performed on PMZ–sugar systems [122], where solubilization of Sudan III dye decreases in presence of sugars.

69.2.8 Effect of Polymers

Pluronics are the triblock copolymers of hydrophilic ethylene oxide (EO) and hydrophobic propylene oxide (PO). They are widely studied for applications in drug delivery [134, 135]. Polymers of the category of polyvinylpyrrolidone (PVP) of different molecular weights also affect the CP [107,136,137] (Fig. 69.13). With PVP 15, three regions––constancy, slight decrease and increase––were observed. As the molecular weight of the polymer increases, the constancy region disappears, the CP-decreasing region increases, and the CP-increasing region decreases. For the highest-molecular-weight polymer used (PVP 90), the CP at all concentrations remained below that of the CP of the pure drug. Polymers interact with drug micelles and affect the micelle hydration to a different extent. Pluronic PF127 increases the CP, while 10R8 decreases it [82]. In PF127, the PO part is in between two EO blocks, whereas in 10R8, EO is in between two PO blocks. As hydrophilic parts in PF127 are at the side, the copolymer increases the CP slightly while the opposite occurs in 10R8 –AMT systems.

69.2.9 Effect of Surfactants

There are many applications of pharmaceutical surfactants; the most important ones are solubilization, inclusion, and vectorization of hydrophobic drugs. Presence of surfactants in drug solutions affects the CP of drugs depending on their concentration, structure, and nature [107,109,110,119,136–140]. Very low concentrations of an ionic surfactant increase the solubility and the cloud point. This is due to either mixed micelle formation (in the case of a clouding surfactant) or an association between the surfactant and the polymer (in the case of clouding polymer). This results in the formation of charged aggregates which are much more difficult to concentrate in one of the phases due to the unfavorable electrostatic interaction. CPs of drug solutions in presence of anionic surfactants sodium dodecylsulfate (SDS) and sodium dodecylbenzenesulfonate (SDBS) show a peaked behavior (Fig. 69.14). The increase is found to be steeper with SDS than SDBS, while the decrease is more pronounced for SDBS. When added in low amounts, these anionic surfactants form ion pairs with the cationic drug molecules and hinder micellar association. Therefore, CP increases up to a certain concentration. Above it, these surfactants begin to form mixed micelles. Because of their long hydrophobic tails, the surfactant monomers intercalate between drug molecules in the micelles. As a result, they increase the hydrophobic interactions and v_c. At the same time, their charge, opposite to the charge of drug molecules, reduces the electrostatic repulsions among micellar heads and decreases the value of a_0.

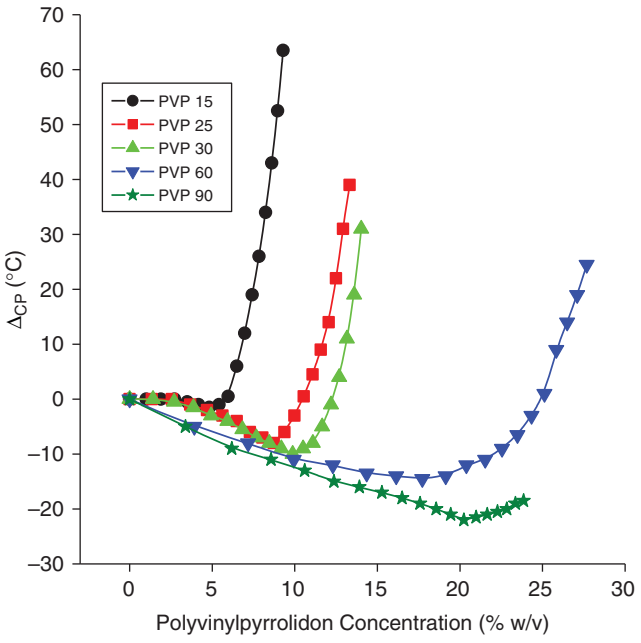

FIGURE 69.13 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of polymer concentration.

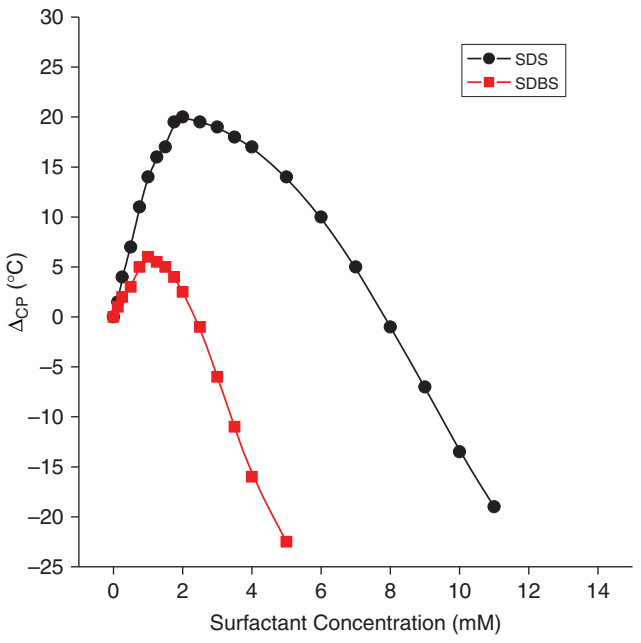

FIGURE 69.14 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of anionic surfactant concentration.

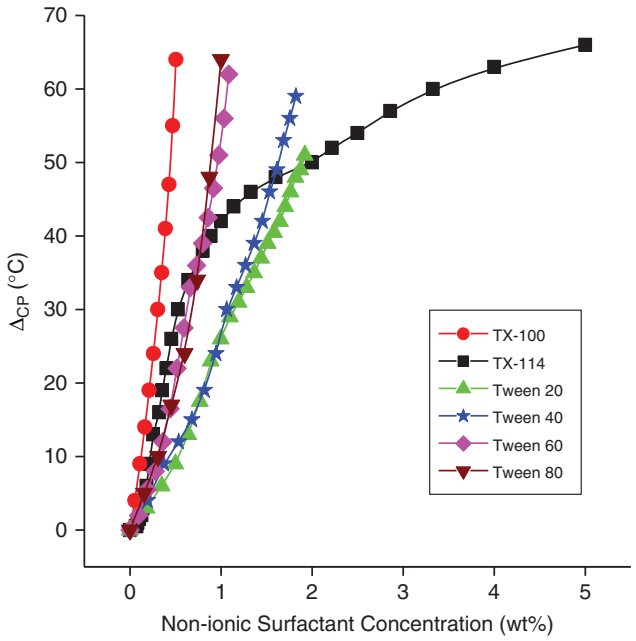

FIGURE 69.15 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of nonionic surfactant (TX and Tweens) concentration.

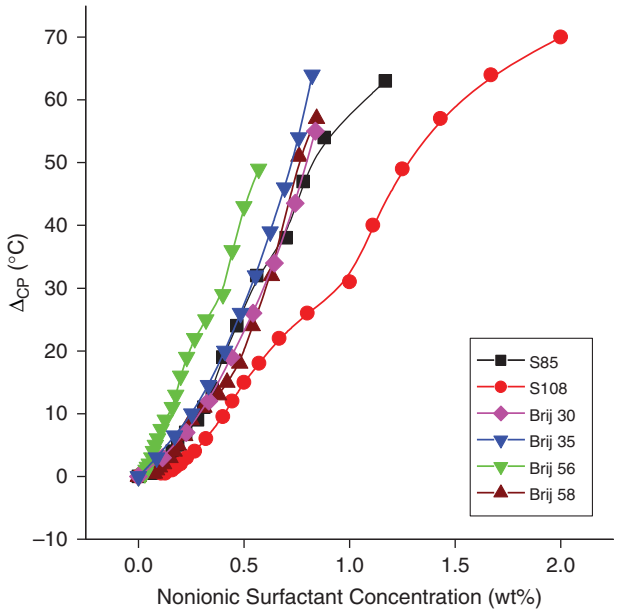

FIGURE 69.16 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of nonionic surfactant concentration.

These two factors increase the R_p value, and CP decreases. SDBS contains a benzene ring in addition to the dodecyl chain. As a phenyl group is considered equivalent to three or four carbons in straight chain [141], the hydrophobic part of SDBS can be taken as longer than that of SDS. That is why CP increase is slower and decrease is sharper with SDBS than with SDS.

Nonionic surfactants of all types increase the CP (Figs. 69.15 and 69.16). As they contain highly hydrophilic oxyethylene chains, the resultant drug–nonionic surfactant mixed micelles would be highly hydrated and extra heating would be required to dehydrate these micelles. As a result, phase separation occurs at higher temperatures.

Cationic surfactants too increase the CP (Fig. 69.17), although the cause of increase is different from that in nonionic or anionic surfactants. Cationic surfactants, as already stated, form mixed micelles with these drugs. During this process they increase the hydration of the mixed micelles. As the chain length of the cationic surfactants increases, their tendency to form mixed micelles also increases. Therefore, surfactant with longer hydrophobic tail begins to increase the CP at lower concentrations.

The addition of cationic geminis of the class alkanediyl – α, ω – bis(dimethylalkylammonium bromides) (m-s-m type) also increases the CP (Fig. 69.18). Their cmc values are much lower [142] than those of conventional surfactants, and hence their CP-boosting effect is found to be higher than that of conventional surfactants. Within a series of geminis (either 16-*s*-16 or 14-*s*-14), the CP-boosting effect increases with increasing spacer length *s*. Increase in length of spacer increases the surface charge of the micelles [142], and the mixed micelles experience more electrostatic repulsions. This increases the headgroup area occupied by a single molecule, and hydration increases which, in turn, results in increase in the CP.

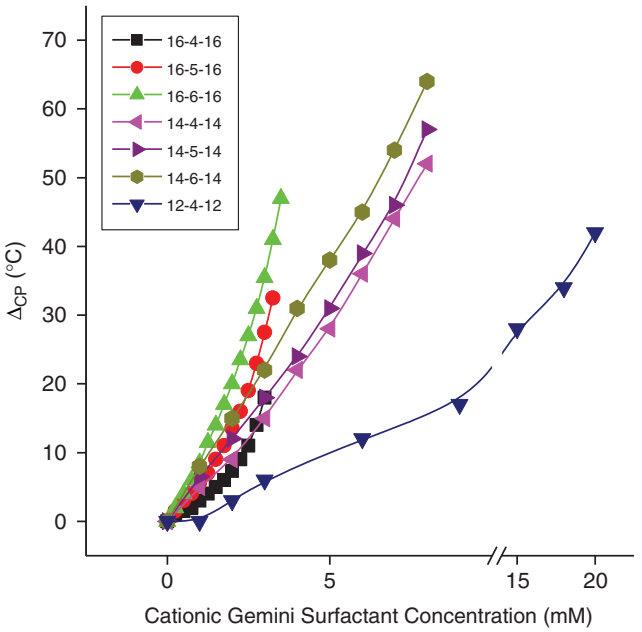

FIGURE 69.18 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of cationic gemini surfactant concentration.

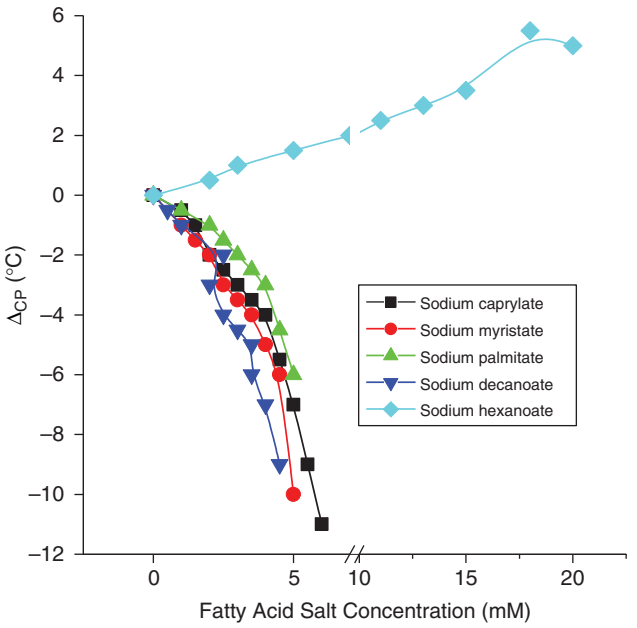

FIGURE 69.19 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of fatty-acid concentration.

69.2.10 Effect of Fatty Acids (Sodium Salts)

The essential fuels of the heart are fatty acids, and thus their role is important in life and death of cardiac cells. Fatty-acid salts with 8-, 10-, 14-, and 16-carbon chains cause a peaked behavior in CP of drugs (except in PMT), while salt with 6-carbon chains continuously increases the CP [139, 140] (Fig. 69.19). As these are sodium salts, their moieties carry a negative charge and their behavior is similar to that of anionic surfactants. The carboxyl group is a highly hydrated group, and its presence in the headgroup region of the micelles increases the water content there. As a result, the fatty acids initially show a CP-boosting effect. However, these fatty-acid salts also possess long alkyl chains, and their penetration into the palisade layer increases the hydrophobic interactions. At low concentrations, the first factor dominates, whereas at high concentrations the second factor dominates and CP decreases. Sodium hexanoate has a relatively shorter chain and is slightly hydrophilic. Therefore, the CP-decreasing region is absent in this salt–drug system.

69.2.11 Effect of Bile Salts

Bile salts are synthesized in the liver, concentrate in the gallbladder, and are discharged into the duodenum through a biliary duct. Hence, the amphiphilic moiety of bile salts carries a negative charge. The effect of NaC and NaDC on the CP of drug solutions is similar to that of fatty acids (Fig. 69.20). NaC and NaDC both showed peak behavior in CP–[bile salt] curves (in all drugs except PMT) [139, 140]. At low concentrations these salts increase the hydration of the micelles, while at high, added concentrations, compact micelles form and hydration of the micelles decreases. Of the two, NaC contains an extra OH group and is more hydrophilic. Therefore,

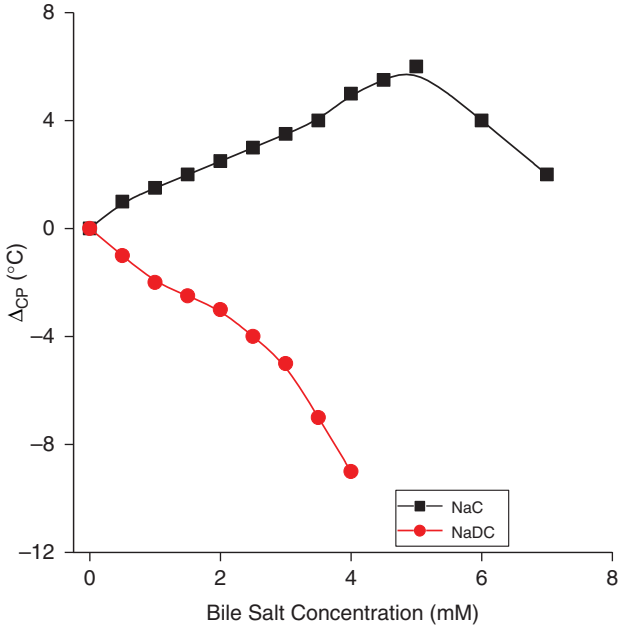

FIGURE 69.20 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of bile acid salt concentration.

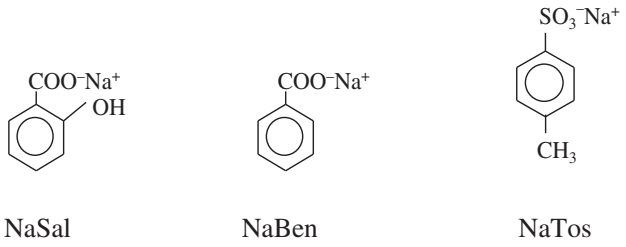

FIGURE 69.21 Structures of hydrotropes used.

CP increase is high and CP decrease is slow in the presence of NaC, as NaC increases the hydration to a greater extent and a higher concentration is required to decrease the CP.

69.2.12 Effect of Hydrotropes

Hydrotropes are surface-active and highly water-soluble compounds that can increase the solubility of sparingly soluble solutes in water. These organic salts are important in pharmaceutical processes such as microemulsion and drug formulations [143, 144]. We have used three hydrotropes having benzene (or substituted benzene) as the hydrophobic part and carboxylate/sulfonate as the hydrophilic part or the headgroup [e.g., sodium salicylate (NaSal), sodium benzoate (NaBen), and sodium tosylate (NaTos)] (Fig. 69.21). Hence, the amphiphilic moiety carries a negative charge. These salts also provide an anionic moiety when dissolved in water and neutralize the charge on drug molecules. At the same time they increase the hydration and also micellar growth by intercalating between the headgroups of drugs (as they contain the hydrophilic groups). The CP of drug solutions shows first an increase and then a decrease with increase in hydrotrope concentration [139, 140] (Fig. 69.22) wherein the magnitude of increase and decrease depends on the structure and nature of hydrotrope. NaBen possesses a carboxylate group, NaSal contains a carboxylate group and a hydroxyl group, and NaTos has a sulfonate group. Hence, the order of their hydrophilicity is as follows: NaSal > NaBen > NaTos. In NaSal, the OH group is at *ortho* position, and in cationic micelles it intercalates between the cationic headgroups [145]. This favors micellar growth, and CP decrease is the fastest with NaSal. Also, the π-electron cloud of the phenyl ring of the hydrotropes interacts with the cationic amine group of drugs.

69.2.13 Effect of Cyclodextrins

Cyclodextrins are toroidally shaped oligosaccharides composed of α-D-glucopyranoside units. α, β, γ-Cyclodextrins contain six, seven, and eight glucose units, respectively, in a ring creating a cone-shaped structure. Cyclodextrins have wide applications in food, pharmaceutical, and chemical industries [146]. β-Cyclodextrin is known for its ability to

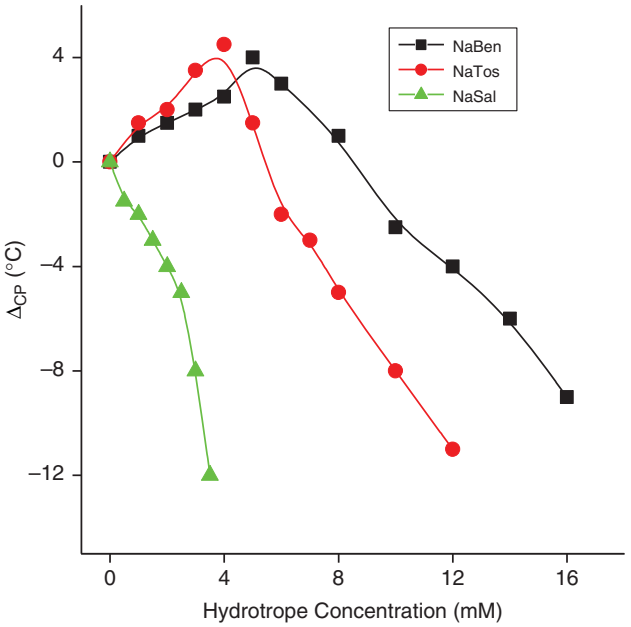

FIGURE 69.22 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of hydrotrope concentration.

form inclusion complexes with surfactants [147] and is found to increase the CP of nonionic surfactants [148]. However, in drug systems, the CP decreases in its presence [139, 140] (Fig. 69.23). Perhaps, with the cationic drugs, cyclodextrin acts as water structure maker and does not form inclusion

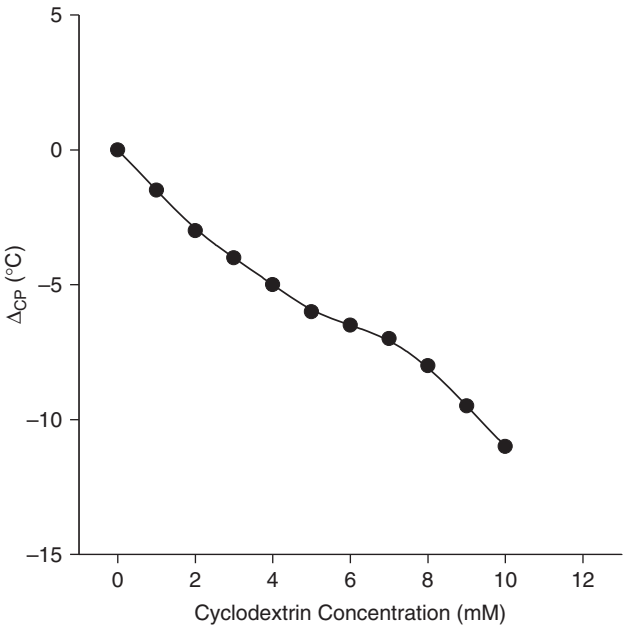

FIGURE 69.23 CP shift values (Δ_{CP}) of 50 mM PMT solutions, prepared in 10 mM sodium phosphate buffer (at pH = 6.7) as a function of cyclodextrin concentration.

complexes. It was mentioned earlier that water structure makers decrease the cmc by increasing the hydrophobic interaction. Increase in hydrophobic interactions decreases the CP also.

69.2.14 Effect of Phospholipids

Phospholipids, the essential constituents of biological membranes, are involved in numerous biological activities in living organisms [149]. Phospholipids and phospholipid derivatives, under special conditions, form mixed micelles with suitable amphiphiles [150, 151]; an important example is the mixed micelles formed between phospholipids (lecithin) and bile salts [152] in the human digestive tract to dissolve cholesterol. Cloud-point temperature measurements, performed with drugs as a function of added phospholipid type and concentration [153] (Fig. 69.24), show that in AMT, all the phospholipids decrease the CP, whereas in CLP systems, the phospholipids increase the CP only at low concentrations. Although PMZ and PMT are almost similar in structure, their behaviors are different. Adding phospholipids to PMZ solutions not only leads to transition temperatures shifted toward lower values but also results in a broader transition as in PMT solutions. For CLP and IMP the behavior is similar, only the values are higher and broader for IMP. Presence of Cl atom in CLP renders the molecule slightly more hydrophobic, and hence increase in CP is higher and decrease in CP is lower.

BILAYER IMAGING OF PHOSPHATIDYLCHOLINES BY HIGH-PRESSURE FLUOROMETRY

MASAKI GOTO, NOBUTAKE TAMAI, AND HITOSHI MATSUKI

Department of Life System, Institute of Technology and Science, The University of Tokushima, 2-1 Minamijosanjima-cho, Tokushima 770-8506, Japan

70.1 INTRODUCTION

Phospholipids form bilayer aggregates called *vesicles* or *liposomes* in aqueous solutions, and they undergo structural changes, namely, phase transitions depending on environmental variables such as temperature, pressure, pH, and added salts. Allthough most studies on the impact of environmental variables on lipid bilayers have focused on the effects of temperature and/or concentration, there have been a few studies on the effect of pressure. The adoption of pressure as an environmental variable enables us to (1) estimate the complete thermodynamic quantities of the bilayer phase transitions, including volume information in addition to thermal information; (2) construct a two-dimensional (2D) temperature (T)–pressure (p) phase diagram; and (3) observe low-temperature transitions that cannot be detected by conventional experimental methods. Pressure studies on phospholipid bilayers have concentrated on bilayers of phosphatidylcholines (PCs) with linear identical acyl chains such as dimyristoyl-PC (DMPC), dipalmitoyl-PC (DPPC), and distearoyl-PC (DSPC). In particular, the DPPC bilayer has been thoroughly examined by using various physicochemical techniques including differential scanning calorimetry (DSC), X-ray diffraction, neutron diffraction, NMR, ESR, Raman spectroscopy, dynamic light scattering, and light transmittance [1–10]. On the other hand, fluorescence measurements using fluorescent membrane probes have also been performed under high pressure, and there have been several reports on microscopic environments around the probe molecules in phospholipid bilayers [11–14].

This review summarizes the high-pressure fluorometry that we have established in our recent high-pressure studies on phospholipid bilayers. We have focused on one polarity-sensitive membrane probe among many probes, 6-propionyl-2-(dimethylamino)naphthalene (Prodan), which changes the maximum fluorescence wavelength (λ_{max}) sensitively in response to the microscopic polarity environment in the phospholipid bilayer [15], and we have shown that an analysis of second derivatives of the Prodan fluorescence spectra in the bilayer can be used for the accurate determination of phase transitions. Subsequently, we demonstrated that a correlation between the location of Prodan molecules in the bilayer and the phase state of the bilayer can be visualized by constructing a three-dimensional (3D) image plot in terms of the second derivatives of fluorescence spectra [16–22]. We call this visualization *bilayer imaging*. Here, using this technique, we explain the packing state of PC molecules in the bilayers of (1) DPPC homologs with different acyl chain lengths, (2) those with different vesicle sizes, and (3) asymmetric PCs with different linear acyl chains at the *sn*-1 and *sn*-2 positions. Furthermore, the formation of a lamellar crystal (L_c) phase of the asymmetric PC bilayer, which is clarified by the technique, is also described.

70.2 PRODAN FLUORESCENCE SPECTRA

70.2.1 Fluorescence Measurements

We employed a Bangham method of liposome preparation [23], or combined use of this method and sonication

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.

treatment to prepare the PC vesicle suspension containing the fluorescence probe Prodan [19, 20]. The total concentration of PC was 1.0 mmol kg^{-1}, and the molar ratio of Prodan to PC was 1:500. Fluorescence spectra of Prodan in the PC bilayers under high pressure were measured by a F2500 fluorescence spectrophotometer (Hitachi High Technology Corp., Tokyo, Japan) equipped with a high-pressure cell assembly PCI-400 (Syn Corp. Ltd., Kyoto, Japan). The spectra were observed by an isobaric thermotropic method with a heating rate of 0.50°C min^{-1}; details of the measurement procedure were described previously [16–22]. The excitation wavelength was 361 nm, and the emission spectra were recorded in the wavelength range from 400 to 600 nm. The second derivative of the emission spectrum was obtained by attached software FL solutions (Hitachi High Technology Corp., Tokyo, Japan) of the apparatus and Origin 7.0 (Lightstone Corp., Tokyo, Japan). Three dimensional image plots were constructed from the spectra by employing SigmaPlot 12 (HULINKS Inc., Tokyo, Japan).

70.2.2 Location of Prodan Distributed in PC Bilayer Membranes

The λ_{max} values of Prodan change depending on the kind of solvent, and there is good correlation between the λ_{max} value and the dielectric constant of a solvent around the probe molecules. A higher value of λ_{max} indicates that the probes exist in a polar or hydrophilic environment, while a lower λ_{max} value indicates that the probes exist in a less polar or hydrophobic environment (Fig. 70.1a) [24]. On the other hand, when the Prodan molecules distribute in the bilayer, the fluorescence spectra of Prodan are highly dependent on the phase states of the lipid bilayers; thus, the λ_{max} value drastically varies at the phase transitions. Alteration of the wavelength accompanying the phase transition is related to the local dielectric constant of the lipid molecule in the bilayer, which has been demonstrated as the *zone model* [25]. Since phospholipids are amphiphilic molecules, the dielectric gradient along the molecular axis of a lipid molecule in the hydrated lipid bilayer is produced, then, the gradient can be divided into three zones by the portions of the lipid molecule with different gradients. Figure 70.1b schematically illustrates the zone model of the lipid bilayer. *Zone I*, the hydrophilic part of the bilayer including the polar headgroups, consists of choline and phosphate groups and exhibits a high dielectric constant. *Zone III*, the hydrophobic part of the bilayer including the hydrocarbon core, exhibits a low dielectric constant. *Zone II*, the interfacial region in which the dielectric constant changes from that of zone I to that of zone III, includes the glycerol backbone and ester carbonyl group. When the PC bilayers form the gel, liquid crystalline (L_α), and interdigitated gel ($L_\beta I$) phases, the λ_{max} values exhibit wavelengths of approximately 430, 480, and 500 nm, respectively. Thus, the 430-nm peak indicates that the Prodan

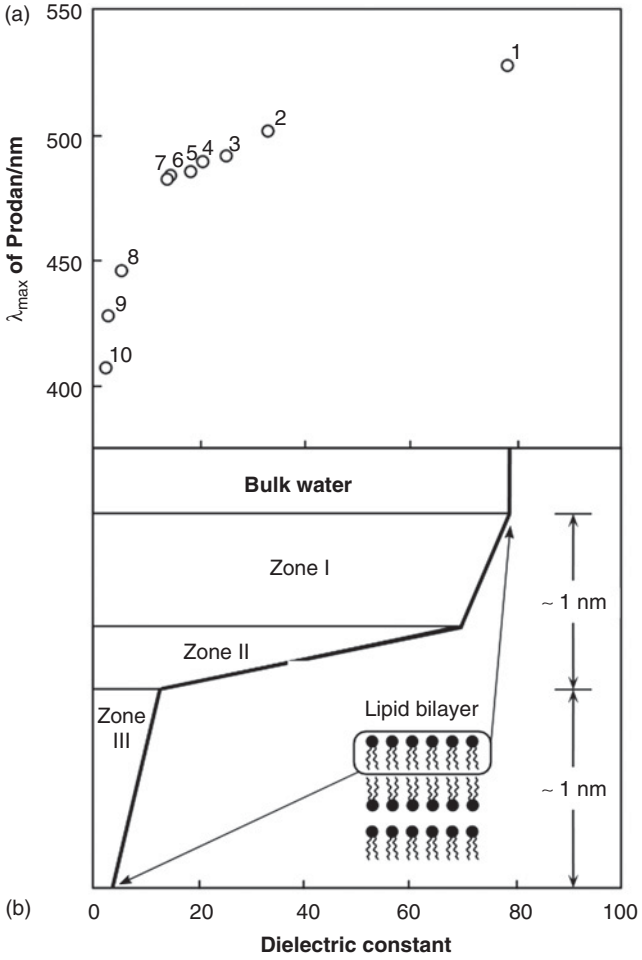

FIGURE 70.1 (a) Wavelength of fluorescence emission maximum for various solvents as a function of solvent dielectric constant at 25°C and 0.1MPa: (1) water, (2) methanol, (3) ethanol, (4) 1-propanol, (5) 1-butanol, (6) 1-pentanol, (7) 1-hexanol, (8) chloroform, (9) benzene, and (10) cyclohexane. (b) A schematic representation of the variation in the dielectric constant from the bilayer core to the bulk water. Three zones of lipid bilayer proposed by the zone model are drawn together with the size of the zones.

molecules exist in less polar regions around the glycerol backbone (zone II); the 480-nm peak, that they exist around the phosphate group (between zones I and II); and the 500-nm peak, that they exist in the hydrophilic region around the lipid headgroup (zone I). This fact signifies that the location of the Prodan molecules distributed in the PC bilayer is closely related to the molecular packing in the bilayer.

The location of the Prodan molecules distributed in the bilayer can be estimated to some extent from the zone model. However, the shape of the emission spectrum of Prodan is not always symmetric, and the spectrum often has a main peak containing shoulder peaks, suggesting that the Prodan molecules are not distributed into only one site in the bilayer. To investigate the location of the Prodan molecules

distributed in the bilayer more accurately, we have developed an analytical method by using the second derivatives of the fluorescence spectra. This method allows us to detect small spectra contained in the shoulder of the fluorescence spectrum [16–22]. The λ_{max} value of the original fluorescence spectrum generally corresponds to the wavelength (λ''_{min}) of minimum intensity in the second-derivative spectrum, whereas the λ''_{min} values of the Prodan spectrum are not always exactly identical to that of the λ_{max} values because the Prodan spectrum in the bilayer is composed of multiple components. In other words, a detailed analysis of the second derivatives of fluorescence spectra provides accurate estimation of the location of the Prodan molecules distributed in multiple sites in the bilayer.

When a series of the Prodan spectra are measured as a function of wavelength, temperature, and pressure, it is possible to construct a 3D image plot of the isobaric thermotropic and/or isothermal barotropic change of the Prodan spectra only if the temperature and/or pressure intervals for a spectrum measurement are narrow and interpolated between consecutive temperatures and/or pressures. The constructed plots provide the visual imaging of packing states of various phases in the PC bilayer by Prodan fluorescence [19–22]. In the next section, we show and discuss bilayer imaging of several PCs with different molecular structures.

70.3 FACTORS AFFECTING THE PACKING STATE IN THE PC BILAYER

70.3.1 Effect of Acyl Chain Length

Figure 70.2 shows *T–p* phase diagrams of the DPPC, diheptadecanoyl-PC (C17PC), and DSPC bilayers together with schematic drawings of each phase state. The DPPC bilayer undergoes the pretransition at 34.3°C from the lamellar gel (L'_β) phase to the ripple gel (P'_β) phase and the main transition at 42.0°C from the P'_β phase to the L_α phase under atmospheric pressure. Both transition temperatures increase by applying pressure, and the pressure-induced $L_\beta I$ phase, whose structure is a kind of nonbilayer that one side of monolayers constituting bilayers mutually interpenetrate the other side of monolayers, appears between the L'_β and P'_β phases at pressures higher than 100 MPa. The phase behavior of the C17PC and DSPC bilayers is similar to that of the DPPC bilayer. The transition temperatures of the PC bilayers increase with an increase in acyl chain length, while the minimum pressure value required for the interdigitation [minimum interdigitation pressure (MIP)] decreases [16,17].

Three 3D image plots of the DPPC, C17PC, and DSPC bilayers obtained under thermotropic conditions at high pressures are depicted in Fig. 70.3 [26]. The heating process of the plots for these PC bilayers under high pressure is given by arrows in Fig. 70.2, and they all undergo the $L'_\beta/L_\beta I$, pre-($L_\beta I/P'_\beta$) and main transitions in turn by this process. Here, the fluorescence intensity is drawn by a color scale as an indicator in the plots; the change from low to high intensity is indicated by the change in color from blue to red in the order of the rainbow colors. Therefore, the location of the Prodan molecules distributed in the PC bilayer can be evaluated from the depth of bluish valleys in the plot. In the case of the DPPC bilayer (Fig. 70.3a), four valleys are seen in the plot, and the respective valleys correspond to the four phase states. Two very deep bluish valleys at ~430 nm correspond to the L'_β (431 nm from 20°C to 45°C) and P'_β (434 nm from 58°C to 74°C) phases, one deep greenish valley at

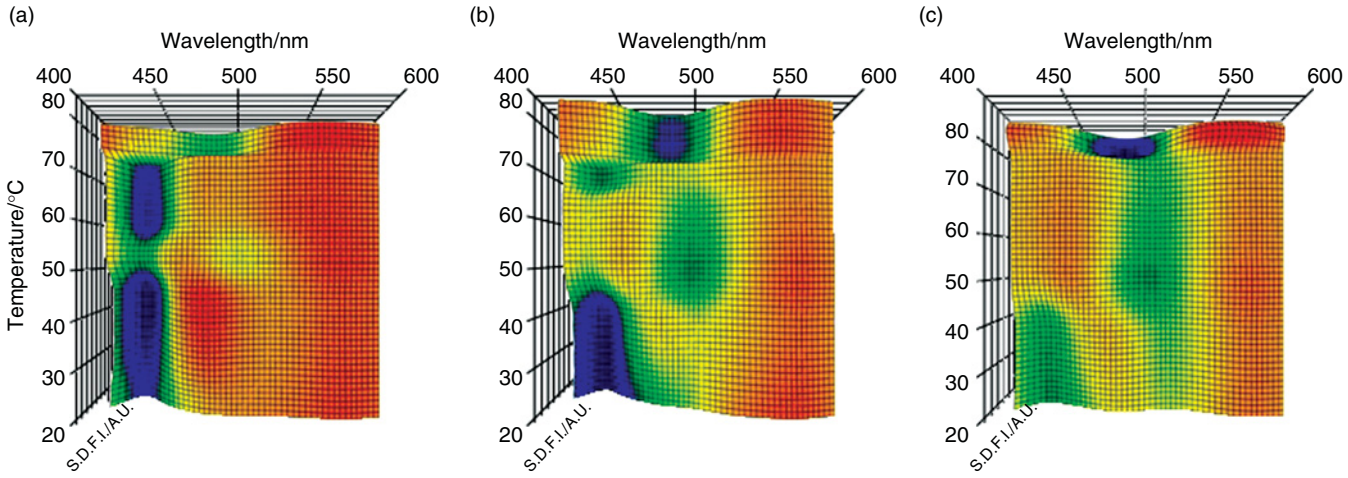

FIGURE 70.3 Image plots for the second derivatives of the fluorescence spectra of Prodan in the (a) DPPC, (b) C17PC, and (c) DSPC bilayers.

482 nm corresponds to the L_α phase (from 74°C to 80°C), and one shallow yellowish valley at 499 nm with a greenish valley at ~430 nm (from 45°C to 58°C) corresponds to the $L_\beta I$ phase. The valleys clearly change at three temperatures corresponding to the $L'_\beta/L_\beta I$ transition, pretransition and main transition temperatures of the DPPC bilayer, which are in good agreement with the transition temperatures in the T–p phase diagram (Fig. 70.2a), except for the $L'_\beta/L_\beta I$ transition. Concerning the $L'_\beta/L_\beta I$ transition, the transition temperature in the plot is ~8°C higher than that shown in the T–p phase diagram. This is attributable to the fact that the second-derivative spectra of the $L_\beta I$ phase in the DPPC bilayer have two $\lambda''_{\min}$ values of 431 and 499 nm and the former minima are greater than the values of the latter minima, suggesting that the packing in the $L_\beta I$ phase of the DPPC bilayer is looser and the Prodan molecules can localize near the glycerol backbone region even in the $L_\beta I$ phase. On the other hand, the valleys of ~500 nm corresponding to the $L_\beta I$ phase in the C17PC and DSPC bilayers become clearer than that in the DPPC bilayer, and their $L'_\beta/L_\beta I$ transition temperatures in the plots agree with those in the T–p phase diagram (Fig. 70.3b,c). This means that the Prodan molecules in both PC bilayers can significantly change the location at the bilayer interdigitation.

Comparing the image plots of the PC bilayers, the bluish valleys for the L'_β and P'_β phases at ~430 nm become shallower with an increase in acyl chain length, whereas the valley for the L_α phase at ~480 nm conversely deepens with an increase in acyl chain length. This contrastive change of the bilayer gel and L_α phases indicates that the quantity of the Prodan molecules distributed in the glycerol backbone region decreases while that in phosphate region increases with chain elongation. Therefore, we can say that the relative ease with which the Prodan molecules partition in the gel phase is inversely proportional to the hydrophobicity of the PC molecules, with an opposite or reverse situation observed in partitioning into the L_α phases. The valleys for the $L_\beta I$ phase observed in the C17PC and DSPC bilayers become deeper than that in the DPPC bilayer. The change in valley depth indicates that greater numbers of Prodan molecules partition into the hydrophilic region around lipid headgroup in the C17PC and DSPC bilayers in comparison with the DPPC bilayer; in other words, the enhanced packing of the $L_\beta I$ phase with the chain elongation excludes the Prodan molecules from the adjacent glycerol backbone to the hydrophilic region. Furthermore, another shallow light greenish valley at ~515 nm and <40°C appears together with the greenish valley at ~430 nm in the plot of the DSPC bilayer (Fig. 70.3c), and the two valleys incorporate into one greenish valley of the $L_\beta I$ phase at ~500 nm with an increase in temperature. The 515-nm valley reflects the fact that the Prodan molecules are distributed within the most hydrophilic region almost at bilayer surface. More specifically, a part of the Prodan molecules is squeezed out from the vicinity of glycerol backbone to the hydrophilic region because of the tight gel-phase packing of the DSPC bilayer.

70.3.2 Effect of Vesicle Size

It is also known that the size of bilayer aggregates affects the bilayer property. DSC, dynamic heat capacity, and solvent relaxation [27–30] measurements indicate that the pretransition of small unilamellar vesicles (SUVs) disappears after excessive sonication and drastically reduces the cooperativity of the main transition. Using high-pressure fluorometry, we investigated the difference in bilayer properties between large multilamellar vesicles (LMVs) with nanometer (nm) sizes described in Section 70.3.1 and giant multilamellar

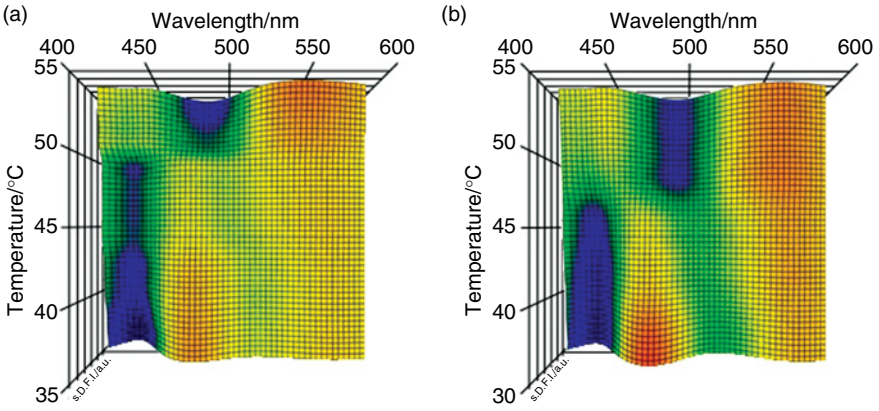

FIGURE 70.4 Image plots for the second derivatives of the fluorescence spectra of Prodan for (a) LMV and (b) GMV of C17PC bilayer.

vesicles (GMVs) with micrometer (μm) sizes. For this purpose, the GMV samples of the C17PC bilayer were prepared by a technique of static hydration using Bangham's method and the corresponding LMV ones were prepared by short-term sonication on the GMV sample immediately after the preparation. The mean diameters of LMVs and GMVs were 170 ± 15 nm and 5000 ± 800 nm, respectively; these sizes were determined by dynamic light-scattering measurements.

Figure 70.4 shows two 3D image plots for LMV and GMV of the C17PC bilayer obtained under thermotropic conditions at atmospheric pressure [20]. Valley depth changed from 431 to 484 nm at ∼50 °C for LMV and from 431 to 491 nm at ∼47 °C for GMV, indicating that the bilayers of LMV and GMV undergo the main transition at those temperatures. Although the pretransition of LMV can be observed as a variation in width of a blue band near 430 nm at ∼43°C, the variation for GMV is barely discernible in the plot. For GMV, a clear green valley band corresponding to another minimum in the second-derivative spectra appears in the wavelength range between approximately 500 and 525 nm in the plot as observed in the DSPC bilayers, indicating that a part of the Prodan molecules partitions into the hydrophilic region at the membrane surface even though the phase is L'_β . Packing stress exists between the outer and inner layers in LMV, which arises from the mismatch between the curvature of the membrane and its spontaneous curvature. The packing stress decreases with increasing vesicle size; as a result, the PC molecules in GMV can be packed more densely and tightly than those in LMV. Then a part of the Prodan molecules is squeezed out of the glycerol backbone region to the most hydrophilic region at the membrane surface near bulk water. It is noteworthy that the depths of the minima corresponding to the three phases are more enhanced in GMV than in LMV. The enhancement of the minima results from an increase in fluorescence intensity. As the partitioning of the Prodan molecules does not seem to change appreciably at the same molar ratio of Prodan and PC in GMV and LMV, enhancement of the minima in GMV is attributable to the increase in surface density of the Prodan molecules per unit area in GMV as compared with that in LMV. On the other hand, the blueish valley corresponding to the P'_β phase for GMV shrinks in the direction of the temperature axis while that to the L_α phase extends as compared with that of LMV. This means that the Prodan molecules in the P'_β phase of GMV can easily transfer from the glycerol backbone region to the adjacent phosphate group because of the tighter packing of the PC molecules in GMV than in LMV, which is in accord with a lower main transition temperature in GMV than in LMV. In addition to the abovementioned behavior, the difference between the $\lambda''_{\min}$ values of the L_α phase in GMV (491 nm) and LMV (484 nm) also support the view that the exclusion effect of Prodan molecules is higher in GMV and that the main transition occurs at a lower temperature in GMV. These results clearly show that the curvature of the vesicle markedly affects the distribution of Prodan molecules in various phases and that Prodan can be an good indicator of change in packing stress or the curvature of lipid bilayers [20].

A 3D image plot for GMV of the C17PC bilayer obtained under thermotropic conditions at a high pressure is depicted in Fig. 70.5, which corresponds to the plot for LMV under high pressure shown in Fig. 70.3b. The four wavelengths characteristic of the L'_β, P'_β, L_α, and $L_\beta I$ phases for LMV under high pressure are 430, 433, 480, and 497 nm, respectively, whereas those for GMV are respectively 430, 433, 482 and 501 nm. The difference in the shape of the spectra in the image plots between LMV and GMV under high pressure is essentially the same as the difference observed for these spectra under atmospheric pressure. The $\lambda''_{\min}$ values in the L_α phase for LMV and GMV under high pressure are lower than those under atmospheric pressure. This is probably because the high pressure almost cancels out the exclusion effect of the Prodan molecules as mentioned above [20].

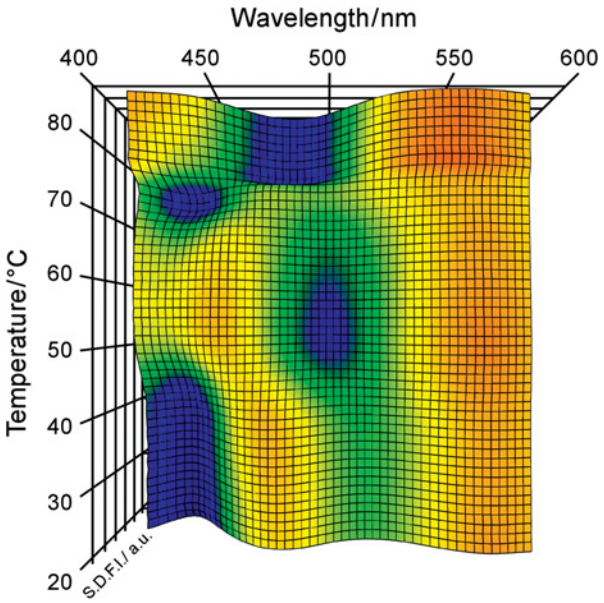

FIGURE 70.5 Image plot for the second derivatives of fluorescence spectra of Prodan for GMV of C17PC bilayer.

70.3.3 Effect of Acyl Chain Asymmetry

Symmetric phospholipids with two identical acyl chains such as DPPC and DSPC are rather minor components of lipids contained in biological membranes. Actually, asymmetric phospholipids with two different acyl chains (length and/or unsaturation) are found abundantly in the membranes. Thus, it is important to study bilayer properties of asymmetric phospholipids for an intrinsic understanding of the biological membranes. We have constructed *T–p* phase diagrams of various asymmetric PC bilayers and evaluated the thermodynamic quantities associated with the phase transitions. Consequently we showed that the bilayer properties of asymmetric PCs are significantly influenced by the effective chain length between the *sn*-1 and *sn*-2 acyl chains; that is, the acyl chain alignment at the terminal methyl ends in the PC molecule [22]. We will now discuss the results of the bilayer imaging for two kinds of asymmetric PCs, palmitoylstearoyl-PC (PSPC), and stearoylpalmitoyl-PC (SPPC). The total carbon number of acyl chains for each PC molecule is 34 and is equivalent to C17PC, and the degree of chain alignment at the terminal methyl ends increases in the order of SPPC < C17PC < PSPC [16]. Figure 70.6 shows *T–p* phase diagrams of the PSPC and SPPC bilayers. Here we focus on the behavior of the $L_\beta I$ phase; detailed discussion of the phase behavior is described elsewhere [16]. The MIP values of the PSPC, SPPC, and C17PC bilayers are different from one another, at 50.6, 93.0, and 79.1 MPa, respectively. In the $L_\beta I$ phase, since two acyl chains of the PC molecule orient perpendicularly to the membrane surface, the alignment of terminal methyl ends that can cause the enhanced cohesive interaction between acyl chains is advantageous for bilayer interdigitaion at a lower pressure. Furthermore, as shown in Fig. 70.6b, we observed in the SPPC bilayer that the $L'_\beta/L_\beta I$ phase transition proceeds stepwise and speculated that the peculiar transition may be ascribed to the appearance of the two-phase (i.e., L'_β and $L_\beta I$) coexistence state at the bilayer interdigitation due to the great chain asymmetry of the SPPC molecules [16].

Figure 70.7 shows 3D image plots for the PSPC and SPPC bilayers obtained at a thermotropic condition under high pressure [22]. The heating process of the plots for both PC bilayers under high pressure is given by arrows in Fig. 70.6, and they undergo the $L'_\beta/L_\beta I$, pre- ($L_\beta I/P'_\beta$), and main transitions in turn by this process. The distinct four bluish valleys are observed in the plot for the PSPC bilayer similar to that for the C17PC bilayer. One deepest valley at ~430 nm

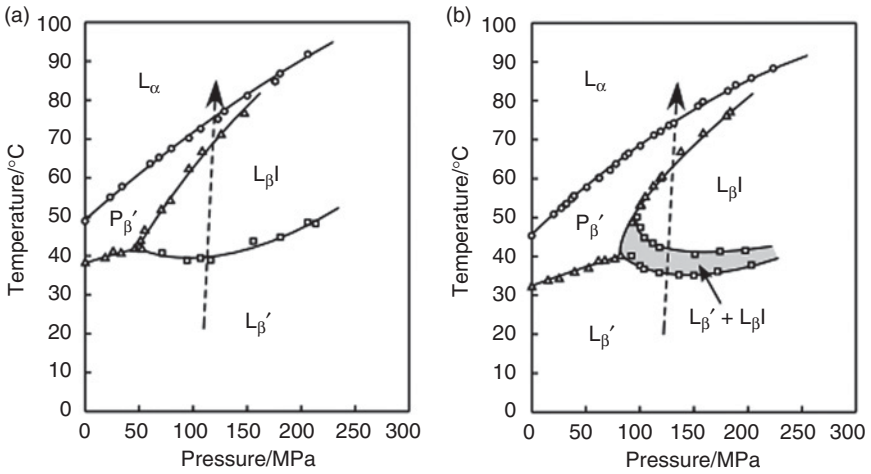

FIGURE 70.6 Temperature–pressure phase diagrams for (a) PSPC and (b) SPPC bilayers. An arrow in each diagram indicates the heating process for Prodan fluorescence measurements in Fig. 70.7.

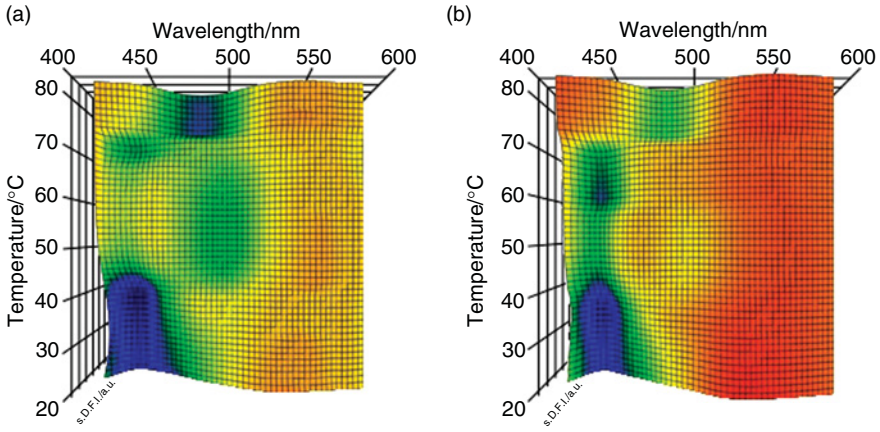

FIGURE 70.7 Image plots for the second derivatives of the fluorescence spectra of Prodan in the (a) PSPC, (b) SPPC bilayers.

(from 20°C to 42°C) corresponds to the L'_β phase, and another bluish valley at ~480 nm (from 78°C to 85°C) corresponds to the L_α phase. Two greenish valleys correspond to the P'_β (~430 nm from 70°C to 78°C) and $L_\beta I$ (~500 nm from 42°C to 70°C) phases. The transition temperatures obtained from the image plots are in good agreement with those from the *T–p* phase diagram in Fig. 70.6a. The image plot of the PSPC bilayer displays behavior similar to that observed in the C17PC bilayer, but the areas of the valleys for the PSPC bilayer extend further than those in the C17PC bilayer, indicating weaker immobilization of the Prodan molecules in the PSPC bilayer than in the C17PC bilayer.

On the other hand, the image plot of the SPPC bilayer is definitely different from those of the PSPC and C17PC bilayers. All valleys corresponding to four phases become shallow; in particular, the valley at 497 nm corresponding to the $L_\beta I$ phase becomes very shallow, to a faintly recognizable degree. In contrast with these behaviors, a distinct green band around 430 nm from 40°C to 60°C is observed, which implies that the Prodan molecules in the $L_\beta I$ phase of the SPPC bilayer partition not into the hydrophilic region, but into the adjacent glycerol backbone. This finding suggests that the great chain asymmetry of the SPPC molecules probably produces a less polar "pocket" in the interdigitated structure in which a Prodan molecule can remain and that they are hardly excluded to the hydrophilic region even if the $L_\beta I$ phase is induced. The fact that the Prodan molecules in the $L_\beta I$ phase of the SPPC bilayer can reside in two locations in the bilayer (i.e., that the Prodan fluorescence exhibits properties such as the L'_β phase even in the $L_\beta I$ phase); this is consistent with the appearance of the two-phase coexistence in the *T–p* phase diagram of the SPPC bilayer. In addition, we have also obtained some interesting data with respect to the effect of vesicle size on asymmetric PC bilayers, described elsewhere [22].

70.4 PACKING STATE IN THE L_c PHASE

Finally, we show the bilayer packing of the most stable phase at a low-temperature, L_c, phase of the PC bilayers examined by the imaging technique. Phospholipid bilayers can form the L_c phase at a low temperature in addition to the gel and L_α phase. Since the L_c phase is usually induced by dehydration of the polar headgroups of lipid molecules in the bilayer, the formation requires a pretreatment, termed *thermal annealing*, which facilitates dehydration prior to experimentation [31]. A period of the annealing treatment for complete L_c phase formation of symmetric PC bilayers increases with an increase in acyl chain length of the PC molecule; for example, about a week is needed for complete induction of the L_c phase in the DPPC bilayer. For the slow kinetics of the phase formation, it is difficult to study the properties and structures of the L_c phase by conventional measurement methods, and there have been few reports on the L_c phase of phospholipid bilayers. To make matters worse, because the annealing treatment enhances the bilayer packing, the probe molecules contained in the bilayer are squeezed out of the bilayer, which makes it difficult to observe the spectrum characteristic of the L_c phase.

We have found that one of the asymmetric PCs, a myristoylpalmitoyl-PC (MPPC) bilayer, can form the L_c phase in an extremely short period of time, unlike the case of symmetric PC bilayers, and that MPPC is suitable for investigation of L_c phase formation [17]. A *T–p* phase diagram of the MPPC bilayer is depicted in Fig. 70.8. In the MPPC bilayer, the subtransition in the low-pressure region is the L_c/P'_β transition, not the L_c/L'_β transition. Since the subtransition temperatures are higher than the pre- (L'_β/P'_β) transition temperatures in the whole range of pressure, the L'_β and P'_β phases and part of the $L_\beta I$ phase become the metastable phase. Therefore, the triple point at which the three gel

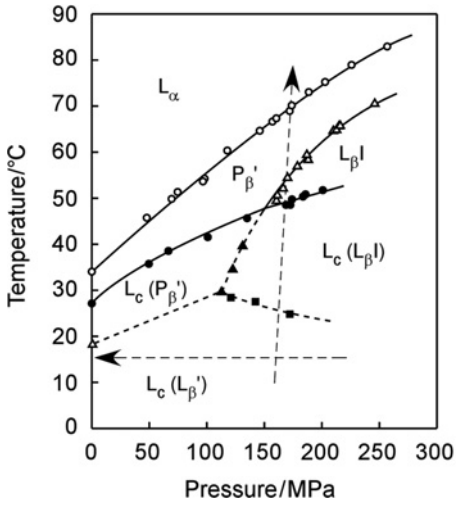

FIGURE 70.8 Temperature–pressure phase diagram for MPPC bilayers. Arrows in the diagram indicate the heating process for Prodan fluorescence measurements in Figs. 70.9 and 70.10.

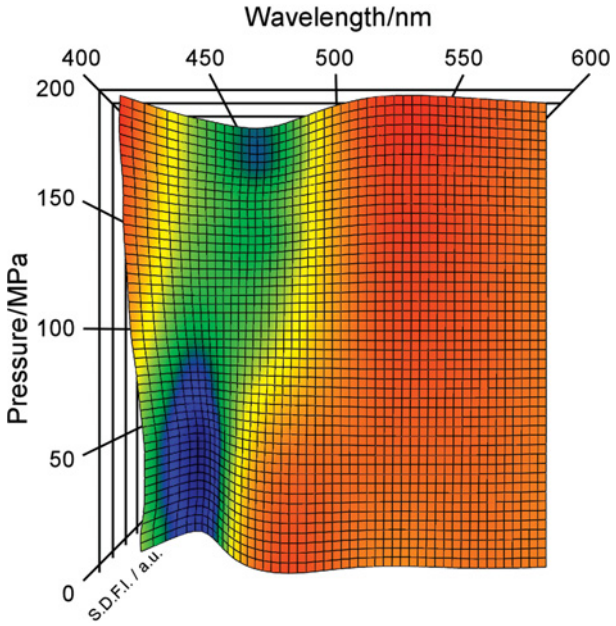

FIGURE 70.9 Decompression effect on image plot for second-derivative spectra of Prodan in MPPC bilayer.

phases coexist is located in the metastable region, and the MIP value is 113 MPa. Although pressure generally facilitates the formation of the L_c phase and hinders observation of the transitions between the gel phases, the Prodan fluorescence measurement can allow us to observe the transitions and simultaneously provide useful information regarding the structure of the L_c phase. The Prodan fluorescence in the L_c phase, which we observed for the first time using fluorometry, is explained here.

Figure 70.9 shows a 3D image plot of the MPPC bilayer obtained under isothermal (15.3°C) barotropic conditions [19]. The decompression process of the plot is indicated by an arrow in Fig. 70.8, and the bilayer undergoes no phase transitions in the process. During the pressurizing process at 15.3°C, the bluish valley at ~430 nm becomes shallower at ~100 MPa while that at ~460 nm becomes deeper, which results in the marked broadening of the valley. With further increasing pressure, the greenish valley at ~460 nm becomes broad but deep abruptly at pressures above ~200 MPa. Since the phase state was identified as the L_c phase by DSC and light transmittance measurements under atmospheric pressure, we judged the broad spectra to be characteristic of the L_c phase. Interestingly, the spectra at pressures below 50 MPa cannot be distinguished from those of the L'_β and P'_β phases. Because this spectral shift is completely reversible, sufficient pressure is essential to form the spectrum characteristic of the L_c phase, suggesting that the packing state of the structure of the L_c phase differs from those of the other phases.

Figure 70.10 shows an image plot of temperature dependence for the MPPC bilayer obtained under thermotropic conditions at a high pressure [19]. Here, the heating process of the plot under high pressure is indicated by an arrow in Fig. 70.8 and the MPPC bilayer undergoes the $L_c/L_\beta I$, pre-($L_\beta I/P'_\beta$), and main transitions in turn by this process. At 10°C, the bluish valley at ~460 nm, which is characteristic of the L_c phase, is broad. In the temperature range from ~10°C to ~20°C, the valley gradually shifts to the short-wavelength region, and the single valley at ~460 nm starts to separate into double local valleys at ~430 and 500 nm at ~26°C. Since

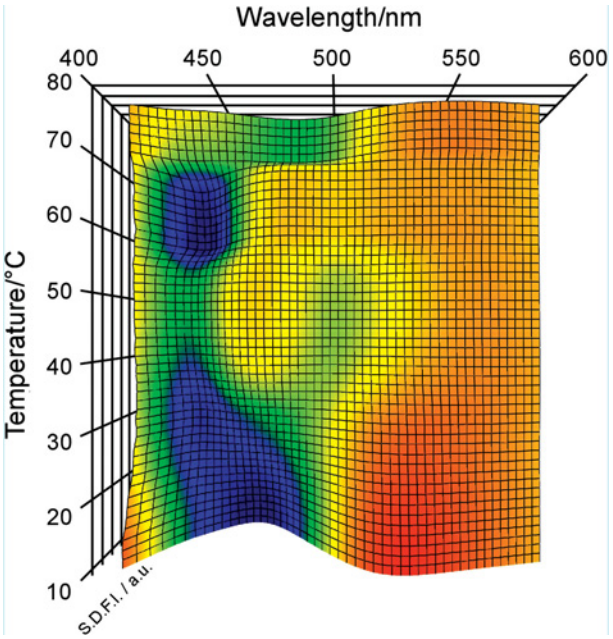

FIGURE 70.10 Image plot for the second derivatives of fluorescence spectra of Prodan in MPPC bilayer.

the temperature is consistent with the metastable $L'_\beta/L_\beta I$ phase transition temperature, we can conclude that the Prodan molecules in the L_c phase can sensitively recognize the metastable $L_\beta I$ phase region and quickly translocate the distribution sites at the transition. This fact suggests that the L_c phase of the MPPC bilayer transforms into two kinds of L_c phases, namely, L_c and interdigitated L_c (L_cI) phases. With an increase in temperature, the double local valleys become sharp while the valley at ~460 nm becomes shallow, and a typical image pattern of the $L_\beta I$ phase is observed at ~48°C. Further increases in temperature produce the valley at 430 nm and subsequently that at 480 nm in response to the pre- and main transitions, respectively, in the same pattern as that observed for the DPPC bilayer. From the bilayer imaging, we could propose a hypothesis that the MPPC molecules in the L_c phase form a staggered configuration, where adjacent polar headgroups of the molecules mutually shift the position up and down against the membrane surface. A detailed explanation is provided elsewhere [19].

70.5 CONCLUSIONS

We showed that a 3D image plot based on the second derivatives of the isobaric thermotropic and/or isothermal barotropic change in the Prodan fluorescence spectra can examine the correlation between the location of the Prodan molecules distributed in the bilayer and the bilayer phase behavior as a function of both temperature and pressure. This imaging method also enables us to visually evaluate the packing state of lipid molecules in the bilayer and the effects of several pertinent factors on the packing state of the PC molecules in the bilayer. Fluorometry is an easier technique than X-ray and neutron scattering for investigating the microscopic states of the phospholipid bilayer; however, several probes of hydrophobic and/or hydrophilic nature are required to observe multiple phase transitions such as gel/gel and gel/L_α transitions simultaneously. It is very significant that the fluorescence measurements using a amphiphilic probe Prodan enables us to observe such plural phase transitions by the only single probe at the same time and makes it possible to construct a map of the packing states in the bilayer. We expect that the bilayer and/or nonbilayer packing of other kinds of phospholipids such as phosphatidylethanolamines, phosphatidylglycerols, and phosphatidylserines will be clarified by this imaging method.

ACKNOWLEDGMENTS

We appreciate Shoji Kaneshina, professor emeritus of The University of Tokushima, for his kind help and advise in discussion of Prodan fluorescence under high pressure. We are also grateful to Mr. Yuji Yamashita, president of Yamashita Technology System Co. Ltd., for development of several experimental devices and continuous technical support.

71.1 INTRODUCTION

Globally, soil salinity is becoming an increasing threaten to plant growth [1, 2]. According to FAO, at least 800 million hectares (ha) of land are subjected to salinity [3], accounting for as much as 6% of the world's total land area. Although some of the salt-affected influence is the result of natural causes, most is derived from the degraded cultivated agricultural land [4, 5]. At present the world's cultivated land affected by salinity has achieved 20% [6]. Currently, food supply is basically sufficient, but approximately 800 million people are undernourished [7]. It has been reported that food production must increase to 150% to meet the constantly growing population by 2050 [3,8]. The amount of cultivated agricultural land is narrowed by the increasingly serious salinization, and there is an increasing demand for food with the increase in population. To meet these challenges, breeding crops which are able to survive abiotic stress, and to maximize performance under unfavorable conditions seem to be the major topics for research [9].

Generally, the so-called saline soil has a high concentration of soluble salts. Soils are regarded as saline if the soil solution electrical conductivity (EC) values reach ≥4 dS/m [10]. The solution concentration is equivalent to 40 mM NaCl, generating an osmotic pressure of approximately 0.2 MPa and significantly reducing the yields of most cereal crops [4]. However, the deleterious effects vary according to several related factors, including climatic conditions, plant species, and soil regime. For instance, rice is the most sensitive species among the grain crops, while barley displays a relatively pronounced resistance [11, 12]. High salinity can threaten plant health by imposing two general types of stress: hyperosmotic stress and hyperionic stress [13]. On the basis of their capacity to grow in high-salinity soil, plants are classified into two types: glycophytes and halophytes [14]. Some of the halophytes have the ability to exclude salts from their roots and shoots, some are able to endure high-concentration salt, and others adopt measures such as ion compartmentalization, synthesis of compatible solute, and osmotic adjustment [15]. Yet almost all the crops are glycophytes, thus two key measures (producing salt-tolerant lines/cultivars through conventional breeding or genetic engineering) to overcome this challlenge have been put forward for a long time [16]. Growing halophytes and salt-tolerant crops on saline soil is regarded as the *biotic approach*, which is similar to the concept of *biosaline agriculture* [17–19]. As is well known, other than animals, plants maintain a sessile lifestyle subjected to various types of environmental stress [20]. Modern-day plants are all the products of primal living, experienced eons of evolution with abiotic and biotic changes. Thus they have acquired various adaptive mechanisms to optimize growth and development under stress [21]. Sodium chloride is the most common and widespread salt in soil, so the evolved

mechanisms of plants regulate its accumulation and distribution [22a]. For glycophytes, high-concentration salts can produce ionic stress, osmotic stress, and secondary stress [23]. In order to guarantee survival under such detrimental circumstances, plants have evolved a series of biochemical and molecular processes to acclimatize themselves to the environment [24–27]. The specific biochemical strategy consists in (1) ion regulation and compartmentalization, (2) induced biosynthesis of compatible solutes, (3) induction of antioxidant enzymes, (4) induction of plant hormones, and (5) changes in the photosynthetic pathway [28]. The molecular mechanism includes (1) the SOS (salt overly sensitive) pathway for ion homeostasis, (2) the protein kinase pathway for stress signaling, (3) the phytohormone signaling pathway under high salt stress [23], and (4) the associated genes encoding salt stress proteins (e.g., genes for photosynthetic enzymes, for synthesis of compatible solutes, for vacuolar sequestering enzymes, and for radical-scavenging enzymes) [29].

In recent years, tremendous advances have been achieved in salt stress studies. Plant breeders have fostered some salt-tolerant lines of crops by conventional breeding; moreover, a transgenic approach is employed to improve the crop salt tolerance, and a number of transgenic lines have been confirmed effective under control conditions [16]. *Metabolomics* is becoming a tool to help researchers understand the cellular mechanism of abiotic stress and is also a viable option for the biotechnological improvement of halophytes [30]. Small noncoding RNAs, mainly microRNAs and siRNAs (short interfering RNAs), can regulate gene expression by silencing of the genes [31]. MiR393 has been reported to be strongly upregulated by drought and high-salinity treatment [32, 33]. In the most recent study, ribosomal RNA methylation was discovered to response to abiotic stress [34]. In addition, the mitogen-activated protein kinase (MAPK) signaling pathways, which are involved in stress response, are highly conserved and important regulating systems in plants [35, 36].

Reviews on salinity responses began to appear three decades ago, and new reports have appeared continuously [1,4,13,14,28,37]. The molecular, cellular, and holistic mechanisms of plant salt tolerance have been discussed in detail [4]. One team of researchers chose to stand at the point of uptake and transport of ions to review the concrete mechanisms of salt tolerance [15]. Two investigators described how plants manage to control ion homeostasis by sensing, transduction, and responding to salt stress signaling [13]. Thanks to the rapid development of life science, our understanding of salinity tolerance in both physiological and molecular fields has experienced a qualitative leap. In this chapter we will focus on the molecular, cellular, and physiological mechanisms of salt tolerance in detail, especially the latest findings in this sphere.

71.2 GROWTH AND PHOTOSYNTHESIS

Environmental stress can trigger various plant responses ranging from gene expression to metabolism, and all the way to growth rate and productivity [38]. Salinity, which is the most common and comprehensive negative influence, can lead to apparent stunting of plant growth [39, 40]. From another perspective, slower growth is an available measure for ensuring plant survival under stress [1]. In other words, adverse environments affect the plant, and the plant takes the necessary measures to accommodate it. Actually, all physiological functions or activities are adaptive strategies for plants under salt stress. Research on *Arabidopsis* revealed a link between stress and cell division, illustrating the mechanism at the molecular level [41]. Cyclin-dependent protein kinase inhibitor (ICK1), which is induced by abscisic acid (ABA), can reduce the activities of cyclin-dependent protein kinase to restrain cell division, and ABA is a central plant hormone under abiotic stress, involved in cellular signaling, regulation of plant growth, and stomatal conductance [37,42]. Yet studies on barley displayed that ABA concentration increased transiently under salt stress and returned to normal after 24 h, with leaf growth rate reduced [43]. More recent research shows that it is a Asp-Glu-Leu-Leu-Ala (DELLA) protein, which is a common negative factor in plant growth and a key component in gibberellic acid (GA) signal transduction that integrates signals from hormones and abiotic stress to plant growth [44].

The accumulated Na^+ within plants also can produce ionic toxicity. With only a few exceptions, the glycophytes, especially a large proportion of crops, cannot tolerate Na^+ concentration at $\geq$50 mM [4]. The excess salt can inhibit enzyme activity and lead to death to leaves [22a]. Or salt may build up in the chloroplast exerting a toxic effect on photosynthetic processes and photosynthetic components directly [4]. Mitogen-activated protein kinase 6 (MPK6) has been demonstrated to play an important role in sodium detoxification through phosphorylation of the Na^+/H^+ antiporters and inducing the efflux of sodium [42].

Biomass is only a broad and morphological parameter, while photosynthesis is one of the most direct and conclusive factors in determining plant growth and crop yields. Photosynthetic rate would decrease if any part of its process was affected [27]. For instance, stress can reduce stomatal and mesophyll conductance and decrease CO_2 availability, ultimately lowering photosynthesis [42]. Carbon fixation can be destroyed by salt stress directly; for example, this can occur in ribulose-1,5-bisphosphate (RuBP) carboxylase/oxygenase (Rubisco) activity, which is the key enzyme in photosynthesis [40,45,46]. Gas exchange and chlorophyll a fluorescence are used to monitor photosynthesis to reflect the disadvantageous influence of salt stress [47]. In order to resist salt stress, some plants choose to change the

photosynthetic pathway to cope with this problem [28]. The plant *Mesembryanthemum crystallinum* opted to transform the C3 pathway to crassulacean acid metabolism (CAM) to reduce water loss [48]. The halophytic plant *Atriplex lentiformis* is able to shift from C3 to C4 to combat salt stress [49]. Some transgenic C3 plants displayed higher photosynthetic efficiency and better growth characteristics [50]. Moreover, salt stress can weaken photosynthesis indirectly by reducing chlorophyll and total carotenoid content. It was reported that the contents of total chlorophyll and carotene were depleted by NaCl stress in leaves of tomato and *B. parviflora* [51, 52]. Overall, salinity is accompanied by a significant reduction in photosynthesis.

71.3 OSMOTIC STRESS EFFECTS AND TOLERANCE

As is mentioned above, there are two aspects of salt tolerance: osmotic stress and ionic stress. Osmotic stress is not only confined to drought but is also a result of salinity. The abundance of ions in saline soil lowers the flow of water, inhibiting water uptake or even causing loss of intracellular water [27]. In such cases, to resist these effects, the plant accumulates many metabolites, which are usually called *compatible solutes*, to increase its osmotic tolerance [13]. These compatible solutes include sugars (fructose, sucrose, and glucose), complex sugars (trehalose, raffinose, and fructans), quaternary amino acid derivatives, tertiary amines, and sulfonium compounds [4]. They are able to not only counteract the ion load but also balance the osmotic potential of Na^+ and Cl^- that are sequestered into the vacuole [53]. Among the compatible solutes, proline (Pro) and glycine betaine (GB) are the most common and efficient. In 1977, a research team reported that Pro or GB is able to accumulate at high concentration, producing as much as 0.1 MPa osmotic pressure [14]. With the continuing in-depth research, their vital functions in salt stress are becoming increasingly clear.

Pro is able to act as molecular chaperone to stabilize the protein conformation, buffer cytosolic pH, and balance cell redox conditions [54]. Under stress, the accumulation of Pro is due to increased biosynthesis and decreased degradation. In leaves of two rice cultivars with different salinity tolerance, the accumulative rate of proline is quicker in the tolerant line [55]. Research on sorghum also illustrated that the proline concentration is at a higher level when subjected to salt stress [56]. It is now known that there are two pathways and three enzymes involved in the synthesis of Pro [57]. For the three synthetic enzymes [pyrroline-5-carboxylate synthase and reductase (P5CS, P5CR) and ord-δ-aminotransferase (OAT)], P5CS is the rate-limiting enzyme and is adjusted by feedback and transcriptional regulation [58, 59]. In *Arabidopsis* the signaling pathway for the induction of P5CS1 expression during salt stress depends on phospholipase C (PLC) and ABA-responsive (ABRE) element [60,61]. Identifciation of the molecular mechanism in Pro metabolism has been accompanied by progress in transgenic engineering. The first transgenic plant with accumulated Pro was acquired in 1995 [62]. In *Arabidopsis*, overexpression P5CS antisense or the insertional mutant of this gene can reduce the salt tolerance of transgenic plants [63,64]. Meanwhile, we may lessen the degradation of Pro to maintain its concentration, so the key enzyme in degradation, proline dehydrogenase (PDH), is also manipulated. However, in PDH antisense, lines with higher stress tolerance have emerged at times but not always [63,65].

Glycine betaine (GB) is synthesized and accumulated under a variety of abiotic stress and acts as an osmolyte to protect PSII under salinity [66]. It can also protect the integrity of membrane and the activity of enzymes against osmotic stress [67]. Generally, high-concentration salt is able to increase GB concentration in many crop plants, such as sugarbeet, spinach, barley, wheat, and sorghum [68–70]. In view of its powerful features, transgenic engineering was also employed to operate GB concentration. Transgenic *Arabidopsis* expressing *N*-methyltransferase gene, which is one of the three key enzymes in GB synthesis, showed improved seed yield compared to the control under salt stress [71]. Similarly, overexpression of galactinol peroxidase 2 (GOLS2), a GB synthase, enhanced tolerance to high salinity in *Arabidopsis* [72].

In fact, there are many other compatible solutes. For example, in *Arabidopsis*, overexpression of mannose-6-phosphate reductase was reported to increase growth and photosynthesis in saline treatment [73]. Some plants that are able to tolerate Na^+ at high levels, such as barley, tend to adapt and maintain turgor in the face of high soil salinities by Na^+ directly. In addition, some plants tend to accumulate carbohydrates such as sugars and starch to cope with salt stress [52]. In conclusion, to survive salt stress successfully, plants have to accumulate high concentrations of compatible solutes to maintain low water potential in cells.

71.4 ION TOXICITY AND ION HOMEOSTASIS

Because of their similarity in physicochemical properties, Na^+ competes with K^+ to bind to the active site of the enzymes, causing the inactivation or degeneration of the enzymes and the disorder of protein synthesis and ribosome function [4]. The toxic position of Na^+ is mainly in the leaf blade, since Na^+ in the transpiration stream is deposited here or in the roots [22b]. One study indicated that the functions of chloroplast were disturbed when K^+ was replaced by Na^+, resulting in uncontrolled water loss [74]. Although Cl^-

is a necessary micronutrient for cells in regulating enzyme activity, maintaining membrane protein and pH gradients, it is toxic to cells at high levels [75, 76]. Accumulated Na^+ in shoots is associated with a decrease in stomatal conductance, while Cl^- in high concentration can damage chloropyll and inhibit photosystem II (PS II) [77]. More seriously, the toxic effects of Na^+ and Cl^- have a cumulative effect. Hence, balancing intracellular ion concentrations by maintaining high K^+ and low Na^+ concentration in the cytosol are crucial for plants [27].

Fortunately, during the lengthy evolution, most plants have acquired capabilities to regulate ions accumulation and to uptake ions selectively. Plants can exclude the toxic excess Na^+ ions from cytosol [78], and almost all the plants are able to take up water and exclude Na^+ and Cl^- from soil effectively [22a]. Some plants, especially halophytes, possess succulent leaves and stems to dilute the concentration of the toxic ions; others evolve salt glands or bladders to secret excess ions [27]. Studies in wheat and wild soybean with better salt tolerance demonstrated that the Na^+ concentration in shoots is maintained at lower levels by withholding it in roots [79, 80]. In other words, the abilities to exclude Na^+ from the cytoplasm and to accumulate Na^+ in vacuoles efficiently are the most important means of maintaining ion homeostasis in cells [81]. By either exclusion by roots or compartmentalization into vacuoles, the transport of ions is mediated by H^+-ATPase, ion channels, and cotransporters in plants. The plasma membrane Na^+/H^+ antiporter SOS1 and the tonoplast membrane antiporters vacuolar Na^+ /H $^+$ antiporter (NHX) are the most important transporters in salt stress and have been investigated extensively [37].

Salinity exposure triggers complicated signaling events, so the means by which stresses are sensed and transported by salt stress signaling provides us with a clue to understand the regulation mechanism of plants. The SOS signaling pathway has been identified in earlier studies as consisting of three key components: SOS3, SOS2, and SOS1. SOS3 is a Ca^{2+} sensor [82]. SOS2 is a serine/threonine protein kinase [83]. SOS3 can sense the perturbation of Ca^{2+} levels in cytoplast caused by salt stress and then bind to the SOS2. Then the SOS3/SOS2 complex phosphorylates and activates SOS1; hence the activated SOS1 has the ability to export excess ions and contribute to Na^+ ion homeostasis [82–84]. SOS1 was also discovered to be the downstream target of MPK6 by GST pulldown assay [85]. Moreover, during salt stress the phosphorylation degree of SOS1 increases [42]. Many other studies have stated that the components of the signaling pathway may be regulated by salt stress directly or influence other signaling pathways of the stress to affect responses indirectly [86–88].

The NHXs are vacuolar Na^+/H^+ antiporters. In one review, NHXs were demonstrated to participate in cell expansion, cell volume regulation, ion homeostasis, osmotic adjustment, pH regulation, protein processing, and other processes [2]. In genetic engineering, the hypersensitive phenotype of *sos1* demonstrated powerfully the key position of SOS signaling pathway in salt stress. Compared to control leaves, the H^+-ATPase in tonoplast vesicles increased twofold in salt-treated leaves [89]. Overexpression of NHX may reduce cytosolic Na^+ concentration and improve salt tolerance by efficient sequestration [90]. Its overexpression confers salt tolerance to a wide range of plants [91]. In Table 71.1, transgenic plants for different ion transporters with enhanced ion homeostasis are listed for reference.

In addition, the HKT family also plays vital functions in maintaining ions homeostasis. The HKT proteins act as Na^+/K^+ symporters and Na^+-selective transporters, involved in balancing of Na^+ and K^+. More recently, AtHKT1 was demonstrated to take charge of the resorption of Na^+ from xylem to reduce the amount of Na^+ reaching the shoot in *Arabidopsis* [112]. In durum wheat, TmHKT1 is correlated with Na^+ exclusion and a high K^+/Na^+ rate in leaves [113]. In rice, OsHKT1 appears to have the same function as AtHKT1 [114], yet much more work is needed to clarify the multiple functions of the gene family.

Recently, maintaining intracellular high cytosolic K^+/Na^+ ratio has been accepted as the key determinant in salinity tolerance [4]. K^+ possesses a significant role in activating enzymes, regulating osmotic pressure, regulating stoma movement, and balancing turgor [115]. In wheat cells, the contents of K^+ and Na^+ are kept at 150 mM and 30 mM, respectively, so the K^+/Na^+ ratio is approximately 5 [116]. Indeed, increasingly reports show that it should be the cytosolic K^+/Na^+ ratio that determine the plant salt tolerance. Two other authors proposed that the low level of KNO_3 could alleviate NaCl-induced stress [117]. Another group further claimed that NaCl stress symptoms can be alleviated by simultaneously applied KNO_3 and that the optimal K^+/Na^+ ratio should be 100:16 for both salt-tolerant and salt-sensitive cultivar [118]. Similarly, overexpression of LeENH1 (a tomato enhancer of SOS3-1) in tobacco enhanced salinity tolerance by excluding Na^+ from cytosol and retained high K^+ levels in the cytosol [119]. Studies on NHXs also attest to this point. More recently, mineral analysis of the transgenic plants with overexpressed NHXs seems to indicate that salt resistance is provided by a high K^+/Na^+ ratio through K^+ retention rather than Na^+ exclusion [120]. In *Arabidopsis*, the phenotype of *sos* mutants may be alleviated by an exogenous supply of K^+ [37]. Compared to *Arabidopsis*, the *Thellungiella* species (see Table 71.1) possess stronger ability to adapt to saline soil. One reason is that the cytosolic K^+ concentration in *Thellungiella* is higher. One group claimed that the transgenic tomato with high resistance depended on cytosolic K^+ homeostasis rather than on vacuolar Na^+ accumulation [121].

71.5 OXIDATIVE STRESS AND ANTIOXIDANT DEFENSE RESPONSES

Besides osmotic stress and ion toxicity, salinity can also induce the generation of reactive oxygen species (ROS) and lead to oxidative stress. ROS derive from the excitation of O_2 including singlet oxygen ($^1O_2$), superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical (OH·), respectively [27]. Unlike atmospheric oxygen, ROS are able to oxidize the various cellular components without unrestriction, leading to the oxidative destruction of plant cells [122]. Actually, ROS are the common byproducts of the metabolic pathways such as photosynthetic electron transport, respiration, and photorespiration processes [123]. For example, salt stress limits the supply of CO_2, causing overreduction of the photosynthetic electron transport chain and a vast production of ROS [13]. The overabundant ROS can oxidize cellular components, hinder metabolic activities, and affect organelle integrity [124]. The destructive effect of ROS is the lipid peroxidation estimated by the content of malonyldialdehyde (MDA) [125]. Generally, under normal conditions, the production and eliminate of ROS are in an equilibrium state [26]. However, under salt stress conditions, the generation rate of ROS overwhelms the scavenging of the antioxidant system, and then oxidative damage occurs, leading to oxidation to lipids, proteins, and nucleic acids. This occcurs precisely because these biomacromolecules are components of the plasma membrane; thus the membrane system is the main subject of the ROS [27].

In higher plants, the ROS removal system includes ROS-scavenging antioxidant enzymes and small nonenzymatic molecules such as ascorbate, glutathione, flavonoids, anthocyanines, and carotenoids [13]. The nonenzymatic molecules are able to donate electrons or hydrogen to scavenge free radicals [26]. The antioxidant enzyme system consists of superoxide dismutase (SOD), peroxidase (POD), ascorbate peroxidase (APX), glutathione peroxidases (GPX), glutathione reductase (GR), catalase (CAT), and the ascorbate–glutathione cycle [16]. The SOD, APX, and GR (glutathione reductase) are reported to scavenge H_2O_2 in chloroplasts and mitochondria, and the others are believed to be capable of removing H_2O_2, neutralizing or scavenging free radicals [126]. Among them, SOD and CAT are the most efficient enzymes. Under salt stress, the second metabolites increased more quickly than did the antioxidant enzyme activities in *Swertia chirata* [127]. The levels and contents of superoxide and hydrogen peroxide can be decreased by most of the antioxidant obviously, so in many species the antioxidant capacity is associated with salinity tolerance tightly. For example, the antioxidant enzyme activities of SOD, APX, and GR increased 10–18 times after salt stress in *P. popularis* [128]. The correlation between antioxidant capacity and salinity tolerance is being discovered in an increasing number of species, containing cotton, citrus, foxtail millet, purslane, sugarbeet, pea, and plantago [13].

During the last few decades, engineering the genes of some antioxidant enzymes has been employed to ameliorate plants exposed to stress. By observing the changes in the

expression level of related genes, researchers were able to produce transgenic plants to probe the effects. Finally, in the transgenic plants, overexpression antioxidant enzymes such as SOD, CAT, and APX displayed elevated tolerance to oxidative stress [13]. The transgenic *Arabidopsis* and *Lycopersicon esculentum* possess a significant increase in salt tolerance with the overexpression of a Mn-SOD [129, 130]. Details are shown in Table 71.2. More importantly, most of the transgenic plants with some overexpressed antioxidant enzymes acquire an elevated tolerance to almost all abiotic stresses instead of a specific stress. In our opinion, the possible reason for this is that the oxidative stress is the result of almost all the abiotic stresses, so the enhancement of the antioxidative capacity is able to boost resistance in general. Although the transgenic plants with overexpressed antioxidant enzymes acquire enhanced tolerance, there exist inevitable contradictions. The *Arabidopsis* mutants with loss of either or both cytosolic and chloroplastic APX show enhanced tolerance on the contrary [131]. Likewise, there is a decline in CAT activity in *Anabaena doliolum* under NaCl stress [132]. In *Glycyrrhiza uralensis* seedlings, CAT activity is also decreased by salt and drought stress [133]. In conclusion, the ROS pathway is plastic and redundant, more strategies and principles remain to be seen.

Reactive oxygen species play a dual role in plants. Superfluous ROS are detrimental to plant cells, yet moderate ROS components are necessary, playing important roles in signaling transduction and cell homeostasis [85]. In fact, upregulation of the expression levels of enzyme genes or the enhancement of their enzymatic activities results from cell signaling. Ahead of their detoxification, the genes will have initiated a series of signaling in cells. MAK3 and MAK6 can be activated by the elevated content of ROS [150], and the activated MAK3 and MAK6 were relocated in the nucleus to strengthen or weaken gene expression, triggering plant responses to ROS. Nevertheless, the MAPK phosphatase 2 (MKP2), which is induced by oxidative stress, is able to dephosphorylate MPK3 and MPK6 to promote oxidative stress tolerance [85]. Therefore, the signal regulatory pathways are intricate.

71.6 PHYTOHORMONE IN SALT STRESS

Plant hormones partipate in almost all plant contents and processes, including different positions, different tissues, and different developmental stages. ABA is the foremost one and is induced by various obvious types of stress. It is able to regulate the adaption of plants to stresses such as cold, drought, salinity, pathogen attacks, injury, and oxidative stress [85]. It has been proved responsible for the change in salt-stress-induced genes back in the 1990s [151]. Its powerful functions in salt stress are reflected in its involvement in the photosynthesis and growth, osmotic tolerance, ion homeostasis, and antioxidant defense responses that we mentioned above. Two decades ago, Popova and colleagues proposed that the inhibitory effect of salt stress on growth and photosynthesis can be alleviated by ABA [152]. Moreover, ABA participates in regulating stress-related gene expression. In ABA-deficient mutants, P5CS, which is the rate-limiting enzyme of the synthesis of Pro, is reduced or completely blocked [153]. For ion homeostasis, ABA has the ability to reduce anion channels to reduce Cl^- transfer in saline conditions [154]. The type 2C protein, phosphatase ABI2, which acts as a vital component in ABA signaling, is able to bind to SOS2 directly and dephosphorylate it [155]. The involvement of ABA in antioxidant defense responses is the induction of antioxidant defense. During the ABA-induced antioxidant defense, hydrogen peroxide (H_2O_2), nitric oxide (NO), and mitogen-activated protein kinase (MAPK) are the major components [156–160]. Zhang and coworkers reported that the zinc finger protein ZFP182 also mediated the ABA-induced antioxidant defense [161]. In rice, ABA can significantly induce the expression and activity of OsCAT to control the accumulation of H_2O_2 under stress [159]. More recently, ABA was discovered to induce the production of primary and secondary metabolites, the photosynthetic capacity, the antioxidant ability, and the antioxidant enzymes [162].

In recent years, phytohormone—salicylic acid (SA) was repeatedly reported to participate in salt stress responses as well [42]. The exogenous SA can ameliorate toxicity stress induced by salt stress, and its vital function under salt stress manifests in its enhancement on antioxidant system. In periwinkle, nonenzymatic and enzymatic antioxidants can be induced by exogenous SA [163]. In mungbean, SA alleviates decreases in photosynthesis by means of enhancing antioxidant metabolism [164]. Furthermore, SA can lessen salt stress by maintaining ion homeostasis. It is well known that ion homeostasis, especially the optimum K^+/Na^+ ratio, is crucial for plants under salt stress. Discoveries achieved by noninvasive microelectrode ion flux estimation (MIFE) technique [165] revealed that SA pretreatment can enhance K^+ retention, increase H^+-ATPase activity, and reduce K^+ loss under salt stress [166]. Generally speaking, the potential mechanism of SA to enhance salt tolerance lies in improving photosynthesis, enhancing antioxidant protection, and maintaining optimum K^+/Na^+ ratio [164,166,167].

71.7 CONCLUSIONS

Salt stress is one of the most common types of abiotic stress. Its negative influence on plants is comprehensive. High-concentration salt can interfere with normal growth and development tremendously and even lead to death to plant. Fortunately, plants have acquired the abilities to ameliorate these adverse effects by physiological, molecular, and genetic by means of regulation. Plants reduce their growth rate to

TABLE 71.2 Genetic Transformation of Antioxidant Enzymes for Enhancing Salt Tolerance

Gene symbol	Donor	Acceptor	Gene functions	Elevated character	Ref.
Ascorbate peroxidase (APX)	*A. thaliana*	Tobacco	Primary H_2O_2-scavenging enzyme	Enhanced tolerance to active oxygen-generating paraquat and sodium sulfite	134
Superoxide dismutase (SOD)	*A. thaliana*	*A. thaliana*	A critical enzyme for eliminating reactive oxygen species (ROS) in plant cells	Lower content of malondialdehyde (MDA) and better growth than control under salt stress	129
Ascorbate peroxidase (APX)	Pea	Tobacco	Primary H_2O_2-scavenging enzyme	Higher germination rate and minimized leaf damage under salt stress	135
Dehydroascorbate reductase (DHAR)	Rice	*A. thaliana*	A critical enzyme for ascorbate recycling	Enhanced resistance to salt stress	136
Ascorbate peroxidase (APX)	Rice	*A. thaliana*	Primary H_2O_2-scavenging enzyme	Longer root length and higher total chlorophyll content	137
Ascorbate peroxidase (APX) Superoxide dismutase (SOD) and DHAR	Tobacco	Tobacco	Primary H_2O_2-scavenging enzyme; A critical enzyme eliminating reactive oxygen species (ROS) in plant cells; a critical enzyme for ascorbate recycling	More resistant to paraquat-induced stress and enhanced tolerance to NaCI	138
Monodehydroascorbate reductase (MDAR)	*A. thaliana*	Tobacco	Crucial for ascorbate (AsA) regeneration and essential for maintaining a reduced pool of AsA	Higher net photosynthesis rates and greater PS II effective quantum yield under salt stress	139
Catalase (CAT)	*Escherichia coli*	Tobacco	Catalyzing the dismutation of H_2O_2 into water and oxygen	Increased the resistance of the chloroplast's translational machinery under salt stress	140
Superoxide dismutase (SOD)	*Avicennia marina*	Rice	The first enzyme in the enzymatic antioxidative pathway	More tolerant to methyl viologen–mediated oxidative stress	141
Superoxide dismutase (SOD)	Tobacco	Pepper	The first enzyme in the enzymatic antioxidative pathway	Increased resistance to oxidative damage	142
Ascorbate peroxidase (APX)	Tomato	Tobacco	Primary H_2O_2-scavenging enzyme	Higher seed germination rate and elevated stress tolerance during postgermination	143
Suaeda salsa glutathione S_transferase gene (GST)	*Suaeda salsa*	*A. thaliana*	Involved in the reduction of most active oxygen radicals generated by stress	Higher photosynthesis rate and fresh weight	144
Monodehydroascorbate reductase (MDAR)	*Avicennia marina*	Tobacco	Crucial for ascorbate (AsA) regeneration and essential for maintaining a reduced pool of AsA	Enhanced redox state of ascorbate and reduced levels of malondialdehyde	145
Ascorbate peroxidase (APX)	*P. populus*	Tobacco	Primary H_2O_2-scavenging enzyme	Resistance to methyl viologen and salt stress	146
Ascorbate peroxidase (APX), Superoxide dismutase (SOD)	Tobacco	Tobacco	Primary H_2O_2-scavenging enzyme; the first enzyme in the enzymatic antioxidative pathway	Improved seed longevity and germination under various types of environmental stress	147
Glutathione peroxidases (GPXs)	Wheat	*A. thaliana*	Reducing H_2O_2 and organic hydroperoxides to water and correspondingly alcohols	Strong tolerance to salt, H_2O_2, and ABA treatment	148
Ascorbate peroxidase (APX), superoxide dismutase (SOD)	Plums	Plums	Primary H_2O_2-scavenging enzyme; the first enzyme in the enzymatic antioxidative pathway	Higher contents of nonenzymatic antioxidants glutathione and ascorbate and lower accumulation of hydrogen peroxide	149

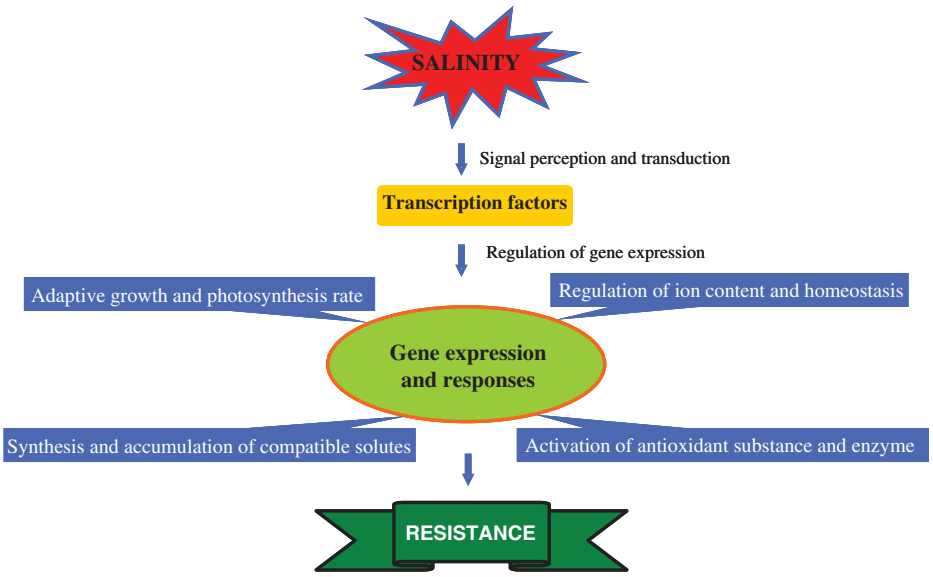

FIGURE 71.1 The general pathway under salt stress.

guarantee their survival and maintain regular photosynthesis by regulating enzymatic activities under salt stress [1]. Facing the osmotic stress produced by salt, plants accumulate compatible solutes actively to reduce cell water potential [4]. Different channels and transporters are activated or inhibited to regulate and maintain ion homeostasis. The clarified signaling pathways tell us the complicated regulatory mechanisms employed by plants under salt stress. The discovery of the SOS signaling pathway is a milestone of the signal pathway in salt stress [82]. The antioxidant system covering nonenzymatic and enzymatic antioxidant systems can help plants escape the damage due to salt stress [26]. Plant hormones are the growth regulators of plants and are involved in the processes in every regard, so salt stress is no exception. ABA plays a pivotal role in the metabolomic, physiological, and signaling procedures. Thus we can conclude that the relationships between salt stress and plants are processes of both influence and adaptation. Exploring and understanding the regulatory mechanisms underlying salt stress can provide us with more methods and ideas to improve plant resistance.

In view of the research and developments in molecular biology and transgenic engineering, plants with enhanced tolerance are generating continuously. For example, overexpression of the synthetic genes of Pro and GB can improve the content of Pro and GB obviously and endow the transgenic plants with enhanced tolerance [62,71]. Similarly, transgenic plants with more SOS1 or NHX1 transporters are able to regulate ion transport more quickly and effectively to improve their growth under salt stress [83, 84,91]. Increasing the antioxidants levels through genetic engineering is widely adopted in breeding to produce crops with enhanced salt stress. Yet the salt tolerance trait is a multigenic property, as salt tolerance is related to physiological, biochemical, and molecular processes, so the ability of genetic engineering to produce salt-tolerant crops is seriously limited by these natural plant processes [37]. More energy, materials, and financial resources are needed to invest in the research. Only in this way can the mechanisms and principles be discovered and corresponding ameliorative solutions be proposed. In addition, there are other factors such as LEA proteins and WRKY and MYB transcriptional factors affecting salt tolerance of plants, which should also arouse attention [168–170]. In the most recent reports, the microorganism in soil is found to be involved in phytohormonal signaling to improve plant nutrition, photosynthesis, and biomass production, thereby enhancing crop salt tolerance [171]. Finally, we summarize our points of view and blueprint for future research in Fig. 71.1.

INTERFACIAL PHENOMENA OF PULMONARY SURFACTANT PREPARATIONS

HIROMICHI NAKAHARA, SANNAMU LEE, AND OSAMU SHIBATA

Department of Biophysical Chemistry, Graduate School of Pharmaceutical Sciences, Nagasaki International University; 2825-7 Huis Ten Bosch, Sasebo, Nagasaki 859-3298, Japan

72.1 INTRODUCTION

Pulmonary surfactant (PS) is a surface-active material that lines the air−alveolar fluid interface. It plays an important role in vital physiological processes, such as respiratory movement and natural immunity (first-line defense). The main interfacial property of PS is to reduce the surface tension at the interface during respiratory movement, preventing alveolar collapses at the end-expired state and minimizing the work of breathing [1]. These functions are based on the formation of a surface-active film that consists of lipid monolayers, and bilayer or multilayer structures (surface-associated reservoirs) closely attached to the alveolar surface. These layered structures have been confirmed in vitro by fluorescence microscopy (FM) and atomic force microscopy (AFM) [2–5], and in vivo by electron microscopy[6].

Pulmonary surfactant is a lipid mixture composed of lipids (∼90 wt%) and proteins (∼10 wt%). The lipids consist mainly of phosphatidylcholines (especially dipalmitoylphosphatidylcholine or DPPC, ∼50 wt%) and smaller but significant amounts of phosphatidylglycerol (PG) and palmitic acid (PA) [7–9]. Among the proteins, the hydrophobic surfactant protein B (SP-B) has a crucial role in lung functions because of the experimental results with its gene knockout in mice [10] and its gene mutation in preterm infants [11, 12]. Moreover, the genetic absence of SP-B induces a deficiency in another hydrophobic surfactant protein, surfactant protein C (SP-C), due to dysfunction of the SP-C proprotein [10]. The human SP-B has a net charge of +7, which is quite important for electrostatic interactions with the headgroups of negatively charged lipids, such as PG [4, 13] and dissociated PA [14].

Fluid components in PS monolayers with less ability to take an ordered and close-packed orientation at the interface are preferentially eliminated from the surface on lateral compression so that the monolayers are enriched in rigid phospholipids (mainly DPPC) [15, 16]. This is known as the "squeeze-out" phenomenon. After the squeeze out of the surface, the organized multilayers are formed just below the interface as a repository for the excluded material. This surface reservoir enables the excluded molecules to respread onto the interface on subsequent expansion [4]. The release of squeezed-out molecules from the surface-associated reservoir is facilitated mainly by SP-B and SP-C. Thus, the composition and molecular structure of the reservoirs are issues of main importance. Synthetic and mimicking peptides based on the amino acid sequence of SP-B have been designed to clarify the mechanism of lipid–protein interactions around the interface and to develop PS preparations for the replacement therapy to patients with respiratory distress syndrome (RDS); examples are KL_4 (KLLLLKLLLLKLLLKLLLLK) [17–19] and Hel 13-5 (KLLKLLLKLWLKLLKLLL) [5, 20–22]. Hel 13-5 is a monomeric synthetic peptide based on the *N*-terminal segment of human SP-B. Its structure and surface activity have been investigated thoroughly both in vitro [5, 21–23] and in vivo [24, 25]. The secondary conformation of Hel 13-5 in the aqueous medium containing various phospholipids is mainly α-helix [26]. The

in vivo experiments show that the PS preparations containing Hel 13-5 improve lung functions and activities in surfactant-deficient rats more than does Surfacten (Surfactant TA) [24], which is an analog to Survanta (Ross Laboratories, Columbus, OH). Surfacten is a bovine lung surfactant extract supplemented with DPPC, PA, and tripalmitin, and is commonly administered to RDS infants in Japan [27].

The polarization-modulation infrared reflection-absorption spectroscopy (PM-IRRAS) measurement provides information on molecular structure of the mimicking peptide of Hel 13–5 in the presence of lipids. SP-B and SP-C have been studied for several decades to understand the PS function at the molecular level. However, the change in protein structures such as α-helix and β-sheet across the interface and their interaction site with lipid monolayers and multilayers, have not been fully discussed. The proteins have several α-helical moieties with different amphiphilicity, hydrophobicity, and amino acid residues in a molecule. Therefore, intramolecular interactions of the proteins such as hydrogen bonding, S–S bonding as a linkage of the moieties, van der Waals force, and electrostatic force among the respective α-helical parts complicate the abovementioned issues. Thus, the lipid/Hel 13-5 systems provide a useful model for in vitro biophysical studies on the surface-associated reservoirs that are formed during respiration in the alveoli. Indeed, in the PS model systems including Hel 13-5, the formation of surface-associated reservoirs has been confirmed [5, 22, 23]. The preparations with the other peptide analogs have also revealed that the reservoirs form at the surface pressure (π) of around 40 mN m^{-1} [4, 13]. One research team have suggested from NMR investigations on interaction between PG and SP-C that positively charged parts of SP-C are located near the bilayer surface [28]. In more recent work, another group has quantitatively revealed the multilayer transition in the DPPC/dipalmitoylphosphatidylglycerol (DPPG)/SP-C system using the IR spectroscopy of films transferred at continuously varying π [29]. In the report, the π-induced formation of reservoirs is possibly based on the intermolecular interaction between the positively charged protein (or peptide) and the negatively charged phospholipid such as PG. As mentioned above, the hysteresis behavior in PS preparations is often observed for a thermodynamic parameter such as π against molecular area (A) during the compression– expansion cycle of monolayers. In addition, other studies have shown the hysteresis for secondary structure of peptides with respect to π employing the IRRAS technique [30–33]. However, it is not yet established at the molecular level how the hysteresis behavior is generated in respective physicochemical parameters, although it is closely related to the reservoir formation beneath the surface monolayer.

In this chapter, we review the hysteresis behavior of π–A isotherms, surface potential (ΔV)–A isotherms, and vibration mode in in situ PM-IRRAS spectra during the compression and successive expansion of PS monolayers. Herein, the following synthetic PS preparations are utilized: DPPC/Hel 13-5, DPPG/Hel 13-5, DPPC/PA(= 90/10, wt/wt)/Hel 13-5, DPPC/PG(= 68/22, wt/wt)/Hel 13-5, DPPC/DPPG(= 4/1, mol/mol), and DPPC/PG/PA(= 68/22/9, wt/wt/wt)/Hel 13-5. PM-IRRAS is almost insensitive to the strong IR absorption of water vapor and allows the extraction of faithful information on conformation and orientation of proteins in the monolayer. It is evident that secondary structure determination of surfactant proteins and their analog peptides in monolayers is essential for understanding their in vivo function during respiration and for designing model peptides toward the replacement therapy to the RDS patients. Unfortunately, however, the peak intensity of PM-IRRAS spectra for monolayers is relatively low because of the low surface density of the peptide. Therefore, attenuated total reflectance (ATR)-FTIR has been employed to confirm the peak frequency of PM-IRRAS spectra. PM-IRRAS spectra of the monolayers are separately analyzed for methylene vibration of the lipid hydrocarbons and for the amide mode of Hel 13-5.

72.2 ISOTHERM BEHAVIOR OF THE LIPIDS AND PEPTIDE

The Hel 13-5 peptide consists of 13 hydrophobic residues (12 Leu and 1 Trp) and 5 hydrophilic residues (5 Lys) [26,34]. The hydrophobic–hydrophilic balance (HHB) was estimated both theoretically from the calculated hydrophobicity value (or the magnitude of hydrophobic faces) and experimentally from the retention times in reverse phase high-performance liquid chromatography (RP-HPLC) [34]. For this modulation (hydrophobicity of Hel 13-5 is 0.07), it is assumed that Hel 13-5 mimics the amphipathic helical structure of SP-B at the alveolar air−liquid interface rather than the transmembrane helical structure of SP-C. In addition, when it forms an ideal α-helical structure, it has the amphiphilic structure with a 260° hydrophobic sector region [20, 26, 34–36]. This means that the hydrophobic part and the hydrophilic one are completely separated in the α-helical structure. Indeed, the α-helical form of Hel 13-5 has been confirmed in the aqueous solution [20, 26, 36]. However, the peptide assuming the α-helical conformation in the bulk is not always estimated to be in the same conformation at the air−water interface. Hel 13-5 forms an expanded monolayer at the interface (Fig. 72.1a). The surface pressure (π)−molecular area (A) isotherm shows no kink corresponding to a phase change such as lipid-expanded (LE)/lipid-condensed (LC) transition. The collapse pressure (π^c) of monolayers is $\sim$ 42.0 mN m^{-1} at $\sim$2.0 nm^2. Above π^c, Hel 13-5 is squeezed out of the surface into the bulk, which reflects slight variation of surface pressure in $A < 2.0$ nm^2. This behavior is also supported by the

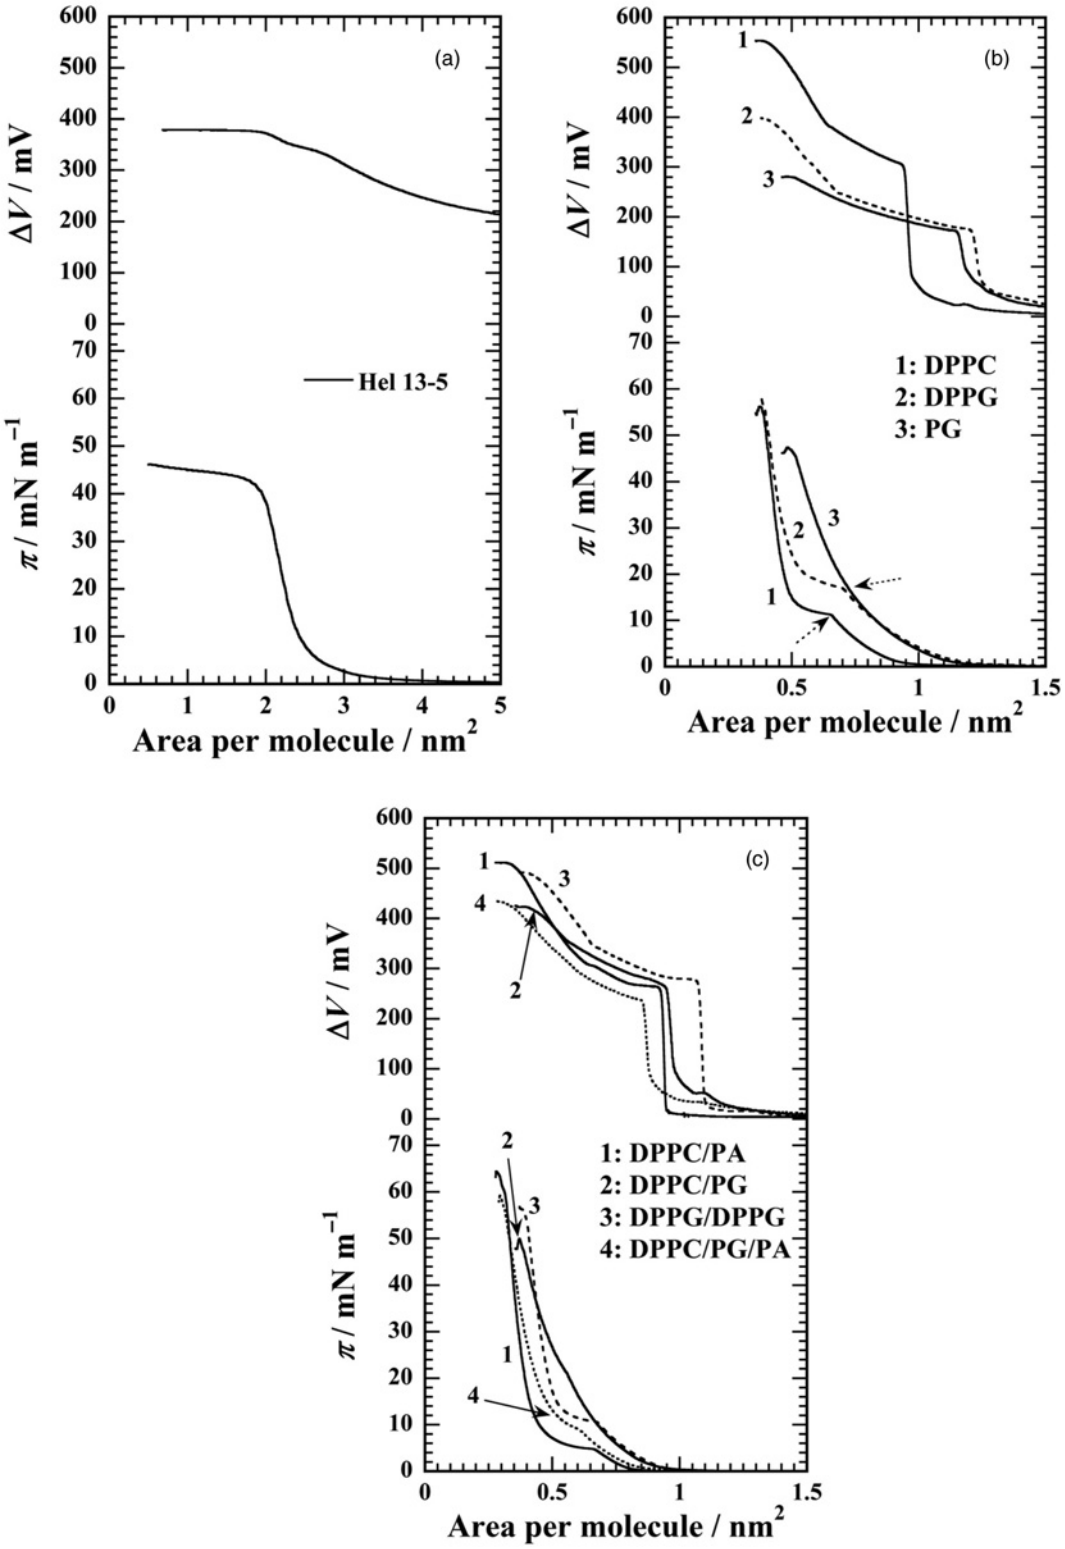

FIGURE 72.1 π–A and ΔV–A isotherms of monolayers on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K: (a) Hel 13-5; (b) DPPC, DPPG, PG; (c) DPPC/PA (= 90/9, wt/wt), DPPC/PG (= 68:22, wt/wt), DPPC/DPPG (= 4/1, mol/mol), DPPC/PG/PA (= 68:22:9, wt/wt/wt).

corresponding surface potential (ΔV)–A isotherm. The ΔV value increases monotonously with decreasing A until 2.0 nm^2. This means that the improved ordering of Hel 13-5 on compression. However, below $A = 2.0$ nm^2, the ΔV value is kept almost constant in spite of monolayer compressing; that is, the extra Hel 13-5 molecules are considered to be excluded into the bulk [21]. The extrapolated area calculated from the π–A isotherm, which can provide information on molecular conformation at the close-packed state, is ~2.6 nm^2. The value is the mean surface area of Hel 13-5 under the assumption of the closest packing. This value can translate into ~0.15 nm^2/amino acid, which is consistent with the values of ~0.2 nm^2/amino acid for SP-B [37]. Thus, when we assume that the α-helical peptide assumes a conformation with its backbone parallel to the interface, the cross-sectional area becomes ~2.6 nm^2 [21]. The dimension of such an α-helix is found to agree well with the experimental value. However, it is noted that the extrapolated area derived from the π–A isotherm expresses the means of molecular ordering at the surface. The secondary structure of peptide at the surface on compression and expansion should be elucidated from the diversified aspects as will be mentioned in a later section.

The DPPC and DPPG monolayers respectively have the first-order LE/LC transitions at ~11 (A = 0.65 nm^2) and ~17 mN m^{-1} ($A = 0.70$ nm^2) on a 0.02 M Tris buffer solution with 0.13 M NaCl (pH 7.4) at 298.2 K, which are indicated by dashed arrows in Fig. 72.1b. The π^c values are ~55 (A = 0.38 nm^2) for DPPC and ~56 mN m^{-1} (A = 0.39 nm^2) for DPPG, respectively. On the other hand, PG forms a typical LE monolayer with π^c = ~46 mN m^{-1} ($A = 0.50$ nm^2), due to its unsaturated hydrocarbon chains. Under these conditions, PA cannot form a stable monolayer at the interface because of the lack of insolubility into the water. The ΔV value of monolayers in Fig. 72.1b always indicates a positive variation on compression. The variational mode is sharper compared than that for Hel 13-5 monolayers, which means that the orientation of the lipid monolayers changes more in degree. The detailed discussion on orientational variation with respect to each phase transition in ΔV–A isotherms has been described elsewhere [38–43]. The maximum ΔV value at the close-packed state is different among the three monolayers. The difference is attributed mainly to the headgroup species of the lipids according to the three-layer model proposed by Demchak and Fort, which postulates independent contributions of the subphase, polar headgroup, and hydrophobic chain to the surface dipole moment [44].

The binary DPPC/PA (= 90/9, wt/wt) monolayer (Fig. 72.1c, curve 1) shows lower LE/LC transition pressure (π^{eq}) and larger π^c than the DPPC monolayer (Fig. 72.1b, curve 1) [14]; that is, the addition of PA causes the condensation of DPPC monolayers. Furthermore, it is found that PA can be located stably at the interface in the system by means of the interactions such as van der Waals forces and miscibility with DPPC. On the other hand, the π^{eq} and π^c values for the DPPC/PG (= 68/22, wt/wt) monolayer become larger and lower, respectively (Fig. 72.1c, curve 2) [5]. This means that PG fluidizes DPPC monolayers as opposed to the DPPC/PA system. However, the similar system of DPPC/DPPG (= 4/1, mol/mol) forms more condensed monolayers to some extents (Fig. 72.1c, curve 3) [23]. The difference in additional effect on DPPC monolayers is significantly related with the ratio of saturation in aliphatic chains of PG molecules. In the case of the ternary DPPC/PG/PA (= 68/22/9, wt/wt/wt) system (Fig. 72.1c, curve 4), the solidifying effect of PA on DPPC monolayers is superior slightly to the fluidizing effect of PG [22].

72.3 INTERACTION BETWEEN THE LIPIDS AND PEPTIDE

The mutual interaction between lipids and Hel 13-5 can be elucidated by measuring the isotherm data as a function of mole fraction of Hel 13-5 ($X_{\text{Hel 13-5}}$). The representative data for the DPPG/Hel 13-5 and the DPPC/PG/PA (= 68/22/9, wt/wt/wt)/Hel 13-5 systems are shown in Fig. 72.2. For the DPPG/Hel 13-5 systems (Fig. 72.2a), the π^{eq} values of monolayers in the presence of Hel 13-5 ($0 < X_{\text{Hel 13-5}} \leq 0.1$) are almost the same as that of DPPG monolayers (~17 mN m^{-1}). The result indicates that the interaction between DPPG and Hel 13-5 is very weak at low surface pressures. At high surface pressures, the π–A isotherms at $X_{\text{Hel 13-5}} = 0.1$ have a plateau at ~50 mN m^{-1} (indicated by a dashed arrow), where Hel 13-5 begins to be gradually squeezed out of the monolayers. It is noted that the surface pressure of the squeeze out is different from the π^c value of Hel 13-5 monolayers (~42 mN m^{-1}). This difference will be discussed below. In the DPPC/PG/PA/Hel 13-5 system (Fig. 72.2b), all of the π–A isotherms indicate the phase transition. As opposed to the DPPG/Hel 13-5 system, the π^{eq} value slightly increases with increasing $X_{\text{Hel 13-5}}$, which means the fluidization of monolayers induced by the addition of Hel 13-5. At ~42 mN m^{-1}, the π–A isotherms in $0.025 \leq X_{\text{Hel 13-5}} \leq 0.1$ exhibit plateau regions, which typically indicated by dashed arrows (curves 3 and 4). These plateaus correspond to the squeeze out of Hel 13-5 from surface monolayers as mentioned above. On further compression, the surface pressures rapidly increase up to a monolayer collapse, resulting in the production of close-packed monolayers (DPPC/PA) at the interface. This surface refining is supported by the fact that the π^c values for the DPPC/PG/PA/Hel 13-5 systems are almost the same as those for the DPPC/PA/Hel 13-5 systems at $X_{\text{Hel 13-5}} = 0.05$ and 0.1[5, 22].

At surface pressures below the plateau, the ΔV–A isotherms for both systems shift to larger ΔV values with increasing $X_{\text{Hel 13-5}}$ (Fig. 72.2). This is attributed to a monotonous increase in ΔV value for Hel 13-5 monolayers

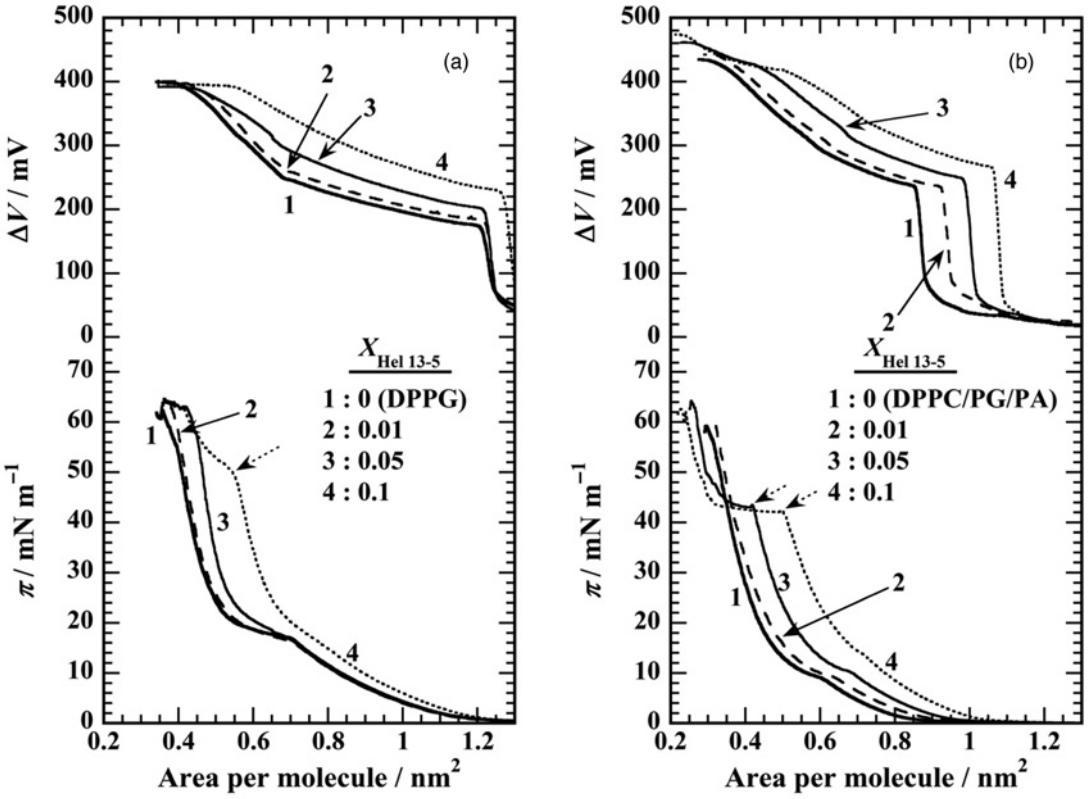

FIGURE 72.2 π–A and ΔV–A isotherms of (a) DPPG and (b) DPPC/PG/PA (= 68:22:9, wt/wt/wt) monolayers containing different amounts of Hel 13-5 on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K.

on compression (Fig. 72.1a). On further compression beyond the plateau on π–A isotherms, however, ΔV–A isotherms for DPPG/Hel 13-5 (Fig. 72.2a) finally converge to the similar ΔV value of ~400 mV, which corresponds to the maximum values of DPPG monolayers (Fig. 72.1b, curve 2). In the DPPC/PG/PA/Hel 13-5 system (Fig. 72.2b), however, the maximum values slightly increase as opposed to the DPPC/PG/PA monolayers (curve 1). Considering the maximum value in Fig. 72.1c, it is found that the dominant exclusion of Hel 13-5 together with PG from surface monolayers in the plateau region at the expense of the improvement in the orientation of the binary DPPC/PA monolayer. On further compression, all of the ΔV–A isotherms converge to ~460 mV, suggesting that the close-packed DPPC/PA monolayers are formed near 60 mN m^{-1}.

The surface pressure where Hel 13-5 is squeezed out of the monolayers is an index for determining the interaction between Hel 13-5 and lipids at the surface. As seen in Fig. 72.3, preparations containing fewer PG components indicate the squeeze-out pressure of ~42 mN m^{-1}, which corresponds to the π^c value of Hel 13-5 monolayers (Fig. 72.1a). Furthermore, the squeeze-out pressure is kept almost constant regardless of $X_{\text{Hel 13-5}}$, which indicates immiscibility among the components. On the other hand, binary DPPG/Hel 13-5 systems show a variation in the squeeze-out pressure (range: 39–49 mN m^{-1}) against $X_{\text{Hel 13-5}}$. The variation demonstrates that cationic Hel 13-5 electrostatically interacts with

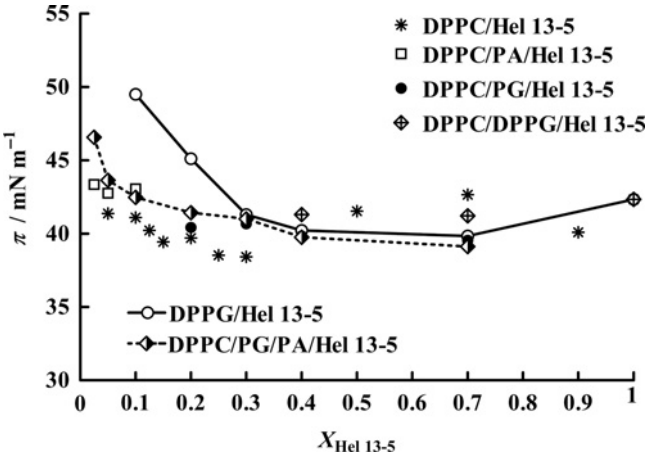

FIGURE 72.3 Changes in surface pressure at onset of the plateau against a molar amount of Hel 13-5 ($X_{\text{Hel 13-5}}$) for DPPC/, DPPG/, DPPC/PA (= 90/9, wt/wt)/, DPPC/PG (= 68:22, wt/wt)/, DPPC/DPPG (= 4/1, mol/mol)/, and DPPC/PG/PA (= 68:22:9, wt/wt/wt)/Hel 13-5.

anionic DPPG at high surface pressures, similarly to miscible behavior between normal lipid monolayers [45–50]. In other words, the positive change in pressure at $X_{\text{Hel 13-5}} = 0.1$ suggests that the mutual electrostatic attractive force prevents Hel 13-5 from being squeezed out of the binary monolayers. A similar variation is also caused in the DPPC/PG/PA/Hel 13-5 system at $X_{\text{Hel 13-5}}$ smaller than 0.05, not in the DPPC/PG/Hel 13-5 system. The carboxyl group in a PA molecule has a pK_a value of 5.1–5.7 [51–54]. Thus, at pH 7.4, the carboxyl group is partially dissociated (30−44%) to be negatively charged [14]. Thus, in addition to the PG components, the dissociated PA molecules are considered to promote the electrostatic interaction with Hel 13-5 in the DPPC/PG/PA/Hel 13-5 system.

72.4 HYSTERESIS IN π−A AND ΔV−A ISOTHERMS

Fluid components such as PG and Hel 13-5 are ejected from the air−water interface to be stored in surface-associated reservoirs on compression above the squeeze-out pressure, which prevents alveolar collapse. During the successive expansion, the squeezed-out molecules reenter with a delay and then spread back into the surface, which is commonly called respreading. The delay produces a large hysteresis loop in π−A isotherms. Both the large hysteresis area and reproducible hysteresis loops are very important for elucidating pulmonary function and activity [55]. In our study [32], the monolayer was compressed up to the respective π^c value and then expanded to the starting molecular areas. This process was successively repeated to examine the reproducibility of the respreading process within a monolayer. All of the preparations ($X_{\text{Hel 13-5}} = 0.1$) shown in Fig. 72.4 exhibit large hysteresis loops in π−A isotherms and good reproducible isotherms during the cycling. The π−A hysteresis curves have a plateau at high surface pressures (∼50 mN m^{-1} for DPPG/Hel 13-5 and ∼42 mN m^{-1} for the others) during lateral compression, where the squeeze-out action and the subsequent formation of 3D aggregates adjacent to the interface gradually occur. Under the expansion, the squeezed-out Hel 13-5 molecules reenter the interface from the aggregates at the slower speed relative to the expansion rate of movable barriers, resulting in a rapid reduction of surface pressures or surface concentrations of monolayers [56]. In this regard, large hysteresis is generated on the cyclic π−A isotherms. An enclosed area in hysteresis loops for the systems here is plotted against the number of cycles in Fig. 72.5. Apparently, the hysteresis areas are kept almost constant irrespective of the cycling number, which supports the reproducibility of repeated compression and expansion isotherms. Furthermore, the DPPG/Hel 13-5 system indicates the maximum hysteresis area among the preparations. This suggests that the PS preparation requires PG components which interact electrostatically with cationic Hel 13-5.

When the π−A hysteresis isotherms for DPPC/PG/Hel 13-5 (Fig. 72.4d) are compared to those for DPPC/DPPG/Hel 13-5 (Fig.72.4e), we would find differences in appearance of the isotherms. In particular, during expansion, the surface pressure indicates a rapid and monotonous decrease until 25 mN m^{-1} for DPPC/DPPG/Hel 13-5. On the other hand, the DPPC/PG/Hel 13-5 system shows a rapid decrease in surface pressure up to 40 mN m^{-1}, and then the decreasing mode becomes slow in magnitude. This difference demonstrates that the PG molecule with unsaturated hydrophobic chains has a closer relationship with stabilization of the surface-associated reservoir formed just below the monolayers.

Among the systems, the π−A hysteresis isotherms for the DPPC/PG/PA/Hel 13-5 system (Fig. 72.4f) have the longest plateaus at ∼44 mN m^{-1}. Commonly, the length of plateau is directly proportional to the amount of squeezed-out molecules. Considering that all the systems contain the same amount of Hel 13-5 ($X_{\text{Hel 13-5}} = 0.1$), it is found that parts of PA molecules are actually eliminated from the surface besides Hel 13-5 and PG. This confirms the abovementioned squeeze-out phenomenon of Hel 13-5 together with dissociated PA molecules. In addition, in terms of a liftoff area, shape, plateau length, and collapse pressure, this preparation possesses surface activity that is similar to that of Surfacten, which contains small amounts of native SP-B and SP-C [22].

It is also notable that the ΔV−A isotherms for the DPPG/Hel 13-5 preparation (Fig. 72.4b) show large and reproducible hysteresis loops. During compression, the ΔV−A isotherms have a plateau, similar to the corresponding π−A isotherms. In the plateau region under compression, Hel 13-5 is preferentially eliminated into the bulk, with the molecular orientation of surface monolayers kept almost constant. Then, the specific interaction stabilizes both the squeezed-out Hel 13-5 beneath the monolayers and the mixed monolayers with Hel 13-5 at the interface. During expansion, the packed monolayers laterally respread in the first stage, and then the molecular ordering and orientation are released again along the expansion of molecular area in the region of 0.40 nm^2 $< A \leq$ 0.70 nm^2. In the subsequent plateau (0.70 nm^2 $< A \leq$ 0.85 nm^2), the squeezed-out Hel 13-5 molecules stepwise reenter to the surface, due to the low surface concentration of the monolayers [23]. The other preparations show the hysteresis only on π−A isotherms, not on ΔV−A isotherms. Although the preparations have the same Hel 13-5 content, a depression in the proportion of PG (especially DPPG) is found to reduce hysteresis properties on ΔV−A isotherms, which means that the specific (or electrostatic) interaction between DPPG and Hel 13-5 specifically promotes the hysteresis behavior of lipid orientation at the surface. This interaction contributes strongly to pulmonary functions such as regulation of the squeeze-out event, 3D aggregates, and orientation of surface monolayers.

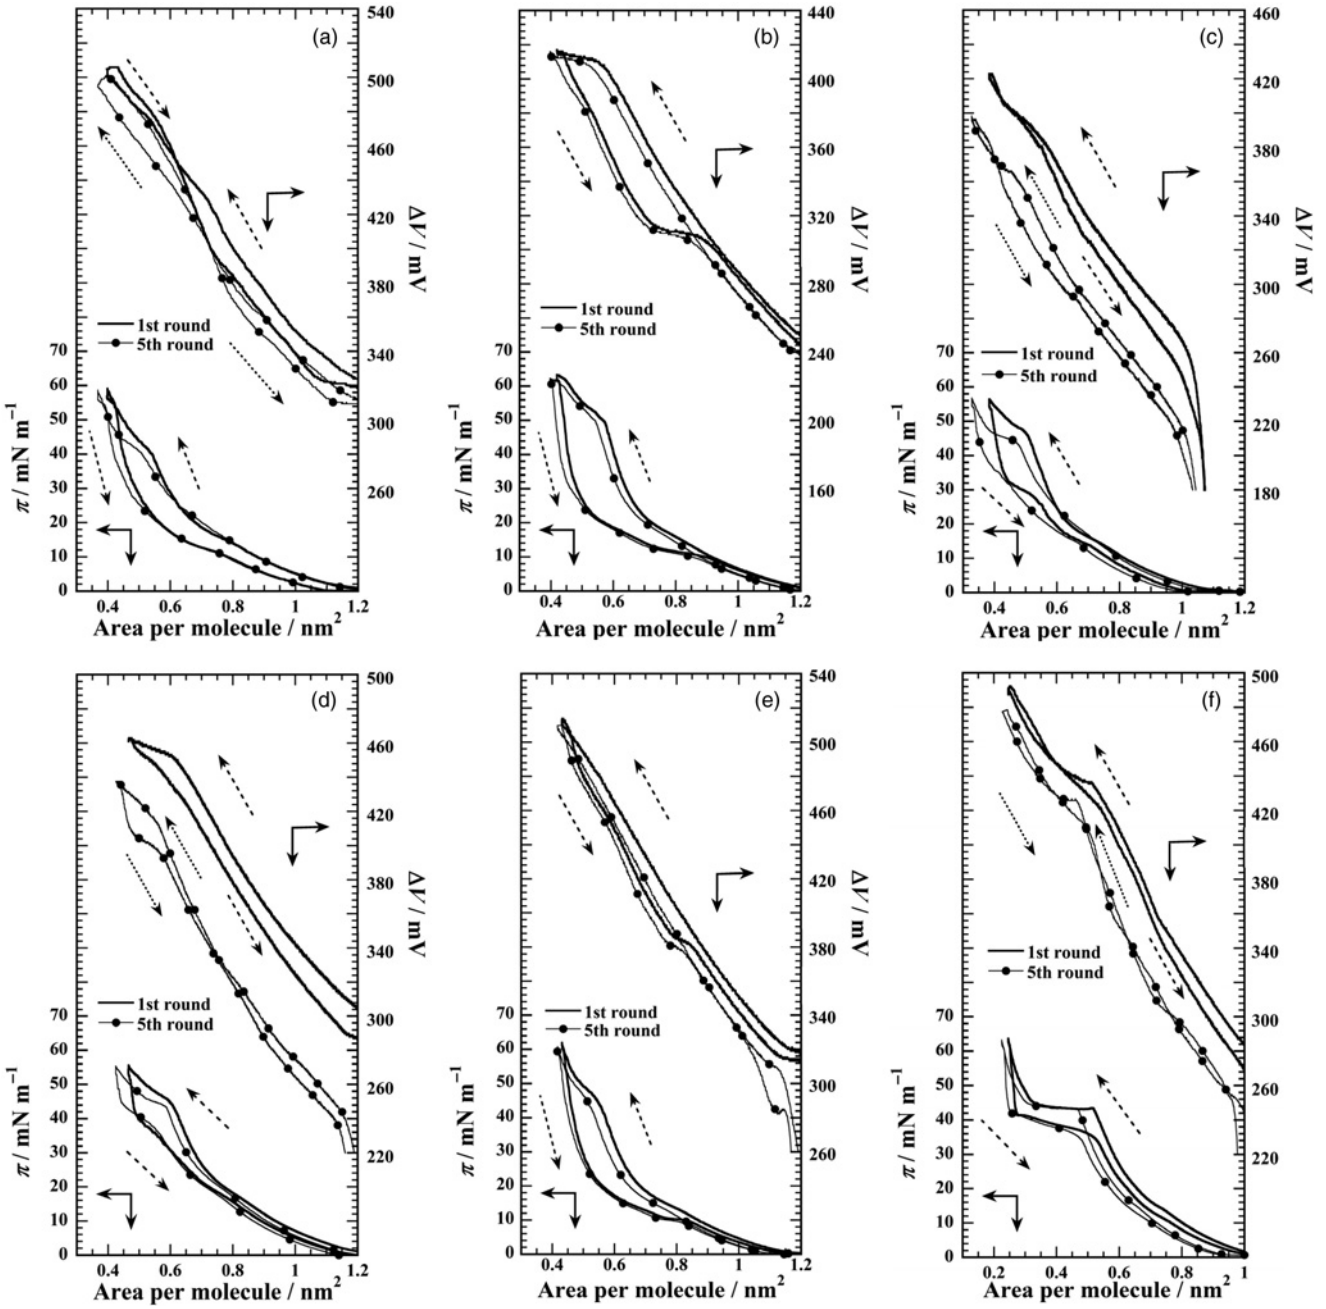

FIGURE 72.4 Cyclic compression and expansion isotherms of the (a) DPPC/, (b) DPPG/, (c) DPPC/PA (= 90/9, wt/wt)/, (d) DPPC/PG (= 68/22, wt/wt)/, (e) DPPC/DPPG (= 4/1, mol/mol)/, and (f) DPPC/PG/PA (= 68/22/9, wt/wt/wt)/Hel 13-5 preparations at $X_{\text{Hel 13-5}} = 0.1$ on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K. The compression–expansion cycle was performed at a compression rate of ~ 90 cm^2 min^{-1}.

72.5 MORPHOLOGICAL PHASE BEHAVIOR

72.5.1 Fluorescence Microscopy (FM)

The in situ morphological behavior of phase transitions for monolayers can be visualized by Brewster angle microscopy (BAM) and fluorescence microscopy (FM). In particular, FM observations provide better performance of surface characteristics in resolution and magnification, although there remains the possibility that FM probes (or dyes) will affect the original phase behavior of monolayers. Thus, it is very important to rule out any influence of the probe on the original properties.

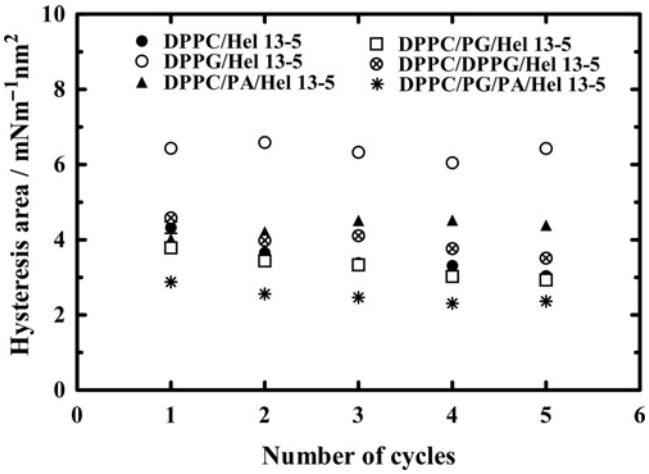

FIGURE 72.5 Changes in integrated hysteresis area surrounded by the compression isotherm and the accompanying expansion isotherm with cycling number of hysteresis measurements.

This is easily accomplished by the isotherm measurement or BAM observation. The LE/LC transition can be analyzed by screening the probe distribution in monolayers. The contrast in FM images depends on the difference in solubility of the probe between LE (disordered) and LC (ordered) phases. As a result, the probe molecules are selectively dissolved in LE phases due to the bulkiness of fluorescent moieties in a probe molecule. The shape of the LC domain is mainly controlled by the line tension of phase boundaries and long-range dipole interactions. The representative FM images for the DPPG/Hel 13-5 system are shown in Fig. 72.6. For DPPG monolayers, the phase behavior and domain shape are quite similar to those obtained from BAM [23]. The LC domains of DPPG monolayers are characterized as a roughly circular shape. FM images of Hel 13-5 alone are homogeneously bright over the entire range of surface pressures as expected obviously from the π–A isotherm (Fig. 72.1a). When Hel 13-5 is added to DPPG monolayers, a unique trend is observed. In the range of $0 < X_{\text{Hel 13-5}} \leq 0.01$, the LC domains of DPPG gradually and monotonously shrink in size with increasing $X_{\text{Hel 13-5}}$. This shows that at low and middle surface pressures, the electrostatic interaction between the two molecules is very weak for the change in phase behavior, nucleation process, and domain shape, due to low surface concentrations of Hel 13-5. In $0.01 < X_{\text{Hel 13-5}} \leq 0.05$, FM images show two kinds of nonfluorescent domains, which are indicated by solid-line and dashed-line circles typically at $X_{\text{Hel 13-5}} = 0.025$. With a decrease in $X_{\text{Hel 13-5}}$ from 0.025, the two populations are observed until $X_{\text{Hel 13-5}} = 0.013$. This indicates that the phase behavior for the DPPG/Hel 13-5 monolayer varies on the border of $X_{\text{Hel 13-5}} = 0.01$[23]. The smaller domains indicated by the dashed-line circles are not intermediate to the larger ones; rather, the two domains grow independently in size and number with an increase in surface pressure. As a result, the small and large domains are found to consist of free DPPG molecules and DPPG/Hel 13-5 complexes, respectively. This irregular behavior suggests the existence of a specific interaction between DPPG and Hel 13-5 such as a miscible monolayer [23].

The domain shape for the DPPC/DPPG (= 4/1, mol/mol) monolayer is different from that of pure DPPG [23, 57] and DPPC [43, 58–60], which indicates that DPPC and DPPG form a miscible monolayer at the surface (Fig. 72.7). When Hel 13-5 is added to the DPPC/DPPG mixture, anticlockwise LC domains shrink in size. As opposed to the DPPG/Hel 13-5 system, the FM images do not show specific behavior. This behavior results from the fact that the ratio of DPPG to Hel 13-5 is too small in the system and/or that the miscible interaction between DPPC and DPPG predominates over the electrostatic interaction between DPPG and Hel 13-5. With an increase in surface pressure to 20 mN m^{-1}, the LC domains become irregular in edge and confused. The variation is attributed to the fact that the electrostatic interaction becomes stronger and stronger as a result of the shortened intermolecular distance between DPPG and Hel 13-5, and thus DPPG can interact with DPPC as well as Hel 13-5.

72.5.2 Atomic Force Microscopy (AFM)

Langmuir–Blodgett (LB) films for the PS preparations deposited onto mica have been visualized by AFM in tapping mode to understand the mechanism of hysteresis behavior in the isotherms at the molecular level. Figure 72.8 shows are the representative AFM images for the DPPC/Hel 13-5, DPPG/Hel 13-5, and DPPC/DPPG/Hel 13-5 systems at $X_{\text{Hel 13-5}} = 0.1$ in the stages of compression and expansion. For the DPPC/Hel 13-5 preparation, the AFM topographic image at 35 mN m^{-1} under the compression shows two different phases in contrast. Considering the diameter of Hel 13-5 (∼1.0 nm) and the height of nontilted phospholipids with saturated dipalmitoyl chains (∼2.5 nm) [21], bright networks and dark domains represent DPPC and Hel 13-5 monolayers, respectively. On further compression of the monolayer, protrusion masses (or dotlike aggregates) are formed at 55 mN m^{-1}, where Hel 13-5 is squeezed out of the interface. The protrusions with a height difference of ∼3.0 nm consist of the ejected Hel 13-5 molecules. In the DPPG/Hel 13-5 system, the image at 35 mN m^{-1} during compression shows a phase behavior similar to that of the DPPC/Hel 13-5 system. However, the protrusions observed at 55 mN m^{-1} differ considerably in shape and number. The squeezed-out Hel 13-5 has a tendency to fuse into new protrusions (or disklike aggregates: tens of nanometers in diameter) with the height difference of ∼3.3 nm. As for the DPPC/DPPG/Hel 13-5 preparation, when the film is compressed to 55 mN m^{-1}, the protrusions are formed on the DPPC/DPPG monolayers but are fewer in number and lateral size compared to the DPPG/Hel 13-5 system. These results strongly suggest that the electrostatic

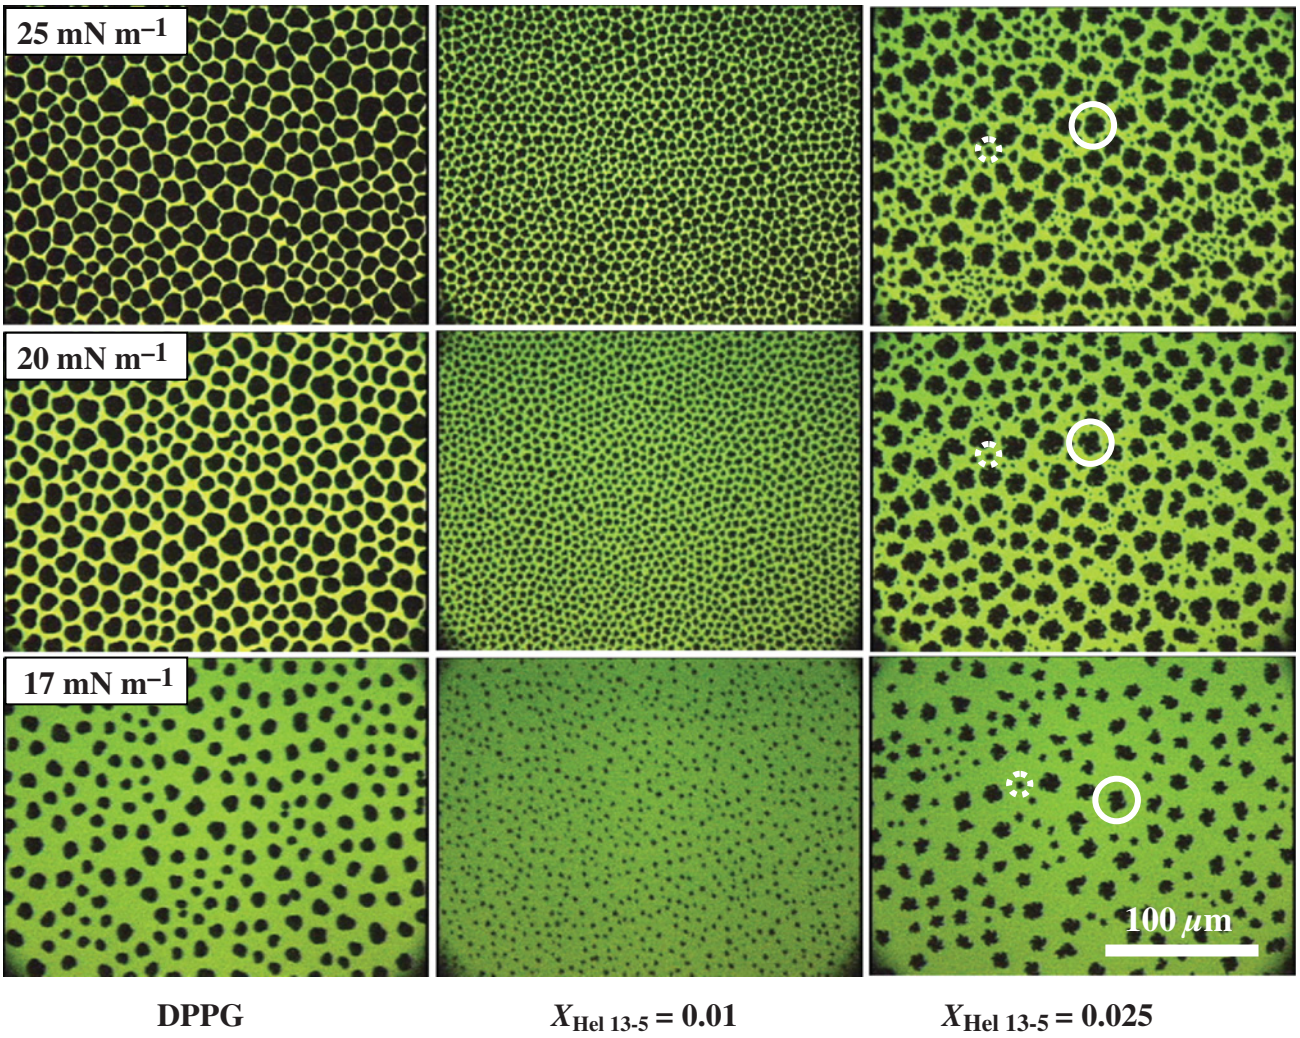

FIGURE 72.6 FM images of the binary DPPG/Hel 13-5 preparations at $X_{Hel\ 13\text{-}5} = 0$ (DPPG), 0.01, and 0.025 at selected surface pressures on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K. The monolayers contain 1 mol% fluorescent probe (NBD-PC). The scale bar in the lower-right corner represents 100 μm.

interaction between DPPG and Hel 13-5 plays an important role in the lateral growth and organization of squeezed-out products at high surface pressures. The surface concentration of anionic charged monolayers are considered to control stabilization of the ejected Hel 13-5. During the first expansion cycle, for the DPPC/Hel 13-5 and DPPC/DPPG/Hel 13-5 systems, the protrusions become smaller in diameter and number, and correspondingly the dark regions of Hel 13-5 monolayers increase with decreasing surface pressures from 55 to 35 mN m^{-1}. On the other hand, the protrusions continue to retain their shape and size laterally and vertically in the DPPG/Hel 13-5 system. This means that the squeezed-out Hel 13-5 molecules do not reenter to the interface, but are rather maintained below the DPPG monolayer for a while after expanding monolayers. It is demonstrated that the squeezed-out Hel 13-5 is stabilized beneath the interface under expansion by the electrostatic interaction with the surface DPPG monolayers. Accordingly, the surface monolayers are restricted to some extents by the ejected Hel 13-5. This retention of the protrusions strongly supports the above-mentioned notion that the independent emergence of the eliminated Hel 13-5 to the surface takes place after the relaxation of surface monolayers under expansion.

Scheme 72.1 provides a possible explanation for the molecular action in the DPPG/Hel 13-5 system across the surface during the compression–expansion cycle. At low surface pressures, the electrostatic interaction is very weak because of the long intermolecular distance between DPPG and Hel 13-5. The lateral compression [route (a) in Scheme 72.1] of the monolayers reduces such distance and the mutual

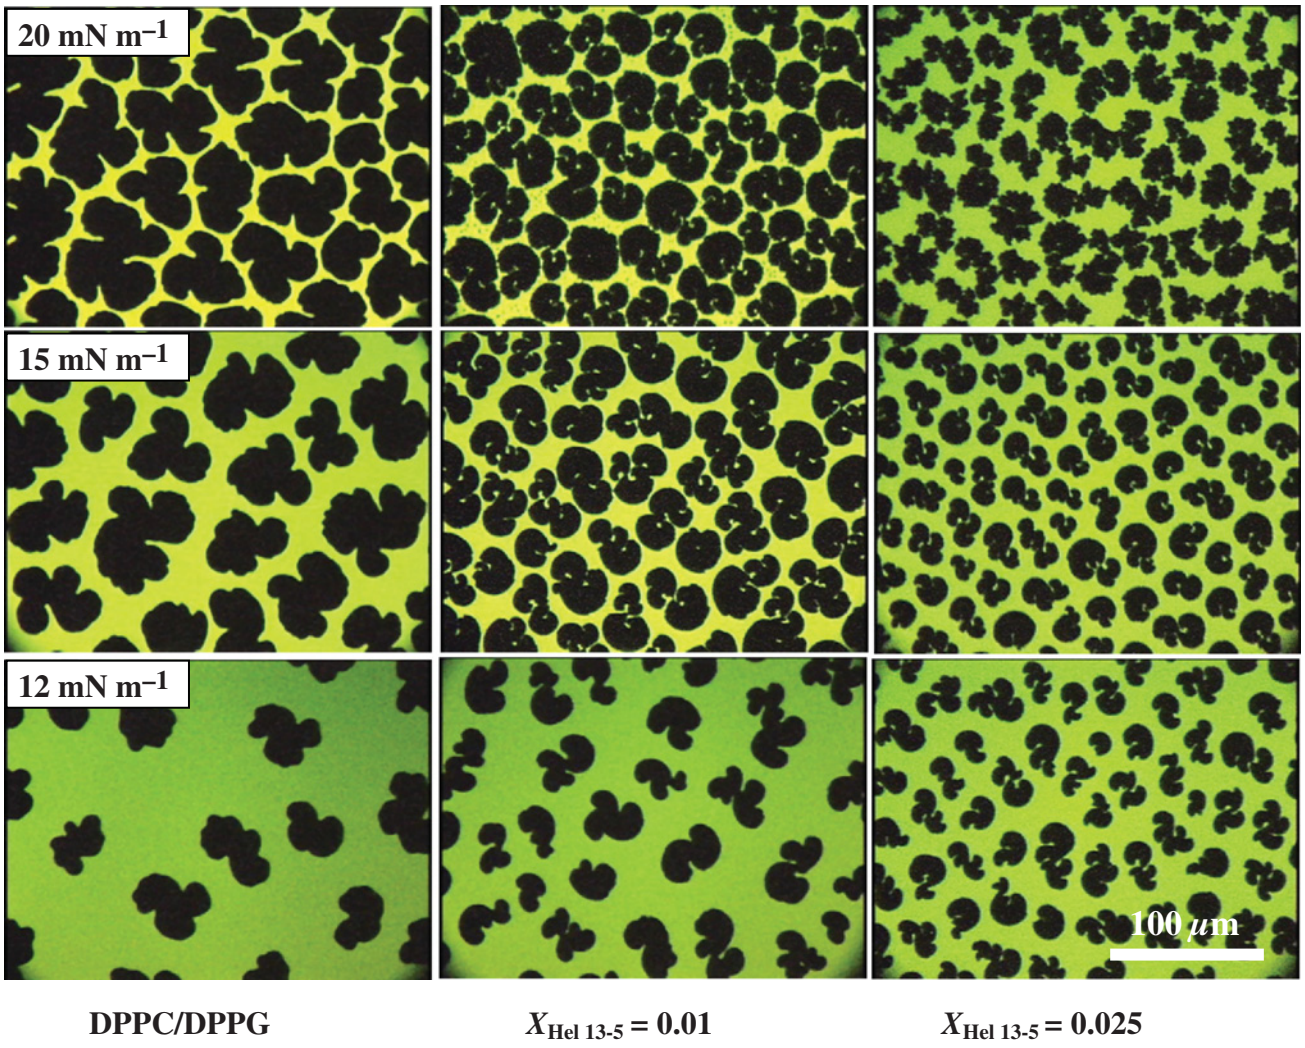

FIGURE 72.7 FM images of the ternary DPPC/DPPG (= 4/1, mol/mol)/Hel 13-5 preparations at $X_{\text{Hel 13-5}} = 0$ (DPPC/DPPG), 0.01, and 0.025 at selected surface pressures on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K. The monolayers contain 1 mol% fluorescent probe (NBD-PC). The scale bar in the lower right corner represents 100 μm.

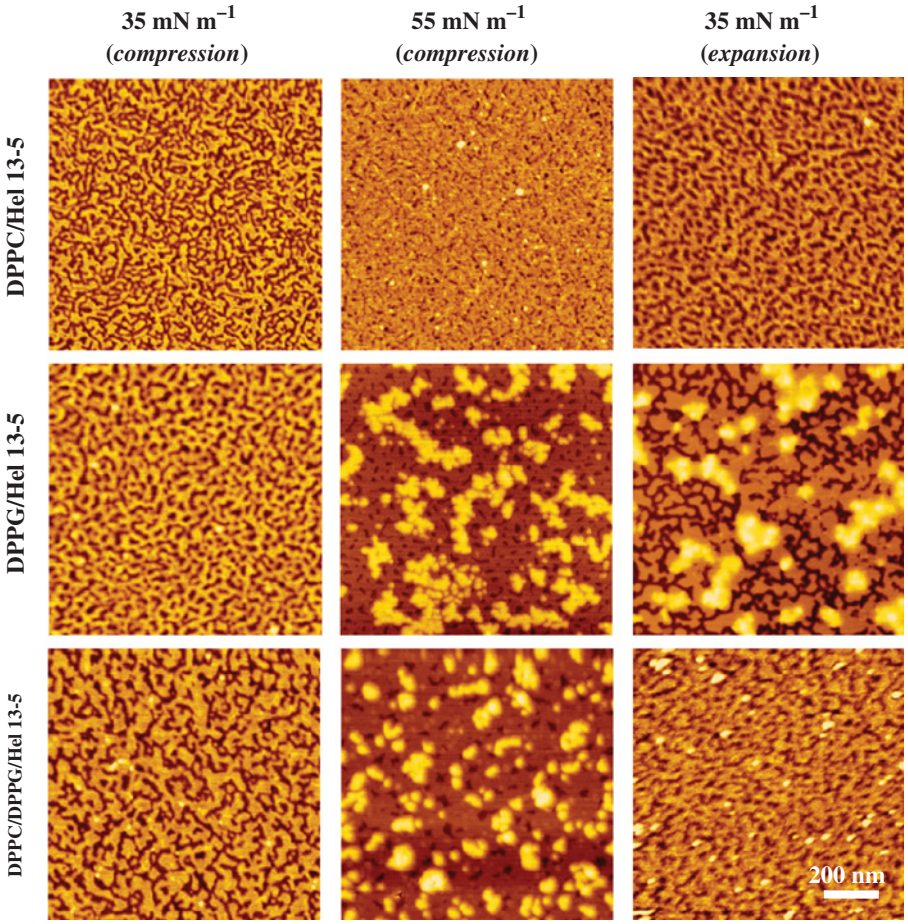
interaction accordingly strengthens, resulting in variation of the squeeze-out pressure (Figs. 72.1a and 72.3). On further compression beyond the squeeze-out pressure [route (b) in Scheme 72.1], Hel 13-5 is preferentially eliminated from the interface and forms mass aggregates like surface-associated reservoirs beneath the surface DPPG monolayer. Considering the saturated acyl chains of DPPG and the results of compression isotherms (Fig. 72.1b), almost all parts of DPPG would not be ejected together with Hel 13-5, but would remain at the interface during the squeeze-out process. The electrostatic interaction across the surface contributes to the formation and stabilization of the aggregates. During the expansion cycle [route (c) in Scheme 72.1], the surface monolayers respread to the interface, where the ejected Hel 13-5 is maintained beneath the monolayers. Then, when the surface concentration of monolayers decreases to a proper extent, the squeezed-out Hel 13-5 molecules reenter to the surface [route (d) in Scheme 72.1]. On further expansion to the initial molecular area [route (e) in Scheme 72.1], both components are completely released up to the gaseous phase of monolayers. Consequently, the specific interaction generates larger hysteresis loops on both the cyclic π–A and ΔV–A isotherms compared to the other preparations.

72.6 POLARIZED ATR-FTIR SPECTRA

It is well established that the frequency and peak of the amide band in the amide I (1600–1700 cm^{-1}) and II (1500–1600 cm^{-1}) regions depend critically on the secondary



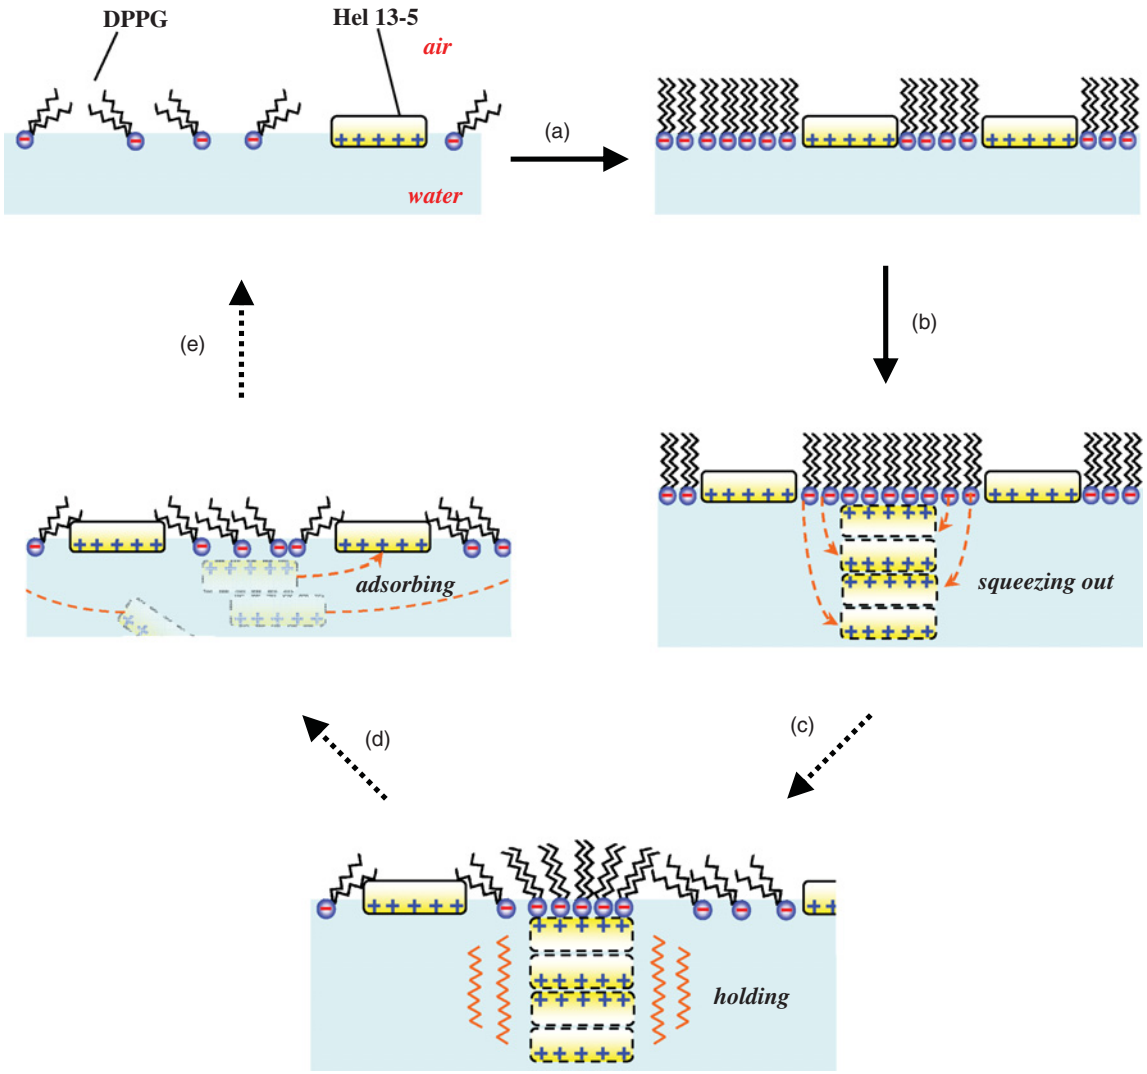


FIGURE 72.8 AFM topographic images of DPPC/, DPPG/, and DPPC/DPPG (4/1, mol/mol)/Hel 13-5 preparations at $X_{\text{Hel 13-5}} = 0.1$ on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K. The monolayers were transferred onto mica at 35 (left column) and 55 (middle column) on the first compression, and 35 mN m^{-1} (right column) on the following first expansion. The scan area is 1 × 1 μm, and the scale bar in the lower right corner represents 200 nm.

structure of peptide and protein films [61–63]. Polarized attenuated total reflectance (ATR)-FTIR spectra of Hel 13-5 films in the amide region are shown in Fig. 72.9. There exist two positive bands at 1656 (amide I) and 1541 (amide II) cm^{-1}, which are indicative of the α-helical structure. In terms of peak intensity, the *p*-polarized spectrum is larger than the *s*-polarized one, which indicates that the molecular backbone of Hel 13-5 is tilted against the germanium (Ge) surface. The ATR-FTIR spectra for the DPPC/Hel 13-5, DPPG/Hel 13-5, and DPPC/PG/PA/Hel 13-5 films containing the fixed amount of Hel 13-5 ($X_{\text{Hel 13-5}} = 0.1$) are shown in Fig. 72.10. All the systems exhibit four major peaks at ∼1740, 1650, 1540, and 1465 cm^{-1}. The peaks at ∼1740 and 1465 cm^{-1} are assigned to the C=O stretching and CH_2 bending vibrations of lipid aliphatic chains, respectively. Both the amide bands at ∼1650 and 1540 cm^{-1} indicate the existence of α-helix in the films. Consequently, it can be concluded that the secondary structure of Hel 13-5 in the phospholipid films is predominantly the α-helix.

72.7 PM-IRRAS SPECTRA AT THE AIR–WATER INTERFACE

72.7.1 The in situ PM-IRRAS Spectra in the Amide Region

The in situ PM-IRRAS spectra of Hel 13-5 monolayers at the air–water interface are shown in Fig. 72.11. Below 35 mN m^{-1}, the amide I band is kept to be located at ∼1660 cm^{-1}, corresponding to the α-helix secondary structure. In addition, the indicative of the α-helix is also observed in the amide II region at ∼1539 cm^{-1}. The surface selection rules of the PM-IRRAS experiment at the interface specify that

Scheme 72.1 Possible explanation for specific interaction between anionic DPPG and cationic Hel 13-5 in the model pulmonary system of DPPG/Hel 13-5 during compression and successive expansion. Hel 13-5 with dashed-line squares means the squeezed-out one: (a) monolayer compression from $A =$ 1.20 to 0.60 nm^2 in Fig. 72.4b; (b) further compression from $A = 0.60$ to 0.40 nm^2; (c) monolayer expansion from $A = 0.40$ to 0.70 nm^2; (d) following expansion from $A = 0.70$ to 0.85 nm^2; (e) further expansion from $A = 0.85$ to 1.20 nm^2.

strong positive absorption bands in the spectrum indicate IR transition dipole moments, which are aligned parallel to the interface [64]. Therefore, the α-helical backbone of Hel 13-5 is found to be oriented parallel to the surface. Above the collapse pressure (~42 mN m^{-1}) of Hel 13-5 monolayers, the spectrum at 45 mN m^{-1} clearly indicates two different peaks at ~1645 and ~1612 cm^{-1} in the amide I region. The former peak frequency somewhat shifts to lower wavenumber, which means that the α-helical structure of Hel 13-5 is exposed by the surrounding water molecule [30, 65]. The latter band is assigned to an extended form, including the antiparallel β-sheet [31, 66]. In other words, the over-compression of Hel 13-5 monolayers induces the structural transformation from the α-helix to β-sheet at the air−water interface.

The PM-IRRAS spectra for the DPPC/Hel 13-5 monolayer at $X_{\text{Hel 13-5}} = 0.1$ during compression are shown in Fig. 72.12a. In comparison to Fig. 72.11, the peak intensities in the amide regions decrease as a result of the small surface concentration of Hel 13-5. To overcome this defect, peak separation to the Gaussian components is faithfully accomplished [32, 33]. At 5 mN m^{-1}, the intense constituents of the amide I (at ~1653 cm^{-1}) and II (at ~1534 cm^{-1}) modes are assigned to the α-helix. As surface pressure increases toward 60 mN m^{-1}, the α-helical marker band almost disappears. Instead, the component near ~1617 cm^{-1} corresponding to

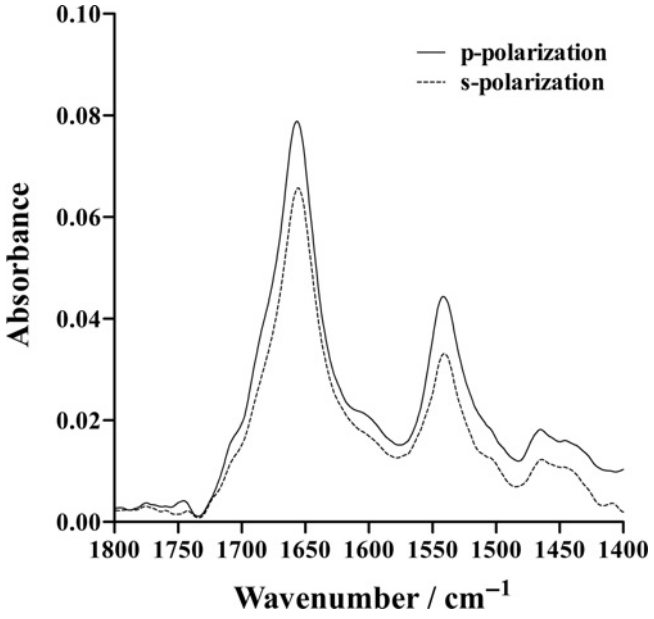

FIGURE 72.9 Polarized ATR-FTIR spectra of Hel 13-5 films in the region of 1400– 1800 cm^{-1} at room temperature. Solid line corresponds to p-polarization and dashed line, to s-polarization of the incident radiation.

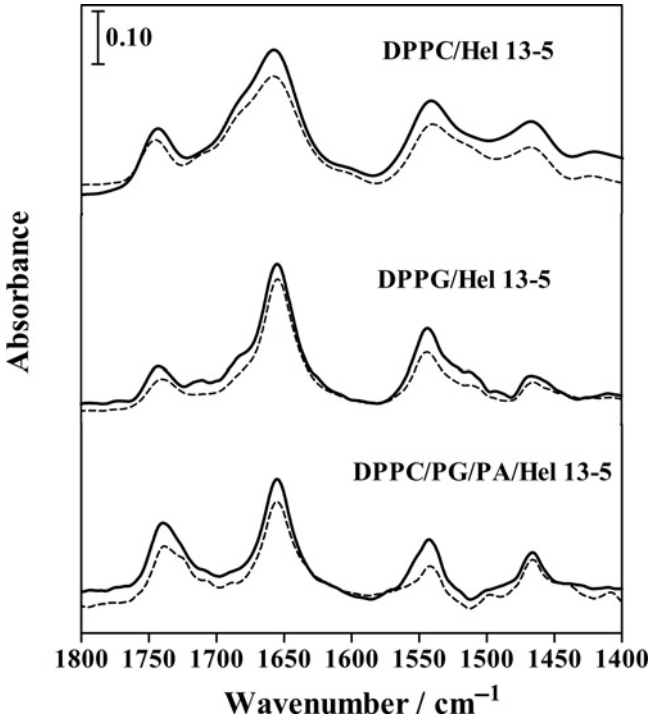

FIGURE 72.10 Polarized ATR-FTIR spectra of films of DPPC/Hel 13-5 (upper), DPPG/Hel 13-5 (middle), and DPPC/PG/PA (= 68/22/9, wt/wt/wt; lower)/Hel 13-5 systems at $X_{\text{Hel 13-5}} = 0.1$ in the region of 1400 – 1800 cm^{-1} at room temperature. Solid lines correspond to p-polarization and dashed lines, to s-polarization of the incident radiation.

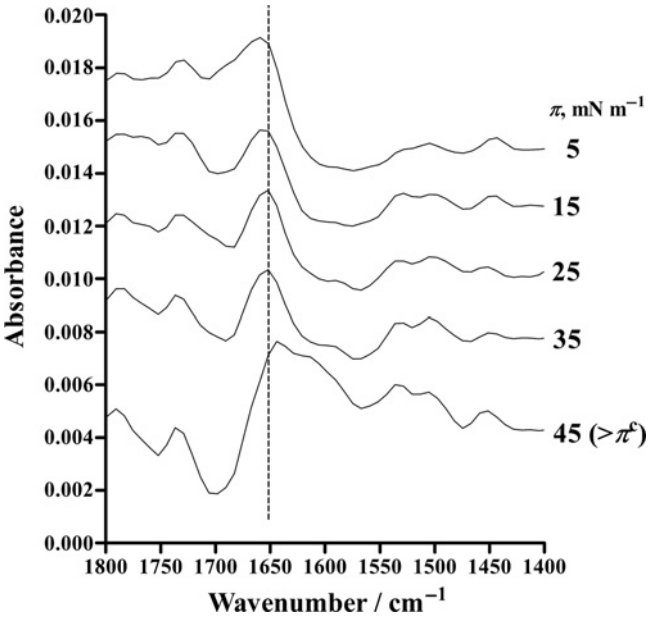

FIGURE 72.11 In situ PM-IRRAS spectra of Hel 13-5 monolayers as a function of surface pressure (π) in the region of 1400 – 1800 cm^{-1} on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K.

the antiparallel β-sheet appears in the spectra, and the peak intensity of the β-sheet marker band increases relative to the α-helical marker band. The β-sheet marker bands near ∼1606 cm^{-1} also emerge in the spectrum for the DPPG/Hel 13-5 system at high surface pressures (Fig. 72.12b). The interconversion from the α-helix to the β-sheet is possibly attributed to the destruction particularly of intramolecular hydrogen bonding, based on the peptide secondary structure, which is facilitated by reduction in intermolecular distance between Hel 13-5 and the aliphatic chains of lipids. The transition of peptide secondary structures in lipid environments has been reported as well by other researchers [31, 67]. In this regard, the peptide structure is strongly deformed by the environmental lipid (especially phospholipids with saturated hydrocarbon chains, e.g., DPPC) density rather than applied surface pressures.

72.7.2 Secondary Structure Transformation of Hel 13–5

An α-helix ratio of Hel 13–5 relative to the (α-helix + β-sheet) component for Hel 13-5 monolayers and all the lipid/Hel 13-5 systems treated here at $X_{\text{Hel 13–5}} = 0.1$ during the compression (solid line with filled circles) and expansion (dashed line with open circles) cycle is plotted against surface pressure in Fig. 72.13. The ratio can be calculated from integrated peak areas of the α-helix (∼1650 cm^{-1}) and of the β-sheet (∼1620 cm^{-1}) marker bands (Gaussian bands) in the amide I region; the ratio α/(α+β) means the peak area

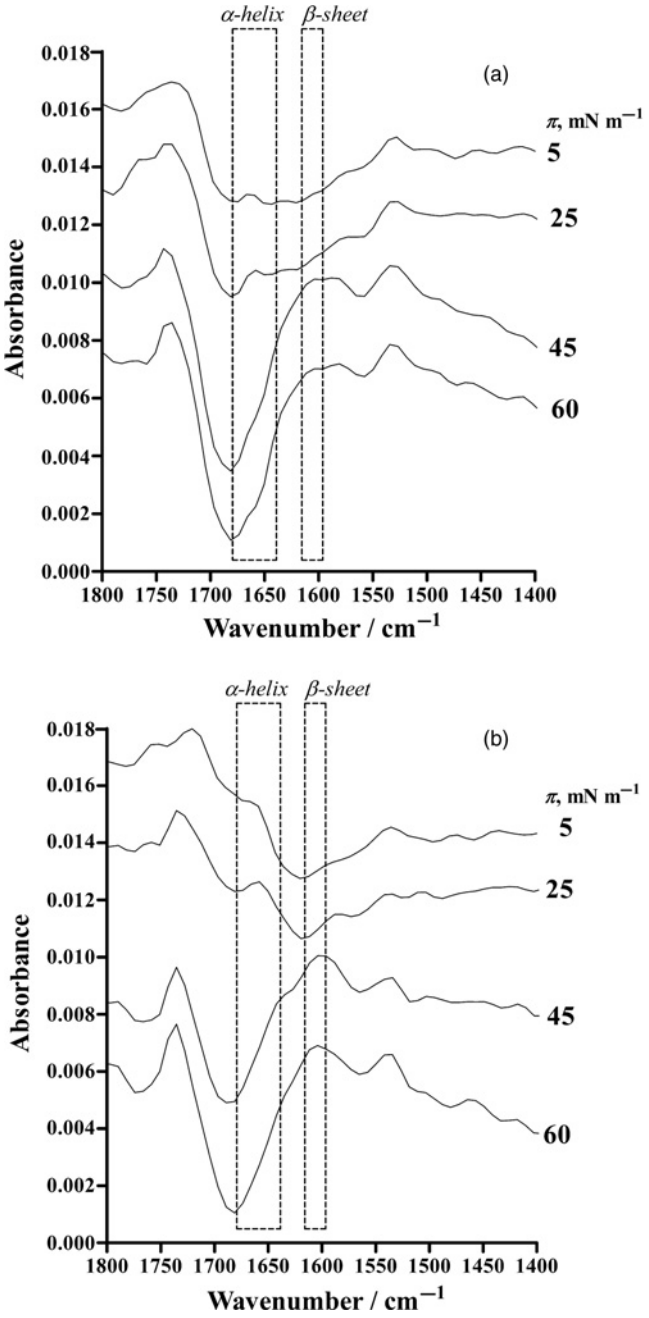

FIGURE 72.12 In situ PM-IRRAS spectra of monolayers of the (A) DPPC/Hel 13-5 and (b) DPPG/Hel 13-5 systems at $X_{\text{Hel 13-5}} = 0.1$ as a function of surface pressure (π) during compression in the region of 1400–1800 cm^{-1} on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K. The marker band regions of the α-helix and the β-sheet in the amide I contour are emphasized in the dashed rectangles.

ratio of amide I band intensities for ~1650 cm^{-1}/(~1650 + ~1620) cm^{-1} [31–33]. Hel 13-5 monolayers in the absence of lipids at the air–water interface are in approximately >70% α-helical structure during compression. However, overcompression above the collapse pressure decreases the α-helix ratio by ~20%. During the successive expansion, the α-helix ratio is kept at >50%. In the DPPC/Hel 13-5 system, the percentage of the α-helical component decreases from 50% to 80% down to near zero with increasing surface pressures up to 60 mN m^{-1} on compression. During the subsequent expansion, the percentage immediately recovers up to ~30%, and the value is kept almost constant as surface pressure reduces further. This suggests the irreversible interconversion of Hel 13-5 secondary structures from the α-helix into the β-sheet, when Hel 13-5 is surrounded by DPPC monolayers. On the other hand, in the DPPG/Hel 13-5 monolayer, it is quite interesting that the percentage of the α-helix marker band reduces from ~60% down to ~30%, not to zero, on compression. As opposed to the DPPC/Hel 13-5 system, interconversion into the β-sheet is restrained by the surrounding DPPG monolayer, which may result from the electrostatic interaction between both components. During the subsequent expansion, the percentage does not return to the initial value but maintains the value of ~30% up to lower surface pressures. In the case of the DPPC/PA/Hel 13–5 system, the percentage of the α-helical component decreases from 30% to 40% down to 20% with increasing surface pressures on compression. This suggests that PA promotes the destruction of hydrogen bonding in Hel 13-5 secondary structures. In the subsequent expansion process, the ratio rapidly restores to the initial values of 30−40%, which indicates that PA components are effective in recovery of the secondary structure. From these results, it is found that the lipid species such as PG and PA are an important factor for deformation of the secondary structure: (1) the hydrogen bonding involved in construction of the secondary structure of Hel 13–5 is broken mainly by DPPC, (2) the surface-associated reservoir including charged PA and PG disturbs the transformation of the secondary structure into β-sheet, and (3) PA promotes the recovery of a secondary structure during expansion. Interestingly, PA exerts effects 2 and 3 during compression and expansion, respectively. The carboxyl group in PA molecules is partially dissociated by 30–40% under the present conditions [14]. Thus, a switching motion between COOH and COO^- is considered to be an effective driving force for the recovery of Hel 13–5 secondary structure from the β-sheet and for the release of surface-associated reservoirs onto the interface during expansion. Considering the predominant α-helical structure of Hel 13–5 in the aqueous solutions containing phospholipids [20, 26] and in the bilayer form [32, 33], it is demonstrated that the surface-associated reservoir prevents the protein structure transition (or surface denaturation) by incorporating the proteins into the reservoir.

72.7.3 Lipid Stretching Vibration Modes

The PM-IRRAS spectra in the region of 2800–3000 cm^{-1} commonly catch stretching vibrations of methylene and

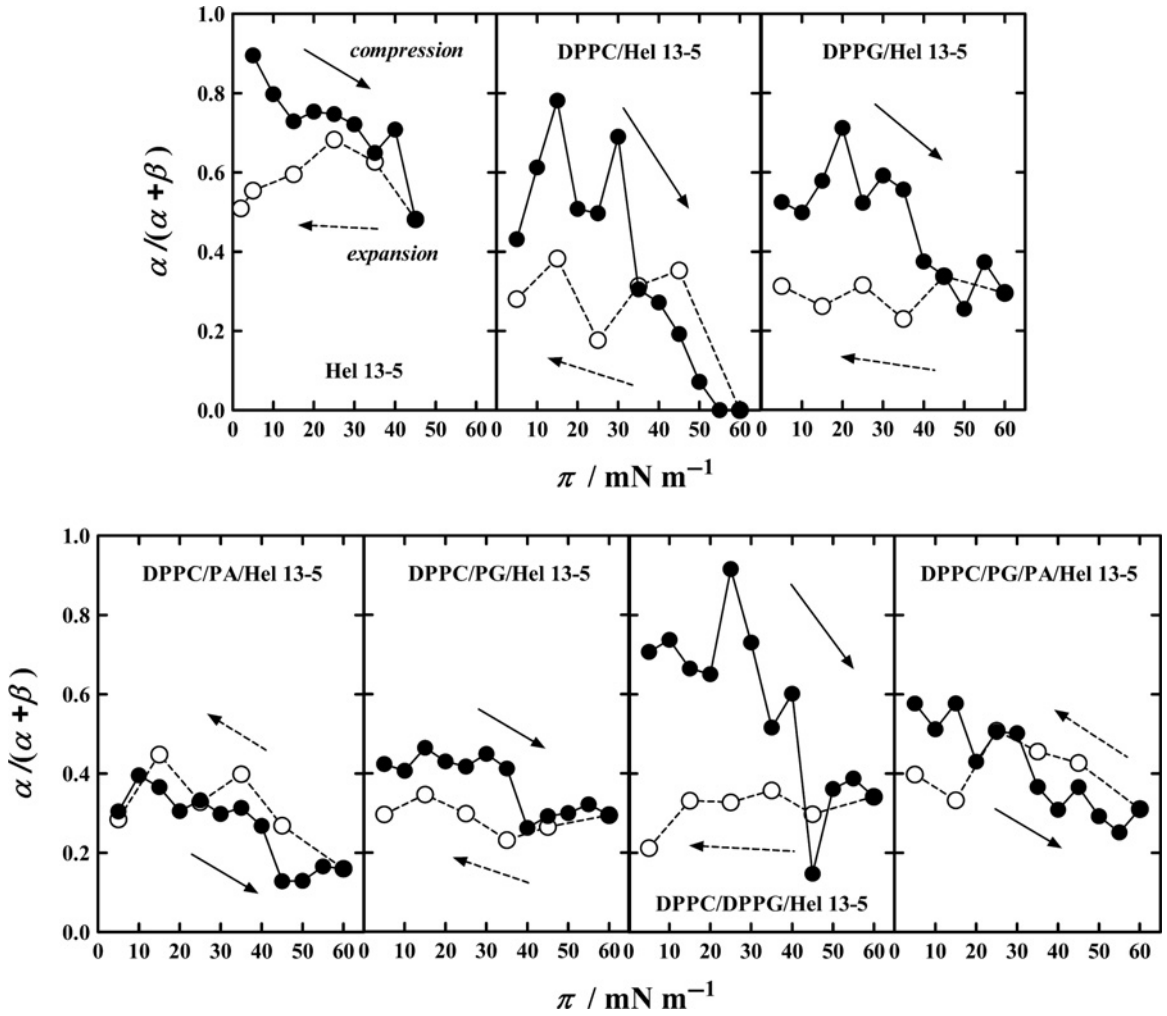

FIGURE 72.13 Peak area ratio $\alpha/(\alpha+\beta)$ of the amide I band intensity for ~1650 cm^{-1}/(~1650 + ~1620) cm^{-1} against surface pressure (π) during compression (filled circles and solid lines) and expansion (open cycles and dashed lines) for the DPPC/, DPPG/, DPPC/PA (= 90/9, wt/wt)/, DPPC/PG (= 68/22, wt/wt)/, DPPC/DPPG (= 4/1, mol/mol)/, and DPPC/PG/PA (= 68/22/9, wt/wt/wt)/Hel 13-5 preparations at $X_{\text{Hel 13-5}} = 0.1$. The peak at ~1650 cm^{-1} is assigned to the α-helical secondary structure and the peak at ~1620 cm^{-1} is assigned to the antiparallel β-sheet.

methyl groups for lipid components [33, 68–70]. The region includes three kinds of specific peaks of the lipids such as a symmetric methylene stretching vibration [or $\nu_s(CH_2)$] at ~2850 cm^{-1}, an asymmetric methylene stretching vibration {or $\nu_a(CH_2)$} at ~2920 cm^{-1}, and a methyl stretching vibration [or $\nu(CH_3)$] at ~2950 cm^{-1}. Among the three, the $\nu_a(CH_2)$ peak is, in general, the largest in intensity and is most sensitive to external stimuli such as lateral compression (or surface concentration) and temperature. Therefore, the $\nu_a(CH_2)$ mode allows us to probe changes in surface concentration and orientation of the lipid components. The intensity of $\nu_a(CH_2)$ modes increases with an increase in surface pressure and subsequently decreases during the expansion cycle. The $\nu_a(CH_2)$ RA intensity at ~2920 cm^{-1} for all the lipid/Hel 13–5 systems at $X_{\text{Hel 13–5}} = 0.1$ during compression (solid line with filled circles) and expansion (dashed line with open circles) is plotted against surface pressure in Fig. 72.14. On compression, the RA value increases with an increase in surface pressure and finally reaches 0.004−0.009 at 60 mN m^{-1}. Considering the maximum $\nu_a(CH_2)$ RA intensity (~0.004) for the binary DPPC/Hel 13–5 system [32], all the systems here indicate larger RA values, which indicates an increase in surface concentration (or density) of aliphatic chains induced by the addition of PA and PG (or DPPG) at the close-packed state. During the expansion stage, the RA intensity decreases with decreasing surface pressure. Notably, all the systems exhibit a hysteresis loop in intensity during the compression–expansion process. The hysteresis regarding the interfacial

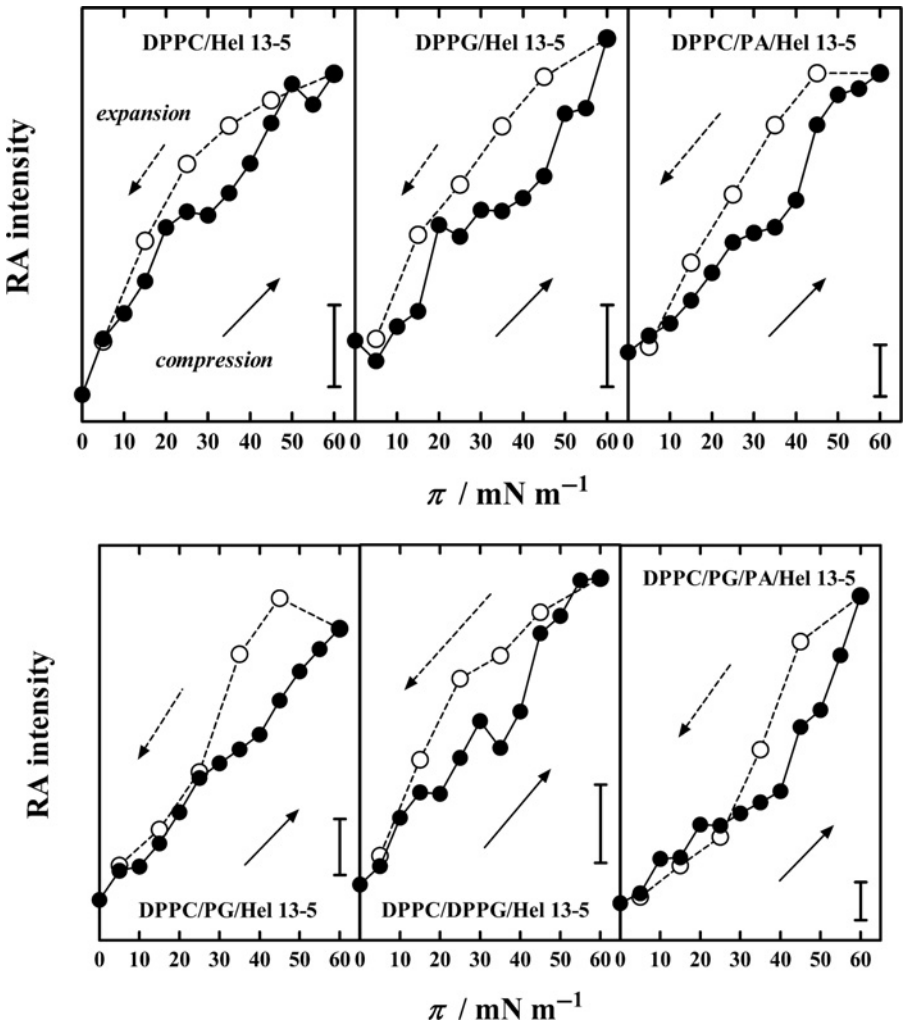

FIGURE 72.14 RA intensity of the asymmetric CH_2 stretching vibrations $\nu_a(CH_2)$ of lipids in the PM-IRRAS spectra at different surface pressures (π) during compression (filled circles and solid lines) and successive expansion (open circles and dashed lines) for the DPPC/, DPPG/, DPPC/PA (= 90/9, wt/wt)/, DPPC/PG (= 68/22, wt/wt)/, DPPC/DPPG (= 4/1, mol/mol)/, and DPPC/PG/PA (= 68/22/9, wt/wt/wt)/Hel 13-5 preparations at $X_{\text{Hel 13-5}} = 0.1$ on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K. Each scale bar in the lower right corner represents 0.001 of RA intensity.

orientation of hydrophobic chains in lipid components is also supported by ΔV–A isotherms (Fig. 72.4). RA intensities for the DPPC/PA/Hel 13–5 system under the expansion stage from 60 down to 10 mN m^{-1} are maintained larger compared with those at the same surface pressures during compression. On the other hand, in the systems containing PG (DPPC/PG/Hel 13-5 and DPPC/PG/PA/Hel 13-5), RA intensities on expansion restore to the initial value down by 25 mN m^{-1}. These results suggest that the addition of PA and PG accelerates monolayer packing at high surface pressures under the compression and respreading of tightly packed monolayers under the expansion, respectively. However, the influence on the respreading in the systems containing DPPG seems to be different from those containing PG. This is considered to result from the saturated hydrocarbon chains in DPPG, which remains at the surface during cycling. Thus, it is demonstrated that the hysteresis behavior of orientation of hydrophobic chains in the lipids could be related to the formation of surface-associated reservoirs.

Besides the RA intensity, a wavenumber (or peak frequency) of $\nu_a(CH_2)$ modes for lipid monolayers is more strongly influenced by packing, orientation, and conformational change of their hydrophobic chains. In particular, the wavenumber near 2920 cm^{-1} is characteristic of all-*trans* conformations of these chains [71–73]. As seen in Fig. 72.15, the wavenumber of $\nu_a(CH_2)$ modes for the DPPC/PA/Hel

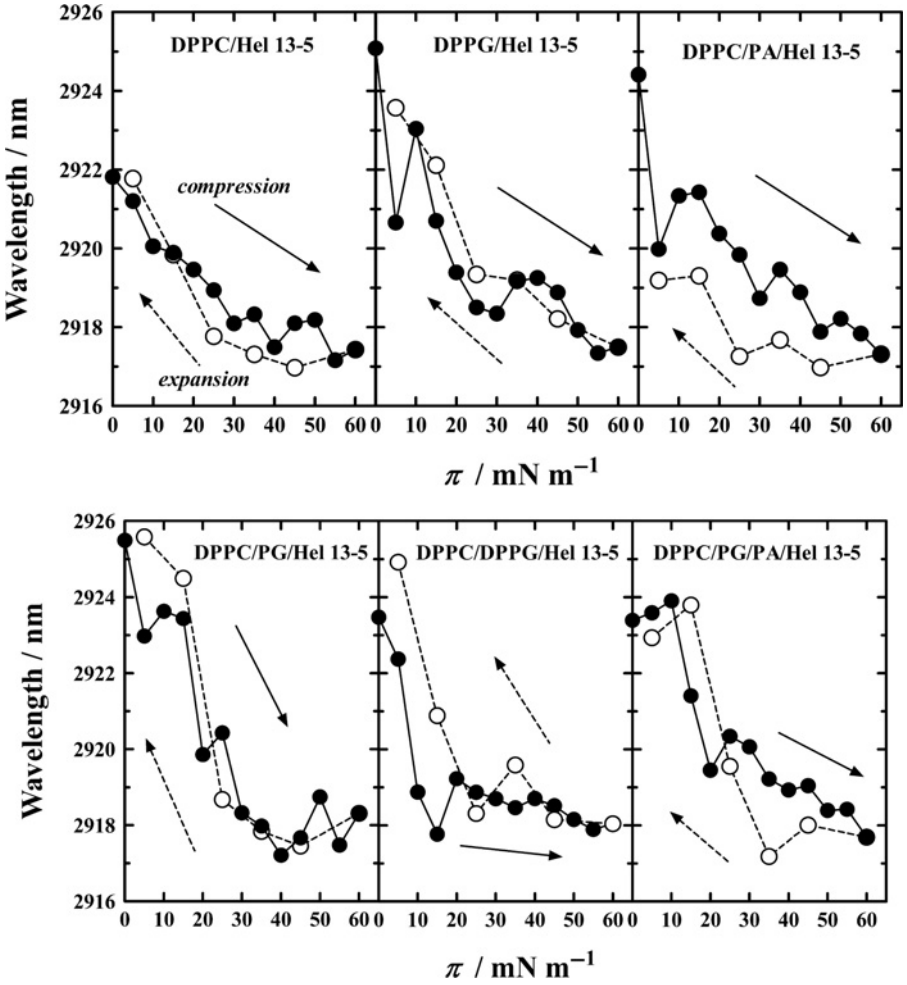

FIGURE 72.15 Wavenumber of the asymmetric CH_2 stretching vibrations $\nu_a(CH_2)$ of lipids in the PM-IRRAS spectra at different surface pressures (π) during compression (filled circles and solid lines) and successive expansion (open circles and dashed lines) for the DPPC/, DPPG/, DPPC/PA (= 90/9, wt/wt)/, DPPC/PG (= 68/22, wt/wt)/, DPPC/DPPG (= 4/1, mol/mol)/, and DPPC/PG/PA (= 68/22/9, wt/wt/wt)/Hel 13-5 preparations at $X_{\text{Hel 13-5}} = 0.1$ on a 0.02 M Tris buffer solution (pH 7.4) with 0.13 M NaCl at 298.2 K.

13–5 and DPPC/PG/PA/Hel 13-5 systems indicates a hysteresis loop during compression and expansion, not for the DPPG/Hel 13-5, DPPC/PG/Hel 13–5, DPPC/DPPG/Hel 13-5 systems. The hysteresis in the wavenumber plots also indicates the condensing effect of undissociated PA components on the monolayer, which prevents it from respreading during expansion. On the other hand, the PG components are found to improve the relaxation of the packed chains of lipid monolayers on expansion.

72.8 CONCLUSIONS

The large hysteresis in the π–A and ΔV–A isotherms for the DPPG/Hel 13-5 system demonstrates that the mutual specific (or electrostatic) interaction triggers completely independent processes for Hel 13-5 during repeated compression and expansion processes: (1) squeeze-out into subsolution and (2) close packing as a monolayer with DPPG at the interface. In addition, the AFM observations reveal that the electrostatic interaction contributes to the formation of the squeezed-out Hel 13-5 aggregates beneath the monolayers under the compression process and to their stabilization up to low surface pressures under the expansion process. In other words, the specific interactions between the PG headgroup and the polarized moiety of Hel 13-5 are closely related to the physiological and biophysical functions of PS. Moreover, the reservoir formation causes a hysteresis in π–A and ΔV–A isotherms as well as spectrum parameters regarding lipid orientations and peptide secondary structures during the compression–expansion cycle. The formation and function of reservoirs across the surface are controlled not only

by the electrostatic attraction between lipids and peptide but also by the structural transition of peptides. The structural transition is considered to be induced by destruction of the hydrogen and S–S bonding constructing higher-order structures of a peptide or protein. In the monolayer study, the destructive factors are typically an applied surface pressure and a surface density of lipids (in particular, their hydrocarbon chains). DPPC-rich surroundings cause the structural transition of Hel 13-5 to β-sheet almost completely. However, the existence of PA and/or PG preserves the α-helical structure. Furthermore, it is suggested that the release of squeezed-out lipids and peptides from the surface-associated reservoir is accelerated by partially charged PA molecules and that PG assumes a strong resistance to the secondary structure transition on compression.

73.1 INTRODUCTION

Surface-active substances, or *surfactants*, are grouped under a large class of various substances with specific physicochemical properties [1]. A vast variety of chemical compounds (synthetic or natural) are surfactants; one distinguishes cationic, anionic, nonionic, zwitterionic, and polymeric surfactants. These include block copolymers, grafted polymers, and proteins, and also complicated natural mixtures such as saponins or pulmonary surfactants, and many others. Their molecules are *amphiphilic*; that is, one part of the molecule is characteristically polar and the other part is nonpolar. That is why the surfactant molecules, dissolved in a liquid solvent, adsorb on the interfaces of the liquid phase (liquid–gas, liquid–solid, or liquid–liquid interfaces), thus modifying the interfacial properties.

The surfactants play an important role in microheterogeneous systems, where the total area of the interfaces is very large. Such systems are all *disperse systems*, like foams, emulsions, sols, and suspensions as well as more complicated systems. The adsorption layers of surfactant molecules usually stabilize the disperse systems. The stability of these systems is bound by the stability and properties of the *thin liquid films*, which are formed when two particles of the disperse phase (solid particles, liquid drops, or gas bubbles) come close to each other [2–7]. The liquid film is symmetric when the two particles are identical; for instance, a symmetric *foam film* appears between two gas bubbles. In the more complicated case, when a gas phase approaches a solid surface, an asymmetric *wetting liquid film* is formed.

Obviously the properties and stability of the thin liquid films strongly depend on the surfactant *adsorption layers* at their interfaces. The experimental study of a single thin liquid film provides important information about the corresponding disperse system stabilized by the same surfactant. On the other hand, the experimental results obtained for single thin liquid film yield knowledge about the surfactant, from the solution of which the thin liquid film was formed. Hence the thin liquid film becomes a felicitous tool for studying surfactant properties. Thus the method involving the use of thin liquid film for studying surfactants was developed.

In this chapter we will briefly review two types of thin liquid films: foam film (symmetric, thin liquid film existing between two identical gas phases) and wetting film (asymmetric thin liquid film existing between a solid phase and a gas phase). The foam films and wetting films studied are circular, horizontal, and microscopic films, formed in special cells under strictly defined conditions. This method allows measurement of some parameters that can be used for physicochemical characterization of the surfactants involved. Further, this method using thin liquid film will be applied for studies of pulmonary surfactants, which will be illustrated by typical experimental results.

73.2 EXPERIMENTAL TECHNIQUE

Small, circular, horizontal foam films or wetting films, the radius of which is within the range of 10–500 μm, are considered as *microscopic films* [3,5,7]. The experimental technique

for their study allows the measurement of thermodynamic quantities, to follow the kinetic behavior, the formation of black films, the realization of metastable states, and so on. An advantage is the possibility of working at very low surfactant concentrations. Microscopic thin liquid films are formed and studied in special glass cells.

Figure 73.1a is a conceptual sketch (not to actual scale) of a cell reported [8, 9] for microscopic foam films, which can also be used for emulsion films. This is already a classical cell, used by many researchers for a long time in different countries. The foam film is formed in the middle of a biconcave drop D situated in a film holder H (glass cylinder of inner radius R) by withdrawing liquid (surfactant solution) from it. The suitable range of R is 0.2 - 0.6 cm, whereas the film radius r ranges from 100 to 500 μm. The holder H together with the foam film is situated in the closed space G of the cell, saturated with the solution vapor; the gas pressure p^G there is equal to the atmospheric pressure p^A. The film holder is welded to the sucking capillary C. The liquid is sucked out of the drop D by decreasing the pressure in the sucking capillary using a fine micrometric syringe S, connected to C. Thus the pressure p^L in the biconcave liquid phase is decreased and a pressure difference $\Delta p = p^G - p^L$ is created, which causes the thinning of the microscopic foam film.

As a result of the thinning process, either the film ruptures or an *equilibrium foam film* is formed. The periphery of the film is in contact with the double meniscus (bulk solution), the radius of curvature of which determines, together with the surface tension γ of the solution studied, the *capillary pressure* P_c. The equilibrium of the foam film is determined by the pressure balance $\Pi = P_c = \Delta p$, where Π is the *disjoining pressure*, which arises in all types of thin liquid films as a result of the action of the surface forces at sufficiently small film thickness [5–7]. The temperature is kept strictly constant. In this cell the microscopic foam films with fixed radius r are studied at constant capillary pressure P_c.

The foam films can be studied at a wide range of capillary pressures using the *porous plate cell* [10]. A conceptual sketch (not to actual scale) of this cell is given in Fig. 73.1b, which shows that the film holder H is a cylindrical hole drilled in a porous sintered glass plate P; the actual hole radius is considerably smaller (e.g., <250 μm). Plates of various pore radii can be used. If the meniscus penetrates into the pores, their radius determines the radius of curvature; that is, the small pore size allows for increase in the capillary pressure P_c until the gas phase can enter the pores. The capillary pressure can be increased to more than 10^5 Pa, depending on the pore size and the surface tension of the solution. A capillary tube C is welded to the porous plate, and its free end is open to the atmosphere. The film holder, together with the foam film, is also situated in the closed space G of the cell, saturated with the solution vapor. The increase in P_c is achieved by increasing the gas pressure p^G in the space of the cell using a membrane pump MP, with the pressure p^L in the liquid phase (in the pores) remaining constant. Thus a high pressure difference $\Delta p = p^G - p^L$ can be created, which at equilibrium is equal to $P_c = \Pi$. The pump MP allows the operator to set each desired p^G value, respectively, the desired P_c and Π values, in a wide range of pressures at constant temperature.

Figure 73.1c is a conceptual sketch (not to actual scale) of a cell described in the literature [11, 12] for formation and study of microscopic wetting films on a solid surface. The films are formed between the horizontal, flat surface of the solid substrate E and the hemispherical meniscus aqueous solution–air that is exiting from the orifice of a vertical tube–film holder H toward the solid plate E. The plate lies on the bottom B of the vessel, filled with the

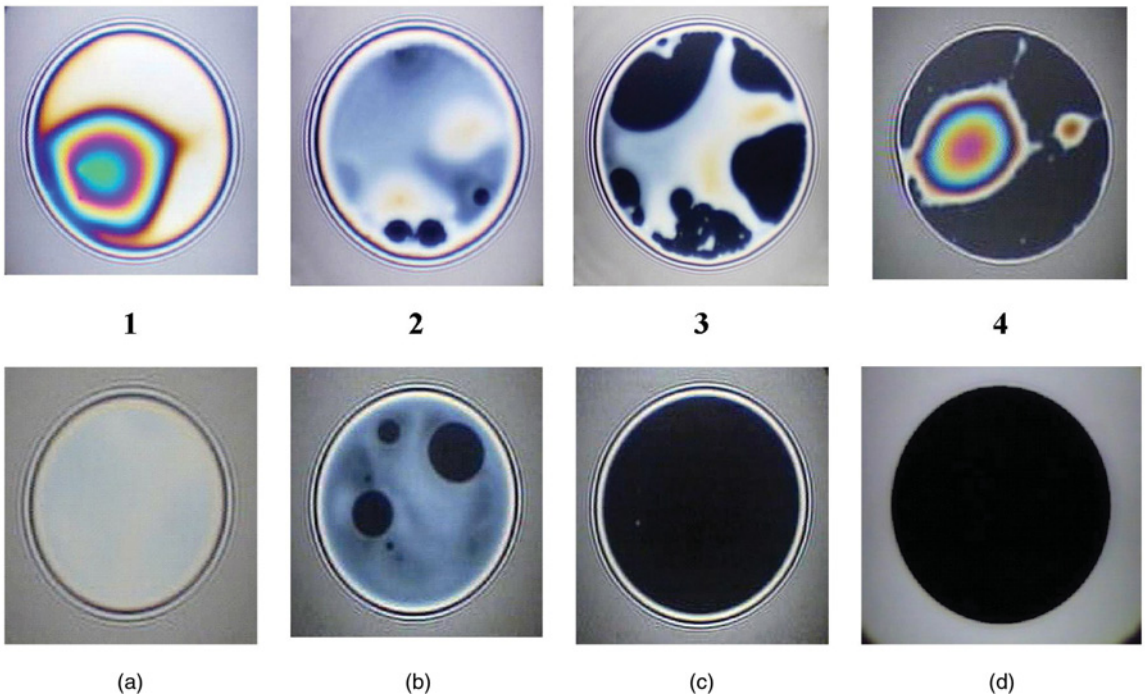

FIGURE 73.2 Photographs of microscopic foam films: (a–d) smooth thinning and formation of black spots and film; (1–4) irregular film drainage that impedes formation of black film.

solution studied; the gas pressure in the cell above the solution is equal to the atmospheric pressure. Hence the pressure p^{L} in the liquid phase at the level of the solid surface remains constant. The distance between the solid surface and the film holder orifice should be less than the inner radius R of the tube–film holder H, which is connected to the capillary C. The meniscus is placed very close to the solid plate, using a fine micrometric syringe S, which increases the gas pressure p^{G} in the tube H and thus creates the pressure difference $\Delta p = p^{G} - p^{L}$ between the gas phase in the glass film holder and the liquid phase in the vessel, around the tube. Here also $\Delta p = P_c = \Pi$ at equilibrium and constant temperature.

The cells illustrated in Fig. 73.1 are housed in a thermostat, fixed on the table of an inverted microscope M, and the thin liquid films are observed through the optically transparent bottom B of the cells in reflected monochromatic light [5].

73.3 PHYSICOCHEMICAL PROPERTIES STUDIED BY THE THIN LIQUID FILM METHOD

The process of formation, thinning, rupture, or establishment of equilibrium films, as well as formation of black spots and black films, can be followed through the microscope. Two typical series of microphotographs of different states of microscopic foam films, taken during the process of film thinning in the cell of Fig. 73.1a, are presented in Fig. 73.2. Photos (a)–(d) show a smooth, regular drainage of the thicker film, with formation of black spots and black film. On the contrary, photos (1)–(4) show irregular film drainage and impeded formation of black spots and black film, due to complicated rheological properties of the aqueous surfactant solution used.

The *film thickness* is measured using the microinterferometric method based on measurement of the intensity of monochromatic light reflected from the film. Foam film thickness is calculated from the ratio between the measured intensities of the reflected monochromatic light I, corresponding to a certain thickness, and I_{max}, corresponding to the interference maximum, according to the formula [13–15]

$$h_w = \frac{\lambda}{2\pi n}\left(k\pi \pm \arcsin\sqrt{\frac{I/I_{max}}{1+[(n^2-1)/2n]^2(1-I/I_{max})}}\right) \tag{73.1}$$

where k is order of interference, λ is the wavelength of light, n is the refractive index of the liquid in the film, and h_w is the *equivalent film thickness* (i.e. the thickness of a foam film with uniform refractive index n of the bulk solution from which the film is formed). For the asymmetric wetting films this formula is more complicated [14]. It is clear that h_w is not exactly equal to the real physical film thickness h. The difference between h_w and h could be neglected for any

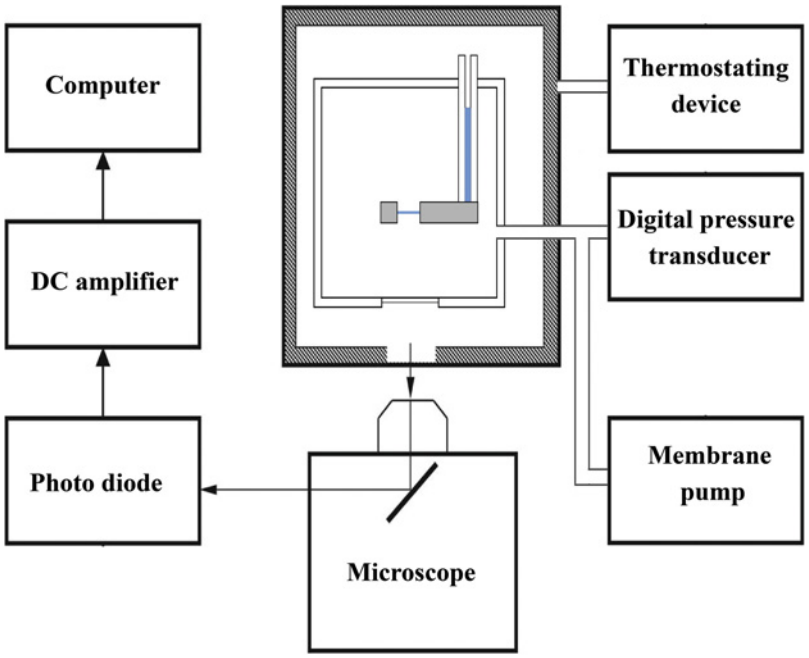

FIGURE 73.3 Block scheme of the microinterferometric method and pressure balance technique for study of black foam films.

thickness exceeding 30 nm. However, for thinner liquid films it is necessary to also account for the film structure [16].

For determination of *disjoining pressure* Π and its dependence on h [disjoining pressure isotherms $\Pi(h)$], an experimental method called the *thin liquid film–pressure balance technique* [5] is used. This is a combination of the microinterferometric technique and the porous plate cell method (Fig. 73.1b). The experimental block scheme of this method is shown in Fig. 73.3. Using the membrane pump, different capillary pressures P_c can be created and measured in a wide range up to 3×10^5 Pa. Since a thickness value can be measured interferometrically at equilibrium $\Pi = P_c$ for each disjoining pressure value, it is possible to obtain the isotherm $\Pi(h)$.

Foam films lose their stability during thinning when they reach a certain critical thickness h_{cr}. There are two plausible explanations for this; either (1) the film ruptures or (2) a local jumplike thinning in the film occurs. As a foam film appears to be black in reflected light at very narrow thicknesses, the jumplike local thinning appearance is called *formation of black spots* (Fig. 73.2). A black spot is a very small round area of a *black film* [2–5] that is much thinner than the surrounding area of the unstable foam film (Fig. 73.2). Black foam films can attain an extremely small thickness. Therefore, they could be called *nanofilms* as well. The IUPAC nomenclature [17] distinguishes two equilibrium phase states of black films: *common black film* (CBF) (Fig. 73.2c) and *Newton black film* (NBF) (Fig. 73.2d), which constitutes a bilayer of amphiphilic molecules.

The stability in respect to *rupture of the bilayer NBF* can be considered as a process of nucleation of a nucleus holes, which, by irreversible overgrowth, cause its rupture [18, 19]. This is possible only at surfactant concentrations C lower than the so-called bilayer equilibrium concentration C_e. When $C \geq C_e$, the bilayer is truly stable. An important quantity proved to be the probability W for black film formation, which depends on C. The nucleation theory [18, 19] yields W as a function of $C \leq C_e$

$$W(C) = \exp[-t_r/A \ \exp[B/\ln(C_e/C)]] \qquad (73.2)$$

where A, B, and t_r are constants. Equation (73.2) shows that W sharply increases with the bulk surfactant concentration C in a relatively narrow range. The dependence $W(C)$ in dimensionless coordinates is shown in Fig. 73.4. The curve runs steep, which justifies the introduction of two new characteristics of black foam film stability: (1) the minimum concentration C_c (critical concentration) required for black film formation and (2) the concentration C_t (threshold concentration) rendering 100% black films [5].The theoretical dependence $W(C)$ can be easily checked since W and C are measurable quantities, and experimental values of C_c and C_t can be obtained. Because of the fluctuation character of the film rupture, the probability W is a random parameter; hence it should be determined by averaging data from a large number of measurements.

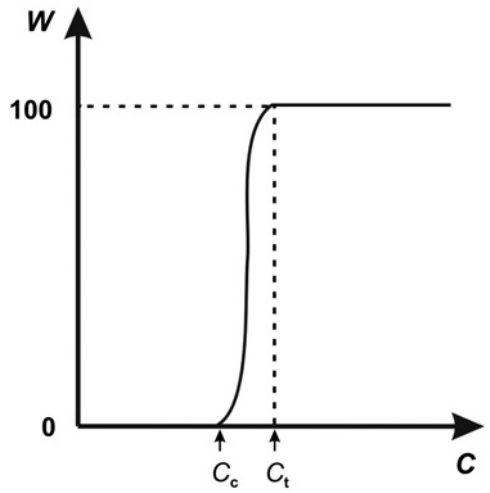

FIGURE 73.4 Probability W for black film formation versus surfactant concentration C [C_c, minimum (critical) concentration required for black film formation; C_t, threshhold concentration rendering 100% black films].

73.4 PULMONARY SURFACTANTS

The surface-active substance covering lung alveolar surface is called *pulmonary surfactant* (or *lung surfactant* or *alveolar surfactant*). It is well known that pulmonary surfactant is crucial for the normal breathing function [20]. Its deficiency, dysfunction, or inactivation can lead to development of the *respiratory distress syndrome* (RDS), an important cause of neonatal mortality of premature newborns [21, 22]. The treatment of such newborns with animal-derived pulmonary surfactant preparations has been shown to be very useful; in most cases it is a decisive factor for survival of premature infants. Clinical practice has proved the benefits of these *therapeutic surfactant preparations*, such as Curosurf, Infasurf, Survanta, and Exosurf, which have been widely applied [20, 23].

The pulmonary surfactant is a multicomponent composition of polar phospholipids [mainly dipalmitoylphosphatidylcholine (DPPC), phosphatidylglycerol (PG)], as well as specific hydrophilic proteins (SP-A and SP-D) and hydrophobic low-molecular-weight proteins (SP-B and SP-C). Table 73.1 illustrates this complicated natural mixture [24].

TABLE 73.1 Pulmonary Surfactant Composition

	DPPC	PC	PG	PE	PI	Sm	Chol	Prot	Specific Prot
Content (%)	45	23	8	3	4	2	5	8	2

Abbreviations: Chol = cholesterol; DPPC = dipalmitoylphosphatidylcholine; PC = phosphatidylcholines; PE = phosphatidylethanolamine; PG = phosphatidylglycerols; PI = phosphatidylinozitol; Prot = proteins; Sm = sphingomyelin.

The most common approach to physicochemical characterization of pulmonary surfactants has been to measure surface tension or surface pressure at the aqueous solution–air interface [25]. The widely spread hypothesis about alveolar surface structure perceives it as being covered by a phospholipid monolayer that is in contact with the hypophase. Our hypothesis differs from the abovementioned one, and we believe that it reflects the in vivo situation better. We have introduced a new method for the study of alveolar surface and stability [26, 27] and have also proposed a new diagnostic method for fetal lung maturity assessment [28]. The model employed in these methods is the black foam film one, including bilayer film. The black foam film model accounts for not only lateral interactions between first-neighbor molecules in the adsorption monolayer but also normal interactions in the bidimensional ordered system such as the bilayer black foam film [5].

73.5 METHOD FOR LUNG MATURITY ASSESSMENT

As mentioned earlier, pulmonary surfactant insufficiency in premature infants leads to RDS and quite frequently, to death. That is why fetal lung maturity requires an approach that enables proper assessment [27, 28]. The black foam film method proved to be very suitable as it possesses a number of advantages compared to the other methods employed; it is very precise (90%), fast (takes only ~20 min), and requires a small quantity of amniotic fluid [5, 28, 29]. For the purpose of this method, surfactant insufficiency (premature lung) versus absence of a black film has been studied. Amniotic fluid (AF) samples are diluted in order to map the dependence between threshold dilutions versus gestation weeks.

Figure 73.5 presents the dependence of threshold dilution [from the $W(C)$ curve] for each sample of amniotic fluid. The immature samples from the clinical result are plotted with filled circles and the mature samples, with open circles. Comparison with clinical results allows us to establish a threshold dilution: a horizontal line (Fig. 73.5) that distinguishes mature from immature samples [5, 28].

Test results obtained by this method correlate very well with the clinical status of newborns (proved by blind comparison of >1000 samples). Clinical application involves AF sample dilution and matching with the *threshold dilution*, that is, by establishing sample maturity or surfactant insufficiency/sufficiency. The approach described has provided a method for rapid and accurate assessment of fetal lung maturity, respectively, for RDS diagnostics [30]. The method is applicable also for blood- and meconium-contaminated AF, as well as for samples of nasopharyngeal aspirates of newborns. Early RDS diagnostics provides for adequate surfactant insufficiency treatment during the prenatal period and for reducing the risk of RDS infants.

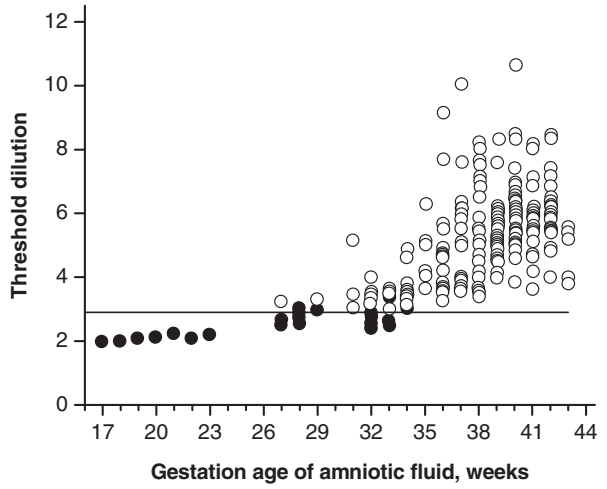

FIGURE 73.5 Dependence of the threshold dilution of amniotic fluid on its gestation age (• development of RDS in neonates; ∘ no RDS in neonates); the line indicates the dilution separating the mature from immature AF samples.

A schematic representation of the black foam film method for assessment of fetal lung maturity is presented in Fig. 73.6. The threshold concentration distinguishes between surfactant insufficiency/surfactant sufficiency, respectively, and lung immaturity/lung maturity. Photos of the corresponding microscopic foam films are also given in Fig. 73.6: (a) unstable film with black spots and (b) stable black foam film.

73.6 FOAM FILMS FROM PULMONARY SURFACTANT AND ITS COMPONENTS

Studies of foam films from pulmonary surfactant began with samples of amniotic fluid and lung lavages about 30 years ago [26,28,29].The conditions of formation of a microscopic foam film in order to "serve" the in vivo situation are close to the physiological: film radius r from 100 to 400 μm, with capillary pressure between 0.3 and 3 kPa and electrolyte (NaCl) concentration at 0.15 mol/dm^3, and ensuring formation of black films [5]. Under such conditions it is possible to study the dependences for foam films and to use parameters related to formation and stability of black foam films (BFFs). Introduction of the "black foam film" model creates new options in the study of pulmonary surfactant behaviors in vitro [5, 27], at the same interface as it is in the alveoli, providing opportunities to measure dependences such as probability for black foam film formation versus surfactant concentration, film thickness versus electrolyte concentration, and interaction forces (disjoining pressure) versus film thickness.

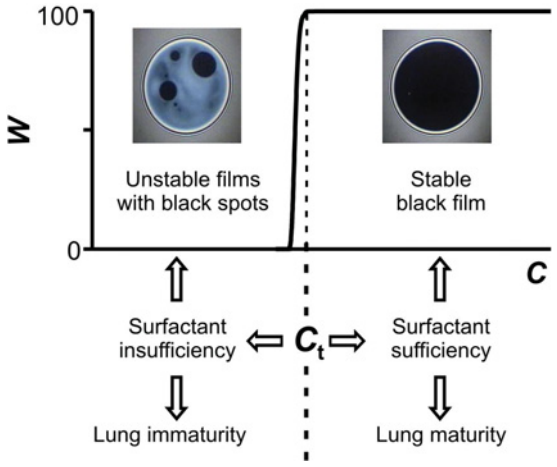

FIGURE 73.6 A schema of the black foam film method for assessment of fetal lung maturity.

The probability W for the formation of a stable black foam film depends strongly on the concentration C of the amphiphile molecules in the film forming bulk solution, according to the hole nucleation theory of Kashchiev and Exerowa [18, 19]; see Eq. (73.2). The $W(C)$ dependence was checked experimentally with a number of phospholipids, and the results revealed that for the phospholipids W changed sharply from 0% to 100 % in a very narrow concentration interval [5, 31]. W can be calculated using the equation $W = (\Delta N/N) \times 100$, where N is the total number of trials and ΔN is the number of trials in which stable BFFs are formed. As already pointed out above, studies of the probability W for black foam film formation versus concentration make it possible to determine two characteristics of black foam film stability: (1) the minimum (critical) concentration C_c required for black film formation and (2) the threshold concentration C_t rendering 100% black films [5,29]. Figure 73.7 depicts three $W(C)$ dependences for amniotic fluid, the main

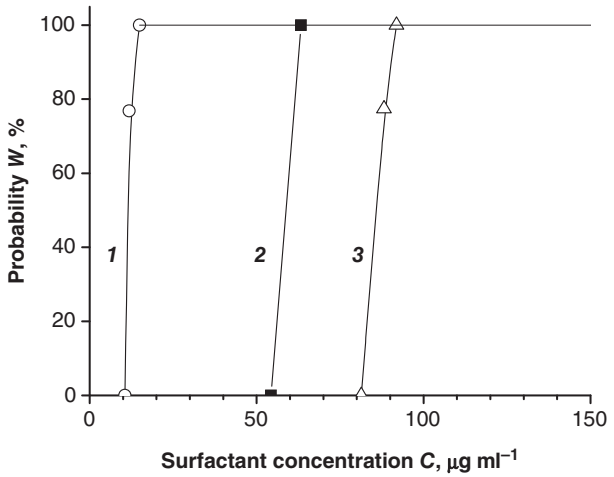

FIGURE 73.7 $W(C)$ dependence for black foam films from AF in 47% ethyl alcohol + 0.07 M NaC1 aqueous solution (curve 1); HF in 0.15 M NaCl aqueous solution (curve 2); DPPC in 47% ethyl alcohol + 0.07 M NaC1 aqueous solution (curve 3).

PS component (DPPC) and hydrophobic fraction (HF)–full set of PS lipids, and hydrophobic surfactant proteins.

The foam films were obtained from a solution of AF in the presence of 47% ethanol and 7×10^{-2} mol/dm^3 NaCl. The above percentage of ethanol ensures predominant adsorption of the phospholipid molecules at the air–solution interface with respect to the proteins present in the AF [5, 31]. The presence of alcohol in the solutions of both the AF and the individual phospholipids also resulted in an increase in the CMC, so that the concentration of monomer lipid could still respond to changes in the total lipid concentration. The electrolyte in the solution is sufficient to eliminate the effect of the electrostatic component of the disjoining pressure and to obtain black foam films. The composition of the hydrophobic fraction (HF) resembles those of the pulmonary surfactant and natural exogenous surfactant preparations.

As can be seen, the $W(C)$ curves run steeply, and the critical concentrations C_c, are quite different: 13 μg/cm^3 for AF, 54 μg/cm^3 for HF, and 80 μg/cm^3 for DPPC. Biochemical analysis of the AF reveals that the maximum weight content of individual phospholipids in the AF is orders of magnitude lower than that of the corresponding to C_c [29]. Thus, only the concentration of the DPPC remains to be considered as close to C_c in the AF. It could be concluded that DPPC is the phospholipid from which the foam bilayer of AF is almost completely formed. The lower C_c for HF in comparison to those for DPPC could be related to the effect of all the remaining phospholipid components and surfactant proteins. They play an essential role in the formation and stability of foam films.

The probability W of black film formation depends not only on concentration C but also on the phase state of the phospholipids. Black film has shown that the lamellar phases disintegrated at air/water interface with a greater tendency than the cubic phase [32]. Studies of the temperature dependence of C_c and film stabilization have revealed that an increase in temperature causes increases in both C_c and phase transitions of the phospholipids in the film. The sharp change in the binding energy of disaturated phospholipid molecule in the foam bilayer is obviously due to the occurrence of a chain melting phase transition in the bilayer. In cases of AF and HF there was no phase transition, in the range around the relevant physiological temperature, even though they contain 80% DPPC [33].

The lateral mobility of adsorbed molecules at the air–water interface is of great importance in the process of breathing. The foam film model has been employed to study molecular interactions at interfaces by estimating the molecular lateral mobility (surface diffusion coefficient D) by the FRAP method [34–36]. It is shown that the D value in the pure DPPC films remains at the immobile level up to 45°C and that higher temperatures only induce small increases in D. In contrast, the D value in films stabilized by the pulmonary phospholipid fraction is much higher. The higher D of the fraction compared with that of DPPC could be explained both by the presence of phospholipids other than DPPC in the fraction and by a shift in the phase transition temperature of the fraction to a lower temperature comparable to that of DPPC, with resultant fluidization of the film surfaces.

The probability of black foam film formation is very sensitive to the addition of surface-active agents to the bulk solution. The shift in the $W(C)$ dependence of pulmonary surfactant to higher C_c after addition of agent is interpreted as an effect of film destabilization. Such a destabilizing effect is observed in the presence of lysophosphatidylcholine and rhamnolipid, well-known inhibitors of pulmonary surfactant [37, 38]. These results indicate that the BFF method can be successfully applied to study the inhibitory effect that diminishes surface activity of endogenous surfactant as well as exogenous surfactant preparations [31, 39].

The black foam film used as a model system opens new horizons to obtain insights into molecular interaction forces, operating in foam films from pulmonary surfactant and to establish the range of long- and short-range molecular interaction forces and the transitions between them. Molecular interaction forces in foam films have been assessed by means of direct measurements of film thickness h versus electrolyte concentration C_{el} and disjoining pressure/film thickness isotherms $\Pi(h)$ [40, 41].

Figure 73.8 shows the dependence of equilibrium thickness h of foam films from AF, DPPC, and HF on NaCl concentration C_{el}. As can be seen, the results are consistent with the general tendency of decreasing h with increase in C_{el} until rather high C_{el}-values at which black films begin to form. For foam films stabilized with AF and DPPC, further increase of electrolyte concentration leads to the formation of only Newton black films (NBFs) with h of the order of 8 nm.

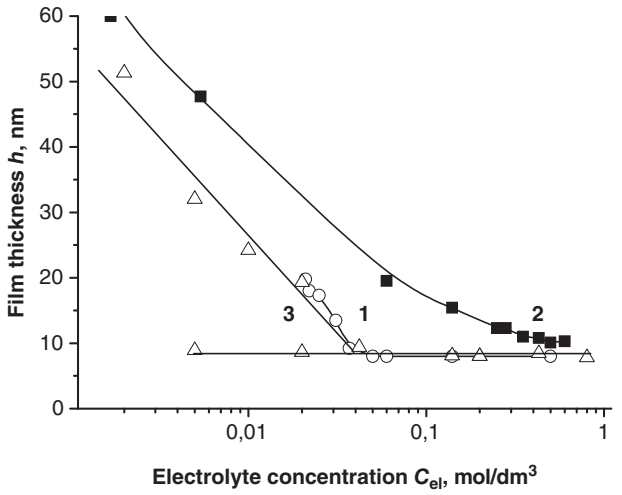

FIGURE 73.8 $h(C_{el})$ dependence for foam films from AF in 47% ethyl alcohol aqueous solution (curve 1); HF in aqueous solution (curve 2); DPPC in aqueous solution (curve 3).

Following the DLVO theoretical assumptions, the decrease in h with increase of C_{el} for AF and DPPC can be considered as evidence of the electrostatic stabilization of films. In the case of DPPC films, $C_{el} = 10^{-3}$ mol/dm^3 marks the onset of a metastable region where both thick and black films are formed in different experiments. The steady thickness of the black films in the metastable region indicates that these are NBF.

For foam films from HF, increased C_{el} leads to a decrease in h (Fig. 73.8). The thickness of BFF films decreases with the increase of C_{el}, showing that these films are *common black films* (CBFs). The range of CBF formation comprises the physiological electrolyte concentration, where $h = 11.7$ nm. Similar results have been obtained for films stabilized by exogenous surfactant preparations under the same conditions. The decrease in h of the CBF with the increase in C_{el} confirms the action of repulsive electrostatic forces in the film. Here it is possible to infer that the continuous film thinning is caused by the action of an additional positive component of the disjoining pressure. The experimental results also show that the HF-stabilized NBFs are ~2 nm thicker than the DPPC ones. Probably, this is again a result of the complex composition of HF leading to a different structure of the adsorbed layers compared to that of the DPPC films. These findings would help us clarify the influence of molecular interaction forces on the interfacial behavior of pulmonary surfactant layer as well as on the stability of DPPC-rich protrusions formed at alveolar surface during expiration.

Additional information about the inhibitor's activity on pulmonary surfactant interfacial properties may be obtained from the $h(C_{el})$. In the case of rhamnolipids, it was found that the rhamnolipid is adsorbed predominantly and participates more significantly in the formation of black film adsorption layers [37].

Disjoining pressure isotherms $\Pi(h)$ provide direct information about molecular interaction forces and have been studied extensively for phospholipids, amniotic fluid, pulmonary surfactant fractions, and a number of exogenous surfactant preparations [5, 26, 29, 40, 41]. Figure 73.9 shows $\Pi(h)$ isotherms measured for films from amniotic fluid and hydrophobic fraction of pulmonary surfactant.

In the case of AF, after a smooth initial decrease of h to ~14 nm, a transition from CBF to NBF is observed. On further increase in Π, the thickness of NBF remains constant and equal to film thickness from the $h(C_{el})$ curve in Fig. 73.8. At higher electrolyte concentration, h does not change with increasing Π and always retains the value of ~8 nm. Thus, by varying the thickness of the foam film through C_{el} or Π the same limiting thickness of ~8 nm is always reached, corresponding approximately to a bilayer of phospholipid molecules.

The steep curves in Fig. 73.9 (squares) show the $\Pi(h)$ isotherms for CBF and NBF from HF. The thickness of the CBF decreases from 19.5 to 10.9 nm with the increase in

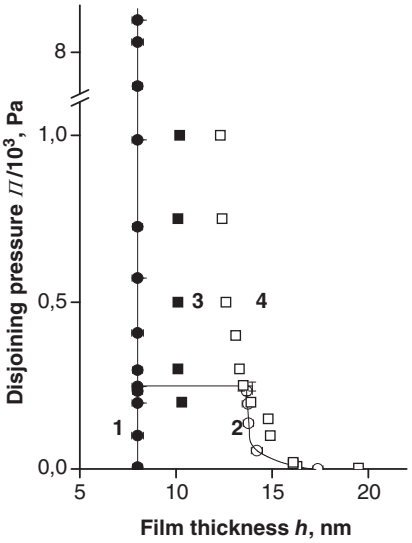

FIGURE 73.9 Disjoining pressure Π versus film thickness h for AF in 47% ethyl alcohol aqueous solution: curve 1 with 0.5 M NaCl and curve 2 with 0.03 M NaCl; HF aqueous solution: curve 3 with 1 M NaCl and curve 4 with 0.15M NaCl.

Π. It is noteworthy to mention that unlike films from AF the studied CBF film does not exhibit jumplike transition to NBF, although it does not rupture until the highest applied pressure. Besides, the smallest h of the films measured at the highest applied pressure does not reach that of the NBF, suggesting the action of additional repulsive forces in the film. In the case of the $\Pi(h)$ isotherm obtained for films formed from HF solutions with higher NaCl concentration, h remains practically constant with the increase in Π. This course of the isotherm demonstrates the lack of a free water core in the film and corroborates the assumption of NBF formation at high C_{el} (see Fig. 73.8).

The black foam film method provides options to assess the effects exerted by pulmonary surfactant components on surface properties of alveolar lining layer. The parameters (critical concentrations, thickness, disjoining pressure, etc.) obtained support the notion that black foam films are a realistic structural analog of surface films existing in vivo in the lung. These parameters may be used as a standard in the process of developing of therapeutic surfactant preparations for RDS therapy.

73.7 THIN LIQUID WETTING FILMS FROM PULMONARY SURFACTANT SOLUTIONS

Many observations show that the breathing function can be strongly affected by air pollution, as inhalation of crystalline silica particles is associated with numerous pathologies [42]. However, the interaction of the particles with the pulmonary surfactant layers in the alveoli has still not been sufficiently

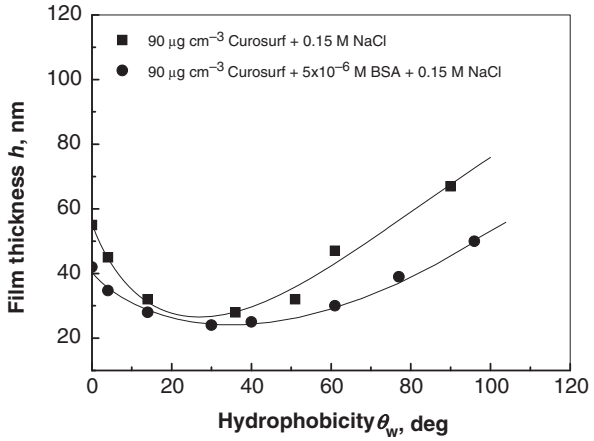

FIGURE 73.10 Dependence of equilibrium film thickness h on hydrophobicity θ_w of the SiO_2-glass surface for Curosurf aqueous solutions with and without bovine serum albumin (BSA) added.

studied. The method of the thin liquid film has been applied [43] to wetting films from pulmonary surfactant aqueous solutions on SiO_2-glass surfaces with different degrees of hydrophobicity.

The well-polished SiO_2-glass smooth, flat plates are carefully washed with acid mixtures and rinsed with doubly distilled water, thereby yielding a substrate with a completely hydrophilic surface. A special procedure for hydrophobization of this hydrophilic surface using trimethylchlorosilane allows the preparation of glass surfaces with different degrees of hydrophobicity [43]. As a measure of the degree of hydrophobicity, the contact angle θ_w of a drop of triple-distilled water on this surface is used.

Measurements of the equilibrium film thickness h have been carried out with thin liquid wetting films from 90 μg/cm^3 Curosurf + 0.15 M NaCl at different degrees of hydrophobicity θ_w of the solid surface. The influence of the addition of bovine serum albumine (BSA) to this solution on the equilibrium film thickness h has been studied as well. Figure 73.10 shows two h (θ_w) dependences for the two solutions, with and without BSA added. An interesting minimum at about $\theta_w = 30°$ in these curves has been obtained in both cases. The equilibrium thickness h, respectively the minimum in the h (θ_w) curves, is determined by the balance of all surface forces operative in the thin liquid wetting film. At 0.15 MNaCl the Van der Waals and the electrostatic disjoining pressures may be neglected. The attractive, hydrophobic (structural), and repulsive steric disjoining pressures actually determine the film thickness [44–46]. Their values depend on the hydrophobic and hydrophilic patches of the solid surface as well as the orientation and conformation of the adsorbed molecules of the phospholipids and the surfactant specific proteins. The minimum in the $h(\theta_w)$ curves could be due to changes in the structure and thickness of the adsorption layer at different areas of the hydrophobic and hydrophilic patches (different hydrophobicity) of the solid surface.

In a short range of θ_w around the minimum, the two curves are close to each other; however, the whole h (θ_w) curve for the aqueous solution, which contains 5×10^{-6} mol/dm^3 BSA, lies below the corresponding h (θ_w) curve for the 90 μg/cm^3 Curosurf + 0.15 mol/dm^3 NaCl solution without BSA added. These results show that BSA decreases the hydrophobization of the solid surface, due to the pulmonary surfactant. It is well known that BSA is an inhibitor of pulmonary surfactant activity [22]. It seems that albumin inhibits Curosurf by competitive adsorption on the alveolus surface (water–air interface). Similar competitive adsorption should occur also at the aqueous solution/solid interface. The BSA molecules prevent the adsorption of the molecules of pulmonary surfactant. Thus they decrease the hydrophobicity of the solid interface. Obviously there is a direct connection between the inhibition of Curosurf activity and the decreased (because of BSA) hydrophobization of solid surface due to the pulmonary surfactant.

73.8 CONCLUSION

Methods employing thin liquid film are useful tools for studying the pulmonary surfactants, including the therapeutic pulmonary surfactant preparations. In particular, the method using microscopic black foam film makes it possible to characterize pulmonary surfactants with the values of physicochemical parameters, such as disjoining pressure, critical surfactant concentration, threshold surfactant concentration, and probability of forming bilayer Newton black foam film. The black foam film method has been further developed into a diagnostic method for fetal lung maturity assessment. The method using microscopic thin wetting film allows for studies on the wetting behavior of pulmonary surfactant solutions on solid surfaces with different hydrophobicities.

74.1 INTRODUCTION

Structure and dynamics of living matter depend strongly on the principle of *receptor–ligand binding*, meaning specific interactions between biomolecules, such as peptides, DNA, antibodies, enzymes, and other biological matter. Furthermore, these interactions play a key role in almost every essential process in the human body (e.g., DNA replication [1], activation of signal cascades [2]). In particular, the immune system has to be emphasized, as being an impressive example for the precision achieved by the principle of specific binding; polyclonal antibodies are able to detect one "wrong" molecule out of 10^9 molecules [3]. In contrast to polyclonal antibodies that bind to multiple epitopes, monoclonal antbodies (mAbs) are targeted only to a single epitope. Therefore, mAbs provide a consensus between achievable specificity and flexibility in the framework of receptor–ligand interactions. On the basis of these special features, the development of monoclonal antibodies and the investigation of their interactions with different ligands are of highest interest for industrial applications (e.g., in the treatment of cancer [4–9] and rheumatoid arthritis [9]).

Recognizing their potential, receptor–ligand interactions also became a focus of research in modern biochemistry and biophysics. In addition, through the rapid development of single-molecule techniques, spectacular research into cellular, molecular, and even atomic structures and processes has been ongoing. Thus, in recent years the elastic properties of double-stranded DNA [10–12] as well as its interaction with binding partners such as transcription factors [13], architectural proteins [14–18], or intercalating dyes [19] have been studied. Other investigations have focused on individual steps of single motor proteins [20] or the translation of a ribosome at the level of single codons [21]. By means of the forced unfolding of proteins or RNA aptamers, new insights in the energetics of molecular folding processes could be gained [22–24].

This book chapter is concerned primarily with the biophysical investigation of receptor–ligand interactions, focusing on optical tweezers–assisted dynamic force spectroscopy. By using this technique it is possible to investigate these interactions on a single-molecule level, and to extract specific binding parameters. In Section 74.2, the methodology of optical tweezers is discussed in detail and other standard methods of investigating these receptor–ligand interactions are briefly introduced. Basic theoretical concepts of analyzing the experimental data are also presented (Section 74.3). In Section 74.4, three case studies, investigating the interactions between the antihuman tau monoclonal antibodies and synthetic τ-peptides with different phosphorylation patterns, are presented.

74.2 METHODOLOGY

The idea of manipulating objects with light goes back to the beginning of the twentieth century, based on the theoretical description of light pressure by Peter Debye [25] and the discovery of wave–particle dualism. However, the realization of a *single-beam gradient force optical trap* took almost 70 years and was finally achieved in 1986 by Arthur Ashkin [26]. Eleven years later one of his former coworkers, Steven Chu, reeived the Nobel Prize for the "development of methods to cool and trap atoms with laser light" [27]. As a result of their extraordinary resolution in determining the relative position (±2 nm) of a microscopic object (radius ∼ 1 μm) and in measuring the forces acting on it (±50 fN), without any mechanical contact, optical tweezers became a standard tool in terms of biophysical and other related issues [28, 29]. In the following sections, we will briefly introduce our setup as well as some theoretical models to describe the forces acting on a trapped particle. The main focus will be on the detection of microparticles with nanometer resolution in all three dimensions, which is required for the experiments described below. In addition, we will briefly describe other biophysical and biochemical methods of characterizing the interactions between receptors and ligands.

74.2.1 The Setup

In order to ensure stable three-dimensional (3D) trapping of microparticles, certain requirements are necessary: (1) an intensive light source, (2) a microscope with high numerical aperture, and (3) that a trapped object must have a higher index of refraction than the surrounding medium. Therefore, every optical tweezers setup has in principle the same basic building blocks: a laser, a (inverted) microscope, and a detection unit, including a CCD camera and a photosensitive detector (PSD), respectively.

Figure 74.1 illustrates the setup we used for the pair interaction measurements described in Section 74.4; based on an inverted microscope (Axiovert S 100 TV, Carl Zeiss, Jena, Germany), the optical trap was realized with a diode pumped Nd:YAG laser (1064 nm, 1 W, LCS-DTL 322; Laser 2000, Wessling, Germany). Power stabilization is achieved with a

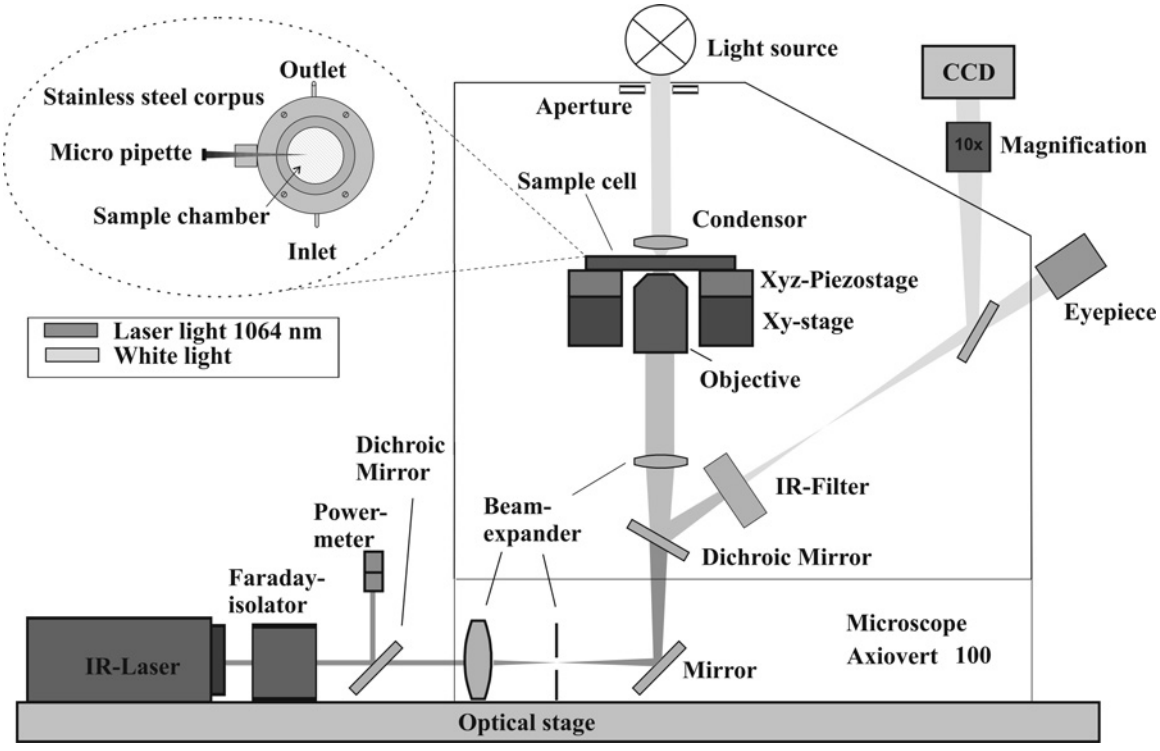

FIGURE 74.1 The optical tweezers setup is shown. The pathway of the laser beam is marked in dark gray. After passing a Faraday isolator, the beam is expanded and coupled into the back aperture of the microscope objective. Afterward it is focused in the sample plane. The path of the illumination light is indicated in light gray. The sample is illuminated from the top by a halogen lamp with an IR filter using Köhler illumination. The microscopic image can be detected from the eyepiece and is acquired, after a further 10-fold magnification, by a CCD camera. The sample cell is mounted on an *xyz* piezo stage for nanopositioning, which is built on a motor stage for rough positioning in a wide range (∼1 cm).

custom-made *LabView* program in order to guarantee long-term stability. Additionally, the profile of the laser beam is monitored to ensure optimal trapping conditions. After passing an optical isolator, a quarter-waveplate is used to produce circularly polarized light to exclude effects due to reflection differences of the mirrors between the *p*- and *s*-polarizations of the laser light. Subsequently, the beam is expanded and coupled into the back aperture of the microscope objective (Plan-Neofluor 100×, NA = 1.30 oil immersion, Carl Zeiss, Jena, Germany). Video imaging and optical particle tracking are accomplished by a digital camera (1M60, Dalsa, Munich, Germany). The optical stage is positioned in three dimensions with nanometer resolution by using piezo actuators (P-5173CD, Physik Instrumente, Karlsruhe, Germany). The sample cell (Fig. 74.1, inset) consists of a closed chamber that can be flushed by a syringe pump with varying solutions. A custom-made micropipette with an inner diameter at the tip of ≈0.5 μm is inserted into the chamber to hold one colloid by capillary action. The whole experimental setup is mounted in an air-conditioned room (T = 298±1 K) [30–32].

74.2.2 Trapping Basics and Force Calculation

Optical tweezers provide an experimental tool to manipulate microscopic objects only by photonic forces – without any mechanical contact. These forces can be divided into the scattering force and the gradient force. Scattering forces tend to push objects in the direction of propagation of the laser beam. In contrast, the gradient force attracts the particle toward the region of highest intensity, the laser focus (Fig. 74.2). Stable trapping is achieved when the gradient forces exceed the scattering forces.

Adequate models for calculating these forces theoretically depend on the ratio between the laser wavelength λ and the particle diameter D. Three cases can be distinguished: (1) $D/\lambda \ll 1$, (2) $D/\lambda \gg 1$, and (3) $D/\lambda \approx 1$. Case 1, where the particle is much smaller than the wavelength, is called the *Rayleigh regime* [33]. Forces are determined according to the formalism of wave optics [34]. The particles are considered as induced dipoles in an electromagnetic field. The forces are generated by changes in momentum of the electromagnetic wave due to the scattering by the dipole and the Lorentz force acting on the induced dipole, respectively [33].

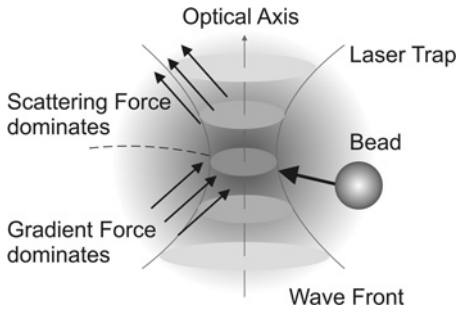

FIGURE 74.2 Schematic representation of photonic forces generated by a laser trap. Stable trapping is achieved when the gradient forces exceed the scattering forces. In this case, the microparticle is pulled into the laser focus and can be manipulated in three dimensions.

For particles having a much larger diameter than the wavelength of the laser light (the so-called Mie regime [34, 35]), the acting forces can be calculated using ray optics. Here, the beads are considered as collecting lenses. Light incident on a bead changes the propagation direction as well as the momentum of the light, generating a force [34].

The colloids used for the experiments in Section 74.4 have a diameter that corresponds approximately to twice the wavelength of the laser light. Therefore, an adequate description with the aforementioned models for Rayleigh and Mie particles is not possible. To determine the forces in this regime (generalized Lorentz–Mie regime [36, 37]), complex models are needed that allow only partly an analytical calculation.

To overcome these inconveniences in calculating the exact forces, different force calibration methods for optical tweezers measurements have been employed. All of them determine the trap stiffness. By knowing the exact bead position and using Hooke's law, one can calculate the acting forces [38,39]. Therefore, force calibration is reduced to calibrating the trap stiffness and separately measuring the relative displacement of the trapped particle. The most commonly used ways to compute the trap stiffness accurately are the drag force method, power spectrum analysis, and application of the equipartition theorem to fluctuation measurements [40]. For a melamine–resin particle having a diameter of ∼1 μm, typical values for optical trap stiffness can be varied in the range of (10^{-4}–1) pn/nm by adjusting the laser power from 10 to 1000 mW [28].

74.2.3 Position Detection in Three Dimensions

74.2.3.1 Position of Colloids in the xy Plane. As mentioned previously, to perform accurate position and force measurements with optical tweezers, it is imperative to localize spherical microparticles with nanometer resolution. Usually this is done either with a quadrant photodiode (QPD) or alternatively by image analysis [40]. In order to perform the measurements described in Section 74.4, we use image analysis for position detection, resulting in a lateral resolution of ±2 nm. This precision is clearly below the pixel size (13.25 nm/pixel) and has to be separated from the optical resolution of a microscope. The Abbe limit [41] describes the minimal separation of two objects that can be resolved by microscope and depends on the wavelength of the illumination, as well as the numerical aperture of the microscope lenses. Typically it is in the order of the half of the wavelength of illumination light. In contrast, the relative position of a single object with known geometry can be determined

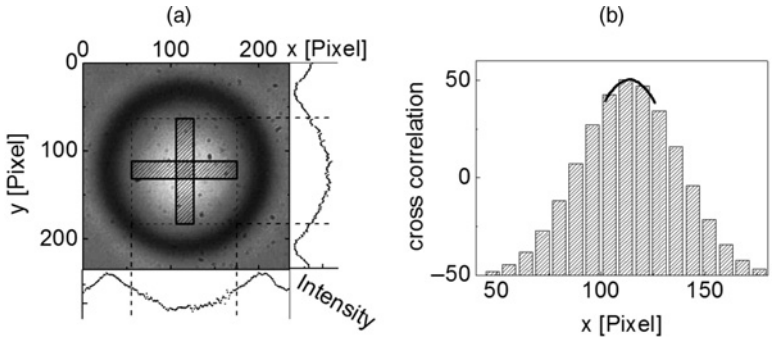

FIGURE 74.3 Position detection using cross-correlation. (a) Diffraction pattern of a melanin–resin microparticle (diameter 2.23 μm) and one-dimensional intensity at $[x, y] = 120$. The ROI is labeled by the dashed black square containing two strips (width 20 pixels) for detection of the position. The upper left corner of the ROI is defined as x_0 and y_0. (b) Shifted cross-correlation $K(d + \frac{L}{2} + x_0)$ (shaded bars) of the one-dimensional intensity profile in x convoluted with the direction inverted. The peak is fitted with a second-degree polynomial (solid line). Its maximum corresponds to the center position of the colloid.

with much higher precision [42]. All image analysis methods used to determine the lateral position are based on identification of the center of a spherical particle. However, they differ in computation time and resolution. An overview of different algorithms has been given [43].

Finding the suitable image analysis algorithm depends strongly on the aim of the measurement. In the case of pair interaction investigations, overlapping diffraction pattern may produce artifacts in the force separation dependence [44]. One method used to overcome these inconveniences is *edge detection* [43, 45, 46]. Here, a certain section, where the two diffraction patterns are overlapping, is omitted from the analysis, and the pathway of the remaining inner edge (given by maximum intensity contrast) is detected and fitted to a circle. The center of the circle defines the center position of the colloid. This algorithm is quite robust (e.g., against intensity fluctuations in the background and in the profile of the colloid), but it requires intensive computation resources, meaning that it is not applicable during the measurement [43, 45].

Another method, realizing pair interaction measurements in real time ("online"), is based on analyzing one-dimensional cross sections along an intensity profile by the use of cross-correlation. In this approach much fewer pixels have to be considered for the calculation; therefore it is more sensitive to image noise and thus, results in a higher uncertainty (usually twice that of edge detection [43]). The primary benefit of the cross-correlation method is the ability to perform a real-time analysis up to a frame rate of 10 kHz [47, 48] and the fact that no image storing is required.

To determine the position of a colloid by the cross-correlation method, a quadratic region of interest (ROI) containing the intensity maximum of a colloid with the edge length L and the coordinates of the upper left edge x_0 and y_0 is selected. The edge length is adjusted according to the reproduction scale and bead size. The pixels inside the ROI are defined as $\tilde{x} = x - x_0$ and $\tilde{y} = y - y_0$, with $\tilde{x}, \tilde{y} \in \mathbb{N}_0 \cap [0, L-1]$. In our particular case, two perpendicular stripes with a width of 20 pixels around position $\tilde{x} = (L-1)/2$ and $\tilde{y} = (L-1)/2$ are selected over the full length of the ROI to determine the center of the bead with the coordinates $\tilde{x}_K$ and $\tilde{y}_K$ (Fig. 74.3a). In the following only the stripe in x direction will be considered. In the y direction the algorithm will proceed in a similar manner.

To obtain a smooth one-dimensional intensity profile at each position $\tilde{x}_i$, the intensity is averaged over all 20 pixels in the y direction. This profile is defined as $A(\tilde{x})$. To determine the colloid center position, the cross-correlation K is calculated by averaging the product of $A(\tilde{x})$ and the direction inverted function $B(\tilde{x}) = A(L - \tilde{x})$:

$$K(d) = \frac{1}{L} \sum_{\tilde{x}=0}^{L-1} (A(\tilde{x}) - \bar{A})(B(\tilde{x} - d) - \bar{A}) = (A * B)(d) \tag{74.1}$$

where d is the offset and $\bar{A}$ is the mean value of the intensity profile. The fact that the cross-correlation is identical to the convolution of two functions enables one to calculate K taking the Fourier transformation of $A(\tilde{x})$ and $B(\tilde{x})$:

$$K(d) = \mathcal{F}^{-1}(\mathcal{F}((A * B)(d))) = \mathcal{F}^{-1}(\mathcal{F}(A)^* \mathcal{F}(B)) \tag{74.2}$$

where $\mathcal{F}(A)^*$ equals the complex conjugated. To calculate the maximum coordinate of $K(d)$, a polynom of the second order is fitted in the range of a few pixels around the (expected) maximum, which enables one to determine the

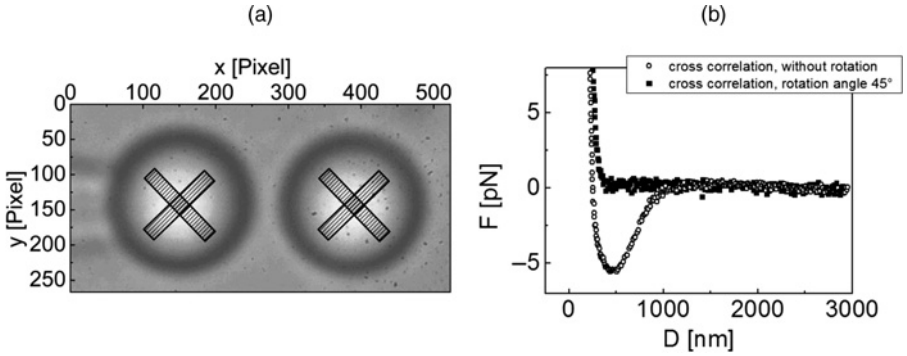

FIGURE 74.4 Position detection in pair interaction measurements using rotated cross-correlation (a) In order to avoid artifacts in the position detection of two colloids in the near contact region, the cross-correlation is rotated by an angle of 45°. Thus, the area where both diffraction patterns overlap is omitted from the analysis. (b) Resulting force–distance dependence without (open spheres) and with (solid squares) the rotated cross-correlation. In the image analysis without 45° rotation, artifacts occur at small surface distances (attractive behavior). These are caused by the overlapping diffraction patterns. To avoid this, the used strips for the cross-correlation algorithm are rotated by 45°.

extremum $\tilde{x}_{\max}$. The center of the colloid is then given by $x_K = \tilde{x}_{\max} + \frac{L-1}{2} + x_0$. Figure 74.3b shows the shifted cross-correlation $K(d + \frac{L}{2} + x_0)$ (shaded bars) and the quadratic fitting (solid line). The maximum corresponds directly to the center position of the colloid (in pixel units). Tracking of a particle is realized by moving the ROI by $\tilde{x}_{\max}$ and $\tilde{y}_{\max}$ to ensure that the center of the colloid is inside the ROI. This procedure provides an accuracy of about ± 2 nm.

For pair interaction measurements this method is only partially applicable, because artifacts based on the overlapping of the diffraction pattern may occur [44] (see Fig. 74.4). These artifacts depend on several parameters such as reproduction scale, colloid size, the colloid's index of refraction, the chosen edge length, and the overall illumination conditions. To avoid unphysical results, the abovementioned cross-correlation was expanded to the rotated cross-correlation [43]. Artifacts as described above occur mainly in the region where the diffraction pattern of the particles touch each other. To omit this area from position analysis, the image is rotated by 45° (see Fig. 74.4a) before the cross-correlation algorithm is used. Afterward the resulting center positions are projected back to the corresponding x and y axes. This enables one to determine the positions of colloids in close proximity (see Fig. 74.4b) without artifacts, as shown by direct comparison with other approaches [43].

74.2.3.2 Height Detection. Knowledge of the axial position (z postion) of a microparticle is usually of major importance, even if the experiment is performed in the xy plane. One example is the pair interaction measurement where the two colloid centers should be positioned in the same lateral plane. Additionally, exact knowledge of the z position enables one to compensate drift effects during long-term measurements (e.g., caused by the movement of a micropipette). However, a fast and stable z position detection based on image analyses is still challenging.

In the literature many methods are described to detect the height of a spherical particle. Most of them are based on a lookup table, where the diffraction patterns of colloids in different heights are stored [49, 50]. However, these methods require an illumination with parallel and monochromatic light to ensure that the diffraction pattern contains a sequence of several diffraction rings. Their number and distance are related to the axial position of the colloid to the focal plane. The height can then be obtained by averaging the diffraction profile over 360° and comparing the obtained value with the lookup table. Alternatively, the radius of the first diffraction ring can be fitted and compared with a lookup table [51].

For the experiments described in Section 74.4, another approach for fast and stable height detection was used. This method enables one to measure the axial position at ordinary white light conditions with a precision of ± 2 nm [46]. The principle for determining the relative height of a microparticle is based on a change in its diffraction pattern in the xy plane. The main maximum of the diffraction pattern depends on the z position with regard to the focal plane. For the used configuration it has been empirically determined that a square of 81*81 pixel (ROI) around the center position of the colloid shows a pronounced height dependence in the xy plane (Fig. 74.5). The matrix elements in the ROI are labeled with $I_{i,j}$, where $i, j \in \mathbb{Z} \cap [-40, 40]$, whereas the colloid center corresponds to $i = j = 0$. The relative height is calculated using a predefined reference polynomial. To calculate this reference polynomial, the diffraction pattern of the colloid at the micropipette is analyzed at different heights. Therefore, an arbitrarily chosen image close to the focal plane is defined as reference image, according to $z = 0$, and is saved.

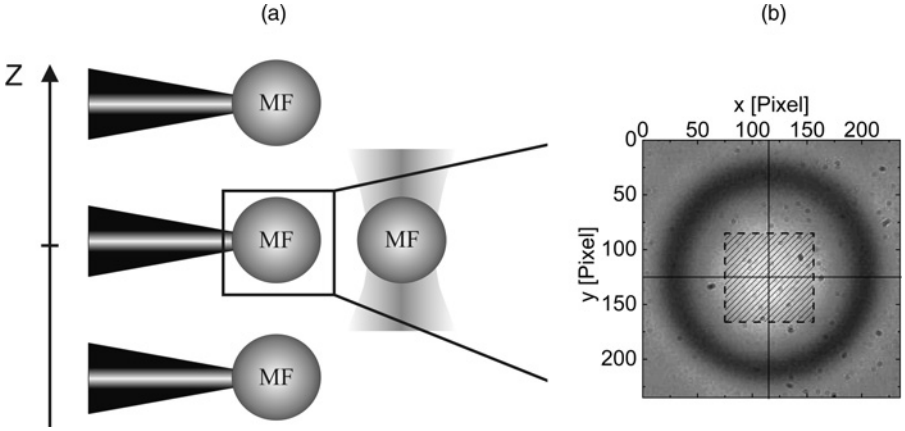

FIGURE 74.5 (a) Sketch of the height detection. The reference polynomial is calculated from the diffraction pattern of a colloid, fixed at the tip of the micropipette. Therefore, the height of the colloid is changed by moving the piezo stage in defined steps of 100 nm in the z direction, over a total distance of 1400 nm around the focal plane. At each height at least 20 images are analyzed. (b) A typical diffraction pattern of a colloid is shown. The center position is indicated by the black cross. The dashed square represents the ROI for the height detection having a width of 81*81 pixels and containing the elements $I_{i,j}$; $i, j \in \mathbb{Z} \cap [-40, 40]$. $i = j = 0$ equals to the center position of the colloid.

Afterward the micropipette is moved with a piezo stage in defined steps of 100 nm in the $\pm z$ direction. At each position the value of $I_{i,j}^{\text{current}}(z)$ is estimated and pointwise subtracted from the initial value $I_{i,j}^{\text{init}}$. Finally, the sum $S(z)$ of all matrix elements is determined, using

$$S(z) = \sum_{i,j} \left(I_{i,j}^{\text{current}}(z) - I_{i,j}^{\text{init}} \right). \tag{74.3}$$

In each height at least 20 images are acquired and the mean of $S(z)$, namely, $\langle S(z) \rangle$, is calculated. Therefore $\langle S(z) \rangle$ gives the relation between the current diffraction pattern and the relative height with regard to the reference image. As can been seen in Fig. 74.6 for the whole range of 1400 nm, a monotonically increasing dependence of $S(z)$ on the height is found and can be described by a polynomial of third order. From here on, we will refer to it as a *reference polynomial*. The height of a microparticle can then be determined by calculating $S(z)$ for the actual image and finding the root of interest of the master curve [46].

74.2.4 Other Methods for Characterizing Receptor–Ligand Interactions

Besides optical tweezers, several other prominent techniques have been established to investigate receptor–ligand interactions in biophysical and biochemical contexts. Their application depends strongly on the aim of the measurement. In order to study nucleic acid enzymes, particularly DNA topoisomerases [52, 53] and the molecular motors [28, 54] using superparamagnetic particles as force sensors, magnetic tweezers (MT) are ideally suited. In contrast to optical tweezers, the concept of MT consists in manipulating the force probe through magnetic field gradients created by a permanent magnet. Therefore, magnetic tweezers can be used to manipulate and rotate magnetic beads ranging from 0.5 to 5 μm in diameter. The trap stiffness can be varied between 10^{-6} and 10^{-3} pN nm^{-1}, resulting in a force range of 10^{-3}–100 pN [28].

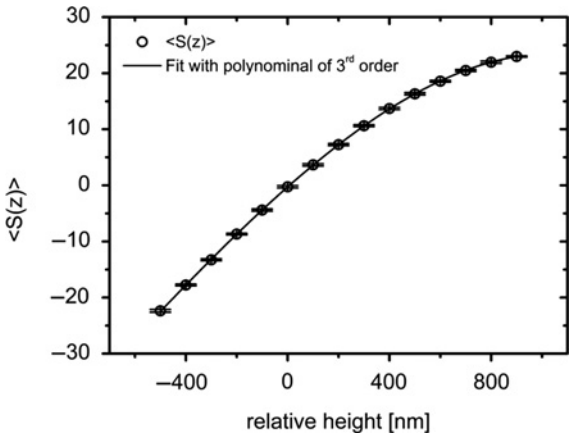

FIGURE 74.6 The reference polynomial. The figure shows the sum $S(z)$ in dependence of the relative height z. The height of the colloid was changed in steps of 100 nm using a piezo stage. The mean value $\langle S(z) \rangle$ (open circles) is calculated out of 20 acquired pictures at one height and is described by the reference third-degree polynomial. For the entire range of 1400 nm a monotonically increasing dependence is found. Finally, the height of the colloid is determined by calculating $S(z)$ for the current image and solving the reference polynomial for that value.

To apply high forces up to the nanonewton (10^{-9} N) range with subnanometer spatial resolution, atomic force microscopes (AFMs) can be used to study biological interactions under physiological conditions [28]. In general, the AFM is counted to the scanning probe techniques and consists of a cantilever with a sharp tip (force sensor) positioned above a piezoelectric scanner and an optical deflection system [55]. Force detection is accomplished using a laser detecting the vertical movement of the cantilever. By applying the TREC (topography and recognition imaging) mode, both surface properties measurements and localizing specific binding sites of a receptor can be performed simultaneously with nanometer resolution [56]. The cantilever stiffness ranges from 10 to 10^5 pN nm^{-1}. However, for biological applications softer cantilevers are used, which allow detection of piconewton forces [57]. Using this technique, phenomena such as the interaction between two complementary DNA strands [58] and the unzipping behavior of DNA [59] have been studied.

In order to perform high-throughput measurements to determine the specificity of biomolecules, other techniques (e.g., EILSA and Western blot) have been developed and became standard tools in biochemical/pharmaceutical research [60]. Enzyme-linked immunosorbent assay (ELISA [61,62]) is a biochemical method used to quantify the amount of an antigen (e.g., proteins, viruses, hormones, or toxins) in different liquid samples (e.g., blood, urine, water) using target-specific antibodies. In recent years, many different ELISA types (e.g., indirect ELISA, sandwich ELISA, competitive ELISA) have been developed. However, the basic principle remains the same; a specific antibody recognizing the antigen of interest is incubated with the sample (e.g., ligand on well plate). Either the first antibody itself or a second antibody specific for the first one is coupled with an enzyme that catalyzes most commonly a color-changing reaction. After addition of the enzyme-specific substrate, the measurable color change indicates the amount of antigen in the sample. From these data, binding constants (e.g., relative affinity) can be derived as well.

Western blotting [63] is another biochemical method employed to detect proteins in tissue homogenates or in other sample mixtures, using specific antibodies against the antigen of interest. Before these proteins/antigens were accessible and detectable by detection antibodies, the sample (e.g., protein mixture) has to be separated according to molecular weight, to isoelectric point, and/or to electric charge by gel electrophoresis. Subsequently, the proteins are transferred from the gel onto a membrane [nitrocellulose or polyvinylidenedifluoride (PVD)], most commonly by *electroblotting*. After blocking of nonspecific binding sites with various chemical agents [e.g., bovine serum albumin (BSA), dry milk, or fetal bovine serum (FBS)], the membrane is incubated with the antigen-specific primary antibody. Finally the protein of interest is visualized, by methods such as chemiluminescence. For this purpose, a secondary antibody against the Fc region of the detection antibody coupled with an enzyme [e.g., horseradish peroxidase (HRP)] is used, similar to EILSA. The HRP catalyzes either the conversion of chromogenic substrates into colored products, or a redox reaction of chemiluminescent substrates leading to a detectable light signal.

74.3 THEORETICAL DESCRIPTION OF RECEPTOR–LIGAND INTERACTIONS

Many biologically relevant interactions such as the binding of an enzyme to a particular substrate, or the detection of foreign substances by antibodies causing an immune response, are based on the principle of a noncovalent specific binding (receptor–ligand binding). The latter is a superposition of several attractive, short-range interactions. These are hydrogen bonds (~2–7 k_BT), van der Waals (<1 k_BT), electrostatic (0.2–10 k_BT), and hydrophobic (1–5 k_BT) interactions (values taken from Ref. 64). Since each of these interactions is in the order of k_BT, only the complex interplay between all of them results in a specific and stable bond. In contrast, the binding energy of a covalent bond exceeds 100 k_BT. Experimentally, the interactions between receptors and ligands are analyzed by *dynamic force spectroscopy* (DFS). By definition, DFS is the investigation of a force-induced dissociation of a single bond and provides information about kinetic parameters as well as parameters that characterize the energy landscape of the binding from the distribution of rupture forces (see Section 74.4). This section focuses on introducing the theoretical concepts to analyze the experimental data by means of characterizing the specific binding between receptor and ligand. In recent years, many reviews [65–67] on theoretical descriptions have been published. Here we restrict ourselves to an ideal bond description and application of the Dudko—Hummer–Szabo [68] approach.

74.3.1 An Ideal Bond

Figure 74.7 displays the simplified energy landscape for an idealized bond along the reaction coordinate x. The bound state (1) is represented as a deep local minimum, which is separated by a barrier from the unbound state (2). Overcoming the barrier is a stochastic process that can be characterized by the kinetic rates k_{on} (ON rate, association) and k_{off} (OFF rate, dissociation). For the dissociation process, the height of the barrier, with its maximum at position x_{ts}, corresponds to the activation energy ΔG. However, it has to be mentioned that representation of the potential along a one-dimensional reaction coordinate is a simplified picture. In more advanced approaches, x is the energetically preferred path in a multidimensional, structured energy landscape. Furthermore, if a force is applied to the bond, the reaction path is not randomly chosen, but often follows the direction of the force. It must

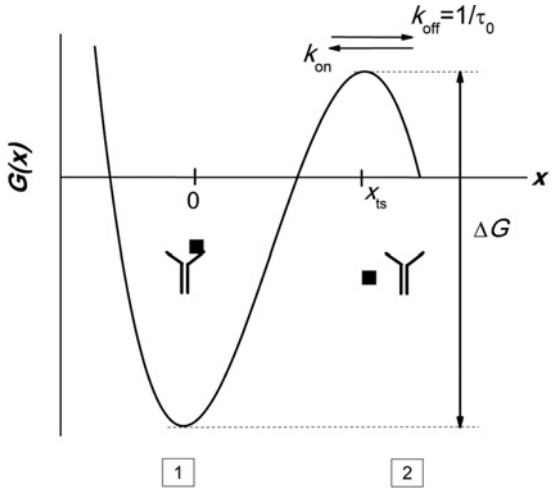

FIGURE 74.7 Depicted is the one-dimensional energy landscape of an idealized specific binding. The reaction coordinate x corresponds to the preferred path for binding and dissociation, respectively. The bound state (1) is separated from the unbound state (2) by an energy barrier with the height of ΔG. x_{ts} denotes binding length and is a measure of the distance between the state (1) and the transition state (local maximum). The kinetic transition rates are given by k_{on} and k_{off}, where the latter is the inverse of the bond lifetime without externally applied force τ_0.

also be noted that the potential form is an idealization, too. Since the bond is the sum of multiple interactions, the true energy landscape is structured and may vary in shape. However, despite these limitations, a majority of the investigated specific binding can be considered as an ideal, single bond as described above [66, 68, 69].

74.3.2 Force-Induced Bond Rupture: The Dudko—Hummer–Szabo Model

Appling a constant external force to a single bond lowers the enthalpic barrier of bond dissociation, making the rupture more probable. Additionally, the position and the shape of the barrier in Fig. 74.7 can be changed as well. The first phenomenological model to describe the dependence of the bond lifetime on the force was proposed in 1978 by Bell [70]:

$$\tau_{\text{Bell}}(F) = \tau_0 \exp\left(-\frac{Fx_{\text{ts}}}{k_B T}\right). \tag{74.4}$$

This equation contains two parameters, which are characteristic of each bond: τ_0, the lifetime of the bond without force, and x_{ts}, the characteristic length, which corresponds to the distance between the energetic minimum of the bound state and the maximum of the barrier. Furthermore, F denotes the applied force; k_B, the Boltzmann constant; and T, the absolute temperature. Obviously, reduction of the energy barrier causes an exponential increase in the OFF rate.

However, in the experiments described in Section 74,4, the applied force rises continuously with time. With increasing load the likelihood of a bond rupture grows. On the other hand, the limited force-dependent bond lifetime determines the moment when the bond breaks, too. Therefore, the rate with which the bond is loaded plays a central role in dynamic force spectroscopy measurements [57]. This correlation is called *loading rate dependence*. The *loading rate* is defined as the increase in force over a certain time interval in which the bond remains intact.

Almost 20 years after Bell, Evans and Ritchie [71] established the cornerstone for dynamic investigation of the forced rupture of single specific bindings by extending Kramers' theory for reaction kinetics in liquids [72] to bond dissociation under force. They obtained the probability density distribution of rupture forces [31]. It depends strongly on the loading rate $\dot{F}(F) = \Delta F/\Delta t$:

$$p(F) = \frac{\exp\left(-\int_0^F [\dot{F}(f)\tau(f)]^{-1} df\right)}{\dot{F}(F)\tau(F)} \tag{74.5}$$

For theoretical description of the following experiments, we use the theory published by Dudko et al. (DHS model) [68]. Here the bond is characterized by three parameters: x_{ts}, which denotes the binding length; τ_0, the bond lifetime in absence of an external force; and ΔG, the potential depth. Applying Kramers' theory to different energy profiles and adding ΔG as a further parameter results in a force dependent bond lifetime $\tau_{\text{DHS}}(F)$ [68]:

$$\tau_{\text{DHS}}(F) = \tau_0 \left(1 - \frac{\nu F x_{\text{ts}}}{\Delta G}\right)^{1-1/\nu} \exp\left(-\frac{\Delta G}{k_B T}\left[1 - \left(1 - \frac{\nu F x_{\text{ts}}}{\Delta G}\right)^{1/\nu}\right]\right). \tag{74.6}$$

This equation holds for forces below a critical force at which the barrier vanishes:

$$F_{\text{crit}} = \frac{\Delta G}{\nu x_{\text{ts}}} \tag{74.7}$$

The factor υ corresponds to the geometry of the underlying free energy profile, which is for $\upsilon = 0.5$ a harmonic well with a cusplike barrier and for $\upsilon = 0.66$ a potential containing linear and cubic terms. For $\upsilon = 1$, it passes into the model from Bell and Evans, which constitutes a special case within the formalism. The rupture-force distributions can be transformed into $\tau(F)$ by inverting Eq. (74.5). Therefore, rupture-force histograms, which are obtained experimentally, are converted into $\tau(F)$ as described in Dudko et al. [68].

By inserting $\tau_{\mathrm{DHS}}(F)$ in Eq. (74.5), we can derive the distribution of rupture forces. An analytical solution of the integral is possible for stiff molecules when the loading rate does not depend on the force:

$$p(F) = \frac{1}{\dot{F}\,\tau_0}\left\{\exp\left[\frac{\Delta G}{k_B T}\left(1-\left(1-\frac{\nu F x_{\mathrm{ts}}}{\Delta G}\right)^{1/\nu}\right)\right.\right. \\ \left.\left.-\left(\frac{\left(-1+\exp\left[\frac{\Delta G}{k_B T}\left(1-\left(1-\frac{\nu F x_{\mathrm{ts}}}{\Delta G}\right)^{1/\nu}\right)\right]\right)k_B T}{x_{\mathrm{ts}}\,\dot{F}\,\tau_0}\right)\right]\right. \\ \left.\left(1-\frac{\nu F x_{\mathrm{ts}}}{\Delta G}\right)^{-1+1/\nu}\right\}. \tag{74.8}$$

74.4 CASE STUDIES

In this section, we describe experimental details of the measurement procedure as well as of three experiments using DFS to characterize the interactions between receptors and ligands. The systems of interest are the interactions between τ-peptides having a varying phosphorylation pattern and their respective monoclonal antibodies. The microtubule-associated protein tau promotes the assembly and stabilization of neuronal microtubules [73]. In Alzheimer's disease tau becomes hyperphosphorylated and self-associates to form paired helical filaments (PHF). This PHF-tau aggregates in tangles in cortical brain areas, which are essential for cognitive function, and is found to be one of the pathological characteristics of Alzheimer's disease [74]. The number and density of tangles correlates well with the progress of the disease [75]. However, up to now the causal background of Alzheimer's disease has remained unclear. Monoclonal antibodies can be used for the histological detection of hyperphosphorylated τ-protein and even to discriminate between different phosphorylation patterns. For the following experiments τ-peptides containing two typical phosphorylation sites (Thr231 and Ser235) have been synthesized and the interactions with the respective mAb are analyzed under different points of view.

74.4.1 Measurement Procedure

The interactions between the receptors and ligands are measured by the following procedure. A particle with one kind of ligand (we will discuss different τ-peptides later) on its surface is trapped with optical tweezers and brought in the vicinity of the custom-made micropipette. This colloid is fixed on the tip of the pipette by capillary forces. Next, a colloid covered with one type of receptor (we discuss different monoclonal antibodies below) is captured and placed in close vicinity to the immobilized bead on the pipette (Fig. 74.8a). Using a custom-made *LabView* program, both particles are approached until a force of (8±2) pN is reached and retracted with a distinct velocity after one second of contact. If a bond has formed, the particle in the optical trap is displaced out if its equilibrium position until the rupture force is exceeded. At this force (*e.g.* rupture force) the bond breaks and the particle snaps back into its initial position (Fig. 74.8b). All experiments are carried out in PBS buffer solution at pH 7.4 and (298±1) K. The force calibration of the bead in the optical trap was accomplished by displacing the particle from

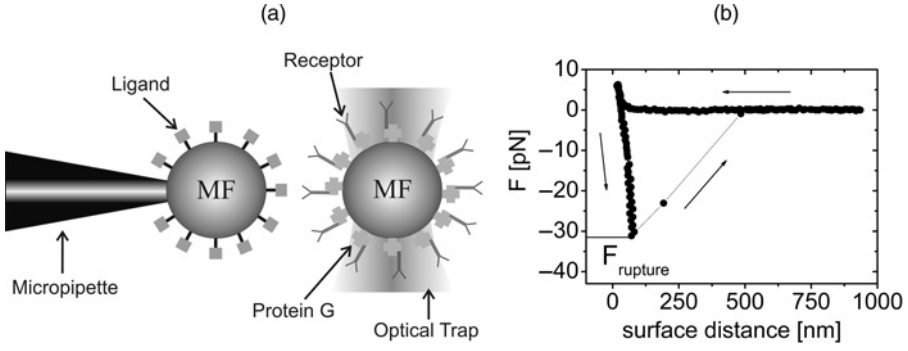

FIGURE 74.8 (a) Sketch of the measurement procedure. One colloid, grafted with the ligand (τ-peptide), is captured by a micropipette via capillary forces, while the other particle, coated with the receptor (monoclonal antibody), is held in the optical trap. The monoclonal antibodies (mAbs) are oriented via protein G in order to ensure optimized binding efficiency. (b) Force–distance curve of a typical measurement cycle. Both particles approached each other until a force of (8±2) pN is reached. After one second of contact, they are again separated with a certain loading rate. If a receptor–ligand bond has been established, the particle in the trap is pulled out of its equilibrium position until the bond breaks (rupture force).

its equilibrium position and applying Stokes' formula to the data. For the experiments this results in a force constant of 0.09 pN nm^{-1} at a laser power of 225 mW [32].

For the following measurements the colloids are prepared according to specific published protocols [31]. Therefore, two types of surface-modified microparticles (melamide group and carboxyl group, respectively) are used; the first is coated with the τ-peptide, and the second one bears the respective protein G oriented mAbs on its surface (Fig. 74.8a).

74.4.2 Ensuring Single Binding Events and Specificity

In order to ensure that the observed binding events originate from specific receptor–ligand interactions, control experiments have to be performed. For this purpose the specificity of the used antibodies against the epitopes of the respective τ-peptides was proved using ELISA [76]. Furthermore, background events (e.g., interactions among peptide/mAb and the functional surface groups of the colloids) are determined to be less frequent than 2% of the cases and are found to be negligible.

Additionally, to guarantee that only single binding events are investigated, the grafting density Σ (e.g., the number of immobilized peptides/mAb on the colloid surface) on the microparticles was varied. It can be assumed that the higher the added volume (of, e.g., peptide solution) during the preparation process, the higher the resulting Σ, meaning that the volume of the peptide solution is directly proportional to the coating density. For the purpose of determining the optimal Σ, relative binding frequencies and median rupture forces are recorded for each surface coverage, by measuring 200 approaches and retraction cycles (see Fig. 74.8b) for at least five pairs of colloids. Figure 74.9 shows the median of the relative binding frequency h_B (a) and the rupture force F (b) at different grafting densities for the interaction between the mAb HPT-110 and the monophosphorylated peptide tau[pSer235]. In order to obtain different coating densities, the added amount of τ-peptide solution was varied during the preparation process. At a fixed antibody volume (5 μL, $c = 1$ mg mL^{-1}), the peptide solution volume ($c = 1.3$ mg mL^{-1}) was reduced successively from 2 μL to 0.1 μL, giving a surface coverage range from 0.11 to 0.005 nm^{-2}, respectively. As shown in Fig. 74.9, this results in a decrease of the binding frequency (shaded bars), while F_{Median} does not undergo a systematic change (open circles). From this it follows that $V_{\text{peptide}} = 2$ μL and $V_{\text{mAb}} = 5$ μL are suitable to investigate the interactions between the mAb and the peptide on single and specific binding events.

This approach provides a simple way to find the best settings for the preparation and measurement procedure, but a reproducible control of the surface coverage and the reduction of the error bars in Fig. 74.9 is not possible using this method.

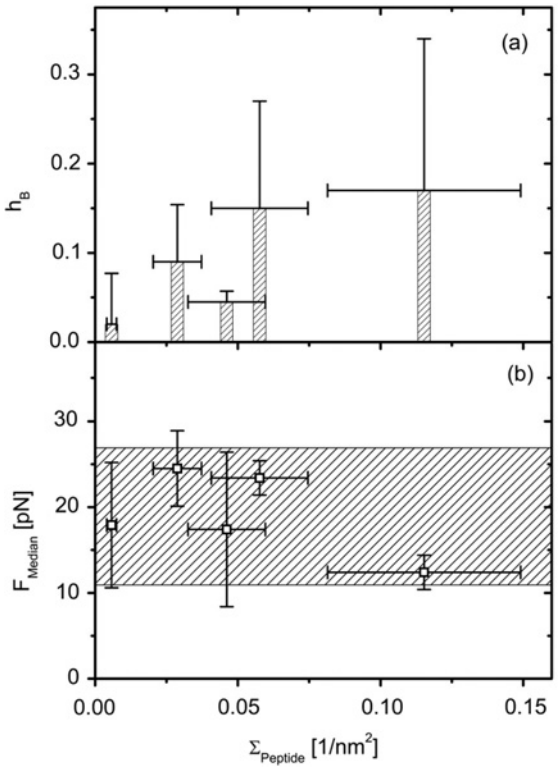

FIGURE 74.9 Adjustment of the surface coverage of peptide-coated colloids for the interaction between mAb HPT-110 and the monophosphorylated peptide tau[pSer235]. The coating density of the mAb-grafted colloids is kept constant. (a) Median of the relative binding frequency h_B and (b) median rupture force for five different coating densities Σ. The coating density is calculated from the respective volume of peptide solution that has been added during the preparation procedure. In order to determine h_B and F_{median}, at least 200 approach and retraction cycles (see Fig. 74.8b) for five colloid pairs and for each surface coverage have been analyzed. The error bars represent the median error. While the binding frequency is reduced with decreasing grafting density (shaded bars), the median rupture force (open symbols) remains unchanged, as indicated by the shadowed area.

74.4.3 Reducing the Data Variance in Dynamic Force Spectroscopy Measurements Using Presorted Particles [32]

Investigation of the bond formation and dissociation process with dynamic force spectroscopy can be reduced to the measurement of the ON rate (k_{on}) and the OFF rate (k_{off}), respectively. However, a major problem in studying these two quantities between surface-attached molecules is their dependence on many parameters [2]. One of these factors is the surface coverage or the grafting density Σ. By influencing both, k_{on} and k_{off}, the grafting density plays a crucial role in measuring relative binding frequencies h_B, which are a measure for the association rate between biomolecules [2].

Because the grafting density on particles out of one preparation procedure is Gaussian-distributed around a mean surface coverage, the varying Σ causes a large data variance (error bars) in relative binding frequency measurements, as can be seen in Fig. 74.9. Therefore, reducing differences in the grafting density results in a more sensitive measurement of h_B values [32]. One method for determining the number of immobilized biomolecules of coated particles is the *fluorescence-activated cell sorting* (FACS [77]) approach. With FACS it is possible to sort and accumulated particles according to their fluorescence intensity and their surface coverage, respectively. Another great advantage of FACS is that dynamic force spectroscopy experiments can be performed with the same colloids as previously sorted using the FACS spectrometer. By combining FACS analysis and DFS, a comparison between different measurements of relative binding frequencies is more sensitive, since smaller differences can be resolved.

For the experimental proof, the interactions between the monoclonal antibody HPT-104 and the carboxyfluorescein-labeled monophosphorylated peptide tau226-240[pThr231] are investigated. The peptides are synthesized according to the protocol published by Stangner et al. [32], and the colloid-coating procedure follows the instructions described in Section 74.4.1. Because of hydrophobic properties and the close vicinity of the fluorescein molecule to the binding site of the mAb, it is necessary to prove that the dye does not influence the specific interaction between peptide and antibody. By performing dynamic force spectroscopy and comparing the bond parameters obtained to data using unsorted beads covered with the nonfluorescence peptide analogue, no effect was found.

To obtain peptide-labeled colloids with similar grafting densities by taking the fluorescence intensity as a measure for a certain surface coverage, a FACS analysis is performed (Fig. 74.10). The plot shows the two fluorescence intensities to record the characteristic emission spectra of carboxyfluorescein. The 2D density plot before the selection process reveals two different populations (Fig. 74.10a). Area A1 contains blank, uncoated particles, whereas A2 comprises the target population with the peptide covered beads. To emphasize that A1 and A2 can be distinguished by the FACS spectrometer, additional blank beads are added. By choosing a narrow region of A2, including roughly the dark area, the selection process is started. After sorting a sufficient number of colloids the solution is reanalyzed to verify the accuracy of the method (Fig. 74.10b). Population A1 is almost removed. The remaining number in this area is less than 0.5% of the total bead number. To compare the population A2 before and after the selection process by grayscale as well as by data variance, it is important to mention that the basic population is kept constant within the experimental accuracy. The used gray code scales with the data point number in each bin and is equal for both plots. Comparing the color scheme of

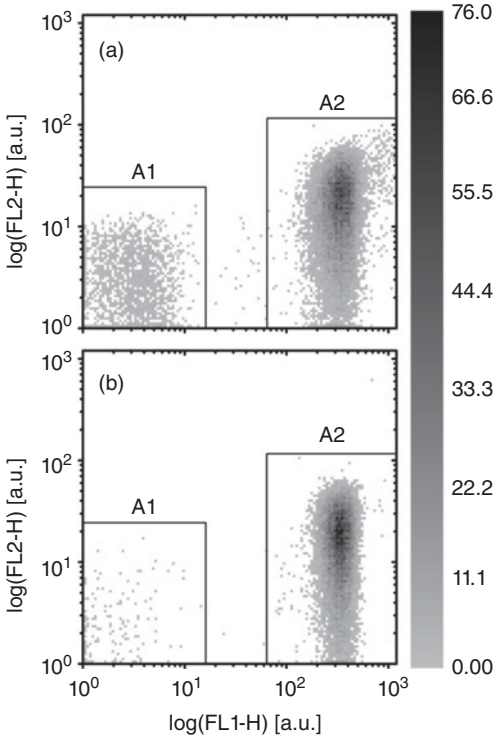

FIGURE 74.10 2D density plot of τ-peptide-labeled MF particles (diameter 2.31 μm) in dependence on intensity signal of channel FL2-H versus FL1-H before (top) and after (bottom) FACS sorting. The grayscale corresponds to the amount of colloids within each bin, whereas black is equivalent to high count numbers and light gray, to low ones. In order to maintain comparability, the color code was kept constant for both plots. (a) FACS data before the selection process. Two populations are visible: A1 contains uncoated colloids, and A2 contains the fluorescence tagged tau-particles. (b) Same batch of colloids as in (a), but after sorting. Population A1 is sorted out, only the target population A2 remains with a significant reduction in width and a pronounced increase in density (dark color).

Fig. 74.10a,b, it becomes obvious that (1) after the selection process the width of A2 is reduced and (2) the density in the middle of A2 is shifted to much higher values (black color). To quantify the difference in the width of both distributions, their standard deviations σ_{FL1-H} are calculated. They deviate by approximately 33% and significance was proven by applying the F test [78].

This implies that by presorting colloidal solutions using FACS, it is possible to accumulate particles with a similar grafting density compared to the unsorted solution. Furthermore, this procedure provides a reliable method for comparing different receptor–ligand systems under the same surface coverage conditions by using the same FACS protocol.

Next, the influence of a constant coating density on the data variance in relative binding frequency (h_B) measurements using presorted tau particles instead of unsorted ones is investigated. For this purpose, the approach and retraction

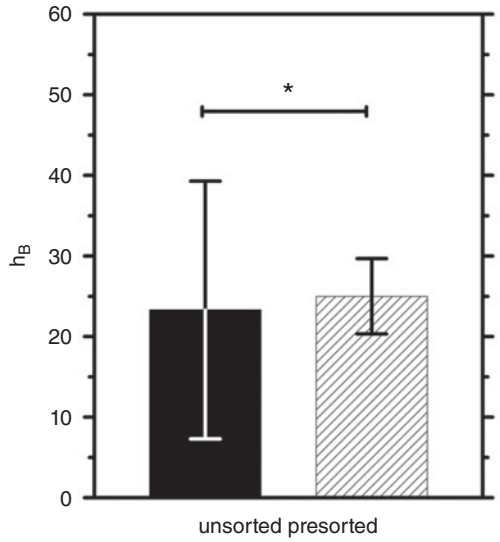

FIGURE 74.11 Median relative binding frequency h_B for unsorted (solid) and sorted (shaded) colloids. The median values are given by $h_B^{\text{solid}} = (23.3 \pm 16.0)\%$ and $h_B^{\text{shaded}} = (25.0 \pm 4.7)\%$. The median variance is decreased significantly, which accounts for an almost constant surface coverage of the presorted colloids.

cycles are recorded for each case (presorted dye-labeled τ-colloids and unsorted unlabeled τ-colloids, respectively) as described in Section 74.4.1. After counting the rupture events, the resulting relative binding frequencies between labeled, presorted, and unlabeled, unsorted colloids are compared (Fig. 74.11). For the unsorted solution large fluctuations in the h_B values are observed (solid bar). In contrast, the presorted colloids constituting a homogeneous surface coverage exhibit only a small spread (shaded bar). Interestingly, the median h_B value for the unsorted colloids differs only slightly from the median relative binding frequency of the presorted ones, but the data variance is reduced significantly. This effect is caused by an almost constant surface coverage achieved by presorting particles via FACS.

74.4.4 Dynamic Force Spectroscopy on the Binding of Monoclonal Antibodies and τ-Peptides [31]

The molecular accuracy of receptor–ligand systems is imperative for all living organisms. These systems play a key role in almost every biological relevant process, including the immune response of the human body. However, specific binding always carries a certain probability for an error, namely, that the receptor may bind to a ligand for which it is not specific. Such unspecific binding is explained by the fact that molecules always interact; there is always a competition between the kinetic energies to be independent and forces of intermolecular attraction. However, a perfect discrimination between "correct" ligands, which are detected by the receptor, and "wrong" ligands, which are discarded, is never possible [79]. The unspecific interaction of the mAbs to the peptides to which the respective mAbs are not specific implies that detected binding events originate from interactions besides the specific binding sites. Therefore it can be assumed that these unspecific attachments occur also between the mAb and its specific peptide. In other words, the distributions of rupture forces (see Section 74.3.2) for the specific interaction contain events that do not only originate from the interaction between specific binding site and epitope. These might be caused by hydrophobic or charged sites on the surface of the molecules. It is not possible to distinguish between specific and unspecific rupture events according to properties of their force–distance curves.

In one report [31] the unspecific interactions of the monoclonal antibodies HPT-110 and HPT-104 were characterized and separated from the specific ones. Except for the respective phosphorylation (at Thr231 and Ser235), both tau226-240 peptides used consist of the same sequence. It was shown by ELISA that HPT-110 binds specifically to the peptide carrying a phosphorylation at Ser235, whereas HPT-104 is specific for tau[pThr231].

To determine the contribution of unspecific binding, the rupture-force distribution of HPT-110 binding specifically to the τ-peptide that is phosphorylated only at Ser235 is analyzed as described in Section 74.4.1. The rupture-force histogram (Fig. 74.12a) is evaluated by means of the DHS model, and the bond parameters are displayed in Fig. 74.12d–f (black circles). The rupture-force distribution of the unspecific interaction between the same mAb HPT-110, and the peptide phosphorylated only at Thr231 is shown in Fig. 74.12b. The histogram is shifted toward lower forces compared to that obtained for the specific interaction. The distribution is broad and cannot be described using the DHS model. As the unspecific interaction is not caused by defined binding sites, the authors assume that the sites and mechanisms of the attachments differ, for example, independently of the direction of the interacting molecules. Such varying interactions cannot be described by the same energy well, which forms the basis for the theoretical description.

Furthermore, it is assumed that the contribution of specific and unspecific interactions to the rupture-force distributions of specific bindings is purely additive. This allows for them to be separated by subtracting the rupture-force histograms. The difference, meaning the corrected distribution of rupture forces, which corresponds to the specific binding between epitope and binding site, is shown in Fig. 74.12c. This distribution is narrower, and the maximum is shifted to higher forces. The corrected dataset is analyzed analogously to the raw data as described above. The resulting parameters are shown in Fig. 74.12d–f (open triangles). Especially the bond lifetime τ_0 determined for the corrected data shows the strongest deviation from the parameter set obtained from the raw data (black circles). But also, the characteristic length from the corrected data is roughly 4 times larger than

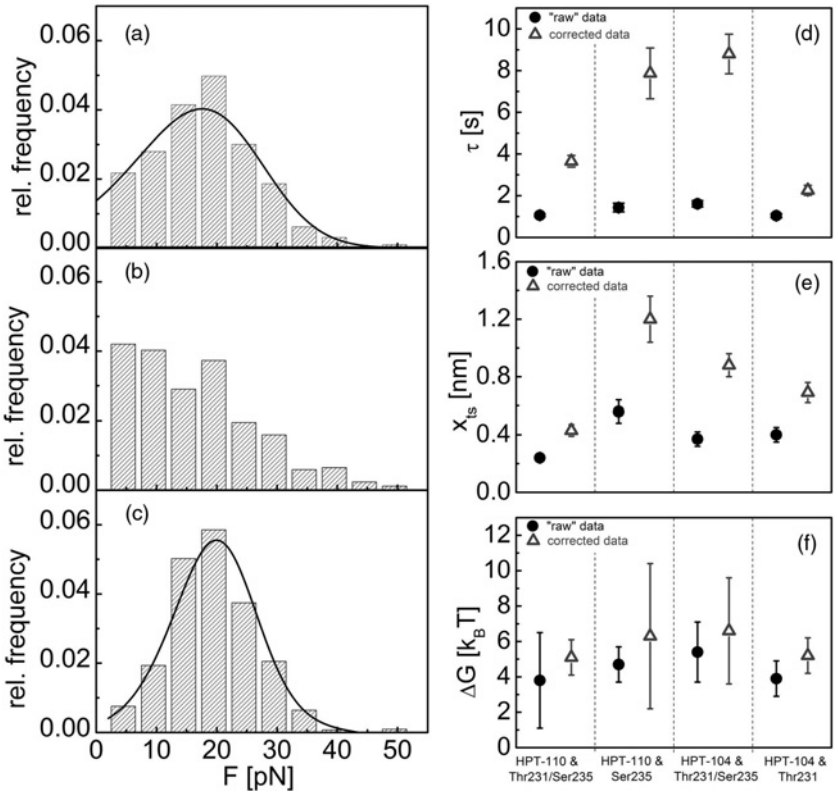

FIGURE 74.12 The rupture-force histogram for (a) the specific interaction between HPT-110 and the monophosphorylated peptide tau[pSer235], (b) the unspecific interaction between HPT-110 and the peptide only phosphorylated at Thr231, and (c) the difference between rupture-force distributions of specific and unspecific binding. The solid line depicts the theoretical description of the rupture-force distribution $p(F)$ [Eq. (74.8)] for the parameters obtained by fitting $\tau_{DHS}(F)$ [Eq. (74.6)] for $\upsilon = 0.5$. (d–f) The binding parameters lifetime τ_0, characteristic length x_{ts}, and free energy of activation ΔG for the specific interactions HPT-110 binding to the double-phosphorylated peptide and to the peptide monophosphorylated at Ser235, respectively, as well as HPT-104 binding to the double-phosphorylated peptide and to the peptide monophosphorylated at Thr231, respectively. For each interaction, the values obtained by fitting the raw data (circles) are opposed to the values from fitting the corrected data after separating the specific from the unspecific interactions (open triangles). The corrected data correspond to a longer lifetime and a higher value for x_{ts}. For the free activation energy, no significant difference is found between the values obtained from the raw data and those from the corrected histograms.

that from the raw data. For the free energy of activation ΔG no significant change is observed.

Following the same procedure, the corrected rupture-force distribution of HPT-110 binding to the double-phosphorylated peptide are obtained. Likewise, the specific binding of HPT-104 and the double-phosphorylated τ-peptide as well as to the one monophosphorylated at Thr231 is separated from the contribution of unspecific interactions. Analyzing the interaction of HPT-104 binding to the peptide monophosphorylated at Ser235 yields the rupture-force distribution of the unspecific interactions. The data are distributed similarly to the unspecific binding of HPT-110 to the peptide monophosphorylated at Thr231 as shown in Fig. 74.12b. In the next step, the resulting rupture-force histogram is subtracted from the one of the respective specific interaction. The parameters obtained by analyzing the raw and the corrected histograms by use of the DHS model are opposed in Fig. 74.12d–f. As the data are no longer overlaid by unspecific interactions, it is assumed that the parameters obtained from the corrected histograms give the better description of the specific binding between the mAbs and the respective peptides.

74.4.5 Determining the Specificity of a Monoclonal Antibody Using Dynamic Force Spectroscopy [80]

Because of the unique properties of mAbs, they are also being used in medical applications. Since their first in vitro

production by Köhler and Milstein [81] in 1975 and two decades of advances in genetic engineering, mAbs are now widely applied medical agents [e.g., in the treatment of cancer using antibody drug conjugates (ADCs) [4–9], rheumatoid arthritis [9], Crohn's disease, multiple sclerosis, and prophylaxis for transplant rejection [82]). In 2012 approximately 30 therapeutic mAbs are being marketed in the United States and/or Europe, and a record number of mAbs are in clinical development [82]. The key feature of mAbs-based therapies is the targeted administration of highly potent drugs in combination with the reduction of negative side effects to healthy tissue due to so called cross-reactions. To achieve this goal a high target selectivity (or specificity) of the used mAb is imperative [5], meaning that the antibody must bind only to the disease-specific marker whereas no cross-reactivity to other tissue should occur. Apart from their applications in drug delivery, mAbs are also being used and developed as diagnostic tools in immunohistochemistry [76, 83] and flow cytometry [84]. In the context of neurodegenerative diseases (e.g., Alzheimer's disease), when symptoms are heterogeneous or their initial manifestation is ambiguous and can be mistaken with that of other conditions [85], the specificity of mAbs can be of invaluable help for the early detection of the disease.

Standard procedures to determine the specificity of a mAb in biochemical and pharmaceutical research include ELISA and Western blot [60] (see Section 74.2.4). Despite their outstanding performance in screening applications, a fundamental understanding of the dynamic binding process is not accessible for both techniques, since they provide only a static, equilibrated picture. However, to comprehend the overall receptor–ligand interaction (e.g., specificity of the mAb), more details on the binding kinetics (e.g., ON and OFF rates) are required [80].

For this purpose, the interactions between mAb HPT-101 and three τ-peptides (tau[pThr231/pSer235], tau[pThr231], and tau[pSer235]), each with a different phosphorylation pattern, are investigated on a single molecule level using DFS. In advance of these measurements, the specificity of mAb HPT-101 to the abovementioned τ-peptides was determined using ELISA. Interestingly, these assays showed that mAb HPT-101 binds specifically only to the epitope of the double-phosphorylated peptide tau226-240[pThr231/pSer235]. Cross reactions to monophosphorylated peptides with the same amino acid sequence were not observed, although the epitope differs only by a single isolated phosphorylation site [76].

In order to determine the ON-rate k_{on} the relative binding frequency h_B for all three mAb/peptide combinations have been measured (Fig. 74.13a), as described in Section 74.4.1. Although the highest binding frequency has been observed for the interaction between mAb HPT-101 and tau[pThr231/pSer235], this single-molecule approach also shows an appreciable binding of mAb HPT-101 to the monophosphorylated peptides. Therefore, the supposed specificity of mAb HPT-101 to the biphosphorylated peptide cannot be confirmed [80]. However, the binding frequency constitutes a measure for the relative ON rate only [2], whereas the affinity of a bond is defined by the association

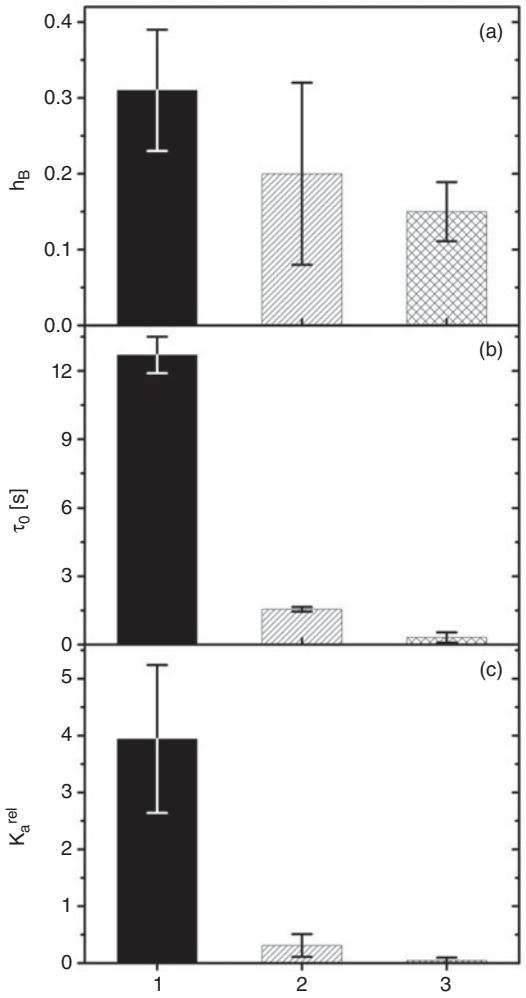

FIGURE 74.13 Median relative binding frequency h_B, bond lifetime τ_0, and relative affinity K_a^{rel} for the binding of mAb HPT-101 to the peptides (1) tau[pThr231/pSer235], (2) tau[pThr231], and (3) tau[pSer235]. (a) The interaction between the mAb and the double-phosphorylated peptide (1) shows the highest binding frequency. In contrast to ELISA measurements, mAb HPT-101 also binds to both monophosphorylated mutants. (b) Bond lifetime without external force, obtained by fitting $\tau_{DHS}(F)$ using Eq. (74.6) (for $\upsilon = 0.5$) to the rupture-force data. The highest τ_0-value is observed for the binding of mAb HPT-101 to tau[pThr231/pSer235] again, followed by the peptide carrying a phosphorylation at Thr231. The shortest lifetime is represented by the interaction between mAb HPT-101 and tau[pSer235]. (c) The relative affinity follows the trend observed for the binding frequency and bond lifetime. The highest relative affinity is obtained for the mAb HPT-101/tau[pThr231/pSer235] system and decreases by reducing the number of phosphorylation sites. The result is in accordance with ELISA measurements.

constant K_a, which is the ON/OFF-rate ratio. Thus, a full characterization requires the determination of the OFF rate as well.

Therefore, the OFF rate k_{off} is determined in a similar manner to that described in previous sections by analyzing the rupture-force distribution with the DHS model ($\nu = 0.5$). Figure 74.13b shows the bond lifetime for all three interactions. Again, the longest lifetime τ_0 is given for the binding of mAb HPT-101 to the double-phosphorylated peptide. MAb HPT-101 binds also to both monophosphorylated peptides, but with bond lifetimes reduced by one order of magnitude compared to the peptide tau[pThr231/pSer235]. In essence, the trend detected for the binding frequencies is reproduced, meaning that the strongest bond occurs for mAb HPT-101 and tau[pThr231/pSer235], followed by the two monophosphorylated peptides tau[pThr231] and tau[pSer235], respectively [80].

Subsequently, the affinity constant (i.e., the ON/OFF-rate ratio) from this single-molecule measurement can be calculated and compared to the data obtained by ELISA. The dissociation rate follows directly from the DFS measurements by the relation $k_{\text{off}} = \tau_0^{-1}$. The ON rate k_{on} is related to the binding frequency h_B in the following way. Neglecting the dissociation process, the mass action law reads as

$$\frac{d\,[RL]}{dt} = k_{\text{on}}\,[R]\,[L] \tag{74.9}$$

where $[RL]$ is the number of formed receptor–ligand complexes in a certain time dt, $[R]$ and $[L]$ are the receptor and ligand concentrations, respectively. For the following calculations $[RL]$ equals the binding frequency h_B. By assuming that the surface coverage of the different microparticles is identical, the product $[R]\,[L]$ becomes a constant. However, this assumption is not totally fulfilled, as can be seen from the error bars Fig. 74.13a. The incubation time dt is set as one second (see discussion of relative binding frequency measurements). Consequently it follows that the ON rate is directly proportional to the binding frequency. Finally the relative affinity is given by

$$K_a^{\text{rel}} = h_B \cdot \tau_0 \propto k_{\text{on}} \cdot \tau_0 = \frac{k_{\text{on}}}{k_{\text{off}}^0} = K_a. \tag{74.10}$$

The relative affinity of mAb HPT-101 to the different types of peptides is shown in Fig. 74.13c. It is evident that the interaction between the mAb and the biphosphorylated peptide shows the highest relative affinity. Compared to this, the affinity of tau[pThr231] is decreased by a factor of 10 and to tau[pSer235] by a factor of almost 100. This strong splitting is caused mainly by the large differences in τ_0 since binding frequencies differ only slightly. By multiplying both quantities to get the relative affinity, this effect is enhanced strongly, resulting in the highest specificity of mAb HPT-101 to the biphosphorylated peptide. This result is in accordance with ELISA. However, the abovementioned cross-reactivity indicates that not only a distinct phosphorylation pattern contributes to the receptor–ligand bond, but also the surrounding amino acids, as they may slightly influence the free energy landscape of the epitope. By assuming that the binding is dominated by the electrostatic interactions between antibody and the negatively charged phosphorylation sites of the peptide, it can be concluded that the cross-reactions between mAb HPT-101 and tau[pThr231] as well as tau[pSer235], respectively, are too weak to be detected by ELISA [80].

74.5 CONCLUSION

The application of physical concepts and measurement procedures to relevant biological and biochemical issues have been well established in recent years. Especially optical tweezers, with the ability to hold and manipulate microscopic objects in three dimensions and with subpiconewton forces, became a standard tool in biophysics. By using appropriate position detection algorithms (e.g., cross-correlation and edge detection) force measurements can be performed with nanometer resolution. Additionally, dynamic force spectroscopy has proved to be a powerful tool for investigating biologically relevant processes, such as receptor–ligand interactions, on a single molecule level. By extracting specific bond parameters such as bond lifetime, binding length, and free energy of activation, DFS measurements offer new insights into the nature of such noncovalent bonds. In this chapter, three experimental studies on small, hyperphosphorylated τ-peptides and their respective monoclonal antibody have been presented. Such well-defined and small systems make it possible to compare the binding of mAbs to peptides containing the sites responsible for specific binding with those not containing them. In this context, the appearance of the distribution of rupture forces of unspecific interactions can be characterized and separated from the specific interactions. From this, detailed insight into the specific binding of different mAbs binding to the respective sorts of τ-peptides can be gained. Furthermore, the abovementioned measurements might help to increase the target specificity of mAbs since cross-reactions to epitopes with similar amino acid sequence can be detected and characterized, even if they are not observed in commonly used ensemble techniques. This precise knowledge might be of fundamental interest in the development and optimization of future therapeutic/diagnostic antibodies that can be used in human medicine.

75.1 INTRODUCTION

It is a well-known fact that dispersions of micro- or nanoparticles are often used in the form of concentrated slurries in very different applications. Volume fractions of solids can be indeed very high (as much as 30–50%) in ceramic or drug suspensions, for example [1–4]. However, many techniques used in the characterization of dilute suspensions are practically useless in the evaluation of such systems, although this chapater focuses on electrokinetic techniques. These methods are based on determination of the response of the solid–solution interface (or of its macroscopic manifestations) to the application of an external field, often (but not always) electric [5–9]. Among these methods, (micro)electrophoresis, electroosmosis, or streaming potential are best known and most frequently employed, and their origins date back to the nineteenth century [10]. More recently, "indirect" techniques based on the measurement of some collective property have be used. In such cases, a theoretical treatment is required even for obtaining single-particle properties as a prior step in surface charge or potential evaluation. To this group belong two of the available techniques for the electrokinetic evaluation of concentrated suspensions. They are based on the application of alternating electric or pressure fields to the disperse system, and conclusions about the particles properties are based on analysis of the electrical permittivity of the suspension, or of the ["dynamic" or alternating-current (AC)] electrophoretic mobility of a single particle. They are obtained, respectively, from the frequency dependences of the conductivity of the system, and of the amplitude and phase of the ultrasound generated when an electric field with frequency in the MHz range is applied.

In both cases we can gain access to rich information about the dynamic processes in very varied systems, considering that the underlying microscopic mechanisms (field-induced or permanent polarization) can have a number of different origins. The associated methodologies are termed *low-frequency dielectric spectroscopy* (LFDD) and *electroacoustics*, respectively. In the first case, the frequency region of interest ranges from approximately 1 kHz to 1 MHz, while the 1–20 MHz interval is preferred for electroacoustic determinations [6, 9, 11–13].

Indeed, while the dielectric spectrum of a pure electrolyte solution in this region is flat, a suspension presents clear relaxation (or frequency dispersion) phenomena, regardless of whether the particles are large or small, polymeric or inorganic, or natural or artificially produced; with the only requirement is that their surface distributed electric charge be nonzero. On the other hand, the dynamic mobility also exhibits frequency dispersion processes related to polarization of the charged particles. Additionally, the shapes of the spectra depend in a nontrivial manner on the surface structure, particle size, conductivity, and permittivity, as well as

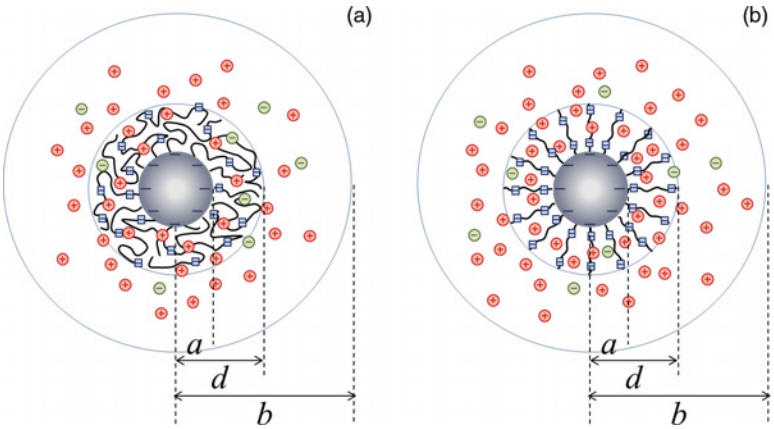

FIGURE 75.1 Schematic illustrations of the structure of a soft particle (a) and a spherical polyelectrolyte brush (b), where a is the core radius, d is the particle+layer thickness, and b is the radius of the electrolyte cell used for simulation of particle–particle interactions at moderate concentrations.

the ionic composition of the dispersion medium and the concentration of dispersed particles.

The number of studies dedicated to the AC electrokinetics of suspensions of rigid (or hard) particles is rather high (although experimental difficulties still limit the use of the technique) [14, 15]. Nevertheless, more recently it was found [16–18] that such properties are very sensitive to the presence of an external layer or shell of polymer or polyelectrolyte, grafted or adsorbed on the rigid core. Such a layer will be deformable, partially penetrable to the liquid, and (often) highly charged, and for this reason the resulting structures are known as *soft particles*, as schematically shown in Fig. 75.1a.

Interest in such particles is fundamental and related to the extremely varied phenomenology of such systems. Furthermore, in many situations modeling the particles as rigid is absolutely wrong, and in many instances the particles are used precisely because of their soft surface structure. In this respect, optimization of layer-by-layer deposition techniques has made it possible to construct model particles with soft interface properties [19]. Of particular importance is the occurrence of these types of structures in biological entities, including viruses and bacteria [20–25], for which the complexity of their external membranes (in the case of bacteria) or capsids (in viruses) rules out the description of their electrokinetic properties in terms of zeta-potential, no matter how sophisticated the theoretical model used.

Applications of soft-particle electrokinetics are very important in these biological systems, but they are not limited to them. Microgels and nanogels, which are of increasing interest, are extreme examples of soft entities in which even the rigid core can be considered absent. Again, these particles have found application in the field of drug transport and release [26–28].

The present contribution is devoted to showing some of the special features of the frequency dependence of the electric permittivity and dynamic mobility of suspensions of these types of materials. The chapter is organized as follows. In Section 75.2, the basic equations of the problem of determining the dielectric permittivity and dynamic mobility of concentrated suspensions of soft particles are presented. In Section 75.3, some representative predictions are discussed. Section 4 is devoted to our experimental results for both homogeneous and brushlike structure of the polymer layer. Finally, Section 75.5 summarizes the contents of the chapter.

75.2 BASIC EQUATIONS

75.2.1 General Overview and Notation Used

The first rigorous evaluations of the electrokinetics of concentrated systems date back to the 1970's, thanks to the contributions of Levine and Neale [29, 30], based on so-called cell models, previously introduced by Happel and Brenner [31] and Kuwabara [32] to account for hydrodynamic interactions between particles, and extended to the case of particles subjected to electrical or any other external fields. The model later received a more solid theoretical basis in work by another team [33–35]. In general terms, it is based on the assumption that an effective way to consider interactions between dispersed particles involves solving the problem for a single particle (a sphere of radius a) immersed in a concentric sphere of solution (the cell) with radius b (Fig. 75.1). The basics of the approach are as follows:

1. b can be defined by the volume fraction of solids in the suspension, ϕ:

$$\left(\frac{a}{b}\right)^3 = \phi \tag{75.1}$$

2. The interactions are mimicked by proper selection of boundary conditions for the velocity of the liquid, the

electric potential, and the concentration of ions on the cell limit, $r = b$.

3. The model can be extended to soft particles with adsorbed or grafted polymer layers, if the thickness of the layer is smaller than b.

Electrokinetic calculations based on the cell approach are very abundant [36] (although not free from criticism). One group of investigators [37,38] clarified some inconsistencies in earlier uses of the model, and several authors have more recently considered the so-called Shilov–Zharkikh method [39–42] as a well-founded alternative.

The basic equations of the problem are well established, in any case. A mean field approach is followed, so that the quantities of interest are functions of the position $\mathbf{r}$ (the position vector has its origin at the particle center). The quantities of interest are the electric potential $\Psi(\mathbf{r})$, the fluid velocity $\mathbf{v}(\mathbf{r})$, and the concentrations and velocities $n_i(\mathbf{r})$, $\mathbf{v}_i(\mathbf{r})$ of each ionic species. The fundamental equations are [11,17,43–45] (an alternating electric field, of frequency ω, $\mathbf{E}\exp(-i\omega t)$, is applied, hence a dependence $\exp(-i\omega t)$ is implicit in all quantities):

1. Poisson–Boltzmann equation

$$\nabla^2\Psi(\mathbf{r}) = \begin{cases} -\dfrac{\rho_{\mathrm{el}}(\mathbf{r})}{\varepsilon_0\varepsilon_{\mathrm{m}}}, & d < r < b \\ -\dfrac{\rho_{\mathrm{el}}(\mathbf{r})}{\varepsilon_0\varepsilon_{\mathrm{m}}} - \dfrac{3Q_{pol}(\mathbf{r})}{4\pi\varepsilon_0\varepsilon_{\mathrm{m}}(d^3 - a^3)}, & a < r < d \end{cases} \tag{75.2}$$

where $\rho_{\mathrm{el}}(\mathbf{r})$ is the local volume charge density $\rho_{\mathrm{el}}(\mathbf{r}) = \sum_{i=1}^{N} z_i e n_i(\mathbf{r})$, and Q_{pol} is the total charge carried by the polyelectrolyte cover.

2. Navier–Stokes equations for an incompressible fluid

$$\rho_m \frac{\partial}{\partial t}[\mathbf{v}(\mathbf{r}) + v_e] = \begin{cases} \eta_m\nabla^2\mathbf{v}(\mathbf{r}) - \nabla p(\mathbf{r}) - \rho_{\mathrm{el}}\nabla\Psi(\mathbf{r}), & d < r < b \\ \eta_m\nabla^2\mathbf{v}(\mathbf{r}) - \nabla p(\mathbf{r}) - \rho_{\mathrm{el}}\nabla\Psi(\mathbf{r}) - \gamma\mathbf{v}, & a < r < d \end{cases}$$
$$\nabla\cdot\mathbf{v}(\mathbf{r}) = 0 \tag{75.3}$$

where $\mathbf{v}$ is the fluid velocity with respect to the particle. The particle velocity with respect to the laboratory frame of reference is the electrophoretic velocity $\mathbf{v}_e exp(-i\omega t)$, and η_m, ρ_m are, respectively, the viscosity and density of the liquid medium. The extra friction in the polyelectrolyte layer is represented by the term $-\gamma\mathbf{v}$ in the Navier–Stokes equation, meaning that the Debye–Bueche model (where the charged layer is represented by a uniform distribution of friction centers) is assumed [16,17,46]. It is customary to use a different quantity to measure the layer resistance; this is the dimensionless product λa, where $\lambda = (\gamma/\eta_m)^{1/2}$. The reciprocal of λ is known as the *Brinkman screening length*, and it is a measure of the permeability of the porous layer or, equivalently, the thickness of the transition region between open flow of the liquid and the Darcy flow inside the pore thickness [46,47].

3. Ion conservation and Nernst–Planck equations

$$\begin{aligned} &\nabla\cdot[n_i(\mathbf{r})\mathbf{v}_{\mathbf{i}}(\mathbf{r})] = -\frac{\partial}{\partial t}[n_i(\mathbf{r})] \\ &\mathbf{v}_{\mathbf{i}} = \mathbf{v} - \frac{D_i}{k_B T}\nabla\mu_i \\ &\mu_i(\mathbf{r}) = \mu_i^{\infty} + z_i e\Psi(\mathbf{r}) + k_B T\ln n_i(\mathbf{r}) \end{aligned} \tag{75.4}$$

where $\mu_i(\mathbf{r})$ is the chemical potential of the ith ions, μ_i^{∞} is the corresponding standard value, and D_i is their diffusion coefficient.

It will be assumed that all quantities can be expressed as the sum of an equilibrium (superscript 0) and a field-dependent perturbation term. For low field strengths, as is the case in the problems considered, the perturbations are linearly dependent on the field, with its same frequency, and complex [44,48]:

$$\mu_i(\mathbf{r}) = \mu_i^0(r) + \delta\mu_i(\mathbf{r}) = \mu_i^0(r) - z_i e\phi_i(r)E\cos\theta \qquad (i = 1,\ldots,N) \tag{75.5}$$

$$\Psi(\mathbf{r}) = \Psi^0(r) + \delta\Psi(\mathbf{r}) = \Psi^0(r) - \Gamma(r)E\cos\theta \tag{75.6}$$

$$\mathbf{v}(\mathbf{r}) = \left\{ -\frac{2}{r}h(r)E\cos\theta, \quad \frac{1}{r}\frac{d}{dr}[rh(r)]\,E\sin\theta, \quad 0 \right\} \tag{75.7}$$

The obvious spherical symmetry in the absence of field renders the equilibrium quantities exclusively dependent on the radial spherical coordinate r. In addition, the perturbed quantities display axial symmetry with respect to the field direction, z. The unknown functions will hence be $h(r)$, $\phi_i(r)$, and $\Gamma(r)$, and θ is the angle between $\mathbf{r}$ and the field axis.

In terms of these new quantities, the partial differential equations of Poisson, Navier–Stokes, and ion conservation become ordinary differential equations, the form of which can be found in the literature [45, 49, 50]. The boundary conditions of the problem are as follows:

1. The surface charge of the particles Q or their surface density σ is defined as follows:

$$\varepsilon_m \varepsilon_0 \left.\frac{d\Psi^0}{dr}\right|_{r=a} = -\sigma = -\frac{Q}{4\pi a^2} \tag{75.8}$$

2. Electroneutrality of the cell is as follows:

$$\left.\frac{d\Psi^0}{dr}\right|_{r=b} = 0 \tag{75.9}$$

Equations (75.8) and (75.9) refer to the equilibrium situation. The conditions in presence of the field follow below.

3. Continuity of the potential and displacement vector perturbations on the particle surface, and on the polyelectrolyte layer, are as follows:

$$\left.\begin{array}{c} \delta\Psi(a^-) = \delta\Psi(a^+) \\ \varepsilon_p \left.\dfrac{\partial\delta\Psi}{\partial r}\right|_{a^-} = \varepsilon_m \left.\dfrac{\partial\delta\Psi}{\partial r}\right|_{a^+} \\ \delta\Psi(d^-) = \delta\Psi(d^-) \\ \left.\dfrac{\partial\delta\Psi}{\partial r}\right|_{d^-} = \left.\dfrac{\partial\delta\Psi}{\partial r}\right|_{d^+} \end{array}\right\} \rightarrow \begin{array}{c} \left.\dfrac{d\Gamma}{dr}\right|_a - \dfrac{\varepsilon_p}{\varepsilon_m a}\Gamma(a) = 0 \\ \Gamma(d^-) = \Gamma(d^+) \\ \left.\dfrac{d\Gamma}{dr}\right|_{d^-} = \left.\dfrac{d\Gamma}{dr}\right|_{d^+} \end{array} \tag{75.10}$$

Here, ε_p is the particle's relative permittivity.

4. The fluid velocity is stagnant on the core surface, and continuous at the polyelectrolyte layer. The vorticity is also taken as continuous on the same ideal surface $r = d$:

$$\left.\begin{array}{l} \mathbf{v}(\mathbf{r})|_{r=a} = 0 \\ \mathbf{v}(\mathbf{r})|_{r=d^-} = \mathbf{v}(\mathbf{r})|_{r=d^-} \\ \nabla\times\mathbf{v}(\mathbf{r})|_{r=d^-} = \nabla\times\mathbf{v}(\mathbf{r})|_{r=d^-} \end{array}\right\} \rightarrow \left\{\begin{array}{l} h(a) = 0 \\ \left.\dfrac{dh}{dr}\right|_{r=a} = 0 \\ h(d^-) = h(d^+) \\ \left.\dfrac{dh}{dr}\right|_{r=d^-} = \left.\dfrac{dh}{dr}\right|_{r=d^+} \\ Lh|_{r=d^-} = Lh|_{r=d+} \end{array}\right. \tag{75.11}$$

Here, L is the differential operator $L(\cdot) = d^2(\cdot)/dr^2 + 2/r\, d(\cdot)/dr - 2(\cdot)/r^2$.

5. Ions cannot penetrate the particle:

$$\left.\mathbf{v}_j \cdot \hat{\mathbf{n}}\right|_{r=a} = 0 \rightarrow \left.\frac{d\phi_j}{dr}\right|_{r=a} = 0, \quad j = 1, \ldots, N \tag{75.12}$$

6. The concentrations and velocities of ionic species are continuous at the interface between the polyelectrolyte layer and the solution:

$$\left.\begin{array}{l} \mathbf{v}_j(d^-) = \mathbf{v}_j(d^+) \\ n_j(d^-) = n_j(d^+) \end{array}\right\} \rightarrow \left\{\begin{array}{l} \phi_j(d^-) = \phi_j(d^-) \\ \left.\dfrac{d\phi_j}{dr}\right|_{d^-} = \left.\dfrac{d\phi_j}{dr}\right|_{d^+} \end{array}\right. , \quad j = 1, \ldots, N \tag{75.13}$$

A careful discussion is available [50] concerning the conditions on the cell external surface $r = b$. We will follow another approach [45], in which a set of general physical statements on the cell dynamics is all that is needed, as given next.

7. The macroscopic electric field $\mathbf{E}$ is given by

$$\mathbf{E} = \langle -\nabla\delta\Psi(\mathbf{r})\rangle \rightarrow \Gamma(b) = -b \tag{75.14}$$

where the average $\langle\bullet\rangle$ must be evaluated throughout the whole cell volume. This is equivalent to Dirichlet conditions as stated elsewhere [38].

8. Similarly, the average of the concentration perturbations is:

$$\langle\nabla\delta n_j(\mathbf{r})\rangle = 0 \rightarrow \delta n_j(b) = 0 \rightarrow \phi_j(b) = b \tag{75.15}$$

9. The average of the pressure perturbation (δp) gradient in the cell volume can be neglected, as no external pressure is imposed on the system:

$$\langle\nabla\delta p(\mathbf{r})\rangle = 0 \rightarrow \left.\frac{d}{dr}\left[r(L+\gamma^2)h\right]\right|_{r=b} - 2h(b)\gamma^2 - \frac{\sum_{i=1}^{N} z_i e n_i^0(b)}{\eta_m} \tag{75.16}$$

Here, $n_i^0(b)$ is the equilibrium concentration of the ith species on the cell boundary.

10. An additional condition is equivalent to Kuwabara's condition, which states that the radial velocity of the fluid on the cell coincides (except for a change of sign) with the component of the electrophoretic mobility in the same direction:

$$\left.\begin{array}{c} v_r(b) = -u_e E\cos\theta \\ \text{or} \\ \langle\mathbf{v}(\mathbf{r})\rangle = 0 \end{array}\right\} \rightarrow u_e = \frac{2h(b)}{b} \tag{75.17}$$

11. Finally the force balance on the cell is required [51]:

$$\oint_{S(r=b)} \overleftrightarrow{\boldsymbol{\tau}} \cdot \hat{\mathbf{n}} dS = -i\omega \left[\frac{4\pi}{3} a^3 \rho_P u_e \mathbf{E} + \rho_m \int_{V_m} [\mathbf{v}(\mathbf{r}) + \mathbf{v}_e] dV \right]$$
$$\rightarrow L[h(r)]|_{r=b} = \gamma^2 \phi \left(\frac{\rho_p - \rho_m}{\rho_m} \right) h(b) \tag{75.18}$$

Here, ρ_p is the particle density and $\overleftrightarrow{\boldsymbol{\tau}}$ is the total stress tensor on the $r = b$ surface. It can be demonstrated that it contains only hydrodynamic interactions.

75.2.2 The Case of Grafted Polymer: Spherical Polyelectrolyte Brushes (SPBs)

This problem has been treated both experimentally and theoretically [18,52]. Typical soft particles are distinguished by the additional assumption that the charged polymer chains are long and grafted on the particle from whose surface they appear to extend as rays; hence the denomination of brush particles [53–55], as schematically shown in Fig. 75.1b. If the ionic strength of the medium is low, the charged groups along the chains will keep them stretched. Shrinking of the chains will likely take place if the ionic concentration is raised or, as it is of interest to us here, if the concentration of SPBs is also large. This radial structure of the polyelectrolyte on the core requires modification of the soft-particle model described above. The homogenous distribution of charged groups is modified and an r^{-2} dependence of the volume charge density of the layer, the drag of the liquid, and the diffusion coefficient of the ions must be considered instead:

$$\rho_{pol} = \frac{Q_{pol}}{4\pi(d-a)} \frac{1}{r^2}$$
$$\lambda = \lambda_0 \frac{a}{r} \tag{75.19}$$
$$D = D_0 \frac{r^2}{d^2}$$

Here, the 0 subscript corresponds to the situation where all charge and frictions centers are homogeneously distributed.

75.2.3 Expressions for Electrophoretic Mobility and Permittivity of the Suspension

Details on the evaluation of the dynamic mobility or the electric permittivity are provided in Ref. 16. For the sake of brevity, only the final expressions will be shown here. These equations reflect the need to obtain the values of h, ϕ_j, and Γ as well as their derivatives on the cell limit. In the case of mobility, the result is rather straightforward:

$$u_e = \frac{2h(b)}{b} \frac{1}{1 + \phi \dfrac{\rho_c - \rho_m}{\rho_m}} \tag{75.20}$$

Here, ρ_c (ρ_m) is the mass density of the core (solution). The permittivity is obtained in a more indirect way, as one starts from the complex frequency-dependent conductivity of the suspension:

$$K^*(\omega) = \sum_{i=1}^{N} \left[\frac{z_i^2 e^2 n_i^\infty k_B T}{D_i} \left(1 - \frac{3\phi}{a^3} \Omega_i \right) - u_e z_i n_i^\infty \right]$$
$$\times \exp\left(-\frac{z_i e \Psi^0(b)}{k_B T} \right) - i\omega \varepsilon_m \varepsilon_0 \left(1 - \frac{3\phi}{a^3} \Omega \right) \tag{75.21}$$

Here

$$\Omega_i \equiv -\frac{b^2}{3} \left(r \frac{d\phi_i}{dr} - \phi_i \right)_{r=b}, \quad i = 1, \ldots, N$$
$$\Omega \equiv -\frac{b^2}{3} \left(\Gamma - r \frac{d\Gamma}{dr} \right)_{r=b} \tag{75.22}$$

From the conductivity, the permittivity follows by simply considering that a complex conductivity can equally be interpreted as a complex permittivity, except for the DC ($\omega = 0$) contribution:

$$K^*(\omega) = K^*(\omega = 0) - i\omega \varepsilon^*(\omega) \varepsilon_0$$
$$= K^*(\omega = 0) - i\omega \varepsilon'(\omega) \varepsilon_0 + \omega \varepsilon''(\omega) \varepsilon_0 \tag{75.23}$$

where we have introduced the real and imaginary components of the relative permittivity (frequently designated as dielectric constant). For practical reasons, the (also complex) dielectric increment is used:

$$\Delta\varepsilon^*(\omega) = \varepsilon^*(\omega) - \varepsilon_m = \Delta\varepsilon'(\omega) - i\Delta\varepsilon''(\omega) \tag{75.24}$$

Let us finally mention that, according to the Maxwell–Wagner derivation [6], a relationship can be established between the complex conductivity of the suspension and the induced dipole coefficient of each particle (in our case, the solid particle plus its electric double layer), C^* (ω):

$$K^*(\omega) = K_m^*(\omega) \frac{1 + 2\phi C^*(\omega)}{1 - \phi C^*(\omega)} \underset{\phi \to 0}{\approx} K_m^*(\omega)(1 + 3\phi C^*(\omega)) \tag{75.25}$$

In this equation, $K_m^*(\omega)$ is the complex conductivity of the liquid medium, which, keeping in mind that the liquid does not

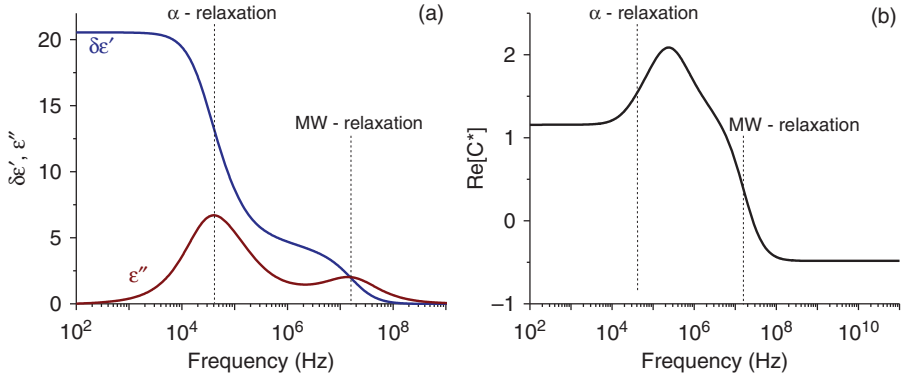

FIGURE 75.2 Schematic representation of the real and imaginary parts of the relative permittivity (a) of a dilute suspension, and real part of the induced dipole coefficient (b) of a 100 nm spherical particle in a 0.1 mM KCl solution with surface charge 10^{-14} C, as a function of the frequency of the field.

undergo any relaxation for frequencies below the microwave regime, can be simplified in terms of the (constant) DC conductivity and the dielectric constant of the medium: $K_m^*(\omega) = K_m + i\omega\varepsilon_m\varepsilon_0$. From this we obtain

$$\varepsilon'(\omega) = \varepsilon_m + 3\phi\varepsilon_m \left\{ \mathrm{Re}[C^*(\omega)] + \frac{K_m}{\omega\varepsilon_m\varepsilon_0} \mathrm{Im}\left[C^*(\omega)\right] \right\} \tag{75.26}$$

an expression allowing us to interpret the dielectric spectra in terms of a microscopic quantity as the polarizability of the particles.

Figure 75.2 shows the two relaxations typically encountered in the dielectric spectrum of a suspension: the α relaxation and the Maxwell–Wagner relaxation. The *α relaxation* is due to polarization of the concentration clouds induced by the field on both sides of the particle (so-called concentration polarization; the neutral electrolyte concentration increases on one side and is depleted on the other). If the frequency is high enough, the relaxation takes place because the clouds cannot be formed. The *Maxwell–Wagner* (*MW*) *relaxation* is higher in frequency and is associated with the heterogeneity of the dispersed system, that is, the fact that the particle and the medium may have different permittivities and/or conductivities. As mentioned, these processes have different timescales [13]: 10^{-7} s in the case of the MW relaxation (typically the time required for the ions to diffuse at a distance equal to the double- layer thickness), and 10^{-4} s (the time for the formation of the electrolyte cloud with characteristic dimension equal to the particle dimension). The correlation with the dipole coefficient is also illustrated in Fig. 75.2. Because the concentration polarization tends to decrease the magnitude of the dipole, the disappearance of the former leads to an increase in the real part of C^*; for high frequencies it is the MW relaxation that appears, and produces a decrease in Re[C^*] because the ions cannot follow the field oscillations. The limiting value of Re[C^*] is $-1/2$, but at low frequency the value will be larger (even positive and equal to 1) for a highly charged particle [7]. For little or no charge, the $-1/2$ value remains constant for the whole frequency range.

75.3 SOME PREDICTIONS

75.3.1 Soft Particles

Figure 75.3 enables comparison between the dielectric behavior of a suspension of hard particles and one with soft structures; the charges of the rigid particle in the former case and of the polyelectrolyte layer in the latter are identical. It is evident that the amplitude of the relaxation is significantly larger in coated particles, an effect hindered by the increase in friction (i.e., the increase in λa), as expected from the subsequent reduction in ion mobility in the layer. The fact that ions in the coating are on the average at larger distances from the rigid core can explain the enhanced response. On the other hand, note that the frequency of the relaxation is not affected by the presence of the layer.

In the same figure, the dynamic mobility is shown. Note that maxima and minima in (minus) the imaginary component of u_e correspond roughly to the decrease (inertial) and increase (Maxwell–Wagner), respectively, of the real part. It is clear that the mobility of the coated particles can be considerably larger than that of the bare ones, as long as the friction in the layer is not too high, becoming a dominant decreasing factor. The presence of the volume-distributed counterions in the layer produces an extended charged interface where the electroosmotic flow is largely favoured; hence the large mobility. We can also see evidence of the well-known fact that at high field frequencies, neither the liquid flow nor the particle motions can follow the fast field oscillations, and the mobility drops to zero in all cases. This so-called inertia relaxation takes place, in the case of rigid particles, at

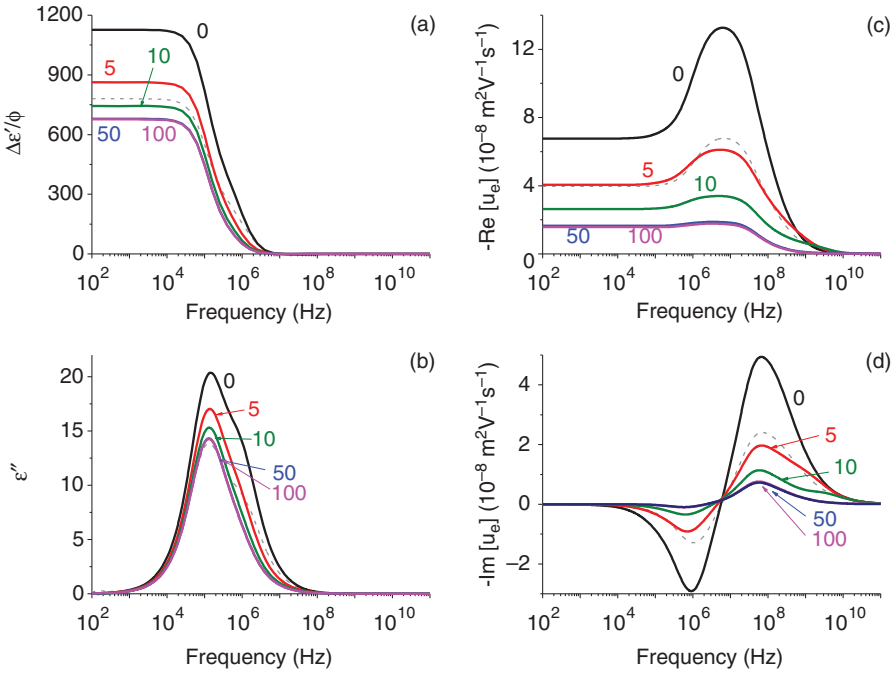

FIGURE 75.3 (a) Specific (per unit volume fraction) dielectric increment, (b) imaginary component of the relative permittivity, and real (c) and imaginary (d) components of the dynamic mobility in suspensions of soft spheres, as a function of frequency. The case of hard particles (dashed lines) is included for comparison. In all cases, the charge (on the bare particles or in the polymer layer) equals -1×10^{-15} C, the volume fraction of solids is 5%, the core radius is 100 nm. The thickness of the polyelectrolyte coating is 40 nm and the dispersion medium is 0.1 mM KCl solution. λa values as indicated.

a frequency $\omega_{in} = 2\pi\eta_m/a^2\rho_m$; the fact that the position of maxima in $-\mathrm{Im}(u_e)$ in Fig. 75.3d does not change in presence of the layer indicates that the inertia relaxation is controlled by the core size, except if the layer is too rigid, when the coated particle differs only slightly from a rigid one with radius d (data not shown).

The effect of the volume fraction on the dielectric and mobility dispersions is depicted in Fig. 75.4. Two features are immediately noticeable. *First*, both the dielectric amplitude and the low-frequency mobility decrease when the volume fraction is increased. In the former case, the reason is the partial compensation of the polarized clouds of neighbor particles when the average interparticle distance (roughly the b parameter of the cell, Fig. 75.1) decreases as a result of particle concentration. In the case of the mobility, the effect of hydrodynamic and electrical interactions can be assumed responsible for the reduction in the dielectric dispersion amplitude [56]. *Second*, Fig. 75.4 shows an increase in α relaxation toward higher frequencies the larger the volume fraction, again well explained in terms of the size of the polarization clouds, controlled by the particle radius at low volume fractions and by the distance b at moderate and high ϕ values. The effect on the inertia relaxation of u_e of the particle concentration is also clear; increasing ϕ raises the characteristic frequency as well. The same reasons can be given for such behavior. It is also apparent that the effect of the volume fraction is more relevant in the case of soft particles; because of the spatial extension of the polymer layers, increasing the volume fraction (i.e., reducing b in Fig. 75.1) more easily affects the volume available for concentration polarization clouds in that case, due to the closer proximity of the polymer layers to the cell limits, or, equivalently, to neighbor particles.

75.3.2 Brushlike Particles

The first point to consider is the difference between the model predictions corresponding to soft-particle and SPB models. Figure 75.5a,b clearly demonstrates the larger amplitude of the α relaxation and the different frequency dependences in the case of brush-like particles. This is because the characteristic dimensions and the magnitudes of the gradients of neutral electrolyte concentration established around the three kinds of particles are significantly different. For soft layers the equilibrium space charge distribution is homogeneous, and both the perturbed concentration of ions and the region where diffusion is maximum (limit of the space charge region) are smaller in comparison to SPBs. In such particles,

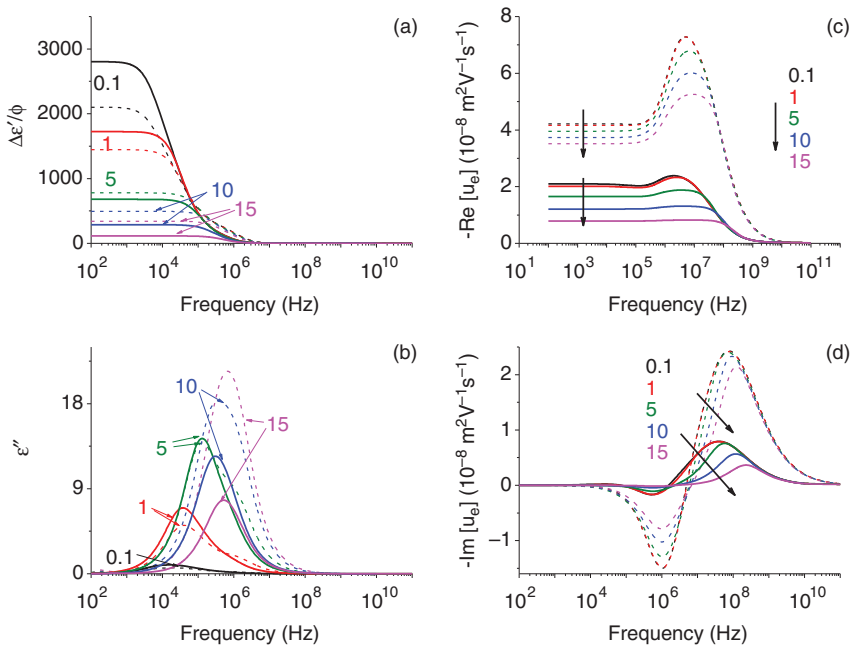

FIGURE 75.4 (a) Specific dielectric increment, (b) imaginary component of the relative permittivity, and real (c) and imaginary (d) components of the dynamic mobility of suspensions of soft (solid lines) and hard (dashed lines) spheres, as a function of frequency. In each case, the figures show the variations with the indicated volume fractions in percent, keeping constant the remaining parameters; the charge equals -1×10^{-15} C (in the polymer layer for soft particles, and on the particle surface for hard ones), the friction parameter $\lambda a = 50$, and the core radius is 100 nm. The thickness of the polyelectrolyte coating is 40 nm, and the dispersion medium is 0.1 mM KCl solution.

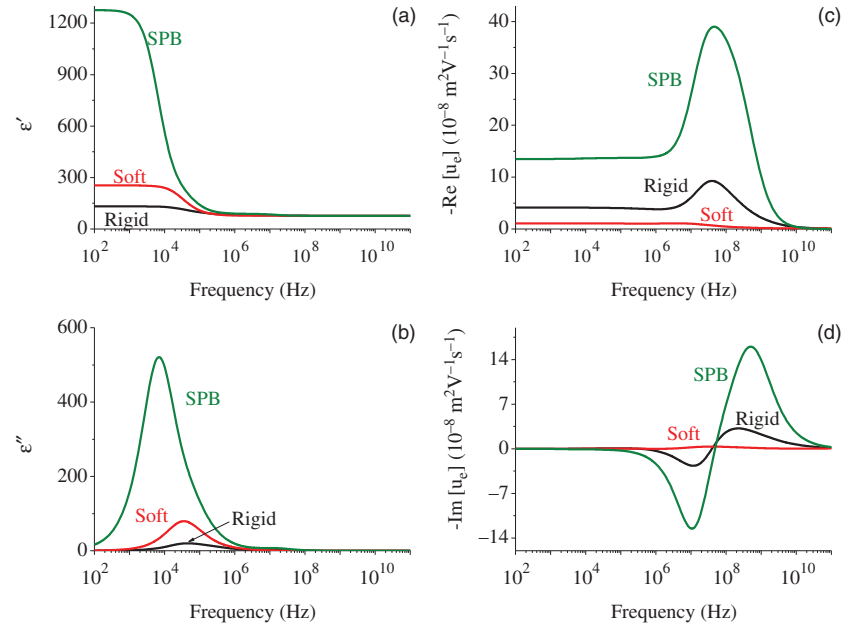

FIGURE 75.5 Real (a) and imaginary (b) parts of the relative permittivity, and real (c) and imaginary (d) components of the dynamic mobility for rigid, soft, and SPB particle suspensions under the same conditions. The total charge (-1×10^{-14} C) in the polymer layer for soft and SPB models is distributed on the core in the case of the rigid model. The friction parameter is $\lambda a = 50$, the core radius is 100 nm, and the volume fraction is 1%. The thickness of the polyelectrolyte coating is 100 nm, and the dispersion medium is 1 mM KCl solution.

the charge is not homogeneously distributed inside the brush, and the cloud of neutral electrolyte can be formed even inside the polyelectrolyte brush. This leads to a considerable concentration polarization and, from this, to a large increase in low-frequency permittivity, as has been found experimentally. Together with the r dependence of the diffusion coefficient, this results in a shift in the relaxation frequency to lower values. For the same reasons, the electrophoretic mobility is much larger in SPBs, as the region of volume charge extends to large distances from the interface, giving rise to a wide conducting layer, and, correspondingly, to a large region where electroosmotic flow can develop around the particle. Therefore, it can be assumed that a thick layer of charged liquid is accelerated by the field. As a result, from the laboratory frame of reference, the mobility will undergo a clear increase.

75.4 EXPERIMENTAL VERIFICATION

75.4.1 Soft Particles

A number of predictions of the models described can be confirmed experimentally [57–59]. For this work, we have used spherical hematite particles (manufactured by Lanxess, Germany) under the tradename of Bayferrox 130. A Malvern Mastersizer 2000 (Malvern Instruments, UK) was used for estimating an average diameter $d_{50} = 253$ nm. Two coatings were deposited on them, one cationic [poly(dialildimethyl ammonium chloride) (PDADMAC)] and the other anionic [sodium polystyrene sulfonate (PSS)]. Figure 75.6 presents data on the electrophoresis of the particles, showing that the coating has been produced as expected, with both polyelectrolytes behaving as strong ones, with full dissociation at any pH.

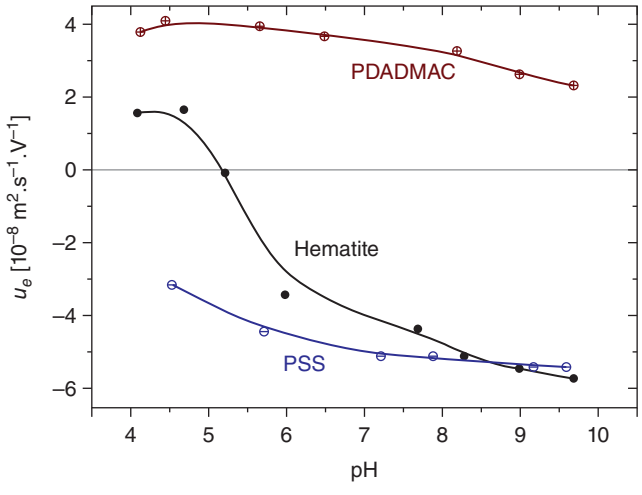

FIGURE 75.6 Effect of pH on electrophoretic mobility of hematite particles, both uncoated and coated with either PDADMAC or PSS. Ionic strength: 1 mM $NaClO_4$.

The permittivity of the hematite suspensions was in this case obtained from the measurements of the complex impedance of the systems in a cylindrical cell with platinized platinum electrodes, with variable separation, using the logarithmic derivative of the real component of the permittivity in order to minimize the effect of electrode polarization [14,15]. The results refer to the imaginary part of the relative permittivity, as shown in Figs. 75.7 and 75.8. The tremendous effect of the coating is clear, and, in addition, our model is capable of fitting the spectra very precisely. Furthermore, these data can be fitted using our model, with the following (reasonable) parameters: Q_{pol} (PDADMAC) $= 15 \times 10^{-15}$ C, Q_{pol}(PSS) $= -6 \times 10^{-15}$ C, λ (PDADMAC) $= 8 \times 10^7$ m^{-1}, and λ (PSS) $= 7 \times 10^7$ m^{-1}. The inner core charges used in the model are pH-dependent as expected in an oxide–solution interface. Some representative values for Q were (units: 10^{-15} C): +1 (pH 4), −1.8 (pH 5.6), −4 (pH 6.7), −6 (pH 7.6), −9 (pH 8.6).

Finally, we point out the following:

- The permittivity increment of coated particles is larger than that of rigid ones.
- The relaxation frequency decreases on coating, something not predicted by the model. This may be a manifestation of an increase in particle size because the coating encloses several particles instead of single ones.
- For negatively charged coating, the permittivity increases clearly with the polymer charge. This is found both experimentally and theoretically. The effect is not so clear for positive layers, because of the interplay between the signs of the core and the coating.

75.4.2 Polyelectrolyte Brushes

Although the most common technique of electrophoresis can be used for inferring structural changes in SPBs, the AC methods presented in this chapter are presumably much more informative. In a more recent contribution from the authors [18, 52] it was found that it is very unlikely that electrokinetic data in AC fields obtained with SPBs can be reasonably explained not only with a rigid particle model but even with a soft particle approach. Indeed, Fig. 75.9 demonstrates that the spectra of dynamic mobility reach values as high as 10^{-7} m^2 V^{-1} s^{-1}, between 2 and 5 times larger than expected for standard, rigid particles. Moreover, the absolute value of the mobility increases with the volume fraction of solids, again a strongly unexpected behavior. The fact that the mobility can be higher in the case of SPBs than in comparable rigid particles was predicted theoretically as described, and was already reported by other authors [46], in cases of highly coated layers. This is an indication of strong electroosmotic flows in the layer (recall that a high velocity of the particles in the laboratory reference frame is equivalent to a high electroosmotic

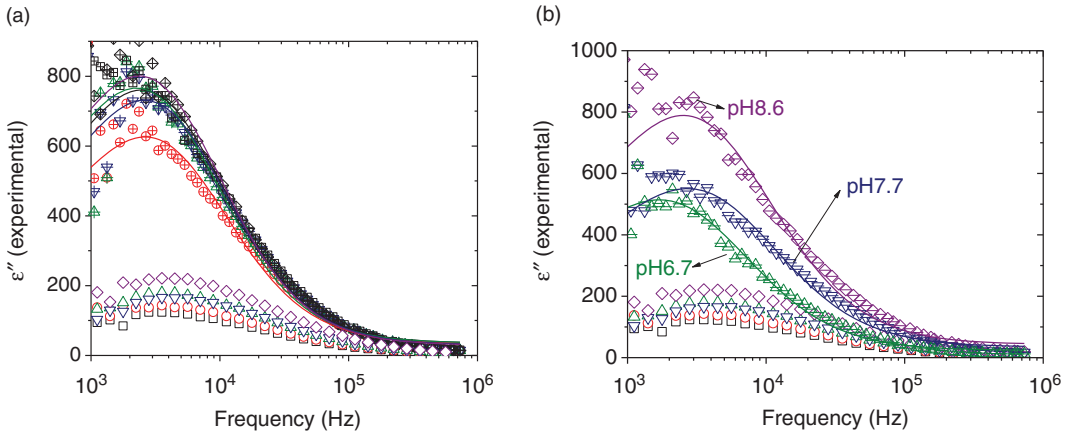

FIGURE 75.7 Experimental values (symbols with "+"/"−") of the imaginary part of the permittivity of suspensions of hematite coated with PDADMAC: (a) (pH 4, squares; pH 5.6, circles; pH 6.7, up triangles; pH 7.6, down triangles; pH 8.6, diamonds) and PSS (b), for different pH values as indicated. Lines: best fit to the model presented. Open symbols: bare hematite.

velocity of the liquid referred to the particle), associated with mobile counterions. Although some data have been reported indicating that the mobility of ions in the layer is reduced as compared to that of free ions, the abundance of ions for highly charged coatings must compensate for that and lead to fast flows.

As discussed, as in other electrokinetic studies dealing with complex systems, the use of more than one technique applied to the very same system is very clarifying, as long as the same set of fundamental parameters can be used to explain both sets of data. In our case, we focus on the electric permittivity spectra of SPBs. The results are depicted in Fig. 75.10, showing that the observed relaxation is significantly high, not comparable to that of rigid particles. In Fig. 75.11 we compare the permittivity of an SPB suspension to that of pure, rigid polystyrene particles with the size of either the core or the whole particle. Note that in neither case do the permittivity spectra of the polystyrene particles approach that of the brush-coated cores.

On the contrary, our model, described above, is capable of explaining the entire set of data using a single set of parameters, as illustrated in Figs. 75.9 and 75.10. It must be admitted that only at low frequency are some discrepancies found between the experimental data and our predictions. Nevertheless, it is also well known that in this range of frequencies, the effect of electrode polarization can be more noticeable, in spite of the methods used for eliminating (or, more realistically speaking, minimizing) such effects. Fortunately, the frequency interval used in dynamic mobility measurements, ranging from 1 to 18 MHz, is much less affected.

The values of the parameters used for fitting can be considered reasonable and comparable to values found

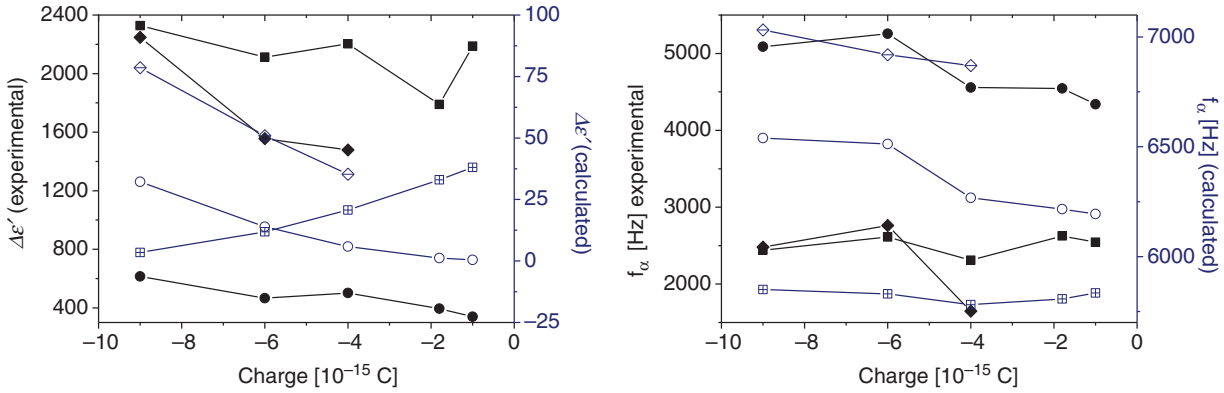

FIGURE 75.8 Comparison between the experimental (left axes, full symbols) and calculated (right axes, open symbols) permittivity increments (a) and relaxation frequencies (b) of hematite particles either bare (circles) or coated with PDADMAC (squares) and PSS (diamonds), as a function of the charge of the bare particle.

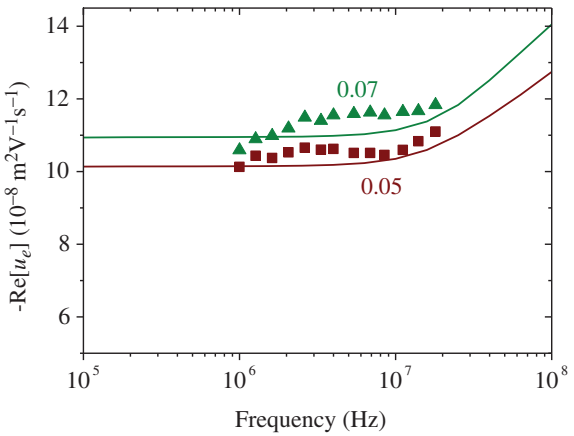

FIGURE 75.9 Symbols: real part of the experimental values of the dynamic mobility of SPBs (polystyrene sulfonate chains grafted on polystyrene core) as a function of frequency, for the volume fractions indicated, in 0.5 mM NaCl. The lines correspond to the best fit to our theoretical predictions, obtained using the following parameters: Particle charge: -5×10^{-16} C; charge of the polyelectrolyte layer plus condensed counterions: -8.5×10^{-14} C, dimensionless friction parameter: $\lambda_0 a = 110$; polymer layer thicknesses: 85 and 55 nm for volume fractions $\phi = 5$ and 7%, respectively. (From Ahualli et al. 2012 [52], p. 16372. © American Chemical Society; reproduced with permission.)

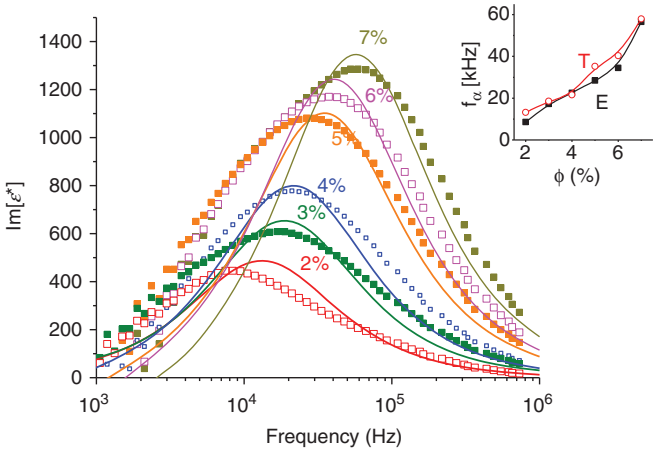

FIGURE 75.10 Symbols: imaginary part of the experimental values of the relative permittivity of SPB suspensions as a function of frequency, for the volume fractions indicated, in 0.5 mM NaCl. The lines correspond to the best fit to our theoretical predictions, obtained using the parameters detailed in the caption to Fig. 75.9; polymer layer thicknesses: 156, 136, 94, 85, 75, and 55 nm for volume fractions $\phi = 2\%$, 3%, 4%, 5%, 6%, and 7%, respectively. The inset allows the comparison between measured (full symbols, E) and fitted (open symbols, T) relaxation frequencies f_α as a function of ϕ. (From Ahualli et al. 2012 [52], p. 16372. @ American Chemical Society; reproduced with permission.)

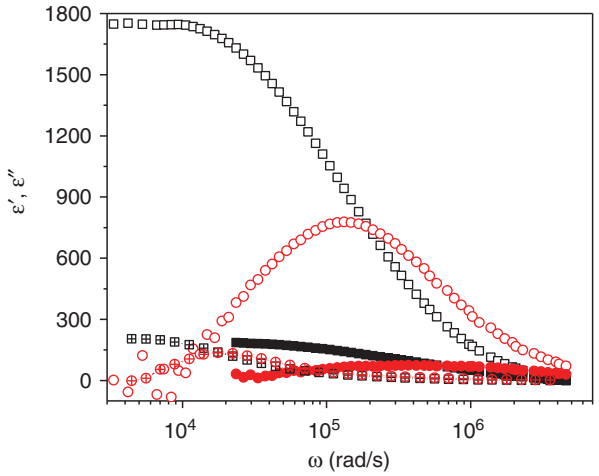

FIGURE 75.11 Real (squares) and imaginary (circles) parts of the relative permittivity of suspensions of SPBs (open symbols), polystyrene 50 nm in radius (filled sysmbols) and polystyrene 168 nm in radius (crossed symbols) as a function of the field frequency. Particle concentration: 4% by weight. Ionic strength 0.5 mM NaCl. (Details in Jiménez et al. 2011 [18]; http:pubs.rsc.org/en/content/articlelanding/2011/sm/c0sm01544j. Reproduced with permission of the Royal Society of Chemistry.)

using other methods. For instance, the core particle charge ($Q = -5 \times 10^{-16}$ C) corresponds to a surface charge density of 6 μ C/cm^2, a very typical value. The polymer charge (-8.5×10^{-14} C) is equivalent to 40 mM, again a moderate charge amount. Finally, the layer thickness changes from 156 nm for 2% volume fraction to 55 nm for 7%; these values should be compared with the thickness deduced from hydrodynamic radius determinations (i.e., very low volume fractions), namely, 150 nm [62]. Concerning the Brinkman screening length that best fits the data, $\lambda^{-1} = 0.5$ nm, it is quite close to the theoretical result of 1 nm [55].

75.5 CONCLUSION

We have given a brief account of the basic features of the dielectric relaxation in suspensions of spheres coated by a polyelectrolyte layer. The predictions are physically explained in terms of polarization mechanisms in the electric double layer. The modeling compares favorably with experimental data obtained with hematite spheres coated with PDADMAC (positive) and PSS (negative), as well as with spherical brushes of polystyrene with polystyrene sulfonate. It is especially worthwhile to mention that the results presented demonstrate that AC electrokinetic techniques provide, if a proper model is used in each case, an amount of information impossible to acquire with standard electrokinetic methods. In particular, the combination of dielectric dispersion and dynamic mobility data yields in situ values

of parameters completely characterizing the soft or SPB particle, including particle and polymer charge, polyelectrolyte thickness, and layer permeability, which are perfectly comparable to those accessible with specifically designed methods.

76.1 INTRODUCTION

Electrophoresis has been widely applied to characterize the physicochemical properties of colloidal particles. Among these, soft biocolloids, biocolloidal particles composed of a rigid core and an ion-penetrable soft layer, belong to a distinct category. Typical examples include biological entities, such as cells, viruses, and proteins, and synthetic particles, such as particles covered by an artificial or a biological membrane layers [1–5], to name only a few. Note that a special case of soft particles is that the rigid core vanishes, becoming a fully porous particle, typically termed a *polyelectrolyte* (PE). Considering the wide variety of applications using soft biocolloids, a systematic approach for the description of the abovementioned electrophoresis problem under general conditions is highly desirable.

Convectional electrophoresis analysis on soft particles is based on assumptions of the low surface potential [6–17] and a constant fixed charge density of the soft layer [7–34]. The former assumption implies that the effect of double-layer polarization (DLP) [23, 24], one of the most interesting phenomena in electrophoresis arising from the deformation of ionic cloud when the particle is in motion, is neglected. That effect, which usually restrains the particle mobility, is most important when the surface potential of a particle is high and its characteristic size is comparable to the thickness of an electrical double layer (EDL) [23]. It has been proved that most biocolloids such as cells and proteins are of charge-regulated nature [35–37]. Stemming from the presence of the dissociation/association reactions of functional groups in the soft layer of a particle, its charge properties and, accordingly, electrophoretic behavior are highly dependent on the solution properties, such as pH and salt concentration. This implies that the assumption of constant fixed charge density of the soft layer is inappropriate for the description of biocolloids.

In this chapter, a continuum-based mathematical model comprising a Poisson equation for the electrical potential, multiple-ion Nernst–Planck equations for the ionic concentrations, and modified Stokes–Brinkman equations for the hydrodynamic field, combined with a skillful superposition solution procedure through a perturbation approach [38], is introduced to evaluate the electrophoretic behavior of a pH-regulated soft biocolloid. The model proposed is verified by comparing its predictions to the existing experimental data obtained from the literature. Therefore, the model is suitable for estimating the charge properties and the electrophoretic mobility of biocolloids under various background solution properties, pH, and salt concentration, because the DLP effect arising from the convective motion of multiple ionic species is taken into account. This chapter is structured as follows. Section 76.2 details the general theoretical model and that based on the perturbation approach for the case of an isolated, pH-regulated, soft particle in an infinite electrolyte solution containing multiple ionic species. Section 76.3 describes the numerical procedures, code validation, and the typical results of the charge properties and the electrophoretic behavior of a pH-regulated soft biocolloid. Section 76.4 concludes the

chapter; this is followed by a list of symbols used in this chapter (Section 76.5).

76.2 THEORETICAL MODEL

Referring to Fig. 76.1, we consider the electrophoresis of a pH-regulated, soft spherical particle of radius a constituting a rigid core of radius b and an ion-penetrable soft layer of thickness c subject to an applied uniform electric field $\mathbf{E_z}$ of strength E_z. The spherical coordinates, r, θ, and φ, are adopted with the origin located at the center of the particle, and E_z is applied in the z direction (parallel to $\theta = 0$), resulting in the electrophoretic velocity U_p in the same direction. Note that, if the rigid core of a soft particle shrinks to a point, it becomes a completely porous particle or a polyelectrolyte (PE) particle.

We assume that (1) the system under consideration is at a pseudo–steady state; (2) the liquid phase is an incompressible Newtonian fluid containing N kinds of ionic species; (3) the rigid core of the particle is nonslip, nonconducting, and impenetrable to ionic species; (4) the soft layer of the particle is penetrable to ions and fluid, and the permittivity and viscosity of the liquid phase inside the soft layer are the same as those outside the particle; (5) the flow field is in the creeping flow regime; (6) both the flow and the electric fields at the point far away from the particle are uninfluenced by its presence; and (7) the dispersion of particles is so dilute that the particle-particle interaction is neglected.

76.2.1 General Electrokinetic Equations

On the basis of the abovementioned assumptions, the electric and ionic concentration fields of the problem illustrated in Fig. 76.1 can be described by the Poisson–Nernst–Planck (PNP) equations [35, 37, 39]:

$$\nabla^2 \phi = -\frac{\rho + h\rho_s}{\varepsilon_f}, \; h = 0, \; 1 \tag{76.1}$$

$$\nabla \cdot \mathbf{J}_i = 0, \; i = 1, \; 2, \ldots, N \tag{76.2}$$

$$\mathbf{J}_i = n_i \mathbf{u}_i = n_i \mathbf{u} - D_i \left(\nabla n_i + \frac{e z_i n_i}{k_B T} \nabla \phi \right), \; i = 1, 2, \ldots, N \tag{76.3}$$

In the above, ∇ and ∇^2 are the gradient and Laplace operators, respectively; ϕ is the electrical potential in the liquid phase; $\mathbf{u}$ and $\mathbf{u}_i$ are the flow velocity of the fluid and that of the ith mobile ionic species, respectively; e, ε_f, k_B, and T are the elementary charge, permittivity of the liquid phase, Boltzmann constant, and absolute fluid temperature, respectively; $\rho = \sum_{i=1}^{N} e z_i n_i$ is the space charge density of mobile ions; ρ_s is the charge density of the soft layer; z_i, n_i, D_i, and $\mathbf{J}_i$ are the valence, number concentration, diffusivity, and flux of ionic species i, respectively; h is a unit step region function ($h = 0$ for the liquid phase outside the particle, $h = 1$ inside the soft layer). Equation (76.3) implies that the mobile ion species are driven by the liquid flow (convective process), the concentration gradient (diffusion process), and the electric field (electromigration process).

Since the Reynolds numbers of the electrokinetic flows in electrophoretic devices are extremely low, the flow field at steady state can be described by the following continuity equation and the modified Stokes–Brinkman equation [35, 37, 39]:

$$\nabla \cdot \mathbf{u} = 0 \tag{76.4}$$

$$-\nabla p + \eta \nabla^2 \mathbf{u} - h\eta \lambda_s^2 \mathbf{u} - \rho \nabla \phi = \mathbf{0}, \; , \; h = 0, \; 1 \tag{76.5}$$

Here, p and η are the pressure and dynamic viscosity of the liquid phase, respectively; $\lambda_s = (\gamma_s/\eta)^{1/2}$ is the reciprocal softness degree (or Brinkman screening length) of the soft layer, where γ_s is the hydrodynamic frictional coefficient of that layer. For biocolloids, λ_s^{-1} typically ranges from 0.1 to 10 nm [1]. The third ($-\eta \lambda_s^2 \mathbf{u}$) and fourth terms ($-\rho \nabla \phi$) of the left-hand side (LHS) of Eq. (76.5) represent the frictional force exerted on the fluid by the molecular chains of the soft layer [40, 41] and the electrical body force acting on the liquid. Note that in the free-draining limit, γ_s can be expressed as $6\pi\eta R_s N_s$, where R_s and N_s respectively are the Stokes radius and the number density of the hydrodynamic frictional polyelectrolyte segments of the entirely soft particle [3].

The charge properties of the soft layer of biocolloids such as cells, virus, and proteins are typically of a charge-regulated nature. This implies that the distribution of ρ_s in Eq. (76.1) is

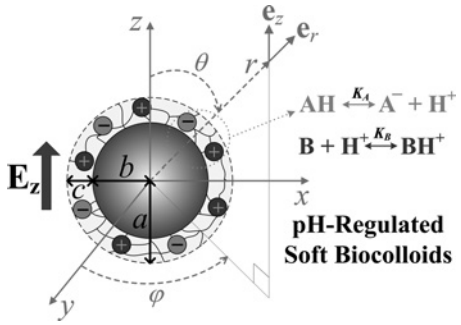

FIGURE 76.1 Electrophoresis of a pH-regulated, soft spherical particle of radius a constituting a rigid core of radius b and an ion-penetrable soft layer of thickness c in an applied uniform electric field $\mathbf{E_z}$. The soft layer carries both acidic and basic functional groups AH and B, respectively, capable of undergoing dissociation and association reactions with protons, and, therefore, its charges possess pH-regulated nature. $\mathbf{e_r}$ and $\mathbf{e_z}$ are the unit vectors in the r and z directions, respectively.

strongly dependent on the degree of dissociation/association reactions of the functional groups contained inside the soft layer of the particle, thus affecting the electrophoretic behavior of soft biocolloids. For illustration, we consider the case where the soft layer of the particle carries zwitterionic functional groups (e.g., lysine), AH (e.g., ∼COOH), and B (e.g., $\sim NH_2$), respectively, capable of undergoing the following dissociation/association reactions:

$$\mathrm{AH} \leftrightarrow \mathrm{A}^- + \mathrm{H}^+ \quad \text{and} \quad \mathrm{B} + \mathrm{H}^+ \leftrightarrow \mathrm{BH}^+ \tag{76.6}$$

Let K_A and K_B be the equilibrium constants of these reactions, as follows:

$$K_A = \frac{N_{\mathrm{A}^-}\left[\mathrm{H}^+\right]}{N_{\mathrm{AH}}} \tag{76.7}$$

$$K_B = \frac{N_{\mathrm{BH}^+}}{N_{\mathrm{B}}\left[\mathrm{H}^+\right]} \tag{76.8}$$

In the above, N_k represents the number density of species k and $[H^+]$ denotes the molar concentration of H^+. Let N_{As} and N_{Bs} be the total number densities of the acidic and the basic functional groups in the soft layer, respectively:

$$N_{As} = N_{\mathrm{A}^-} + N_{\mathrm{AH}} \tag{76.9}$$

$$N_{Bs} = N_{\mathrm{B}} + N_{\mathrm{BH}^+} \tag{76.10}$$

Applying Eqs. (76.7)–(76.10) yields the charge density of the soft layer

$$\begin{aligned}\rho_s &= F(-N_{\mathrm{AH}^-} + \Gamma_{\mathrm{BH}^+}) \\ &= F\left(-\frac{K_A N_{As}}{K_A + [\mathrm{H}^+]} + \frac{K_B N_{Bs}\left[\mathrm{H}^+\right]}{1 + K_B\left[\mathrm{H}^+\right]}\right)\end{aligned} \tag{76.11}$$

where F is Faraday constant. For biocolloids, N_{As} or N_{Bs} typically ranges from 10 to 2635 mol/m^3 [1, 42].

76.2.2 Boundary Conditions

The boundary conditions associated with Eqs. (76.1)–(76.5) include the following. For convenience, we first let the soft particle be fixed and the liquid far away from it moves with a relative velocity $\mathbf{u}_\infty = -U_p\mathbf{e}_z$, where $\mathbf{e}_z$ is the unit vector in the z direction. To simulate biocolloids [22, 39], we assume that the rigid core ($r = b$) of the soft biocolloids is uncharged [22, 39], impenetrable to ionic species, and nonslip. These yield the following boundary conditions:

$$\mathbf{n} \cdot \nabla\phi = 0 \tag{76.12}$$

$$\mathbf{n} \cdot \mathbf{J}_i = \mathbf{n} \cdot \mathbf{u}_i = 0 \tag{76.13}$$

$$\mathbf{u} = \mathbf{0} \tag{76.14}$$

Here, $\mathbf{n}$ is the unit outer normal vector on the surface of the rigid core. Note that Eq. (76.12) stems from the assumption that the permittivity of the rigid core is much smaller than that of the liquid phase. Equation (76.14) implies that the shear plane on which $\mathbf{u} = \mathbf{0}$ is located on the surface of the rigid core.

Because the values of ε_f and η for the liquid phase inside the soft layer are the same as those outside the particle, the electrical potential, the electric field, the ionic concentrations, the ionic fluxes, the flow velocity, and the flow field are continuous on the soft particle–liquid interface ($r = a$) [23]:

$$\phi|_{r=a^-} = \phi|_{r=a^+} \tag{76.15}$$

$$\mathbf{n} \cdot \nabla\phi|_{r=a^-} = \mathbf{n} \cdot \nabla\phi|_{r=a^+} \tag{76.16}$$

$$n_i|_{r=a^-} = n_i|_{r=a^+} \tag{76.17}$$

$$\mathbf{J}_i|_{r=a^-} = \mathbf{J}_i|_{r=a^+} \tag{76.18}$$

$$\mathbf{u}|_{r=a^-} = \mathbf{u}|_{r=a^+} \tag{76.19}$$

$$\mathbf{n} \cdot \mathbf{u}|_{r=a^-} = \mathbf{n} \cdot \mathbf{u}|_{r=a^+} \tag{76.20}$$

$$\mathbf{n} \times \mathbf{u}|_{r=a^-} = \mathbf{n} \times \mathbf{u}|_{r=a^+} \tag{76.21}$$

$$\mathbf{n} \cdot (\boldsymbol{\sigma}^{\mathbf{H}} \cdot \mathbf{n})\Big|_{r=a^-} = \mathbf{n} \cdot (\boldsymbol{\sigma}^{\mathbf{H}} \cdot \mathbf{n})\Big|_{r=a^+} \tag{76.22}$$

$$\mathbf{n} \times (\boldsymbol{\sigma}^{\mathbf{H}} \cdot \mathbf{n})\Big|_{r=a^-} = \mathbf{n} \times (\boldsymbol{\sigma}^{\mathbf{H}} \cdot \mathbf{n})\Big|_{r=a^+} \tag{76.23}$$

In the above, $\boldsymbol{\sigma}^{\mathbf{H}} = -p\mathbf{I} + 2\eta\Delta$ is the hydrodynamic stress tensor, and $\mathbf{I}$, $\Delta = [\nabla\mathbf{u} + (\nabla\mathbf{u})^{\mathrm{T}}]/2$, and the superscript $\mathbf{T}$ are the unit tensor, the rate of deformation tensor, and the matrix transpose, respectively.

Because the particle is in an infinite liquid medium and the particle–particle interaction is neglected, the electric field, the ionic concentrations, and the flow field far away from the particle ($r \to \infty$) are not influenced by its presence. This assumption yields the following boundary conditions:

$$\nabla\phi = -\mathbf{E}_z \tag{76.24}$$

$$n_i = n_{i0} \tag{76.25}$$

$$\mathbf{u} = -U_p\mathbf{e}_z \tag{76.26}$$

Note that for the case where the aqueous solution takes multiple ionic species into account [36, 37, 43, 44], the electroneutrality must be satisfied in the bulk phase:

$$\sum_{i=1}^{N} ez_i n_{i0} = 0 \tag{76.27}$$

76.2.3 Forces Acting on a Soft Particle

The spatial distributions of the electrical potential (ϕ), the fluid velocity ($\mathbf{u}$), and the number concentration of ith ionic

species (n_i) can be obtained by simultaneously solving the electrokinetic governing equations [Eqs. (76.1)–(76.5) and (76.11)] subject to the appropriate boundary conditions, such as those expressed in Eqs. (76.12)–(76.26). Then, the sum of forces, including the electrical force F_e and the hydrodynamic force F_h acting on the soft particle in the z direction, can be evaluated by integrating the Maxwell stress tensor ($\boldsymbol{\sigma}^{\mathbf{E}} = \varepsilon_f \mathbf{E}_z \mathbf{E}_z - (1/2)\varepsilon_f E_z^2 \mathbf{I}$) and the hydrodynamics stress tensor ($\boldsymbol{\sigma}^{\mathbf{H}}$) over the particle surface Ω_p. It can be shown that [32,38,39,42,45]

$$F_e = \int_{\Omega_p} (\boldsymbol{\sigma}^{\mathbf{E}} \cdot \mathbf{n}) \cdot \mathbf{e}_z d\Omega_p = \int_{\Omega_p} \varepsilon_f \left[\frac{\partial \phi}{\partial n}\frac{\partial \phi}{\partial z} - \frac{1}{2}\left(\frac{\partial \phi}{\partial n}\right)^2 n_z - \frac{1}{2}\left(\frac{\partial \phi}{\partial t}\right)^2 n_z \right] d\Omega_p \tag{76.28}$$

$$F_h = \int_{\Omega_p} \left(\boldsymbol{\sigma}^{\mathbf{H}} \cdot \mathbf{n}\right) \cdot \mathbf{e}_z d\Omega_p = \int_{\Omega_p} \left[-p n_z + 2\eta \frac{\partial u_n}{\partial n} n_z + \eta \left(\frac{\partial u_n}{\partial t} + \frac{\partial u_t}{\partial n} \right) t_z \right] d\Omega_p \tag{76.29}$$

In the above, $\mathbf{E}_z = -\nabla\phi = \mathbf{n}(\partial\phi/\partial n) + \mathbf{t}(\partial\phi/\partial t)$, $\mathbf{u} = \mathbf{n}u_n + \mathbf{t}u_t = \mathbf{n}(\mathbf{u}\cdot\mathbf{n}) + \mathbf{t}(\mathbf{u}\cdot\mathbf{t})$, and $E_z^2 = \mathbf{E}_z \cdot \mathbf{E}_z$; $\mathbf{t}$ is the unit tangential vector on Ω_p; n_z and t_z are the z components of the unit normal vector $\mathbf{n}$ and the unit tangent vector $\mathbf{t}$, respectively; $\partial/\partial n$ and $\partial/\partial t$ are the derivatives along the normal and tangential directions on the particle surface, respectively.

At steady state, the electrophoretic velocity U_p of the soft biocolloid can be determined based on the balance of the z-component forces acting on the particle:

$$F_e + F_h = 0 \tag{76.30}$$

However, solving this problem under general conditions is nontrivial, if possible, because of the coupled, highly nonlinear nature of the partial differential equations involved. In addition, a tedious trial-and-error procedure is typically needed to obtain U_p. To circumvent this difficulty, the perturbation approach described below [38, 46, 47] has been developed.

76.2.4 Perturbation Approach

Suppose that the strength of the applied electric field ($\mathbf{E}_z$) is much weaker than that established by the soft biocolloidal particle, which is usually satisfied in practice. For example, the surface potential of a biocolloid is typically lower than ~200 mV and its Debye length ranges from 0.1 nm to 1 μm, yielding the strength of the equilibrium electrical field established by a charged particle ranging from 2×10^5 to 2×10^9 V/m. Because the strength of $\mathbf{E}_z$ is much lower than this level, the assumption of weak applied electric field is realistic. Therefore, all the relevant dependent variables, ϕ, n_i, p, and $\mathbf{u}$, can be partitioned into an equilibrium term, denoted with a subscript e, and a perturbed term, denoted with a prefix δ, as follows:

$$\phi = \phi_e + \delta\phi \tag{76.31}$$

$$n_i = n_{ie} + \delta n_i \tag{76.32}$$

$$p = p_e + \delta p \tag{76.33}$$

$$\mathbf{u} = \mathbf{u}_e + \delta\mathbf{u} \tag{76.34}$$

In these expressions, the equilibrium terms arise from the presence of the particle in the absence of the applied electric field $\mathbf{E}_z$, and the perturbed terms arises from the application of $\mathbf{E}_z$. Suppose that $\mathbf{u}_e = \mathbf{0}$ if $\mathbf{E}_z$ is not applied and, therefore, Eq. (76.34) becomes $\mathbf{u} = \delta\mathbf{u}$. Substituting Eqs. (76.31)–(76.34) into the general electrokinetic equations, Eqs. (76.1)–(76.5), governing this problem yields two sets of linear expressions, one describing the equilibrium-dependent variables and the other describing the perturbed dependent variables [38].

76.2.4.1 Equilibrium Problem. Collecting terms involving the equilibrium variables yields the following set of equations for the equilibrium electric, concentration, and flow fields:

$$\nabla^2\phi_e = -\sum_{i=1}^{N} \frac{e z_i n_{ie}}{\varepsilon_f} - \frac{h\rho_s}{\varepsilon_f},\ h = 0,\ 1 \tag{76.35}$$

$$\nabla n_{ie} + \frac{e z_i n_{ie}}{k_B T}\nabla\phi_e = 0 \tag{76.36}$$

$$-\nabla p_e + \left[\varepsilon_f \nabla^2\phi_e + h\rho_s\right]\nabla\phi_e = \mathbf{0} \tag{76.37}$$

The Boltzmann distribution for the concentration of ith ionic species can be obtained by integrating Eq. (76.36) from a point far away from the particle, where $\phi_e = 0$ and $n_{ie} = n_{i0}$, to a point near the particle, where $\phi_e = \phi_e$ and $n_{ie} = n_{ie}$:

$$n_{ie} = n_{i0} \exp\left(-\frac{e z_i \phi_e}{k_B T}\right),\ i = 1,\ 2,\ \ldots,\ N \tag{76.38}$$

Substituting this expression into Eq. (76.35), we obtain the following governing equation for the equilibrium electric potential (ϕ_e):

$$\nabla^2\phi_e = -\sum_{i=1}^{N} \frac{e z_i n_{i0}}{\varepsilon_f} \exp\left(-\frac{e z_i \phi_e}{k_B T}\right) - \frac{h\rho_s}{\varepsilon_f},\ h = 0,\ 1 \tag{76.39}$$

76.2.4.2 Perturbation Problem. As is well known, the effect of double-layer polarization (DLP), arising from the convective flow of ionic species and thus yielding a deformation of a double layer surrounding a particle, has a significant effect on its electrophoretic behavior [22–24, 32, 37]. In general, the DLP of a particle induces an internal polarized electric field, the direction of which is opposite that of the applied electric field, making the electrophoretic velocity of the particle slower than that for the case where the double layer is not polarized. To take the DLP effect into account, the spatial number concentration of the ith ionic species, n_i, can be expressed by [37, 38, 46]

$$n_i = n_{i0} \exp\left[-\frac{ez_i(\phi_e + \delta\phi + g_i)}{k_B T}\right], \quad i = 1, 2, \ldots N \tag{76.40}$$

where g_i is a hypothetical perturbed potential function for a polarized double layer. Note that although this expression is of Boltzmann type, the actual distribution of n_i, depending on the value of g_i, can deviate appreciably from that distribution.

Based on Eqs. (76.1), (76.30), (76.35), and (76.40), one obtains the following governing equation for the perturbed potential $\delta\phi$:

$$\begin{aligned}\nabla^2\delta\phi &= \nabla^2\phi - \nabla^2\phi_e \\ &= -\sum_{i=1}^{N} \frac{ez_i n_{i0}}{\varepsilon_f}\left\{\exp\left[-\frac{ez_i(\phi_e + \delta\phi + g_i)}{k_B T}\right]\right. \\ &\quad \left. - \exp\left(-\frac{ez_i\phi_e}{k_B T}\right)\right\}\end{aligned} \tag{76.41}$$

Applying Eqs. (76.31), (76.38), and (76.40) yields

$$\begin{aligned}\delta n_i &= n_{i0}\exp\left[-\frac{ez_i(\phi_e + \delta\phi + g_i)}{k_B T}\right] \\ &\quad -n_{i0}\exp\left(-\frac{ez_i\phi_e}{k_B T}\right),\ i = 1, 2, \ldots, \quad N\end{aligned} \tag{76.42}$$

Substituting Eqs. (76.30), (76.33), and (76.42) into Eqs. (76.2) and (76.3) yields

$$\begin{aligned}&\nabla^2 g_i - \frac{ez_i}{k_B T}\nabla\phi_e \cdot \nabla g_i \\ &= \frac{1}{D_i}\mathbf{u}\cdot\nabla\phi + \frac{1}{D_i}\mathbf{u}\cdot\nabla g_i + \frac{ez_i}{k_B T}\nabla\delta\phi\cdot\nabla g_i \\ &\quad + \frac{ez_i}{k_B T}\nabla g_i\cdot\nabla g_i, \quad i = 1, 2, \ldots, N\end{aligned} \tag{76.43}$$

If the applied electric field is weak compared to that established by the particle, then $\phi_e \gg \delta\phi$ and $\phi_e \gg \delta\phi + g_i$. In this case, Eq. (76.40) can be approximated by [38]

$$\begin{aligned}n_i &\cong n_{i0}\exp\left(-\frac{ez_i\phi_e}{k_B T}\right)\left[1 - \frac{ez_i}{k_B T}(\delta\phi + g_i)\right], \\ &\quad i = 1, 2, \ldots, N\end{aligned} \tag{76.44}$$

This expression describes the concentration of ith ionic species after the external electric field is applied. Because the perturbed variables, $\delta\phi$, δn_i, δp, and $\delta\mathbf{u}$ are all on the order of E_z, substituting Eq. (76.44) into Eqs. (76.41) and (76.43) and neglecting terms involving the product of two or more those perturbed terms, one obtains the following approximated equations for the disturbed electrical field:

$$\nabla^2\delta\phi = -\sum_{i=1}^{N}\frac{ez_i n_{i0}}{\varepsilon_f}\left[-\exp\left(-\frac{ez_i\phi_e}{k_B T}\right)\right]\left[-\frac{ez_i}{k_B T}(\delta\phi + g_i)\right] \tag{76.45}$$

$$\nabla^2 g_i - \frac{ez_i}{k_B T}\nabla\phi_e\cdot\nabla g_i = \frac{1}{D_i}\mathbf{u}\cdot\nabla\phi_e, \quad i = 1, 2, \ldots, N \tag{76.46}$$

Substituting Eqs. (76.1), (76.31), (76.33), and (76.34) into Eqs. (76.4) and (76.5) and collecting terms of the order of E_z, one obtains the following perturbed expressions for the flow field:

$$\nabla\cdot\mathbf{u} = 0 \tag{76.47}$$

$$\begin{aligned}&-\nabla\delta p + \eta\nabla^2\mathbf{u} - h\eta\lambda_s^2\mathbf{u} + \left(\varepsilon_f\nabla^2\phi_e + h\rho_s\right)\nabla\delta\phi \\ &\quad + \varepsilon_f\nabla^2\delta\phi\nabla\phi_e = \mathbf{0},\ h = 0, 1\end{aligned} \tag{76.48}$$

Note that after applying the perturbation approach, the linearized expressions, Eqs. (76.39) and (76.45)–(76.48), are applicable to arbitrary charge density of soft layer, double-layer thickness, and geometry.

76.3 ELECTROPHORESIS OF A pH-REGULATED SOFT BIOCOLLOID

Let us first discuss the electrophoretic behavior of pH-regulated soft biocolloids. For illustration, we consider the general case where a soft particle of radius a consisting of a rigid core of radius b and an ion-penetrable soft layer of thickness c, $a = b + c$, in an infinite general electrolyte solution containing N kinds of ionic species, is electrophoretically driven by an uniform applied electric field $\mathbf{E_z}$ of strength E_z, as depicted in Fig. 76.2. For convenience, a cylindrical computational domain of radius d ($d \gg a$) is defined and the cylindrical coordinates, r, θ, and z, are chosen with the origin located at the center of the domain. $\mathbf{E_z}$ is in the z direction. Let Ω_p, Ω_r, Ω_w, and Ω_e be the soft layer–liquid interface and the rigid core of the particle, and the lateral and the end surfaces

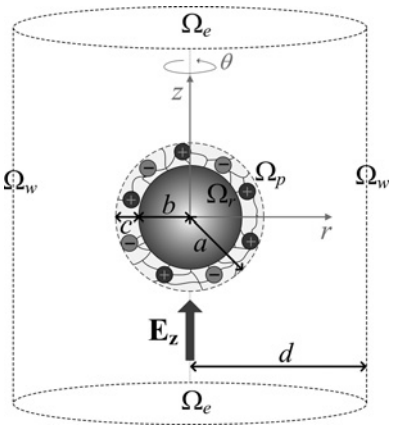

FIGURE 76.2 Electrophoresis of a soft spherical particle of radius a making up a rigid core of radius b and an ion-penetrable soft layer of thickness c along the axis of a cylindrical computational domain of radius d ($d \gg a$); r, θ, and z are the cylindrical coordinates with the origin at the center of the domain; $\mathbf{E_z}$ is in the z direction; Ω_p, Ω_r, Ω_w, and Ω_e represent the soft layer–liquid interface and the rigid core of the particle, and the lateral and the end surfaces of the computational domain, respectively.

of the computational domain, respectively. For convenience, the slipping plane, where the liquid velocity relative to the particle vanishes, is assumed to be on the surface of the rigid core of the particle, that is, the computational domain moves with a relative velocity of $-U_p\mathbf{e}_z$.

To simulate experimental conditions, we assume that the background salt is KCl (or NaCl), and the solution pH is adjusted by HCl and KOH (or NaOH). Therefore, four kinds of ionic species (i.e., $N = 4$) need be considered: K^+ (or Na^+), Cl^-, H^+, and OH^-. Let $C_{i0} = n_{io}/1000N_a$ (in the unit of M), i =1,2,3,4, be the bulk molar concentrations of these ions, respectively. Electroneutrality yields the following relations [37, 48]: $C_{10} = C_{\mathrm{KCl}}$, $C_{20} = C_{\mathrm{KCl}} + 10^{-\mathrm{pH}} - 10^{-(14-\mathrm{pH})}$, $C_{30} = 10^{-\mathrm{pH}}$, and $C_{40} = 10^{-(14-\mathrm{pH})}$ for pH ≤ 7; $C_{10} = C_{\mathrm{KCl}} - 10^{-\mathrm{pH}} + 10^{-(14-\mathrm{pH})}$, $C_{20} = C_{\mathrm{KCl}}$, $C_{30} = 10^{-\mathrm{pH}}$, and $C_{40} = 10^{-(14-\mathrm{pH})}$ for pH > 7. Here, N_a is the Avogadro constant, and C_{KCl} (C_{NaCl}) is the background salt concentration when KCl (NaCl) is used.

To simulate biocolloids, it is assumed that the soft layer carries pH-regulated, zwitterionic, functional groups, AH and B, capable of experiencing dissociation and association equilibrium reactions, expressed in Eq. (76.6), with protons. If we assume that the equilibrium concentration of H^+ follows the Boltzmann distribution, $[H^+] = C_{30}\exp(-e\phi_e/k_BT)$, the charge density of the soft layer expressed in Eq. (76.11) can be expressed as

$$\rho_s = F\left(-\frac{K_A N_{As}}{K_A + C_{30}\exp\left(-\dfrac{e\phi_e}{k_BT}\right)} + \frac{K_B N_{Bs} C_{30}\exp\left(-\dfrac{e\phi_e}{k_BT}\right)}{1 + K_B C_{30}\exp\left(-\dfrac{e\phi_e}{k_BT}\right)}\right) \tag{76.49}$$

where C_{30} is the bulk molar concentration of H^+. This expression implies that ρ_s is not uniformly distributed, and depends on the physicochemical properties (e.g., K_A, K_B, N_{As}, N_{Bs}) of the soft layer of biocolloids and the background solution properties such as pH and salt concentration.

76.3.1 Governing Equations

If the applied electric field is relatively weak compared to that established by the soft particle, the electrostatics, ionic mass transport, and momentum transport of the problem described in Fig. 76.2 can be governed by the electrokinetic equations, Eqs. (76.39) and (76.45)–(76.48), based on the perturbation approach described in Section 76.2. To provide a more concise presentation, we have rewritten Eqs. (76.39) and (76.45)–(76.48) in dimensionless forms, as follows [37]:

$$\nabla^{*2}\phi_e^* = -\frac{(\kappa a)^2}{\sum_{i=1}^{4}\alpha_{21}}\sum_{i=1}^{4}\alpha_{11}\exp\left(-\alpha_{10}\phi_e^*\right) - h\rho_s^*,\ h = 0,\ 1 \tag{76.50}$$

$$\nabla^{*2}\delta\phi^* = \frac{(\kappa a)^2}{\sum_{i=1}^{4}\alpha_{21}}\sum_{i=1}^{4}\alpha_{21}\left(\delta\phi^* + g_i^*\right)\exp\left(-\alpha_{10}\phi_e^*\right) \tag{76.51}$$

$$\nabla^{*2}g_i^* = \alpha_{10}\nabla^*\phi_e^*\cdot\nabla^* g_i^* + Pe_i\left(\mathbf{u}^*\cdot\nabla^*\phi_e^*\right),\ i = 1, 2, 3, 4 \tag{76.52}$$

$$\nabla^*\cdot\mathbf{u}^* = 0 \tag{76.53}$$

$$-\nabla^*\delta p^* + \nabla^{*2}\mathbf{u}^* - h\left(\lambda_s a\right)^2\mathbf{u}^* + \left[\left(\nabla^{*2}\phi_e^* + h\rho_s^*\right)\nabla^*\delta\phi^* + \nabla^{*2}\delta\phi^*\nabla\phi_e^*\right] = \mathbf{0},\ h = 0,\ 1 \tag{76.54}$$

In these expressions, $\nabla^* = a\nabla$, $\nabla^{*2} = a^2\nabla^2$, $\phi_e^* = \phi_e/\phi_{\mathrm{ref}}$, $\delta\phi^* = \delta\phi/\phi_{\mathrm{ref}}$, $g_i^* = g_i/\phi_{\mathrm{ref}}$, $\rho_s^* = \rho_s a^2/\varepsilon_f\phi_{\mathrm{ref}}$, $\delta p^* = \delta p/[\varepsilon_f(\phi_{\mathrm{ref}})^2/a^2]$, and $\mathbf{u}^* = \mathbf{u}/U_{\mathrm{ref}}$, where $\phi_{\mathrm{ref}} = k_BT/ez_1$ and $U_{\mathrm{ref}} = \varepsilon_f(\phi_{\mathrm{ref}})^2/\eta a$ are a reference potential and a reference velocity, respectively; $\alpha_{\beta\zeta} = z_i^\beta n_{i0}^\zeta/z_1^\beta n_{10}^\zeta$; $\kappa = \left(\sum_{i=1}^{4}\left[n_{i0}(ez_i)^2/\varepsilon_f k_BT\right]\right)^{1/2}$ is the reciprocal Debye length; $\mathrm{Pe}_i = \varepsilon_f(\phi_{\mathrm{ref}})^2/\eta D_i$ the electric Peclet number of ith ionic species. As an example for an aqueous general NaCl solution at $T =$ 298K, $D_1(Na^+) = 1.33\times10^{-9}\mathrm{m}^2/\mathrm{s}$, $D_2(C1^-) = 2.03\times10^{-9}\mathrm{m}^2/\mathrm{s}$, $D_3(H^+) = 9.31\times10^{-9}\mathrm{m}^2/\mathrm{s}$, $D_4(OH^-) = 5.30\times10^{-9}\mathrm{m}^2/\mathrm{s}$, $\varepsilon_f = 7.08\times10^{-10}$ F/m, $\eta = 1\times10^{-3}\mathrm{Pa}\cdot\mathrm{s}$, $e = 1.602\times10^{-19}\mathrm{C}$, and $k_B = 1.38\times10^{-23}\mathrm{J/K}$, yielding $\mathrm{Pe}_1(Na^+) = 0.351, \mathrm{Pe}_2(Cl^-) = 0.230, \mathrm{Pe}_3(H^+) = 0.050$, and $\mathrm{Pe}_4(OH^-) = 0.088$ [24].

76.3.2 Boundary Conditions

Let us introduce next the boundary conditions associated with the governing equations for the electric, the ionic concentration, and the flow fields for the problem illustrated in Fig. 76.2. We assume the following: (1) the rigid core surface (Ω_r) of the soft particle is uncharged, nonconductive, impermeable to ionic species, and nonslip; (2) both the electrical potential and the corresponding electric field are continuous on the soft layer–liquid interface (Ω_p); (3) both the concentration and the flux of *i*th ionic species are continuous on the soft layer–liquid interface (Ω_p); (4) the fluid velocity and both the normal and the tangential components of the hydrodynamic stress tensor are continuous on the soft layer–liquid interface (Ω_p); and (5) the electric field, the concentration, and the flow fields at a point far away from the soft particle (i.e., on the cylindrical computational domain, Ω_e and Ω_w) are uninfluenced by its presence. If the permittivity ε_f and the viscosity η of the liquid phase inside the soft layer are identical to those outside it, the above conditions yield the following boundary conditions associated with Eqs. (76.50)–(76.54) [22, 35, 37]:

$$\mathbf{n}\cdot\nabla^*\phi_e^* = 0 \text{ on } \Omega_r \tag{76.55}$$

$$\mathbf{n}\cdot\nabla^*\delta\phi^* = 0 \text{ on } \Omega_r \tag{76.56}$$

$$\mathbf{n}\cdot\nabla^* g_i^* = 0,\ i = 1,1,2,3,4 \text{ on } \Omega_r \tag{76.57}$$

$$\mathbf{u}^* = 0 \text{ on } \Omega_r \tag{76.58}$$

$$\phi_e^*\big|_{\Omega_p^-} = \phi_e^*\big|_{\Omega_p^+} \text{ and } \mathbf{n}\cdot\nabla^*\phi_e^*\big|_{\Omega_p^-} = \mathbf{n}\cdot\nabla^*\phi_e^*\big|_{\Omega_p^+} \tag{76.59}$$

$$\delta\phi^*\big|_{\Omega_p^-} = \delta\phi^*\big|_{\Omega_p^+} \text{ and } \mathbf{n}\cdot\nabla^*\delta\phi^*\big|_{\Omega_p^-} = \mathbf{n}\cdot\nabla^*\delta\phi^*\big|_{\Omega_p^+} \tag{76.60}$$

$$g_i^*\big|_{\Omega_p^-} = g_i^*\big|_{\Omega_p^+} \text{ and } \mathbf{n}\cdot\nabla^* g_i^*\big|_{\Omega_p^-} = \mathbf{n}\cdot\nabla^* g_i^*\big|_{\Omega_p^+},\ i = 1,2,3,4 \tag{76.61}$$

$$\mathbf{u}^*\big|_{\Omega_p^-} = \mathbf{u}^*\big|_{\Omega_p^+},\ \mathbf{n}\cdot\mathbf{u}^*\big|_{\Omega_p^-} = \mathbf{n}\cdot\mathbf{u}^*\big|_{\Omega_p^+}, \text{ and } \mathbf{n}\times\mathbf{u}^*\big|_{\Omega_p^-} = \mathbf{n}\times\mathbf{u}^*\big|_{\Omega_p^+} \tag{76.62}$$

$$\mathbf{n}\cdot(\boldsymbol{\sigma}^{\mathbf{H}^*}\cdot\mathbf{n})\Big|_{\Omega_p^-} = \mathbf{n}\cdot(\boldsymbol{\sigma}^{\mathbf{H}^*}\cdot\mathbf{n})\Big|_{\Omega_p^+} \text{ and } \mathbf{n}\times(\boldsymbol{\sigma}^{\mathbf{H}^*}\cdot\mathbf{n})\Big|_{\Omega_p^-} = \mathbf{n}\times(\boldsymbol{\sigma}^{\mathbf{H}^*}\cdot\mathbf{n})|_{\Omega_p^+} \tag{76.63}$$

$$\mathbf{n}\cdot\nabla^*\phi_e^* = 0 \text{ on } \Omega_e \tag{76.64}$$

$$\mathbf{n}\cdot\nabla^*\delta\phi^* = -E_z^* \text{ on } \Omega_e \tag{76.65}$$

$$g_i^* = -\delta\phi^* \text{ on } \Omega_e \tag{76.66}$$

$$\mathbf{u}^* = -U_p^*\mathbf{e}_z \text{ on } \Omega_e \tag{76.67}$$

$$\mathbf{n}\cdot\nabla^*\phi_e^* = 0 \text{ on } \Omega_w \tag{76.68}$$

$$\mathbf{n}\cdot\nabla^*\delta\phi^* = 0 \text{ on } \Omega_w \tag{76.69}$$

$$\mathbf{n}\cdot\nabla^* g_i^* = 0,\ i = 1,2,3,4 \text{ on } \Omega_w \tag{76.70}$$

$$\mathbf{u}^* = -U_p^*\mathbf{e}_z \text{ on } \Omega_w \tag{76.71}$$

In the above, $\boldsymbol{\sigma}^{\mathbf{H}^*} = \boldsymbol{\sigma}^{\mathbf{H}}/[\varepsilon_f(\phi_{\text{ref}})^2/a^2]$, $E_z^* = E_z/(\phi_{\text{ref}}/a)$ and $U_p^* = U_p/U_{\text{ref}}$, where U_p is the electrophoretic velocity of the soft particle in the z direction. Equation (76.65) depicts the fact that the local electric field on Ω_e arises from the applied electric field [49]. Equation (76.66) implies that the number concentration of *i*th ionic species on the outer computational domain, which is very large compared to the size of the particle, reaches the Boltzmann distribution at equilibrium state:

$$n_i = n_{ie} = n_{i0}\exp\left(-\frac{ez_i\phi_e}{k_BT}\right),\ i = 1,2,3,4 \tag{76.72}$$

Here, n_{ie} is the bulk number concentration of *i*th ionic species at equilibrium.

76.3.3 Solution Procedure

The forces acting on the particle include an electric force and a hydrodynamic force. In this case, only z components of these forces, F_e and F_h, respectively, need to be considered. Because the problem under consideration is θ-symmetric, F_e and F_h, expressed in Eqs. (76.28) and (76.29), can be rewritten, in the cylindrical coordinates, as [32, 42]

$$F_e = \int_{\Omega_p}\varepsilon_f\left[\frac{\partial\phi}{\partial z}\frac{\partial\phi}{\partial r}n_r - \frac{1}{2}\left(\frac{\partial\phi}{\partial z}\right)^2 n_z - \frac{1}{2}\left(\frac{\partial\phi}{\partial r}\right)^2 n_z\right]d\Omega_p \tag{76.73}$$

$$F_h = \int_{\Omega_p}\left[-pn_z + 2\eta\frac{\partial u_z}{\partial z}n_z + \eta\left(\frac{\partial u_z}{\partial r} + \frac{\partial u_r}{\partial z}\right)n_r\right]d\Omega_p \tag{76.74}$$

Here, n_r is the r component of $\mathbf{n}$ and u_r and u_z are the r and the z components of $\mathbf{u}$, respectively.

Suppose that the applied electric field is weak relative to that established by the charged particle and the equilibrium electric field induced by the particle has no contribution to its movement. Substituting $\phi = \phi_e + \delta\phi$ into Eq. (76.73), neglecting the terms involving $(\partial\phi_e/\partial z)(\partial\phi_e/\partial r)$, $(\partial\phi_e/\partial z)^2$, and $(\partial\phi_e/\partial r)^2$ because the particle is unable to be driven by its equilibrium electric field, and the terms associated with the product of two perturbed quantities, $(\partial\delta\phi/\partial z)(\partial\delta\phi/\partial r)$, $(\partial\delta\phi/\partial z)^2$, and $(\partial\delta\phi/\partial r)^2$ because they are relatively small, and collecting the rest terms that are on the order of E_z, one

obtains

$$F_e = \int_{\Omega_p} \left\{ \varepsilon_f \left[\frac{\partial \phi_e}{\partial z}\frac{\partial \delta\phi}{\partial r} + \frac{\partial \delta\phi}{\partial z}\frac{\partial \phi_e}{\partial r} \right] n_r - \varepsilon_f \left[\frac{\partial \phi_e}{\partial z}\frac{\partial \delta\phi}{\partial z} + \frac{\partial \phi_e}{\partial r}\frac{\partial \delta\phi}{\partial r} \right] n_z \right\} d\Omega_p \quad (76.75)$$

This expression is suitable for various kinds of biocolloids with arbitrary geometry and arbitrary level of the charge density of soft layer. If we let $\mathbf{u} = u_r \mathbf{e}_r + u_z \mathbf{e}_z$, then it can be shown that Eq. (76.74) can be rewritten as [32, 38]

$$F_h = \int_{\Omega_p} \left[\left(-\delta p + 2\eta \frac{\partial u_z}{\partial z} \right) n_z + \eta \left(\frac{\partial u_z}{\partial r} + \frac{\partial u_r}{\partial z} \right) n_r \right] d\Omega_p \quad (76.76)$$

In terms of the scaled symbols, $F_e^* = F_e/\varepsilon_f(\phi_{\text{ref}})^2$ and $F_h^* = F_h/\varepsilon_f(\phi_{\text{ref}})^2$, results in

$$F_e^* = \int_{\Omega_p^*} \left\{ \left[\frac{\partial \phi_e^*}{\partial z^*}\frac{\partial \delta\phi^*}{\partial r^*} + \frac{\partial \delta\phi^*}{\partial z^*}\frac{\partial \phi_e^*}{\partial r^*} \right] n_r - \left[\frac{\partial \phi_e^*}{\partial z^*}\frac{\partial \delta\phi^*}{\partial z^*} + \frac{\partial \phi_e^*}{\partial r^*}\frac{\partial \delta\phi^*}{\partial r^*} \right] n_z \right\} d\Omega_p^* \quad (76.77)$$

$$F_h^* = \int_{\Omega_p^*} \left(\boldsymbol{\sigma}^{\mathbf{H}^*} \cdot \mathbf{n} \right) \cdot \mathbf{e}_z d\Omega_p^* = \int_{\Omega_p^*} \left[\left(-\delta p^* + 2\frac{\partial u_z^*}{\partial z^*} \right) n_z + \left(\frac{\partial u_z^*}{\partial r^*} + \frac{\partial u_r^*}{\partial z^*} \right) n_r \right] d\Omega_p^* \quad (76.78)$$

Here, $z^* = z/a$, $r^* = r/a$, $u_r^* = u_r/U_{\text{ref}}$, $u_z^* = u_z/U_{\text{ref}}$, and $\Omega_p^* = \Omega_p/a^2$ is the scaled surface area of the soft particle. The electrophoretic mobility of the soft particle can be determined from the fact that the net force acting on it in the z-direction vanishes at steady state:

$$F_e^* + F_h^* = 0 \quad (76.79)$$

In general, the procedure for solving Eqs. (76.49)–(76.54) subject to the prespecified boundary conditions, such as Eqs. (76.55)–(76.71), involves a tedious trial-and-error numerical procedure. However, because the problem under consideration is of linear nature, that procedure can be avoided by adopting a supposition method [23, 37, 50]. Similar to the treatment of O'Brien and White [46], the present electrophoresis problem is decomposed into two subproblems: (1) the soft particle moves with a constant scaled velocity U_p^* in the absence of $\mathbf{E}_z$; and (2) $\mathbf{E}_z$ is applied, but the particle is held fixed. Let F_{ej}^* and F_{hj}^* be the scaled electric and hydrodynamic forces acting on the soft particle in the z direction in subproblem j, $j = 1,2$, respectively. Then, the total force acting on the soft particle in the z direction in subproblem j, that is, F_j^*, is

$$F_j^* = F_{ej}^* + F_{hj}^*, \; j = 1, 2 \quad (76.80)$$

Because the total force acting on the particle in the z direction must vanish at steady state, $F_1^* + F_2^* = 0$, yielding

$$\mu^* = \frac{U_p^*}{E_z^*} = -\frac{f_2}{f_1} \quad (76.81)$$

where μ^* is the scaled electrophoretic mobility of the soft particle, $F_1^* = f_1 U_p^*$ and $F_2^* = f_2 E_z^*$, where the proportional constants f_1 and f_2 are independent of U_p^* and E_z^*, respectively. The solution procedure for μ^* includes the following steps [23, 51]: (1) assume an arbitrary value for U_p^* in Eqs. (76.67) and (76.71), and solve the governing equations for the electric, the concentration, and the flow fields [Eqs. (76.49)–(76.54)] numerically, subject to the associated boundary conditions [Eqs. (76.55)–(76.71); (2) calculate F_{ej}^*, F_{hj}^*, and F_j^* $(= F_{ej}^* + F_{hj}^*)$, $j = 1$ and 2, using Eqs. (76.77) and (76.78); and (3) apply $F_1^* = f_1 U_p^*$ and $F_2^* = f_2 E_z^*$ to obtain f_1 and f_2, and then to evaluate μ^* using Eq. (76.81). Several finite-element method based commercial software, such as COMSOL, Fluent, FlexPDE, FIDAP, to name only a few, can be applied to directly solve the system under consideration.

76.3.4 Model Validation by Experimental Data

The applicability of the numerical model introduced above is verified by fitting it to experimental data given in two studies [52, 53]. In the former, the electrophoresis of creatine-covered gold nanoparticles of radius $a = 15$ nm, comprising a rigid gold core of radius $b = 10.5$ nm and an biological creatine soft layer of thickness $c = 4.5$ nm, in an aqueous NaCl solution at pH = 7.4 was conducted, and, in the latter, the electrophoresis of succinoglycan polyelectrolytes (PEs) of radius $a = 10.8$ nm, viewed as a fully porous spherical particle (i.e., $a = c$ and $b = 0$), was examined in an aqueous NaCl solution at pH = 10.3. Figure 3 shows the variation of the electrophoretic mobility of the creatine-covered gold nanoparticle, $\mu = U_p/E_z = \mu^* \times (aU_{\text{ref}}/\phi_{\text{ref}})$, as a function of the background NaCl concentration C_{NaCl}; both the experimental results of Lopez-Viota et al. [52] (symbols with error bars) and the result predicted by the abovementioned numerical model (solid line) are presented. In this case, pK_A and pK_B, with $pK_m = -\log K_m$ ($m = A$ or B), are fixed at 3.43 and -10.57 [54, 55], respectively, because the soft layer of the particle is creatine. As can be seen in Fig. 76.3, the

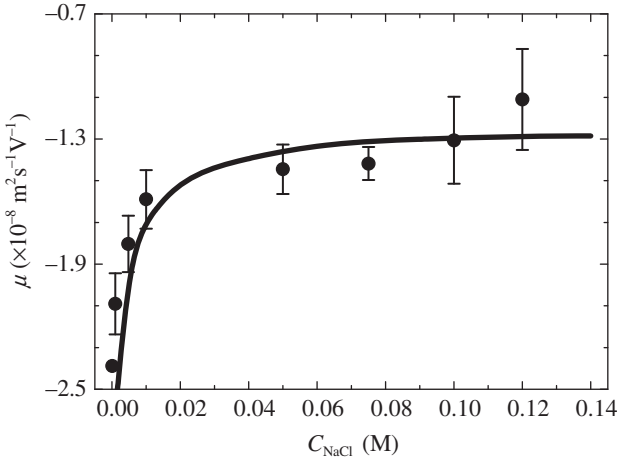

FIGURE 76.3 Dependence of the electrophoretic mobility μ on NaCl concentration C_{NaCl} for the case where the liquid phase contains creatine-covered gold nanoparticles of radius 15 nm, comprising a rigid gold core of radius 10.5 nm and an ion-penetrable creatine soft layer of thickness 4.5 nm, at pH = 7.4. Circles with error bars: experimental data of Lopez-Viota et al. [52]; solid line: results predicted by the present model at $pK_A = 3.43$, $pK_B = -10.57$, $N_{As} = 338$ mol/m^3, $N_{Bs} = 322$ mol/m^3, and $\lambda_s a = 3$.

prediction from the present model, with $N_{As} = 338$ mol/m^3, $N_{Bs} = 322\,x$mol/m^3, and $\lambda_s a = 3$, is in good agreement with the general trend of the experimental data.

To model succinoglycan in the second case, we let $pK_A = 4.58$ and $pK_B = -8.6$ [53], implying that it is negatively charged at the experimental condition of pH = 10.3. In addition, we further let $b = 0$ to simulate a PE, an entirely porous particle, and therefore, the corresponding boundary conditions on the rigid core of a soft particle, Eqs. (76.55)–(76.58), should be replaced by the fact that the electrical potential, the concentration of ionic species i, and the fluid velocity are all finite in the interior of PE. Figure 76.4 illustrates the variation of the scaled electrophoretic mobility of the succinoglycan μ^* with the ionic strength of NaCl. The solid line represents the abovementioned numerical result with considering the DLP effect, and circles with error bars represent the experimental data obtained by Duval et al. [53]. For comparison, the corresponding result for the case where the DLP effect is neglected (dashed line) is also presented. As shown in Fig. 76.4, the present model with $N_{As} = 213$ mol/m^3, $N_{Bs} = 26$ mol/m^3, and $\lambda_s^{-1} = 0.635$ nm successfully captures the dependence of the scaled electrophoretic mobility on the ionic strength of NaCl, and its predictions agree well with the experimental results. However, if the DLP effect is neglected, the predicted μ^* increases monotonically with decreasing ionic strength, and significantly deviates from the experimental data, especially at low ionic strength. This arises from the fact that the effect of DLP, which retards the particle motion [22, 23, 37], is significant when the Debye length is comparable to the particle radius (i.e., $\kappa a \cong 1$).

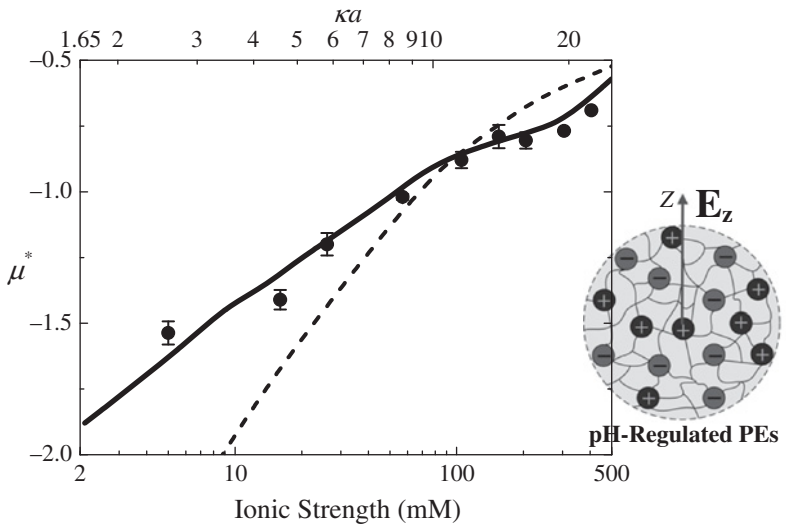

FIGURE 76.4 Dependence of the scaled electrophoretic mobility μ^* on NaCl ionic strength (and the corresponding κa) for the case where the liquid phase contains pH-regulated succinoglycan PEs, schematically represented in the inset, of radius 10.8 nm at pH = 10.3. Circles with error bars: experimental data of Duval et al. [53]; solid (dashed) line: results predicted by the present model with (without) taking into account the DLP effect at $pK_A = 4.58$, $pK_B = -8.6$, $N_{As} = 213$ mol/m^3, $N_{Bs} = 26$ mol/m^3, and $\lambda_s^{-1} = 0.635$ nm. (Adapted with permission from Yeh et al. 2012 [37], pp. 7575—7584.)

76.3.5 Electrokinetics of a pH-Regulated Soft Biocolloid

In the last section, it was verified that the numerical procedure described earlier is capable of capturing the underlying physics of the electrophoretic mobility of pH-regulated biocolloids, including soft particles and PEs. For example, the numerical model is applied to examine the electrophoretic behavior of a pH-regulated soft biocolloid under various general background solution properties such as pH and salt concentration. To simulate a pH-regulated soft biocolloid, we consider the typical case of a soft particle of radius $a = 10$ nm, constituting a rigid core of radius $b = 7$ nm and a soft layer composed of amino acid with thickness $c = 3$ nm, $pK_A = 2.5$ (α-carboxyl), $pK_B = -9.5$ (α-amino) [56], $N_{As} = 500$ mol/m^3, and $N_{Bs} = 500$ mol/m^3 [1]. The values of pK_A and pK_B considered imply that the isoelectric point (IEP) of the soft particle is 6. For illustration, we assume that the liquid phase is filled with KCl electrolyte and that its pH is adjusted by KOH and HCl, implying that four major kinds of ionic species, namely, K^+, Cl^-, H^+, and OH^-, are considered. Therefore, the following electric Peclet number of the ionic species i, $Pe_1(K^+) = 0.238$, $Pe_2(Cl^-) = 0.230$, $Pe_3(H^+) = 0.050$, and $Pe_4(OH^-) = 0.088$ [24], are used in the simulations.

As is well known, the electrophoretic behavior of soft biocolloids is highly dependent on the charge properties of the ion-penetrable soft layer in contact with an aqueous electrolyte solution, due to the dissociation/association chemistry reactions of molecular chains in the soft layer. The charge properties of soft biocolloids, therefore, depend apparently on the background medium environments such as pH and salt concentration [35–37, 39]. To clearly visualize these effects, the influences of the solution properties, pH and the background salt concentration C_{KCl}, on the scaled volume-averaged charge density of the soft layer, $\bar{\rho}_s^*$, of a pH-regulated soft particle are illustrated in Fig. 76.5, and those on its scaled Donnan potential, $\psi_d^* = \psi_d/\phi_{ref}$, where ψ_d is defined as the electric potential (i.e., Donnan potential) on the rigid core–liquid interface of the soft particle [3,4,7], in Fig. 76.6. Here, $\bar{\rho}_s^*$ is defined as [36, 37]

$$\bar{\rho}_s^* = \frac{\int_{V_s^*} \rho_s^* dV_s^*}{\int_{V_s^*} dV_s^*} \tag{76.82}$$

where $V_s^* = V_s/a^3$, where V_s is the volume of the soft layer. As expected, because the IFP of the soft layer of a soft particle is 6, the soft particle is positively charged (i.e., $\bar{\rho}_s^* > 0$) if pH < 6 and negatively charged (i.e., $\bar{\rho}_s^* < 0$) if pH > 6, as depicted in Fig. 76.5a, which also shows that $\left|\bar{\rho}_s^*\right|$ increases with a more significant deviation of the solution pH from 6. This arises from the fact that the larger the deviation, the more amounts of A^- (or BH^+) formed from AH (B), yielding more amount of fixed charges in the soft layer. It is worth noting in Fig. 76.5b that $\left|\bar{\rho}_s^*\right|$ increases monotonically with an increase in C_{KCl}. This interesting behavior is unexpected and can be explained by the spatial distribution of H^+ illustrated in Fig. 76.7, where the radial variations in the scaled equilibrium number concentration of H^+, n_{3e}/n_{30}, for various levels of C_{KCl} are presented. Because the soft particle is negatively charged at pH = 10, counterions, including K^+ and H^+, are electrostatically attracted into the soft layer (light gray region) of a soft particle. As C_{KCl} increases, most of H^+ are excluded by the other cations, K^+, from the interior of the soft layer of a soft particle to its exterior. In this case, a greater number of A^- are dissociated from HA molecules and, therefore, a higher negative $\left|\bar{\rho}_s^*\right|$.

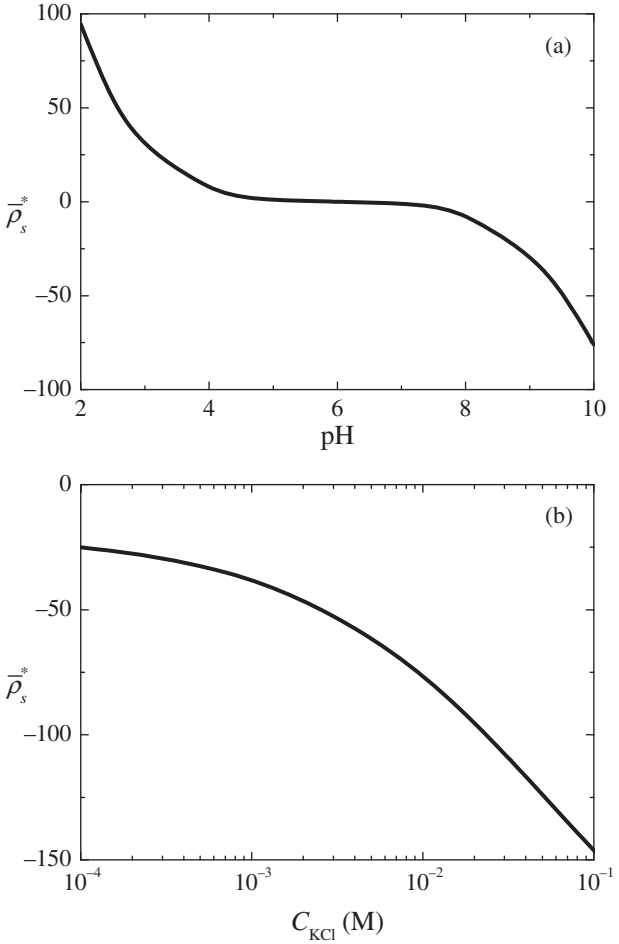

FIGURE 76.5 Scaled volume-averaged charge density of the soft layer $\bar{\rho}_s^*$ of a pH-regulated soft particle as a function of pH at the background salt concentration $C_{KCl} = 0.01$M (a) and as a function of C_{KCl} at pH = 10 (b).

Figure 76.6a indicates that the magnitude of ψ_d^*, namely, $\left|\psi_d^*\right|$, increases with an increase in the deviation of the solution pH from 6, which is expected because of an increase in

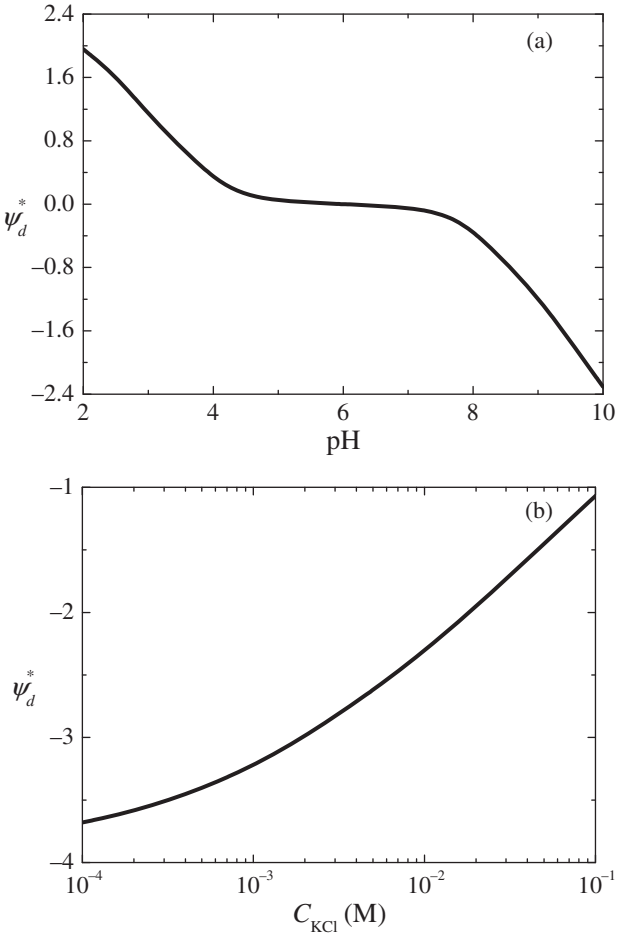

FIGURE 76.6 Scaled Donnan potential ψ_d^* of a pH-regulated soft particle as a function of pH at the background salt concentration $C_{KCl} = 0.01$M (a) and as a function of C_{KCl} at pH = 10 (b). Other parameters are the same as those in Fig. 76.5.

the corresponding $\bar{\rho}_s^*$ observed in Fig. 76.5a. It is interesting to note in Fig. 76.6b that $\left|\psi_d^*\right|$ decreases monotonically with increasing C_{KCl}, which is opposite to the trend of the corresponding $\left|\bar{\rho}_s^*\right|$ depicted in Fig. 76.5b. This is because although $\left|\bar{\rho}_s^*\right|$ increases with increasing C_{KCl}, the increases in $\left|\bar{\rho}_s^*\right|$ and C_{KCl} also lead to an increase in the net amount of counterions condensed inside the soft layer of a soft particle, yielding a lower $\left|\psi_d^*\right|$.

Figure 76.8 summarizes the influence of the background salt concentration C_{KCl} and pH on the scaled electrophoretic behavior μ^* of a pH-regulated soft particle for various values of the scaled softness parameter $\lambda_s a$. As expected, the larger the value of $\lambda_s a$, the more compact is the structure of the soft layer of a soft particle, yielding a larger hydrodynamic drag force originating from the soft layer and a smaller electrophoretic mobility. Figure 76.8a indicates that μ^* is positive if pH < 6 and becomes negative if pH > 6, and that the

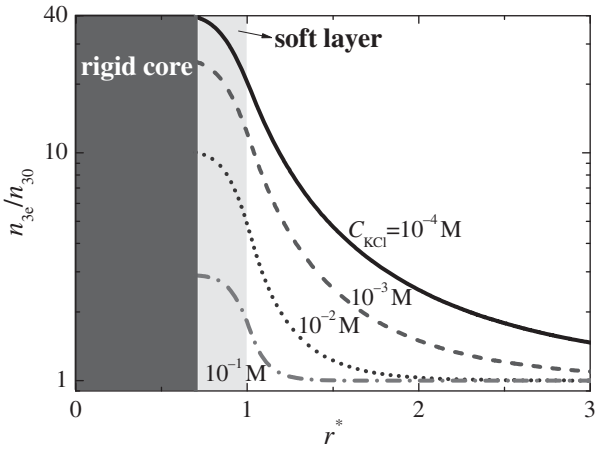

FIGURE 76.7 Variations of the scaled equilibrium number concentration of H^+, namely, n_{3e}/n_{30}, as a function of r^* $(= r/a)$ near a pH-regulated soft particle for various background salt concentrations C_{KCl} at pH = 10. The deep and light gray regions highlight, respectively, the interiors of the rigid core and the ion-penetrable soft layer of the soft particle. Other parameters are the same as those in Fig. 76.5b.

magnitude of μ^* increases with increasing deviation of pH from 6. These findings are consistent with the qualitative behaviors of $\bar{\rho}_s^*$ and ψ_d^* seen in Fig. 76.5a and 76.6a and can be explained by the same reasoning.

Figure 76.8b suggests that the qualitative behavior of μ^* as C_{KCl} varies depends highly on the level of $\lambda_s a$. If $\lambda_s a$ is small (a loose-structured soft layer), $|\mu^*|$ shows a local minimum as C_{KCl} varies; however, if $\lambda_s a$ is large (a compact-structured soft layer), then $|\mu^*|$ decreases monotonically with increasing C_{KCl}. The former can be attributed to the DLP effect, which becomes significant and remarkably reduces electric driving force acting on a particle when the thickness of the electric double layer is comparable to the particle radius (i.e., $\kappa a \cong 1$) and its surface potential is apparently larger than a thermal potential (25.68 mV) [24,37,44]. In the present case, because the Donnan potential of the soft particle is extremely high at low salt concentration, as shown in Fig. 76.6b, the effect of DLP becomes significant and apparently reduces the particle mobility when $C_{KCl} \approx 0.001$ M (i.e., $\kappa a \cong 1$). On the other hand, a monotonic decrease in $|\mu^*|$ with C_{KCl} at sufficiently high $\lambda_s a$ can be explained by the fact that the DLP effect is offset by the electroosmotic flow of counterions [24]. As pointed out by Yeh and Hsu [24], the more compact the structure of the soft layer of a soft particle the less significant is the convective flow of ionic species inside the soft layer.

76.4 SUMMARY

A multiple-ion model for analyzing both the charge properties and the electrophoretic behavior of a pH-regulated soft

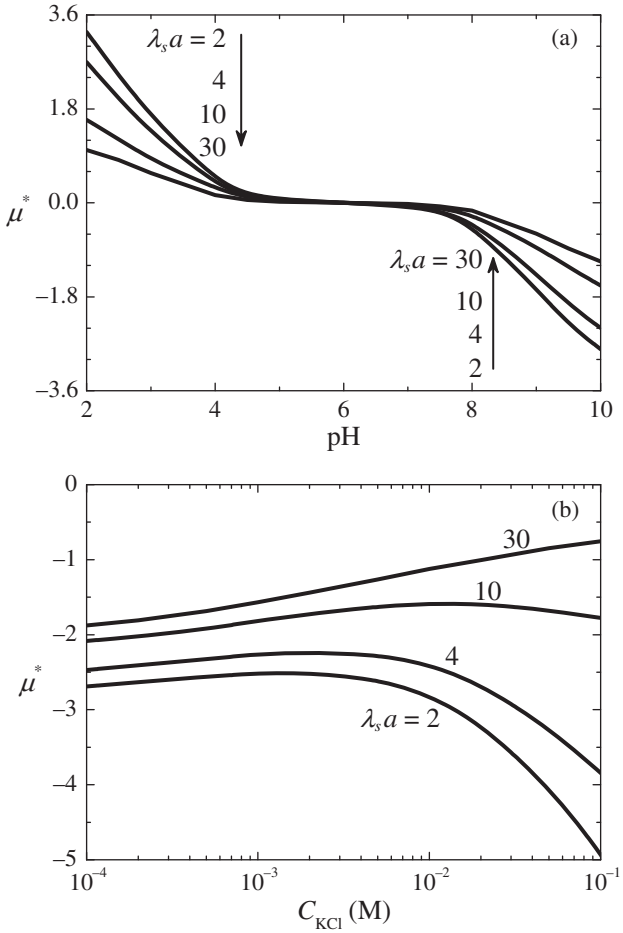

FIGURE 76.8 Scaled electrophoretic mobility μ^* of a pH-regulated soft particle as a function of pH for various scaled softness parameters $\lambda_s a$ at the background salt concentration $C_{\mathrm{KCl}} = 0.01$ M (a) and as a function of C_{KCl} at pH = 10 (b). Other parameters are the same as those in Fig. 76.5.

particle, making up a rigid core and a porous soft layer containing both dissociable acidic functional groups AH and associable basic functional groups B, has been developed and verified. This type of soft particle is capable of simulating biocolloids such as proteins, viruses, and cells. The model introduced takes into account the effect of double-layer polarization (DLP) arising from the convective flow of ionic species surrounding a charged particle, and its predictions agree well with the existing experimental data of creatine-covered gold nanoparticles and succinoglycan polyelectrolytes, fully porous charged particles. Therefore, the model successfully captures the underlying physics of the electrophoresis of pH-regulated soft biocolloids. Simulations exemplified show that in addition to its softness degree of the soft layer, the qualitative electrophoretic behavior of a pH-regulated soft particle depends highly on the solution properties such as pH and background salt concentration. If pH deviates apparently from the isoelectric point of a pH-regulated soft particle, yielding a higher charge density of the soft layer and Donnan potential, the DLP effect becomes significant, which limits the mobility of a soft particle. For a loose-structured soft particle, the behavior of its mobility is significantly influenced by the DLP effect and shows a local minimum as the salt concentration varies. On the contrary, for a compact-structured soft particle, the effect of DLP on its electrophoretic behavior is insignificant, and, therefore, the mobility decreases with increasing salt concentration. The model proposed can be applied directly to interpret the observed experimental data of pH-regulated biocolloids, to estimate the key adjustable parameters in the model, and to design a relevant electrophoresis apparatus.

76.5 NOTATIONS

a = radius of a soft particle (m)
b = radius of rigid core of a soft particle (m)
A^- = dissociated form of the functional group AH (–)
AH = acidic functional group (–)
B = basic functional group (–)
BH^+ = associated form of B (-)
c = thickness of soft layer (m)
C_{i0} = bulk molar concentration of ionic species i (M)
C_{10} = bulk molar concentration of K^+ (or Na^+) (M)
C_{20} = bulk molar concentration of Cl^- (M)
C_{30} = bulk molar concentration of H^+ (M)
C_{40} = bulk molar concentration of OH^- (M)
C_{KCl} = background KCl concentration (M)
C_{NaCl} = background NaCl concentration (M)
d = radius of cylindrical computational domain (m)
D_i = diffusivity of ionic species i (m^2/s)
e = elementary charge (C)
$\mathbf{e}_r$ = unit vector in radial direction (–)
$\mathbf{e}_z$ = unit vector in z direction (-)
E_z = strength of applied electric field (V/m)
E_z^* = $E_z/(\phi_{\mathrm{ref}}/a)$, scaled E_z (–)
$\mathbf{E}_z$ = applied uniform electric field (V/m)
f_1, f_2 = proportional constant (–)
F = Faraday constant (C/mol)
F_1^* = $F_{e1}^* + F_{h1}^*$, z component of scaled forces in subproblem 1 (see Section 76.3.3) (–)
F_2^* = $F_{e2}^* + F_{h2}^*$, z component of scaled forces in subproblem 2 (–)
F_e = electrical force acting on a particle in z direction (N)
F_e^* = $F_e/\varepsilon_f(\phi_{\mathrm{ref}})^2$, scaled form of F_e defined by Eq. (76.77) (–)
F_{ej}^* = z component of scaled electrical force in subproblem j (–)
F_h = hydrodynamic force acting on a particle in z direction (N)

F_h^* = $F_h/\varepsilon_f(\phi_{\text{ref}})^2$, scaled form of F_h defined by Eq. (76.78) (α)
F_{hj}^* = z component of scaled hydrodynamic force in subproblem j (–)
F_j^* = $F_{ej}^* + F_{hj}^*$, scaled total force acting on a particle in z direction in subproblem j (N)
g_i = perturbed potential associated with ionic species i (V)
g_i^* = g_i/ϕ_{ref}, scaled form of g_i (–)
h = unit step region function"n ($h = 0$ for the liquid phase outside of a soft particle $h = 1$ inside soft layer) (–)
H^+ = hydrogen ion (–)
$[H^+]$ = molar concentration distribution of H^+ (M)
i = index for ionic species (–)
$\mathbf{I}$ = unit tensor (–)
$\mathbf{J}_i$ = flux of ionic species i (1/s/m^2)
k_B = Boltzmann constant (J/K)
K_A = equilibrium dissociation constant defined by Eq. (76.7) (mol/m^3)
K_B = equilibrium association constant defined by Eq. (76.8) (mol/m^3)
n_i = number concentration of ionic species i (#/m^3)
n_{ie} = number concentration of ionic species i at equilibrium (#/m^3)
n_{3e} = number concentration of H^+ at equilibrium (#/m^3)
n_{i0} = bulk number concentration of ionic species i (#/m^3)
n_{30} = bulk number concentration of H^+ (#/m^3)

ELECTROPHORETIC MOBILITY OF SOFT PARTICLES

Kimiko Makino and Hiroyuki Ohshima

Faculty of Pharmaceutical Sciences, Tokyo University of Science, 2641 Yamazaki Noda, Chiba 278-8510, Japan

77.1 INTRODUCTION

Measurement of the electrophoretic mobility of charged colloidal particles in an electrolyte solution is a powerful tool for estimating their surface properties. Under an external electric field $\boldsymbol{E}$, charged colloidal particles move with a constant velocity $\boldsymbol{U}$ in a liquid, as a result of the balance between the electric force accelerating the particles and a viscous force exerted by the liquid on the particles tending to retard the particles. This phenomenon is called *electrophoresis*. Usually, we treat the case where the magnitude of the applied electric field $\boldsymbol{E}$ is not very large. In such cases the velocity $\boldsymbol{U}$ of the particles, which is called *electrophoretic velocity*, is proportional to $\boldsymbol{E}$ in magnitude. The magnitude ratio of $\boldsymbol{U}$ to $\boldsymbol{E}$ is called *electrophoretic mobility* μ, which is defined by $\mu = U/E$ (where $U = |\boldsymbol{U}|$ and $E = |\boldsymbol{E}|$). In this chapter we consider the electrophoretic mobility of a soft particle (i.e., a hard particle covered with an ion-penetrable surface layer of polyelectrolytes) in comparison with that of a hard particle without surface structures.

77.2 ELECTROPHORETIC MOBILITY OF HARD PARTICLES

The most widely employed formula for the electrophoretic mobility μ of a charged spherical particle of radius a in an electrolyte solution is Smoluchowski's formula [1], which relates the electrophoretic mobility μ of the particle to its zeta-potential ζ:

$$\mu = \frac{\varepsilon_r \varepsilon_0}{\eta} \zeta \tag{77.1}$$

Here, ε_r and η are, respectively, the relative permittivity and the viscosity of the electrolyte solution and ε_0 is the permittivity of a vacuum. The *zeta-potential* ζ is defined as the potential at the plane where the liquid velocity relative to the particle is zero. This plane, which is called the *slipping plane* or the *shear plane*, does not necessarily coincide with the particle surface. Only if the slipping plane is located at the particle surface does the zeta-potential ζ become equal to the surface potential ψ_0. Equation (77.1) is the correct limiting mobility equation for very large particles and is valid irrespective of the shape of the particle, provided that the dimension of the particle is much larger than the Debye length $1/\kappa$, where κ is the Debye–Hückel parameter, and thus the particle surface can be considered to be locally planar. For a symmetric electrolyte solution of valence z and bulk concentration (number density) n, the Debye–Hückel parameter κ is given by

$$\kappa = \left(\frac{2z^2 e^2 n}{\varepsilon_r \varepsilon_0 kT} \right)^{1/2} \tag{77.2}$$

where e is the elementary electric charge, k is Boltzmann's constant, and T is the absolute temperature.

For a planar surface, the surface potential ψ_0 is related to the surface charge density σ of the particle by

$$\sigma = (8n\varepsilon_r \varepsilon_0 kT)^{1/2} \sinh\left(\frac{ze\psi_0}{2kT} \right) \tag{77.3}$$

or

$$\psi_0 = \left(\frac{2kT}{ze} \right) \ln \left[\frac{\sigma}{(8n\varepsilon_r \varepsilon_0 kT)^{1/2}} + \left(\frac{\sigma^2}{8n\varepsilon_r \varepsilon_0 kT} + 1 \right)^{1/2} \right] \tag{77.4}$$

77.3 ELECTROPHORETIC MOBILITY OF SOFT PARTICLES

This section deals with a general theory of electrophoresis of soft particles and approximate analytic expressions for the mobility of soft particles [2–15]. This theory unites the electrophoresis theories of hard particles and of polyelectrolytes, since a soft particle tends to become a hard particle in the absence of the polymer layer and to become a polyelectrolyte in the absence of the particle core.

Consider a spherical soft particle, that is, a charged spherical particle covered with an ion-penetrable layer of polyelectrolytes moving with a velocity $\boldsymbol{U}$ in a liquid containing a general electrolyte in an applied electric field $\boldsymbol{E}$. We assume that the uncharged particle core of radius a is coated with an ion-penetrable layer of polyelectrolytes of thickness d and that fixed charges are distributed at a density of $\rho_{\text{fix}}(\boldsymbol{r})$. If ionized groups of valence Z are distributed within the polyelectrolyte layer at a uniform density N, then the polyelectrolyte later is uniformly charged at a constant density $\rho_{\text{fix}} = ZeN$. The polymer-coated particle has thus an inner radius a and an outer radius $b \equiv a + d$ (Fig. 77.1).

We adopt the model of Debye–Bueche [16] that the polymer segments are regarded as resistance centers distributed in the polyelectrolyte layer, exerting frictional forces on the liquid flowing in the polyelectrolyte layer. In the following text, we consider the case where a is much larger than $1/\kappa$ so that the particle surface can be considered as planar (Fig. 77.2).

We take an x axis perpendicular to the particle surface with its origin at $x = 0$ so that the region $-d < x < 0$ corresponds to the surface layer and the region $x > 0$ corresponds to the external region of the surface layer. The fundamental electrokinetic equations for the liquid velocity $u(x)$ at position

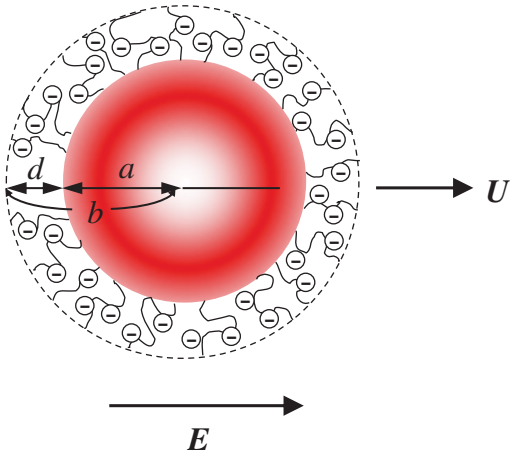

FIGURE 77.1 Spherical soft particle consisting of the particle core of radius a covered with an ion-penetrable surface layer of thickness d; $b = a + d$ is the outer radius. The particle moves with a velocity $\boldsymbol{U}$ in an applied electric field $\boldsymbol{E}$.

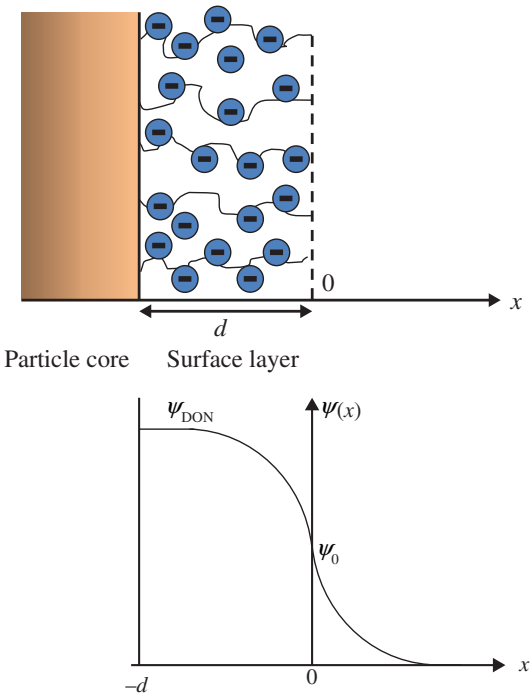

FIGURE 77.2 Schematic representation of the distribution of electrolyte ions and the potential distribution across a surface layer of thickness d.

x relative to the particle [$u(x) \to -U$ as $x \to \infty$] follow the one-dimensional Navier–Stokes equations for the regions outside and inside the surface layer:

$$\eta \frac{d^2u}{dx^2} + \rho_{\text{el}}(x)E = 0, \quad 0 < x < +\infty \tag{77.5}$$

$$\eta \frac{d^2u}{dx^2} - \gamma u + \rho_{\text{el}}(x)E = 0, \quad -d < x < 0 \tag{77.6}$$

Here, Eq. (77.5) is the usual Navier–Stokes equation. The term γu on the left-hand side (LHS) of Eq. (77.6) represents the frictional forces exerted on the liquid flow $u(x)$ by the polymer segments in the polyelectrolyte layer, and γ is the frictional coefficient. If it is assumed that each resistance center corresponds to a polymer segment, which, in turn, is regarded as a sphere of radius a_{p} and the polymer segments are distributed at a uniform volume density of N_{p} in the polyelectrolyte layer, then each polymer segment exerts the Stokes resistance $6\pi\eta a_{\text{p}}u$ on the liquid flow in the polyelectrolyte layer so that

$$\gamma = 6\pi\eta a_{\text{p}} N_{\text{p}} \tag{77.7}$$

Similarly, the Poisson equations relating the charge density $\rho_{\text{el}}(x)$ resulting from the mobile charged ionic species and

the electric potential $\psi(x)$ are also different for the different regions:

$$\frac{d^2\psi}{dx^2} = -\frac{\rho_{\rm el}(x)}{\varepsilon_{\rm r}\varepsilon_0}, \quad 0 < x < +\infty \tag{77.8}$$

$$\frac{d^2\psi}{dx^2} = -\frac{\rho_{\rm el}(x) + \rho_{\rm fix}(x)}{\varepsilon_{\rm r}\varepsilon_0}, \quad -d < x < 0 \tag{77.9}$$

Here, the relative permittivity $\varepsilon_{\rm r}$ is assumed to take the same value both inside and outside the polyelectrolyte layer. Note that the right-hand side (RHS) of Eq. (77.9) contains the contribution of the fixed-charges of density $\rho_{\rm fix}(x)$.

It can be shown that Eqs. (77.5) and (77.6) are solved to give

$$u(x) = \frac{\varepsilon_{\rm r}\varepsilon_0 E}{\eta}\psi(x) - U \text{ for } x \geq 0 \tag{77.10}$$

$$\begin{aligned} u(x) = \frac{\varepsilon_{\rm r}\varepsilon_0 E}{\eta}\Bigg[&\psi(x) - \psi(-d)\frac{\cosh(\lambda x)}{\cosh(\lambda d)} \\ &- \frac{\lambda\sinh(\lambda(x+d))}{\cosh(\lambda d)}\int_{-d}^{0}\psi(x)\cosh(\lambda x)\,dx \\ &+ \lambda\int_{-d}^{x}\psi(x')\sinh(\lambda(x-x'))\,dx'\Bigg] \\ &+ \frac{E}{\eta\lambda}\Bigg[\int_{-d}^{x}\rho_{\rm fix}(x')\sinh(\lambda(x-x'))\,dx' \\ &- \frac{\sinh(\lambda(x+d))}{\cosh(\lambda d)}\int_{-d}^{0}\rho_{\rm fix}(x)\cosh(\lambda x)dx\Bigg] \\ &\text{for } -d < x < 0 \end{aligned} \tag{77.11}$$

where λ is defined by $\lambda = (\gamma/\eta)^{1/2}$.

The electrophoretic mobility $\mu = U/E = -u(\infty)/E$ is thus

$$\begin{aligned} \mu = \frac{\varepsilon_{\rm r}\varepsilon_0}{\eta}\cdot\frac{1}{\cosh(\lambda d)}\left[\psi(-d) + \lambda\int_{-d}^{0}\psi(x)\sinh(\lambda(x+d))\,dx\right] \\ + \frac{1}{\eta\lambda}\cdot\frac{1}{\cosh(\lambda d)}\int_{-d}^{0}\rho_{\rm fix}(x)\sinh(\lambda(x+d)\,dx \end{aligned} \tag{77.12}$$

We treat the case where $\rho_{\rm fix}(x) = ZeN$ and κd, $\lambda d \gg 1$. In such cases the potential $\psi(x)$ inside the polyelectrolyte layer can be approximated by

$$\psi(x) = \psi_{\rm DON} + (\psi_0 - \psi_{\rm DON})e^{\kappa_{\rm m}x} \text{ for } -d < x < 0 \tag{77.13}$$

with

$$\psi_{\rm DON} = \left(\frac{kT}{ze}\right)\ln\left[\frac{ZN}{2zn} + \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right] \tag{77.14}$$

$$\begin{aligned} \psi_0 = \frac{kT}{ze}\Bigg(&\ln\left[\frac{ZN}{2zn} + \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right] \\ &+ \frac{2zn}{ZN}\left[1 - \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right]\Bigg) \end{aligned} \tag{77.15}$$

$$\kappa_{\rm m} = \kappa\left[1 + \left(\frac{ZN}{2zn}\right)^2\right]^{1/4} \tag{77.16}$$

where $\kappa_{\rm m}$ is the Debye–Hückel parameter in the surface layer and $\psi_{\rm DON}$ and $\psi_0 = \psi(0)$ are, respectively, the Donnan potential and the surface potential of the surface charge layer. Note that the surface potential ψ_0 is determined by the surface charge density σ (C/m^2) but for a soft particle it is determined by the volume charge density ZeN (C/m^3).

Similarly, from Eq. (77.11) we obtain

$$\begin{aligned} u(x) = \frac{\varepsilon_{\rm r}\varepsilon_0 E}{\eta}(\psi_0 - \psi_{\rm DON})\frac{\kappa_{\rm m}(\kappa_{\rm m}e^{\kappa_{\rm m}x} - \lambda e^{\lambda x})}{\kappa_{\rm m}^2 - \lambda^2} \\ + \frac{ZeNE}{\eta\lambda^2}\{e^{-\lambda(x+d)} - 1\} \text{ for } -d < x < 0 \end{aligned} \tag{77.17}$$

We thus obtain the following expression for the electrophoretic mobility of a soft particle [3]:

$$\mu = \frac{\varepsilon_{\rm r}\varepsilon_0}{\eta}\frac{\psi_0/\kappa_{\rm m} + \psi_{\rm DON}/\lambda}{1/\kappa_{\rm m} + 1/\lambda} + \frac{ZeN}{\eta\lambda^2} \tag{77.18}$$

Equation (77.18) consists of two terms; the first term is a weighted average of the Donnan potential $\psi_{\rm DON}$ and the surface potential ψ_0. It should be stressed that only the first term is subject to the shielding effects of electrolytes, tending to zero as the electrolyte concentration n increases, while the second term does not depend on the electrolyte concentration. In the limit of high electrolyte concentrations, all the potentials vanish and only the second term of the mobility expression remains:

$$\mu \to \mu^\infty = \frac{ZeN}{\eta\lambda^2} \tag{77.19}$$

This last equation shows that as $\kappa \to \infty$, μ tends to a nonzero limiting value μ^∞. This is a characteristic of the electrokinetic behavior of soft particles, in contrast to the case of the electrophoretic mobility of hard particles, which should reduce to zero as a result of the shielding effects, since the mobility expressions for rigid particles do not have μ^∞.

It is also to be noted that in the limit of $1/\lambda$ tending to zero, Eq. (77.18) becomes Smoluchowski's formula [Eq. (77.1)]. This means that in this limit a soft particle becomes a hard particle carrying zeta-potential $\zeta = \psi_0$. In other words, the parameter $1/\lambda$ can be regarded as a softness parameter.

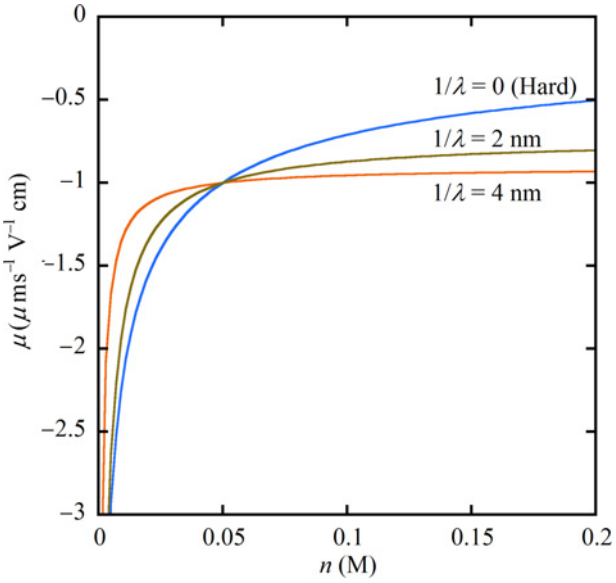

FIGURE 77.3 The electrophoretic mobility μ of soft particles as a function of the electrolyte concentration n for three values of the softness parameter $1/\lambda$. A particle with $1/\lambda = 0$ corresponds to a hard particle. Calculated via Eq. (77.18) with z = l, $\eta = 0.891$ mPa · s, $\varepsilon_r = 78.5$, and $T = 298$ K. The values of the fixed charge density ZeN for the soft particles and the surface charge density σ for the hard particle are chosen so that three curves give the same μ value at $n = 0.05$ M, that is, $ZN = 16.9$ mM for a curve with $1/\lambda = 2$ nm, $ZN = 5.2$ mM for a curve with $1/\lambda = 4$ nm, and $\sigma = 6.6$ mC/m^2 for a curve with $1/\lambda = 0$ nm (hard particle).

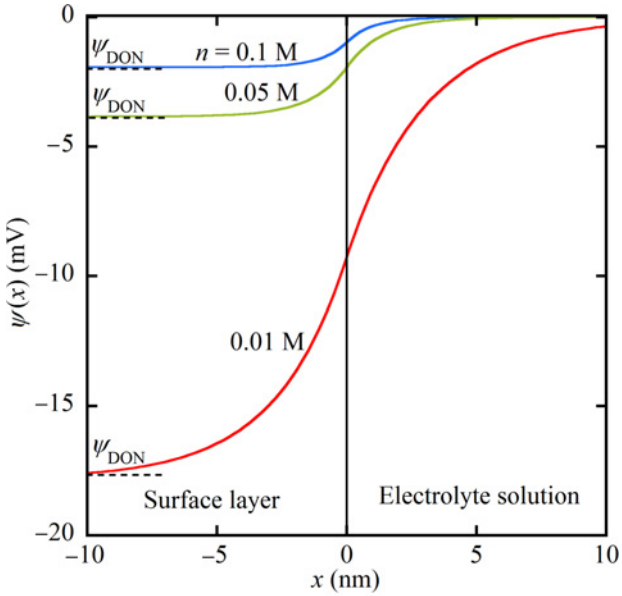

FIGURE 77.4 The potential distribution $\psi(x)$ across the uniformly charged surface layer for several values of n, calculated with z = l, $ZN = -0.015$ M, $d = 10$ nm, $\eta = 0.891$ mPa · s, $\varepsilon_r = 78.5$, and $T = 298$ K for $n = 0.1$ M, 0.05 M, and 0.01 M [2].

Figure 77.3 shows the electrophoretic mobility μ of soft particles (curves with $1/\lambda = 2$ nm and 4 nm) in comparison with the mobility of a hard particle (curve with $1/\lambda = 0$).

The values of the charge density N or σ are chosen so that the mobility values for all the cases show the same value of -1 μm s^{-1} V^{-1} cm^{-1} at $n = 0.05$ M. We see that for a hard particle μ approaches zero but for a soft particle it tends to a nonzero limiting value μ^∞.

In order to see this more clearly, in Figs. 77.4 and 77.5 we give examples of the liquid velocity $u(x)$ and the potential distributions $\psi(x)$ and the liquid velocity $u(x)$ across the surface layer of thickness 10 nm on a soft particle [2].

It is seen that the liquid velocity $u(x)$ in the middle region of the surface charge layer (the plateau region) (Fig. 77.5), where the potential is almost equal to the Donnan potential ψ_{DON} (Fig. 77.4), gives μ^∞. It is this term that yields the term independent of the electrolyte concentration. We also note that $1/\lambda$ is the distance between the slipping plane at the core surface at $x = 0$ and the bulk phase of the surface layer (the plateau region in Fig. 77.5), where $u(x)/E$ is given by $-\mu^\infty$. Figure 77.5 shows that a small shift of the slipping plane causes no effects on the mobility value. Therefore the mobility of soft particles is insensitive to the position of the slipping plane, and the zeta-potential loses its meaning.

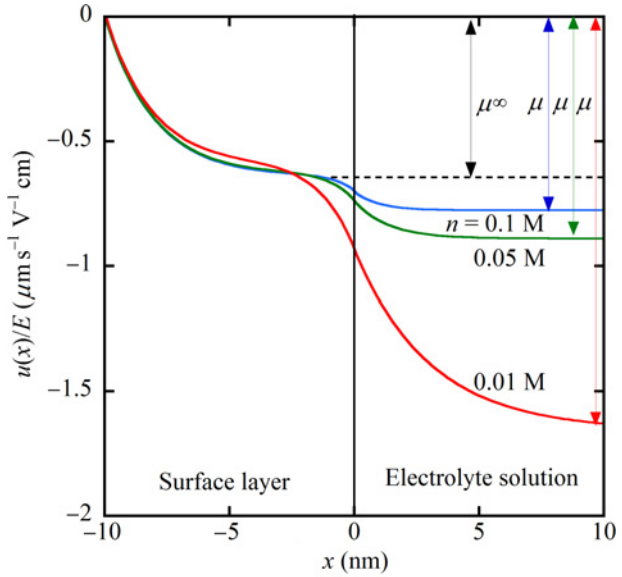

FIGURE 77.5 The velocity distribution of liquid flow $u(x)$ across the uniformly charged surface layer for several values of n. Calculated with $z = 1$, $ZN = -0.015$ M, $d = 10$ nm, $l/\lambda = 2$ nm, $\eta = 0.891$ mPa · s, $\varepsilon_r = 78.5$, and $T = 298$ K for $n = 0.1$ M, 0.05 M, and 0.01 M. The value of - $u(+\infty)/E$ gives the mobility μ. The dashed line indicates the contribution from the term independent of the electrolyte concentration μ_∞ [2].

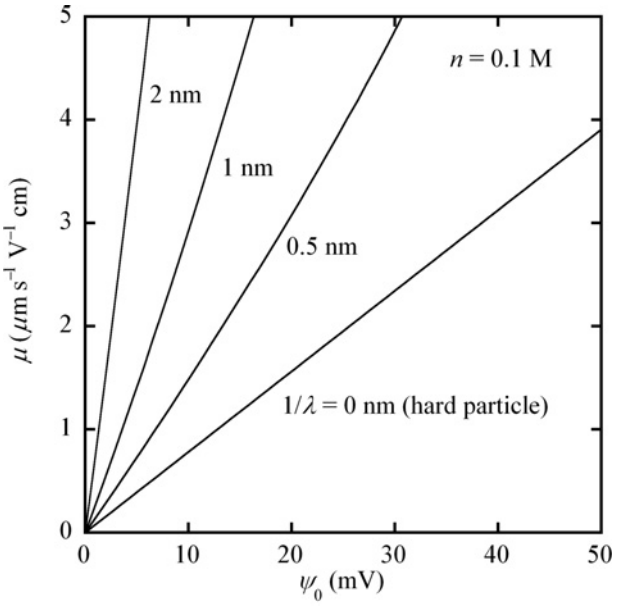

FIGURE 77.6 The electrophoretic mobility μ as a function of the surface potential ψ_0 for several values of $1/\lambda$. Calculated with Eq. (77.18) at $z = 1$, $\eta = 0.891$ mPa · s, $\varepsilon_r = 78.5$, and $T = 298$ K. The curve with $1/\lambda = 0$ (or $\lambda = \infty$) corresponds to the mobility of hard particles [Eq. (77.1)] [12].

It has been shown that the electrical behaviors of soft particles are quite different from those of hard paticles. As is seen from Eqs. (77.1) and (77.18), the magnitude and the electrolyte concentration dependence of the electrophoretic mobility μ of soft particles, in particular, differ considerably from those of hard particles. Figure 77.6 shows the electrophoretic mobility μ as a function of the surface potential ψ_0 at $n = 0.1$ M for various values of the softness parameter $1/\lambda$. The curve with $1/\lambda = 0$ corresponds to hard particles [Eq. (77.1)]. Figure 77.4 demonstrates a remarkable difference between soft and hard particles. For example, at $n = 0.1$ M, $ZN = 0.15$ M and $1/\lambda = 2$ nm, despite the fact that the surface potential ψ_0 is only 1 mV, the mobility μ amounts to 0.78 μm s^{-1} V^{-1} cm^{-1}. With Smoluchowski's formula [Eq. (77.1)], on the other hand, this mobility value is converted to the surface potential (or the zeta-potential) of approximately 10 mV. Thus, in order to analyze the mobility data of soft particles, the soft particle theory [Eq. (77.18)] should be applied, instead of Smoluchowski's formual [Eq. (77.1)]. Otherwise the surface potential would be considerably overestimated.

77.4 ANALYSIS OF ELECTROPHORETIC MOBILITY OF SOFT PARTICLES

Equation (77.18) contains two unknown parameters: the density of fixed charges ZN and the softness parameter $1/\lambda$. We calculate the electrophoretic mobility μ as a function of the electrolyte concentration n in the suspending medium for various ZN and $1/\lambda$ in order to determine the values of ZN and $1/\lambda$ by a curve-fitting procedure. A number of experimental studies have been carried out in order to analyze experimental mobility data by using Eq. (77.18) [17–36]. Note that N and n are given in units of m^{-3}. If one uses the units of M, then N and n must be replaced by $1000N_AN$ and N_An, where N_A is Avogadro's number. In the remainder of this section we present some examples of the analysis of the electrophoretic mobility of soft particles.

77.4.1 RAW117 Lymphosarcoma Cells and Their Variants

Makino et al. [18] measured the electrophoretic mobilities of the cells of malignant lymphosarcoma cell line RAW117-P and its variant H10 with a highly metastatic property to the liver at various ionic strengths. The cells of the parental cell line (RAW117-P) show mobility values that are higher in magnitude than those of its variant line (RAW117-H10) in the whole range of electrolyte concentration measured. The mobility data obtained have been analyzed via Eq. (77.18). By a curve-fitting procedure, we have found that the best-fit curves (shown as solid lines in Fig. 77.7) are obtained with $zN = -0.04$ M and $1/\lambda = 1.5$ nm for RAW117-P cells and $zN = -0.03$ M and $1/\lambda = 1.7$ nm for RAW117-H10 cells.

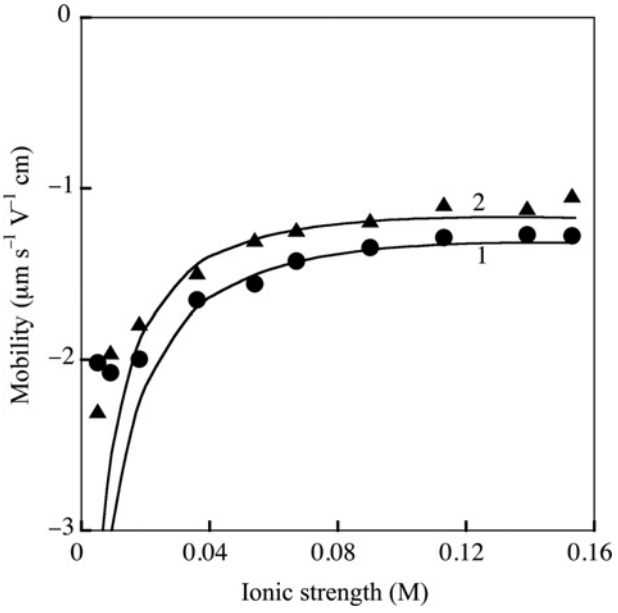

FIGURE 77.7 Electrophoretic mobilities of RAW117-P cells and RAW117-H10 cells. Symbols represent experimental data measured as a function of the ionic strength in the suspending medium at pH 7.4 and 37°C: ●, RAW117-P cells ▲, RAW117-H10 cells. Solid-line curves indicate theoretical results calculated via Eq. (77.18) with $ZN = -0.04$ M and $1/\lambda = 1.5$ nm (curve 1), and $ZN = -0.03$ M and $1/\lambda = 1.7$ nm (curve 2). (From Ref. 18.)

It is observed that the theoretical curves and the experimental data points are in good agreement with each other over a wide range of electrolyte concentration. The mobility difference between RAW117-P and RAW117-H10 cells is attributed to the differences in both $1/\lambda$ and charge density ZeN in their surface layers. Among these differences, the difference in N is corresponds to the difference in sialic acid contents in both cells, while the difference in $1/\lambda$ may possibly reflect a change of packing state of polymer chains in the cell surface layer. The result that $1/\lambda$ is greater for RAW117-H10 cells than for RAW117-P cells implies that the friction exerted by the surface layer on the liquid flow around the cells is less for RAW117-H10 than for RAW117-P. In other words, the surface layer of RAW117-H10 cells is "softer" than that of RAW117-P cells.

77.4.2 Poly(*N*-isopropylacrylamide) Hydrogel–Coated Latex

Poly(*N*-isopropylacrylamide) hydrogel is known to be temperature-sensitive, exhibiting a phase transition at about 32°C [17,18]; that is, it swells below 32°C and shrinks above 32°C. In Refs. 17 and 18, the measurements and the analysis are given for the electrophoretic mobility of latex particles composed of a poly(styrene-*co*-ethylhexyl methacrylate) core and a poly(*N*-isopropylacrylamide) hydrogel layer in an electrolyte solution as a function of the ionic strength and temperature of the suspending media. Although poly(*N*-isopropylacrylamide) is itself electrically neutral, the hydrogel layer on the particle carries fixed negative charges, arising from dissociation of sulfate groups in the hydrogel layer, since potassium persulfate is used as an initiator of soap-free emulsion copolymerization.

Figure 77.8 shows that the electrophoretic mobility of the latex particles was measured in a phosphate buffer solution at pH 7.4 at four different temperatures, namely, 25°C, 30°C, 35°C, and 40°C [above and below the phase transition temperature of the poly(*N*-isopropylacrylamide) hydrogel] [17].

Figure 77.8 shows results of the calculation of the mobility as a function of the electrolyte concentration on the basis of Eq. (77.18). Theoretical curves calculated via Eq. (7718) with a single value of each of N and $1/\lambda$ are found to be in good agreement with the experimental data over a wide range of the ionic strength except in cases where it is too low. The deviation at very low ionic strengths at 35°C and 40°C, where Eq. (77.18) yields overestimation in magnitude, may be due to the fact that the hydrogel layer suffers an additional minor expansion due to reduction of the ionic shielding effects, resulting in a decrease in N. The overall agreement between theory and experiment implies that hydrogel-layer-coated latex particles show the electrophoretic behavior of "soft particles" described by Eq. (77.18) and also enables us to estimate the values of the unknown parameters N and $1/\lambda$ via a curve-fitting procedure.

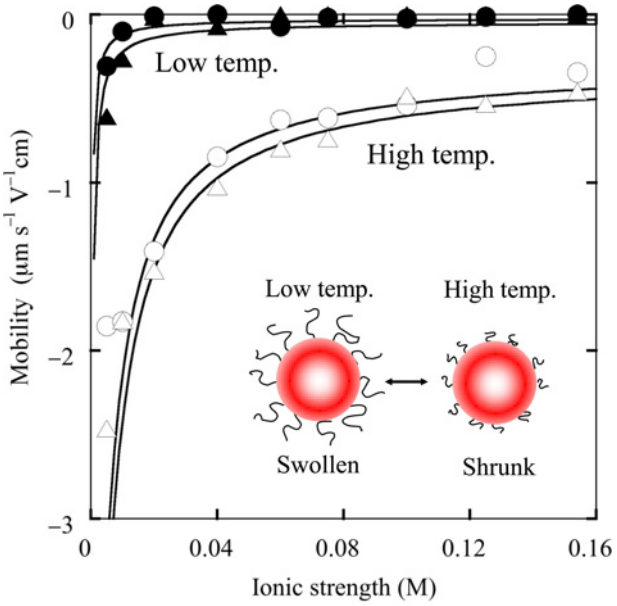

FIGURE 77.8 Electrophoretic mobility of latex particles with temperature-sensitive poly(*N*-isopropylacrylamide) hydrogel layers as a function of ionic strength at pH = 7.4 at several values of the temperature of the suspending medium. Symbols represent experimental data: ●, 25°C; ▲, 30°C (below the phase transition temperature); ○, 35°C; △, 40°C (above the phase transition temperature). Solid-line curves give theoretical results calculated from Eq. (77.18) with $ZN = -0.0015$ M and $1/\lambda = 1.2$ nm at 25°C; $ZN = -0.0025$ M and $1/\lambda = 1.2$ nm at 30°C, $ZN = -0.03$ M and $1/\lambda = 0.9$ nm, both at 35°C and 40°C. (From Ref. 17.)

The best-fit curves (shown as solid lines in Fig. 77.8) at different temperatures are obtained with $zN = -0.0015$ M and $1/\lambda = 1.2$ nm at 25°C, $zN = -0.0025$ M and $1/\lambda = 1.2$ nm at 30°C, and $zN = -0.03$ M and $1/\lambda = 0.9$ nm, at both 35°C and 40°C. The best-fit values of zN and $1/\lambda$ are thus the same for 35°C and 40°C. The observed small difference in the mobility values between 35°C and 40°C can be explained by the temperature dependence of the relative permittivity ε_r and viscosity η of the suspending media, that is, ($\varepsilon_r = 75.1$ and $\eta = 0.719 \times 10^{-3}$ mPa • s at 35°C and $\varepsilon_r = 73.4$ and $\eta = 0.653 \times 10^{-3}$ mPa • s at 40°C). This implies that the values of N and $1/\lambda$ do not change appreciably in the temperature range 35–40°C. On the other hand, the large mobility increase from 30°C to 35°C across the phase transition temperature (which correlates with the large change in size of the latex particles) is due mainly to an increase in the charge density ZeN. Thus, below the phase transition temperature, where the hydrogel layer swells, the charge density decreases, while above the phase transition temperature the hydrogel layer shrinks and the charge density increases, causing a large change in the mobility. Note that the mobility given by Eq. (77.18) is determined not by the total amount of fixed charges carried by a colloidal particle but by their volume density. Thus, below

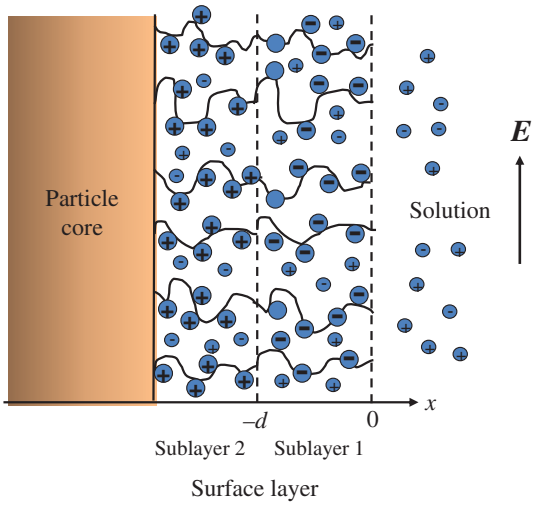

FIGURE 77.9 A surface charge layer consisting of two oppositely charged sublayers 1 and 2.

the phase transition temperature, when the hydrogel layer swells, the decreased charge density leads to a large reduction of the mobility, even if the total number of the fixed charges remains constant. The minor difference in the estimated values of N between 25°C and 30°C may also be due to a small change in the thickness of the hydrogel layer in this temperature range. The observed reduction of the "softness parameter" $1/\lambda$ implies that the hydrogel layer becomes "harder," which is inconsistent with the observed shrinkage of the hydrogel.

77.5 ELECTROPHORESIS OF NONUNIFORMLY CHARGED SOFT PARTICLES

We consider the case in which the surface charge layer consists of a positive-charge inner sublayer and a negative-charge outer sublayer (Fig. 77.9).

In such cases the surface potential is negative at high electrolyte concentrations but may become positive at low concentrations. The reason for the sign reversal of the surface potential can be explained as follows. It is the fixed charges located through the depth (from the boundary between the outer sublayer and the surrounding electrolyte solution) of the order of the Debye length $1/\kappa$ that mainly contribute to the membrane surface potential. At high electrolyte concentrations, $1/\kappa$ is small, so that the sign of the surface potential is determined mainly by the sign of the fixed charges present in the outer layer. On the other hand, at low electrolyte concentrations, $1/\kappa$ is large and the contribution from the fixed-charges in the inner layer becomes appreciable. Thus, if the inner layer is sufficiently highly charged, then at low electrolyte concentrations the sign of the surface potential may coincide with the sign of the fixed charges in the inner layer.

The sign reversal takes place also in the electrophoretic mobility of a nonuniformly charge soft particles, as shown below. We treat a large soft particle. The x axis is taken to be perpendicular to the soft surface with its origin at the front edge of the surface layer (Fig. 77.9). The soft surface consists of the outer layer ($-d < x < 0$) and the inner layer ($x < -d$), where the inner layer is sufficiently thick so that the inner layer can be considered practically to be infinitely thick. Consider the case where the outer sublayer (sublayer 1) carries ionized groups of valence Z_1 and number density N_1, while the inner sublayer (sublayer 2) carries ionized groups of valence Z_2 and number density N_2. Let the thickness of layer 1 be d. Then, we have

$$\rho_{\text{fix}}(x) = \begin{cases} Z_1 eN_1, & -d \le x \le 0 \\ Z_2 eN_2, & x \le -d \end{cases} \tag{77.20}$$

where $Z_1 eN_1$ and $Z_2 eN_2$ are, respectively, the charge densities of fixed charges in sublayers 1 and 2.

By solving the Navier–Stokes equations for sublayers 1 and 2, we finally obtain the following expression for the electrophoretic mobility:

$$\mu = \mu_1 + \mu_2 \tag{77.21}$$

with

$$\mu_1 = \frac{Z_1 eN_1}{\eta\lambda^2}\left[1 + \left(\frac{\lambda}{\kappa}\right)^2 \left\{\frac{1+\lambda/2\kappa}{1+\lambda/\kappa} + \frac{\lambda}{2(\kappa-\lambda)}e^{-\kappa d}\right\} - \frac{\kappa^2}{(\kappa^2-\lambda^2)}e^{-\lambda d}\right] \tag{77.22}$$

$$\mu_2 = -\frac{Z_2 eN_2}{\eta\lambda^2}\left[\left(\frac{\lambda}{\kappa}\right)^2 \frac{\lambda}{2(\kappa-\lambda)}e^{-\kappa d} - \frac{\kappa^2}{(\kappa^2-\lambda^2)}e^{-\lambda d}\right] \tag{77.23}$$

Variation of the mobility with electrolyte concentration n is caused not only by the shielding effects of electrolyte ions but also by the change in the relative contributions from the fixed-charges in layer 1 and from those in layer 2. The latter effects correspond to the fact that fixed charges located through the depth of around $1/\kappa$ mainly contributes to the mobility. Figure 77.10 gives μ_1 and μ_2 and their sum $\mu = \mu_1 + \mu_2$ plotted as functions of electrolyte concentration n, showing the sign reversal of the electrophoretic mobility μ.

Makino et al. [25] measured the electrophoretic mobility of four types M_1–M_4 of hydrophilic gel microcapsules containing water prepared by an interfacial polymerization method. Each type of microcapsules has membranes of different compositions. The results of the analysis of the measured mobilitiy values on the basis of Eq. (77.21) are given in Figs. 77.11 and 77.12, showing good agreement between theory and experiment.

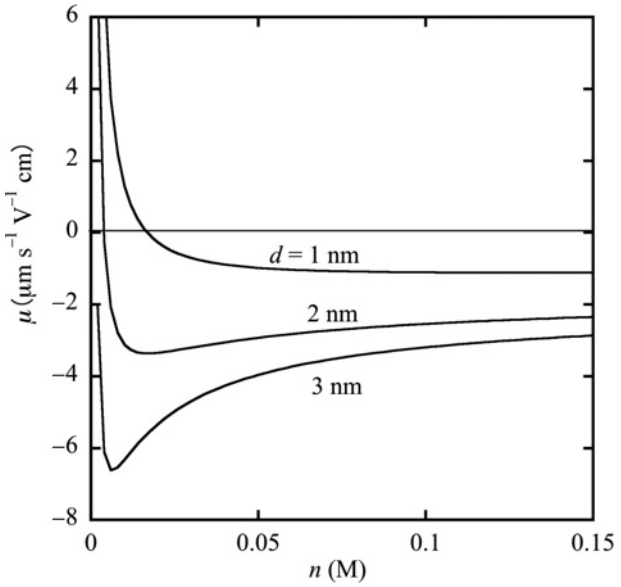

FIGURE 77.10 Electrophoretic mobility μ as a function of electrolyte concentration n for various values of d at $1/\lambda = 1$ mm, calculated using Eq. (77.21) with $z = 1$, $Z_1N_1 = -0.2$ M, $Z_2N_2 = 0.1$ M, $\eta = 0.89$ mPa • s, $\varepsilon_r = 78.5$, and $T = 298$ K. Curves: (1) $d = 0.2$ nm; (2) $d = 1$ nm; (3) $d = 2$ nm; (4) $d = 3$ nm.

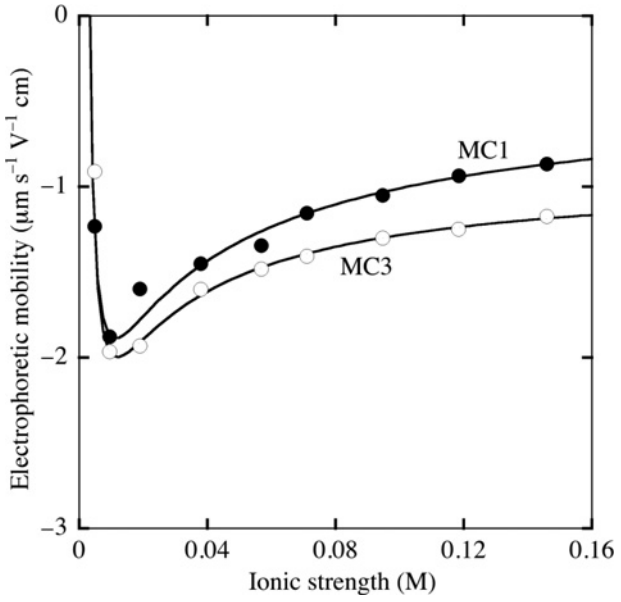

FIGURE 77.11 Electrophoretic mobility of MC 1 and 3. Symbols represent experimental data with MC 1 and 3 measured as a function of ionic strength in surrounding medium at pH 7.4 and 37°C. Solid-line curves represent theoretical vaues calculated with $Z_1N_1 = -0.111$ M, $Z_2N_2 = 0.041$ M, $1/\lambda = 0.505$ nm, $d = 1.706$ nm (MC 1), and with $z_1N_1 = -0.048$ M, $z_2M_2 = 0.048$ M, $1/\lambda = 1{,}230$ nm, Z_1N_1, $d = 3.758$ nm (MC 3). (From Ref. 24.)

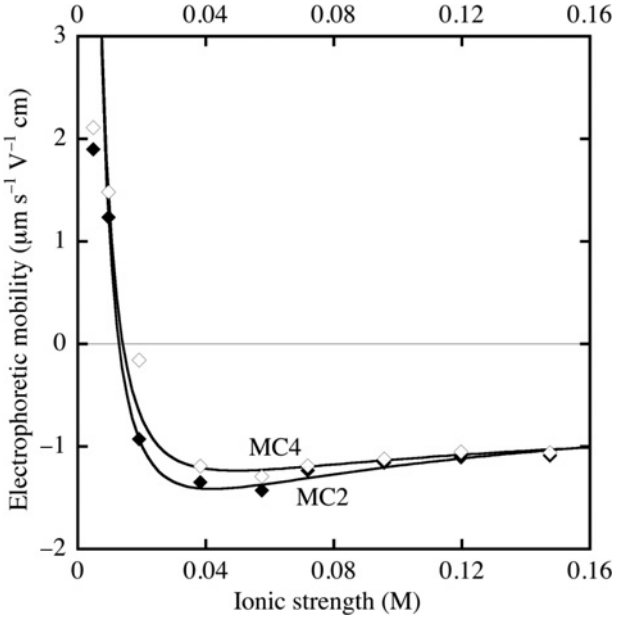

FIGURE 77.12 Electrophoretic mobility of MC 2 and 4. Symbols represent experimental data with MC 2 and 4 measured as a function of ionic strength in surrounding medium at pH 7.4 and 37°C. Solid-line curves represent theoretical values calculated with $Z_1N_1 = -0.140$ M, $Z_2N_2 = 0.166$ M, $1/\lambda = 0.471$ nm, $d = 2.090$ nm (MC 2), and with $Z_1N_1 = -0.084$ M, $Z_2N_2 = 0.159$ M, $1/\lambda = 0.778$ nm, $d = 2.751$ nm (MC 4). (From Ref. 25.)

POTENTIAL DISTRIBUTION AROUND A HARD PARTICLE AND A SOFT PARTICLE

Hiroyuki Ohshima

Faculty of Pharmaceutical Sciences, Tokyo University of Science, 2641 Yamazaki Noda, Chiba 278-8510, Japan

78.1 INTRODUCTION

Around a charged colloidal particle immersed in an electrolyte solution, mobile electrolyte ions form an ionic cloud around the particle. In the ionic cloud the concentration of counterions (electrolyte ions with charges of the sign opposite to that of the particle surface charges) becomes very high while that of coions (electrolyte ions with charges of the same sign as the particle surface charges) is very low, due to electrostatic interaction between electrolyte ions and particle surface charges. Figure 78.1 schematically shows the distribution of ions around a charged spherical particle of radius a. The ionic cloud together with the particle surface charge forms an electrical double layer.

Such an electrical double layer is often called an *electrical diffuse double layer*, since the distribution of electrolyte ions in the ionic cloud takes a diffusive structure because of the thermal motion of ions. Electrostatic and electrokinetic behaviors (interaction between colloidal particles and motion of colloidal particle in an external field, e.g., electric field and gravitational field) depend on the distribution of electrolyte ions and of the electric potential across the electrical double layer around the particle surface [1–6].

78.2 HARD PARTICLES

Consider a uniformly charged particle immersed in a liquid containing N ionic species with valence z_i and bulk concentration (number density) n_i^∞ ($i = 1,2,\ldots,N$) (in units of m^{-3}). From the electroneutrality condition, we have

$$\sum_{i=1}^{N} z_i n_i^\infty = 0 \tag{78.1}$$

The electric potential $\psi(\boldsymbol{r})$ at position $\boldsymbol{r}$ outside the particle, measured relative to the bulk solution phase, where ψ is set equal to zero, is related to the charge density $\rho_{\mathrm{el}}(\boldsymbol{r})$ at the same point by the Poisson equation as

$$\Delta\psi(\boldsymbol{r}) = -\frac{\rho_{\mathrm{el}}(\boldsymbol{r})}{\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}} \tag{78.2}$$

where Δ is the Laplacian, ε_{r} is the relative permittivity of the electrolyte solution, and ε_{o} is the permittivity of a vacuum. We assume that the distribution of the electrolyte ions $n_i(\boldsymbol{r})$ obeys Boltzmann's low as

$$n_i(\boldsymbol{r}) = n_i^\infty \exp\left(-\frac{z_i e\psi(\boldsymbol{r})}{kT}\right) \tag{78.3}$$

where $n_i(\boldsymbol{r})$ is the concentration (number density) of the i th ionic species at position $\boldsymbol{r}$, e is the elementary electric charge, k is Boltzmann's constant, and T is the absolute temperature. The charge density $\rho_{\mathrm{el}}(\boldsymbol{r})$ at position $\boldsymbol{r}$ is thus given by

$$\rho_{\mathrm{el}}(\boldsymbol{r}) = \sum_{i=1}^{N} z_i e n_i(\boldsymbol{r}) = \sum_{i=1}^{N} z_i e n_i^\infty \exp\left(-\frac{z_i e\psi(\boldsymbol{r})}{kT}\right) \tag{78.4}$$

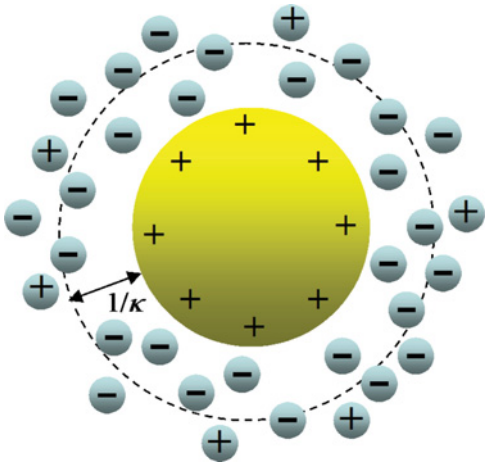

FIGURE 78.1 Electrical double layer around a charged colloidal particle. The thickness of the electrical double layer is given by the Debye length $1/\kappa$.

Combining Eqs. (78.2) and (78.4) gives

$$\Delta\psi(\boldsymbol{r}) = -\frac{1}{\varepsilon_r\varepsilon_o}\sum_{i=1}^{N} z_i e n_i^{\infty} \exp\left(-\frac{z_i e\psi(\boldsymbol{r})}{kT}\right) \tag{78.5}$$

This is the Poisson–Boltzmann equation for the potential distribution $\psi(\boldsymbol{r})$, which is subject to the following boundary conditions:

$$\psi(\boldsymbol{r}) = \psi_o \text{ at the particle surface} \tag{78.6}$$

$$\psi(\boldsymbol{r}) \to 0 \text{ as } r = |\boldsymbol{r}| \to \infty \tag{78.7}$$

If the internal electric fields inside the particle can be neglected, then the surface charge density σ of the particle is related to the potential derivative normal to the particle surface as

$$\frac{\partial\psi}{\partial n} = -\frac{\sigma}{\varepsilon_r\varepsilon_o} \tag{78.8}$$

where n is the outward normal at the particle surface.

If the potential ψ is low, that is

$$\left|\frac{z_i e\psi}{kT}\right| \ll 1 \tag{78.9}$$

then Eq. (78.5) reduces to the following linearized Poisson–Boltzmann equation (Debye–Hückel equation):

$$\Delta\psi = \kappa^2\psi \tag{78.10}$$

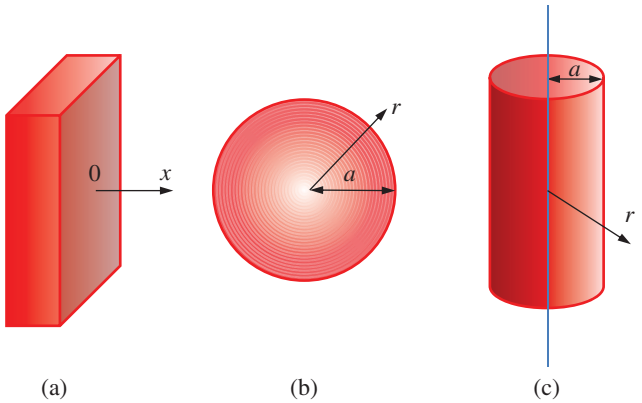

FIGURE 78.2 Colloidal particles of various geometry: (a) plate; (b) sphere; (c) cylinder.

with

$$\kappa = \left(\frac{1}{\varepsilon_r\varepsilon_o kT}\sum_{i=1}^{N} z_i^2 e^2 n_i^{\infty}\right)^{1/2} \tag{78.11}$$

where κ is called the *Debye–Hückel parameter*. The reciprocal of κ (i.e., $1/\kappa$), which is called the *Debye length*, corresponds to the thickness of the double layer. Note that n_i^{∞} in Eqs. (78.5) and (78.10) is given in units of m^{-3}. If one uses the units of M (mole/liter), then n_i^{∞} must be replaced by $1000N_A n_i^{\infty}$, where N_A is Avogadro's number.

The linearized equation [Eq. (78.10)] can be solved for particles of various shapes. We give below the potential distribution for a planar surface, a sphere of radius a, and a cylinder of radius a, which can be obtained by solving Eq. (78.10) (with $\Delta = d^2/dx^2$ for a planar surface, $\Delta = d^2/dr^2 + 2/r\cdot\, d/dr$ for a sphere, and $\Delta = d^2/dr^2 + 1/r\cdot\, d/dr$ for a cylinder) subject to Eqs. (78.6) and (78.7), where x is the distance from the planar surface located at $x = 0$ and r is the distance from the sphere center or the cylinder axis (Fig. 78.2):

1. Planar surface

$$\psi(x) = \psi_o e^{-\kappa x} \tag{78.12}$$

with

$$\psi_o = \frac{\sigma}{\varepsilon_r\varepsilon_o\kappa} \tag{78.13}$$

2. Sphere of radius a

$$\psi(r) = \psi_o\frac{a}{r}e^{-\kappa(r-a)} \tag{78.14}$$

with

$$\psi_o = \frac{\sigma}{\varepsilon_r \varepsilon_o \kappa (1 + 1/\kappa a)} \tag{78.15}$$

3. Cylinder of radius a

$$\psi(r) = \psi_o \frac{K_0(\kappa r)}{K_0(\kappa a)} \tag{78.16}$$

with

$$\psi_o = \frac{\sigma}{\varepsilon_r \varepsilon_o \kappa} \frac{K_0(\kappa a)}{K_1(\kappa a)} \tag{78.17}$$

where $K_n(z)$ is the modified Bessel function of the second kind of order n.

For the arbitrary potential case, one must solve the nonlinear Poisson–Boltzmann equation [Eq. (78.5)]. For a planar surface in contact with a z:z symmetric electrolyte solution, a 2:1 electrolyte solution, or a mixed solution of 1:1 electrolyte of bulk concentration n_1 and 2:1 electrolyte of bulk concentration n_2, the potential distribution $\psi(x)$ and the surface potential ψ_0/surface charge density σ relationship are as follows:

1. Symmetric electrolytes of valence z

$$\psi(x) = \frac{2kT}{ze} \ln\left(\frac{1 + \gamma e^{-\kappa x}}{1 - \gamma e^{-\kappa x}}\right) \tag{78.18}$$

with

$$\sigma = \frac{2\varepsilon_r \varepsilon_o \kappa kT}{ze} \sinh\left(\frac{ze\psi_o}{2kT}\right) \tag{78.19}$$

$$\gamma = \tanh\left(\frac{ze\psi_o}{4kT}\right) = \frac{\exp(ze\psi_o/2kT) - 1}{\exp(ze\psi_o/2kT) + 1} \tag{78.20}$$

2. 2:1 electrolyte solution

$$\psi(x) = \frac{kT}{e} \ln\left[\frac{3}{2}\left(\frac{1 + \frac{2}{3}\gamma' e^{-\kappa x}}{1 - \frac{2}{3}\gamma' e^{-\kappa x}}\right)^2 - \frac{1}{2}\right] \tag{78.21}$$

with

$$\sigma = \frac{2\varepsilon_r \varepsilon_o \kappa kT}{e} \left\{1 - \exp\left(-\frac{e\psi_o}{kT}\right)\right\} \times \left\{\frac{2}{3}\exp\left(\frac{e\psi_o}{kT}\right) + \frac{2}{3}\right\}^{1/2} \tag{78.22}$$

$$\gamma' = \frac{3}{2}\left\{\frac{\left(\frac{2}{3}e^{y_o} + \frac{1}{3}\right)^{1/2} - 1}{\left(\frac{2}{3}e^{y_o} + \frac{1}{3}\right)^{1/2} + 1}\right\} \tag{78.23}$$

where $y_o = e\psi_o/kT$ is the scaled surface potential.

3. Mixed solution of 1:1 electrolyte of concentration n_1 and 2:1 electrolyte of concentration n_2

$$\psi(x) = \frac{kT}{e} \ln\left[\left(\frac{1}{1 - \eta/3}\right)\left\{\frac{1 + \left(1 - \frac{\eta}{3}\right)\gamma'' e^{-\kappa x}}{1 - \left(1 - \frac{\eta}{3}\right)\gamma'' e^{-\kappa x}}\right\}^2 - \left(\frac{\eta/3}{1 - \eta/3}\right)\right] \tag{78.24}$$

with

$$\sigma = \frac{2\varepsilon_r \varepsilon_o \kappa kT}{e}(1 - e^{-y_o})\left[\left(1 - \frac{\eta}{3}\right)e^{y_o} + \frac{\eta}{3}\right]^{1/2} \tag{78.25}$$

$$\gamma'' = \left(\frac{1}{1 - \eta/3}\right)\left[\frac{\left\{\left(1 - \frac{\eta}{3}\right)e^{y_o} + \frac{\eta}{3}\right\}^{1/2} - 1}{\left\{\left(1 - \frac{\eta}{3}\right)e^{y_o} + \frac{\eta}{3}\right\}^{1/2} + 1}\right] \tag{78.26}$$

$$\eta = \frac{3n_2}{n_1 + 3n_2} \tag{78.27}$$

For a sphere, the nonlinear Poisson–Boltzmann equation has not been solved analytically. Loeb et al. [7] tabulated numerical computer solutions to the nonlinear spherical Poisson–Boltzmann equation, and approximate analytic solutions are given in Refs. 8 and 9.

$$\psi(r) = \frac{2kT}{ze} \ln\left[\frac{(1 + Bs)\left(1 + \frac{Bs}{2\kappa a + 1}\right)}{(1 - Bs)\left(1 - \frac{Bs}{2\kappa a + 1}\right)}\right] \tag{78.28}$$

with

$$s = \frac{a}{r}\exp(-\kappa(r - a)) \tag{78.29}$$

$$B = \frac{\left(\frac{2\kappa a + 1}{\kappa a + 1}\right)\tanh\left(\frac{y_o}{4}\right)}{1 + \left\{1 - \frac{2\kappa a + 1}{(\kappa a + 1)^2}\tanh^2\left(\frac{y_o}{4}\right)\right\}^{1/2}} \tag{78.30}$$

Approximate analytic expressions for the relationship between the surface charge density σ and the surface

potential ψ_o of a plate in various types of electrolyte solutions are given below [8, 9].

1. Symmetric electrolytes of valence z

$$\sigma = \frac{2\varepsilon_r\varepsilon_o\kappa kT}{ze}\sinh\left(\frac{ze\psi_o}{2kT}\right) \times \left[1 + \frac{1}{\kappa a}\frac{2}{\cosh^2(ze\psi_o/4kT)} + \frac{1}{(\kappa a)^2}\frac{8\ln[\cosh(ze\psi_o/4kT)]}{\sinh^2(ze\psi_o/2kT)}\right]^{1/2} \quad (78.31)$$

2. 2:1 electrolyte solution

$$\sigma = \frac{\varepsilon_r\varepsilon_o\kappa kT}{e}pq\left[1 + \frac{4}{\kappa a}\frac{(3-p)q-3}{(pq)^2} + \frac{4}{(\kappa a)^2(pq)^2}\left\{6\ln\left(\frac{q+1}{2}\right) + \ln(1-p)\right\}\right]^{1/2} \quad (78.32)$$

3. Mixed solution of 1:1 electrolyte of concentration n_1 and 2:1 electrolyte of concentration n_2

$$\sigma = \frac{\varepsilon_r\varepsilon_o\kappa kT}{e}\left[pt + \frac{2}{\kappa apt}\left\{(3-p)t - 3 - \frac{3^{1/2}(1-\eta)}{2\eta^{1/2}}\ln\left(\frac{\{1+(\eta/3)^{1/2}\}\{t-(\eta/3)^{1/2}\}}{\{1-(\eta/3)^{1/2}\}\{t+(\eta/3)^{1/2}\}}\right)\right\}\right] \quad (78.33)$$

Here

$$p = 1 - \exp(-e\psi_o/kT) \quad (78.34)$$

$$q = \left[\frac{2}{3}\exp\left(\frac{e\psi_o}{kT}\right) + \frac{1}{3}\right]^{1/2} \quad (78.35)$$

$$t = \left[\left(1 - \frac{\eta}{3}\right)\exp\left(\frac{e\psi_o}{kT}\right) + \frac{\eta}{3}\right]^{1/2} \quad (78.36)$$

where η is given in Eq. (78.27).

For the case of an infinitely long cylindrical particle of radius a, approximate solutions are derived in Refs. 8 and 10. The potential distribution around a cylinder of radius a and surface potential ψ_o are given by

$$\psi(r) = \frac{2kT}{ze}\ln\left[\frac{(1+Dc)\left\{1 + \left(\frac{1-\beta}{1+\beta}\right)Dc\right\}}{(1-Dc)\left\{1 - \left(\frac{1-\beta}{1+\beta}\right)Dc\right\}}\right] \quad (78.37)$$

with

$$c = \frac{K_0(\kappa r)}{K_0(\kappa a)} \quad (78.38)$$

$$\beta = \frac{K_0(\kappa a)}{K_1(\kappa a)} \quad (78.39)$$

$$D = \frac{(1+\beta)\tanh\left(\frac{y_o}{4}\right)}{1 + \left\{1 - (1-\beta^2)\tanh^2\left(\frac{y_o}{4}\right)\right\}^{1/2}} \quad (78.40)$$

Approximate analytic expressions for the relationship between the surface charge density σ and the surface potential of a cylinder of radius a in various types of electrolyte solutions are given below:

1. Symmetric electrolytes of valence z

$$\sigma = \frac{2\varepsilon_r\varepsilon_o\kappa kT}{ze}\sinh\left(\frac{y_o}{2}\right) \times \left[1 + \left(\frac{1}{\beta^2} - 1\right)\frac{1}{\cosh^2(y_o/4)}\right]^{1/2} \quad (78.41)$$

2. 2:1 electrolyte solution

$$\sigma = \frac{\varepsilon_r\varepsilon_o\kappa kT}{e}pq\left[1 + 2\left(\frac{1}{\beta^2} - 1\right)\frac{(3-p)q-3}{(pq)^2}\right]^{1/2} \quad (78.42)$$

where p and q are given by Eqs. (78.34) and (78.35), respectively.

3. Mixed solution of 1:1 electrolyte of concentration n_1 and 2:1 electrolyte of concentration n_2

$$\sigma = \frac{\varepsilon_r\varepsilon_o\kappa kT}{e}pt\left[1 + \frac{2(\beta^{-2}-1)}{(pt)^2}\left\{(3-p)t - 3 - \frac{\sqrt{3}(1-\eta)}{2\sqrt{\eta}}\ln\left(\frac{\left(t-\sqrt{\frac{\eta}{3}}\right)\left(1+\sqrt{\frac{\eta}{3}}\right)}{\left(t+\sqrt{\frac{\eta}{3}}\right)\left(1-\sqrt{\frac{\eta}{3}}\right)}\right)\right\}\right]^{1/2} \quad (78.43)$$

where t and η are given by Eqs. (78.36) and (78.27), respectively.

78.3 SOFT PARTICLES

We consider the case where the particle core is covered by an ion-penetrable surface layer of polyelectrolytes, which we term a *surface charge layer* (or, simply, a *surface layer*). Polyelectrolyte-coated particles are often called *soft particles* (Fig. 78.3) [3–6].

Soft particles serve as a model for biocolloids such as cells. Figure 78.3 is a schematic representation of ion and potential distributions around a soft surface, which shows that the potential deep inside the surface layer is practicably equal to the Donnan potential ψ_{DON}, if the surface layer is much thicker than the Debye length $1/\kappa$. Also we denote $\psi_0 \equiv \psi(0)$ (which is the potential at the boundary between the surface layer and the surrounding electrolyte solution) as the surface potential of the polyelectrolyte layer.

Consider a surface charge layer of thickness d coating a planar hard surface in a general electrolyte solution containing M ionic species with valence z_i and bulk concentration (number density) n_i^{∞} ($i = 1,2, \ldots, M$). We treat the case where fully ionized groups of valence Z are distributed at a uniform density of N in the surface charge layer and the particle core is uncharged. We take an x axis perpendicular to the surface charge layer with its origin $x = 0$ at the boundary between the surface charge layer and the surrounding electrolyte solution, so that the surface charge layer corresponds to the region $-d < x < 0$ and the electrolyte solution corresponds to $x > 0$ (Fig. 78.3). The Poisson–Boltzmann equations for the regions inside and outside the surface charge layer are given by

$$\frac{d^2\psi}{dx^2} = -\frac{1}{\varepsilon_r \varepsilon_\circ} \sum_{i=1}^{M} z_i e n_i^{\infty} \exp\left(-\frac{z_i e \psi(x)}{kT}\right), 0 < x < +\infty \tag{78.44}$$

$$\frac{d^2\psi}{dx^2} = -\frac{1}{\varepsilon_r \varepsilon_\circ} \sum_{i=1}^{M} z_i e n_i^{\infty} \exp\left(-\frac{z_i e \psi(x)}{kT}\right) - \frac{ZeN}{\varepsilon_r \varepsilon_\circ}, -d < x < 0 \tag{78.45}$$

We have assumed here that the relative permittivity ε_r takes the same value in the regions inside and outside the surface charge layer. Note that the right-hand side (RHS) of Eq. (78.45) contains the contribution of the fixed charges of density $\rho_{\mathrm{fix}} = ZeN$ in the polyelectrolyte layer. The boundary conditions are

$$\left.\frac{d\psi}{dx}\right|_{x=-d^+} = 0 \tag{78.46}$$

$$\psi(-0^-) = \psi(-0^+) \text{ and } \left.\frac{d\psi}{dx}\right|_{x=-0^+} = \left.\frac{d\psi}{dx}\right|_{x=-0^+} \tag{78.47}$$

$$\psi(x) \to 0 \text{ and } \frac{d\psi}{dx} \to 0 \text{ as } x \to \infty \tag{78.48}$$

Equation (78.46) corresponds to the situation in which the particle core is uncharged.

For the low-potential case, we give below analytic approximate expressions for the potential distribution $\psi(x)$ for a soft plate or $\psi(r)$ for a soft sphere or cylinder of radius a, where x is the distance from the planar soft surface located at $x = 0$ and r is the distance from the sphere center or the cylinder axis (Fig. 78.4) and the surface potential ψ_o/charge density N.

The following equations are relevant for soft particles:

1. Planar soft surface

$$\psi(x) = \frac{ZNkT}{4z^2ne}(1 - e^{-2\kappa d})e^{-\kappa x}, \mathrm{x} > 0 \tag{78.49}$$

$$\psi(x) = \frac{ZNkT}{2z^2ne}\left\{1 - \frac{e^{\kappa x} + e^{-\kappa(x+2d)}}{2}\right\}, -d < x < 0 \tag{78.50}$$

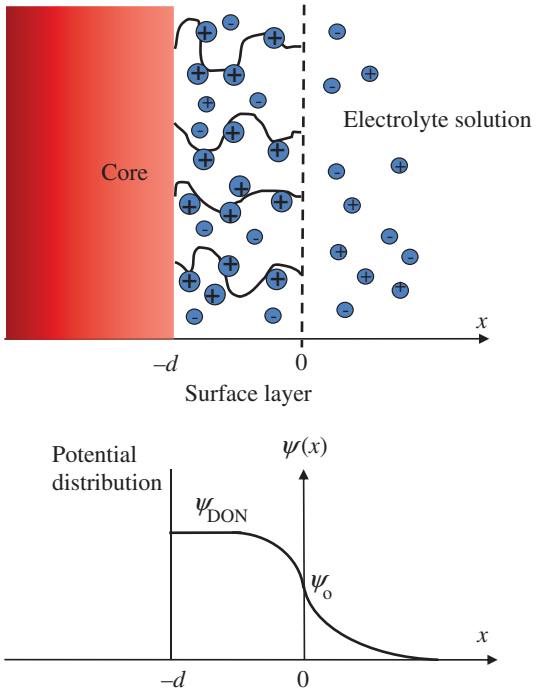

FIGURE 78.3 A soft surface, that is, a hard surface covered with an ion-penetrable surface layer of polyelectrolytes of thickness d and the potential distribution around the soft surface.

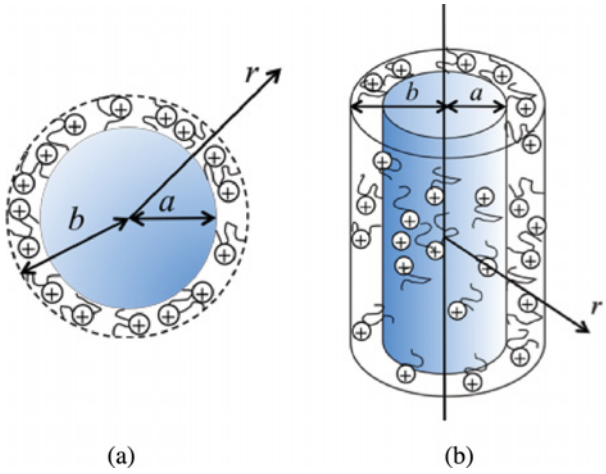

FIGURE 78.4 A soft sphere (a) and a soft cylinder (b).

with

$$\psi_o = \frac{ZeN}{2\varepsilon_r\varepsilon_o\kappa^2}(1 - e^{-2\kappa d}) \tag{78.51}$$

2. Soft sphere

$$\psi(r) = \frac{ZeN}{\varepsilon_r\varepsilon_o\kappa^2}\left[1 - \left(\frac{1+\kappa b}{1+\kappa a}\right)e^{-\kappa(b-a)} \times \left\{\frac{\sinh[\kappa(r-a)]}{\kappa r} + \frac{a\cosh[\kappa(r-a)]}{r}\right\}\right] a < r < b \tag{78.52}$$

$$\psi(\boldsymbol{r}) = \psi_o\frac{b}{r}\exp[-\kappa(r-b)], r > b \tag{78.53}$$

with

$$\psi_o = \frac{ZeN}{2\varepsilon_r\varepsilon_o\kappa^2}\left\{1 - \frac{1}{\kappa b} + \frac{(1-\kappa a)(1+\kappa b)}{(1+\kappa a)\kappa b}e^{-2\kappa(b-a)}\right\} \tag{78.54}$$

3. Soft cylinder

$$\psi(r) = \frac{ZeN}{\varepsilon_r\varepsilon_o\kappa^2}\left[1 - \kappa bK_1(\kappa b)\left\{I_0(\kappa r) + \frac{I_1(\kappa a)}{K_1(\kappa a)}K_0(\kappa r)\right\}\right], \quad a < r < b \tag{78.55}$$

$$\psi(r) = \psi_o\frac{K_0(\kappa r)}{K_0(\kappa b)}, r > b \tag{78.56}$$

with

$$\psi_o = \frac{ZeN}{\varepsilon_r\varepsilon_o\kappa^2}\kappa bK_0(\kappa b)\left\{I_1(\kappa b) - \frac{I_1(\kappa a)}{K_1(\kappa a)}K_1(\kappa b)\right\} \tag{78.57}$$

For the arbitrary potential case, we give below an approximate expression for the potential distribution $\psi(x)$ for the case where a planar soft surface is in contact with a z–z symmetric electrolyte solution and the thickness of the surface layer d is much greater than the Debye length $1/\kappa$.

$$\psi(x) = \psi_{DON} + (\psi_o - \psi_{DON})e^{-\kappa_m|x|}, x \le -d \tag{78.58}$$

with

$$\kappa_m = \kappa\cos\ h^{1/2}y_{DON} = \kappa\left[1 + \left(\frac{ZN}{2zn}\right)^2\right]^{1/4} \tag{78.59}$$

$$\psi_{DON} = \left(\frac{kT}{ze}\right)\ln\left[\frac{ZN}{2zn} + \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right] \tag{78.60}$$

$$\psi_o = \left(\frac{kT}{ze}\right)\left(\ln\left[\frac{ZN}{2zn} + \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right] + \frac{2zn}{ZN}\left[1 - \left\{\left(\frac{ZN}{2zn}\right)^2 + 1\right\}^{1/2}\right]\right) \tag{78.61}$$

where $\psi_0 = \psi(0)$ is the surface potential of the soft plate, that is, the potential at the front edge of the surface layer, and ψ_{DON} is the Donnan potential in the surface layer. Note that for the low-potential case, Eqs. (78.60) and (78.61) tend to

$$\psi_{DON} = \frac{ZeN}{\varepsilon_r\varepsilon_o\kappa^2} \tag{78.62}$$

$$\psi_o = \frac{\psi_{DON}}{2} = \frac{ZeN}{2\varepsilon_r\varepsilon_o\kappa^2} \tag{78.63}$$

78.4 DISCRETE-CHARGE EFFECT

The Donnan potential and surface potential of soft particles (i.e., polyelectrolyte-coated hard particles) in an electrolyte solution play an essential role in their electrical behaviors. As described before, these potential are usually derived via a continuum model in which fixed charges inside the surface layer are distributed with a continuous charge density. As shown below, for a platelike soft particle consisting of a cubic lattice of fixed point charges, on the basis of the

linearized Poisson–Boltzmann equation, we derive expressions for the electric potential distribution in the regions inside and outside the surface layer [11], by extending a method of Nelson and McQuarrie [38],who considered a charged surface carrying a squared lattice of point charges and solved the two-dimensional linearized Poisson–Boltzmann equation for the potential distribution.

Consider the case where fixed charges are distributed within the surface layer ($-\infty < z \leq 0$) at a discrete density of $\rho(\boldsymbol{r})$, which is not uniform but a function of position $\boldsymbol{r}(x, y, z)$. Here we consider the case where the thickness of the surface layer is much thicker than the Debye length $1/\kappa$ so that the surface layer can be considered to be infinitely thick. Let us obtain the electric potential $\psi(\boldsymbol{r})$ at position $\boldsymbol{r}$, which depends not only on z but also on x and y. In this case Eqs. (78.44) and (78.45) are replaced by the following three-dimensional linearized Poison–Boltzmann equations:

$$\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)\psi(\boldsymbol{r})=\kappa^2\psi(\boldsymbol{r})-\frac{\rho(\boldsymbol{r})}{\varepsilon_r\varepsilon_o}, -\infty < z \leq 0 \tag{78.64}$$

$$\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)\psi(\boldsymbol{r})=\kappa^2\psi(\boldsymbol{r}), 0 < z < +\infty \tag{78.65}$$

In order to solve Eqs. (78.64) and (78.65), we write $\psi(\boldsymbol{r})$ and $\rho(\boldsymbol{r})$ by their Fourier transforms as

$$\psi(\boldsymbol{r})=\psi(s,z)=\frac{1}{(2\pi)^2}\int\hat{\psi}(\boldsymbol{p},z)\exp(i(\boldsymbol{p}\cdot s))d\boldsymbol{p} \tag{78.66}$$

$$\rho(\boldsymbol{r})=\rho(s,z)=\frac{1}{(2\pi)^2}\int\hat{\rho}(\boldsymbol{p},z)\exp(i(\boldsymbol{p}\cdot s))d\boldsymbol{p} \tag{78.67}$$

where $\hat{\psi}(p,z)$and$\hat{\rho}(p,z)$are the Fourier coefficients, $\boldsymbol{s}=(x,y)$ and $\boldsymbol{p}=(p_x,p_y)$.

Substitution of Eqs. (78.22) and (78.23) into Eq. (78.12) yields

$$\begin{aligned}\psi(\boldsymbol{r})=\frac{1}{2(2\pi)^2\varepsilon_r\varepsilon_o}\Bigg[&\int\frac{1}{\sqrt{\kappa^2+p^2}}\\&\times\left\{\int_{-\infty}^{z}\hat{\rho}(\boldsymbol{p},z')\exp(+\sqrt{\kappa^2+p^2}\cdot z')dz'\right\}\\&\times\exp(-\sqrt{\kappa^2+p^2}\cdot z)\cdot\exp(i(\boldsymbol{p}\cdot s))d\boldsymbol{p}\\&+\left\{\int_{z}^{0}\hat{\rho}(\boldsymbol{p},z')\exp(-\sqrt{\kappa^2+p^2}\cdot z')dz'\right\}\\&\times\exp(+\sqrt{\kappa^2+p^2}\cdot z)\cdot\exp(i(\boldsymbol{p}\cdot s))d\boldsymbol{p}\Bigg], -\infty < z \leq 0\end{aligned} \tag{78.68}$$

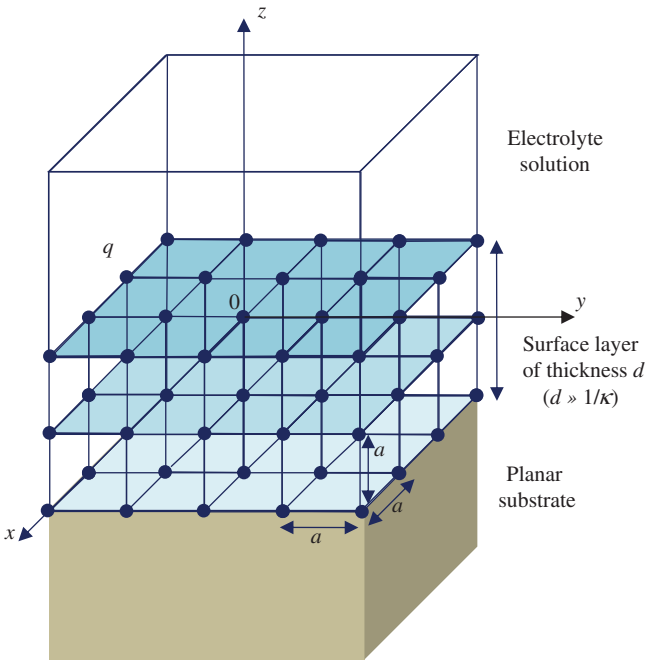

FIGURE 78.5 Soft plate consisting of a discrete cubic lattice of fixed point charges q with a spacing of a within a surface layer.

$$\begin{aligned}\psi(\boldsymbol{r})=&\frac{1}{2(2\pi)^2\varepsilon_r\varepsilon_o}\int\frac{1}{\sqrt{\kappa^2+p^2}}\\&\times\left\{\int_{-\infty}^{0}\hat{\rho}(\boldsymbol{p},z')\exp(+\sqrt{\kappa^2+p^2}\cdot z')dz'\right\}\\&\times\exp(-\sqrt{\kappa^2+p^2}\cdot z)\cdot\exp(i(\boldsymbol{p}\cdot s))d\boldsymbol{p}, 0 < z < \infty\end{aligned} \tag{78.69}$$

where

$$p=|\boldsymbol{p}|=\sqrt{p_x^2+p_y^2} \tag{78.70}$$

Now we deal with the case in which a surface layer consists of a cubic lattice of point charges q with spacing a (Fig. 78.5).

The point charges are thus located at lattice point (la, ma, na), where m and n take both positive and negative integers and n takes only negative integers, since the surface layer occupies the half-space $-\infty< z \leq 0$. The volume charge density $\rho(\boldsymbol{r})$ ($-\infty< z \leq 0$) is then expressed as

$$\begin{aligned}\rho(\boldsymbol{r})&=\rho(s,z)\\&=q\sum_{\substack{-\infty<l,m<\infty,\\-\infty<n\leq 0}}\delta(x-la)\delta(y-ma)\delta(z-na), -\infty < z \leq 0\end{aligned} \tag{78.71}$$

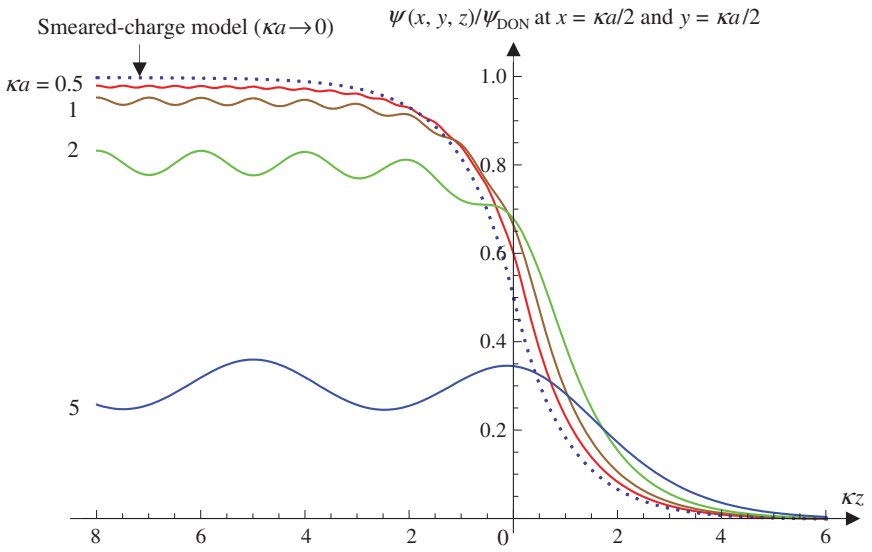

FIGURE 78.6 Change in $\psi(x, y, z)/\psi_{\mathrm{DON}}$ along the z direction at $x = \kappa a/2$ and $y = \kappa a/2$. (From Ref. 11.)

Thus Eqs. (78.66) and (78.71) give

$$\psi(\boldsymbol{r}) = \frac{q}{4\pi\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}} \sum_{\substack{-\infty<l,m<\infty,\\ -\infty<n\le 0}} \times \frac{\exp[-\kappa\sqrt{(x-la)^2+(y-ma)^2+(z-na)^2}]}{\sqrt{(x-la)^2+(y-ma)^2+(z-na)^2}}, \quad -\infty < z < +\infty \tag{78.72}$$

Equation (78.72) is the required expression for the potential distribution $\psi(\boldsymbol{r})$ for the case of the cubic lattice of charges. The surface potential, which is a function of x and y, is given by the potential at $z = 0$, that is, $\psi(x, y, 0)$, which is a function of x and y, is given by

$$\psi(x, y, 0) = \frac{q}{4\pi\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}} \sum_{\substack{-\infty<l,m<\infty,\\ -\infty<n\le 0}} \times \frac{\exp[-\kappa\sqrt{(x-la)^2+(y-ma)^2+(na)^2}]}{\sqrt{(x-la)^2+(y-ma)^2+(na)^2}} \tag{78.73}$$

It is seen that Eq. (78.72) is just a sum of screened Coulomb potentials produced by point charges located at the lattice points. The results of some calculations for the electric potential $\psi(\boldsymbol{r})$ are given in Fig. 78.6, which shows $\psi(x, y, z)/\psi_{\mathrm{DON}}$ as a function of scaled distance κz calculated at $x = \kappa a/2$ and $y = \kappa a/2$ for several values of κa in comparison with the continuous model (given by the dotted line).

We see that $\psi(x, y, z)$ oscillates with a period of κa and the amplitude of the oscillation decreases with decreasing κa. The potential $\psi(x, y, z)$ in the region outside the surface layer shows no oscillation, monotonically decreasing in magnitude with increasing z. It should also be noted that there is considerable deviation of the continuous-charge model. This deviation becomes smaller as the ratio κa of the lattice spacing a to the Debye length $1/\kappa$. Indeed, in the limit of $\kappa a \to 0$, the continuous-charge model approaches the discrete-charge model, as shown in Fig. 78.6.

It can be shown analytically on the basis of Eq. (78.72) that the discrete charge model approaches the continuous charge model in the limit of $\kappa a \to 0$. In this limit, the discrete sum with respect to l, m, and n in Eq. (78.72) can be replaced by a continuous integration. By introducing a smeared continuous charge density $\rho = q/a^3$, we consider the following potential in the deep inside the surface layer, which is shown to equal to the Donnan potential below:

$$\lim_{\substack{z\to-\infty\\ \kappa a\to 0}} \psi(\boldsymbol{r}) = \lim_{\substack{z\to-\infty\\ \kappa a\to 0}} \frac{q}{4\pi\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}} \sum_{-\infty<l,m,n<\infty} \times \frac{\exp[-\kappa\sqrt{(x-la)^2+(y-ma)^2+(z-na)^2}]}{\sqrt{(x-la)^2+(y-ma)^2+(z-na)^2}} \tag{78.74}$$

Here the range of n (i.e., $-\infty < n \le 0$) has been extended to approximately $-\infty < z < +\infty$, since we are treating the limiting case of $z \to -\infty$. We introduce $r = \sqrt{(x-la)^2+(y-ma)^2+(z-na)^2}$ and replace the discrete sum with a continuous integration:

$$\sum_{-\infty<l,m,n<+\infty} \to \frac{1}{a^3}\int_0^\infty 4\pi r^2 dr \text{ as } \kappa a \to 0 \tag{78.75}$$

Then Eq. (78.74) becomes the Donnan potential, that is

$$\psi_{\mathrm{DON}} = \frac{\rho}{4\pi\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}} \int_0^{\infty} \frac{e^{-\kappa r}}{r} 4\pi r^2 dr = \frac{\rho}{\varepsilon_{\mathrm{r}}\varepsilon_0\kappa^2} \tag{78.76}$$

which agrees with the result obtained by the continuous-charge model [Eq. (78.62)]. We thus see that integration of the screened Coulomb potential over the entire space $-\infty < z < +\infty$ yields the Donnan potential. If the integration is made over a half-space $-\infty < z \leq 0$, then the surface potential ψ_0 is obtained and its value is half the Donnan potential (i.e., $\psi_0 = \psi_{\mathrm{DON}}/2$), which agrees with the result of the continuum approximation [Eq. (78.63)]. The overall potential distribution in the limit of $\kappa a \to 0$ can also be derived in a similar manner. We introduce cylindrical coordinates: $s = \sqrt{(x - la)^2 + (y - ma)^2}$ and $z = na\text{-}z'$, and replace the discrete sum with a continuous integration:

$$\sum_{\substack{-\infty<l,m<+\infty \\ -\infty<n\leq 0}} \to \frac{1}{a^3} \int_{s=0}^{\infty} \int_{z'=-\infty}^{-z} 2\pi s ds dz' \text{ as } \kappa a \to 0 \tag{78.77}$$

Then Eq. (78.70) tends to

$$\begin{aligned} \psi(z) &= \frac{\rho}{4\pi\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}} \int_{s=0}^{\infty} \int_{z'=-\infty}^{-z} \frac{\exp[-\kappa\sqrt{s^2 + z'^2}]}{\sqrt{s^2 + z'^2}} 2\pi s ds dz' \\ &= \begin{cases} \dfrac{\rho}{\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}\kappa^2} \left(1 - \dfrac{1}{2} e^{\kappa z}\right), -\infty < z \leq 0 \\ \dfrac{\rho}{\varepsilon_{\mathrm{r}}\varepsilon_{\mathrm{o}}\kappa^2} e^{-\kappa z}, 0 < z < +\infty \end{cases} \end{aligned} \tag{78.78}$$

Equation (78.78), which depends only on z, agrees with Eqs. (78.49) and (78.50) for the case of $d \to \infty$.

SOIL INTERFACIAL ELECTRICAL PHENOMENA

Munehide Ishiguro

Laboratory of Soil Conservation, Research Faculty of Agriculture, Hokkaido University, Sapporo, Japan

79.1 INTRODUCTION

Soils have electric charges. In particular, clayey soil contains a significant amount of negative charge, roughly equivalent to 1 mole of electron per kilogram of soil [i.e., equal to the Faraday constant, 9.64×10^4 C (coulmbs)]. As the typical soil density is about 1000 kg/m^3, the soil has 100 million C in 1 cubic meter. When we use an electric heater of 1 kW ($=3.6 \times 10^6$ J/h) at 100 V, it requires a charge current of 3.6×10^4 C/h. Thus, the soil can theoretically supply electric current to such a heater for about 120 days [1]. Practically, however, the soil cannot do this because its charge cannot be separated. Nonetheless, the electric charge stored in soils is significant. This charge affects various soil phenomena such as soil structure, permeability, soil erosion, nutrient transport, and contaminant transport. These phenomena also strongly affect agricultural technology and environmental problems. In this chapter, such phenomena induced by soil electric charge are introduced.

79.2 ION TRANSPORT IN SOILS

79.2.1 Influence of Electric Charge on Ion Transport

An ion transport experiment was conducted using a soil column 30 cm in height and 5 cm in diameter. Allophanic andisol, which is a typical volcanic ash soil, was uniformly packed and saturated with a $CaCl_2$ solution. Then, a $SrBr_2$ solution was continuously infiltrated vertically into the column, and the ion concentrations of the outflow solution were measured. Figure 79.1 shows the experimental result. The abscissa indicates the normalized cumulative volume of the outflow solution divided by the water volume in the soil column. The units of the normalized volume are called *pore volume*; 1 pore volume equals the water volume in the soil column. The Sr^{2+} breakthrough curve shifted to the right as the pH increased; that is, Sr^{2+} moved more slowly in the soil when the pH increased. On the other hand, the Br^- breakthrough curve shifted to the left as the pH increased; Br^- moved more quickly in the soil when the pH increased. Figure 79.2 shows the cation exchange capacity (CEC) and the anion exchange capacity (AEC) of the soil; the CEC and AEC correspond to the negative and positive charge densities of the soil, respectively. The CEC increased and AEC decreased as the pH increased. Therefore, Sr^{2+} moved more slowly and Br^- more quickly as the pH increased because the Sr^{2+} adsorption increased and the Br^- adsorption decreased in the soil [2, 3].

The delay of ion transport corresponds to the amount of electric charge in the soil. When we use the normalized cumulative volume (pore volume) as the abscissa, the average delay of the ion transport by the adsorption is equal to the distribution ratio D_g, which is defined by

$$D_g = \frac{\rho q_0}{\theta c_0} \tag{79.1}$$

where ρ is the bulk density (kg/m^3), q_0 is the ion exchange capacity (mol$_c$/kg), θ is the volumetric water content (m^3/m^3), and c_0 is the input ion concentration (mol$_c$/m^3) [4]. The relative concentration of the outflow solution becomes about 0.5 at $D_g + 1$ pore volumes in the breakthrough curve. That is because Dg is the ratio of ions in the adsorption phase to ions in the solution phase.

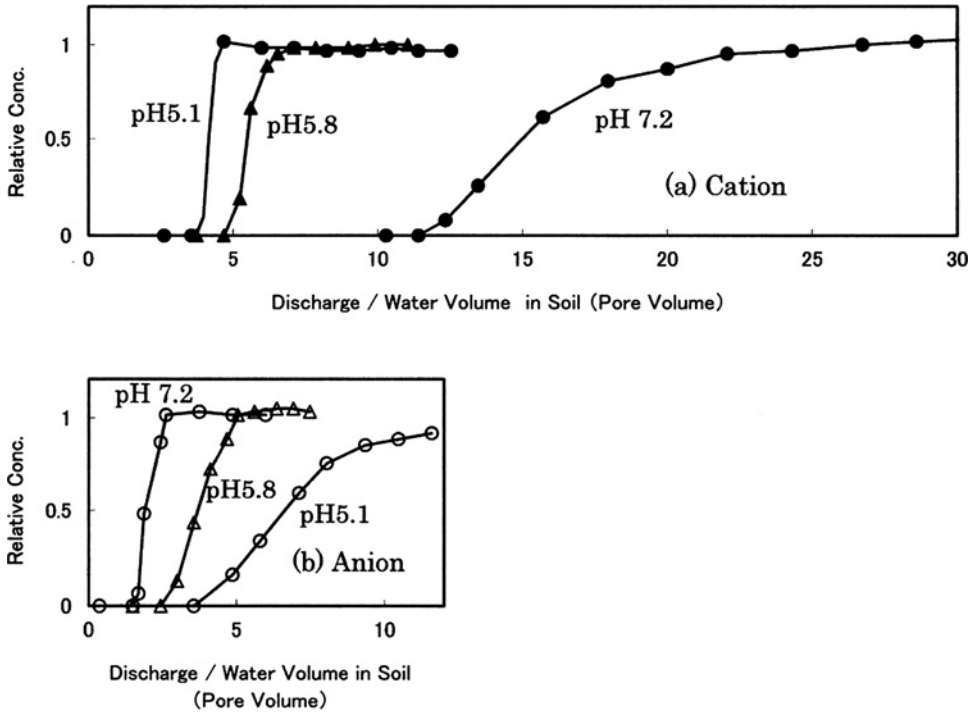

FIGURE 79.1 Breakthrough curves of the allophanic andisol for (a) cations and (b) anions. Inflow solution concentration was 0.01 $mmol_c/L$ [3].

Affinity of adsorbed ions to the soil affects the ion transport when two ions with the same sign of charge are present. Figure 79.3 shows the SO_4^{2-} and NO_3^- adsorption amounts in the soil at pH 3.3 and 1.0 $mmol_c/L$ with a mixture of H_2SO_4 and HNO_3. Because the SO_4^{2-} adsorption is stronger than that of NO_3^- in the allophanic andisol, the amount of SO_4^{2-} adsorption was much larger than that of NO_3^-. Figure 79.4 shows the state of SO_4^{2-} adsorption at pH 3.3 and 1.0 $mmol_c/L$ with a mixture of H_2SO_4 and HNO_3. Exchangeable SO_4^{2-} was obtained by exchanging the solution with 1 mol_c/L KCl solution after the soil was equilibrated at the prescribed solution condition. SO_4^{2-} in the diffuse layer was calculated by the Stern–Gouy–Chapman model, assuming that the adsorbed NO_3^- was all in the diffuse layer. The adsorbed SO_4^{2-} obtained by subtracting the exchangeable SO_4^{2-} from the total SO_4^{2-} is assumed to be an inner-sphere complex that is chemically adsorbed. More than 95 % of the adsorbed SO_4^{2-} remained on the soil surface from the calculation [5] because SO_4^{2-} is strongly adsorbed. Figure 79.5 shows the influence of coexisting SO_4^{2-} on NO_3^-

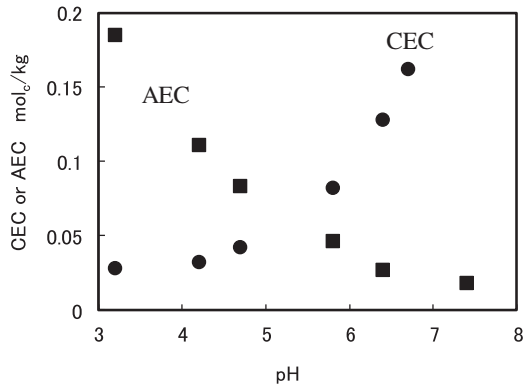

FIGURE 79.2 Amounts of electric charges of the allophanic andisol (AEC, anionic exchange capacity; CEC, cation exchange capacity) [2].

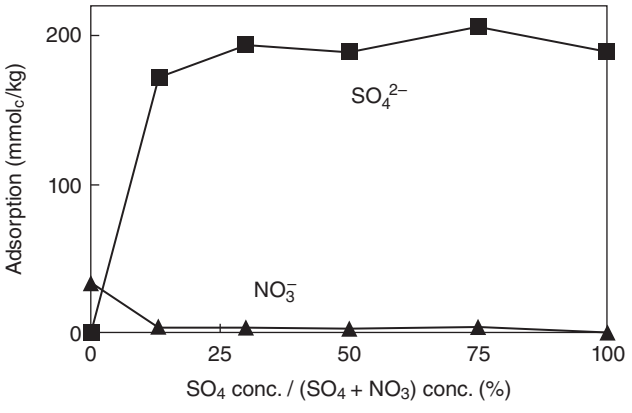

FIGURE 79.3 SO_4^{2-} and NO_3^- adsorption in the allophanic andisol at pH 3.3 and 1.0 $mmol_c/L$ with the mixture of H_2SO_4 and HNO_3 [5].

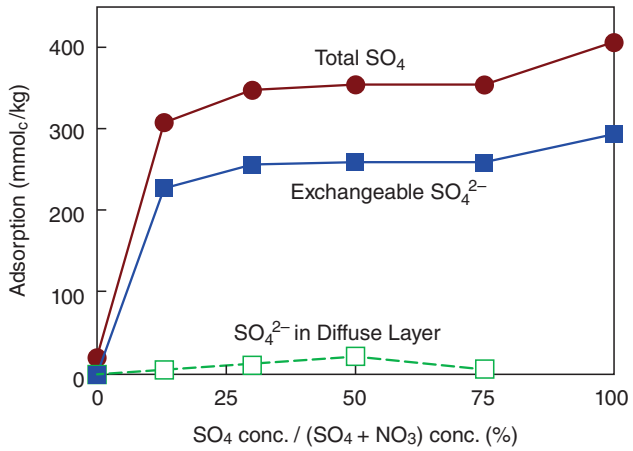

FIGURE 79.4 SO_4^{2-} adsorption in the allophanic andisol at pH 3.3 and 1.0 $mmol_c$/L with the mixture of H_2SO_4 and HNO_3. Exchangeable SO_4^{2-} was exchanged with a 1 mol_c/L KCl solution. SO_4^{2-} in diffuse layer was calculated by the Stern–Gouy–Chapman model [5].

breakthrough curves when a 10 $mmol_c$/L NO_3^- solution was percolated in the allophanic andisol. NO_3^- flowed out faster from the soil when SO_4^{2-} coexisted, because the affinity of SO_4^{2-} to the soil is much larger than that of NO_3^-. NO_3^- flowed out more slowly as a result of adsorption when SO_4^{2-} was not there. However, NO_3^- flowed out more quickly when the soil was initially equilibrated with a 10 $mmol_c$/L SO_4^{2-} solution (symbol □ in Fig. 79.5). The NO_3^- flow also became faster when SO_4^{2-} was included in the inflow NO_3^- solution at the same concentration of 10 $mmol_c$/L (symbol △ in Fig. 79.5). Because NO_3^- is a water contaminant and yet an important nutrient input for crops, it must be effectively used in the crop fields, and it must not be allowed to

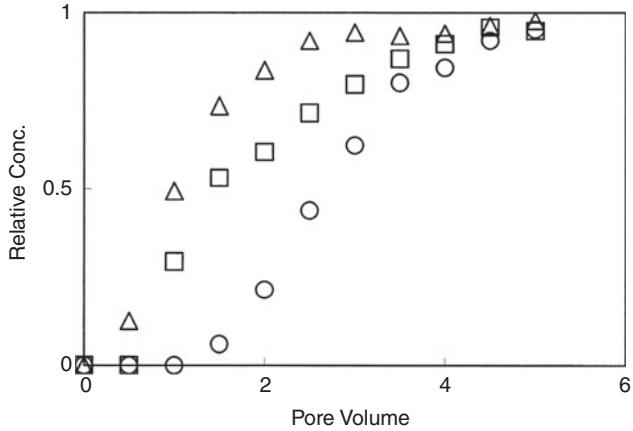

FIGURE 79.5 Effect of coexisting SO_4^{2-} on NO_3^- transport. NO_3^- breakthrough curves at10 $mmol_c$/L for the allophanic andisol; with no SO_4^{2-}(○), for the soil initially equilibrated with a 10 $mmol_c$/L SO_4^{2-} solution (□), and with a 10 $mmol_c$/L SO_4^{2-} solution(△) [6].

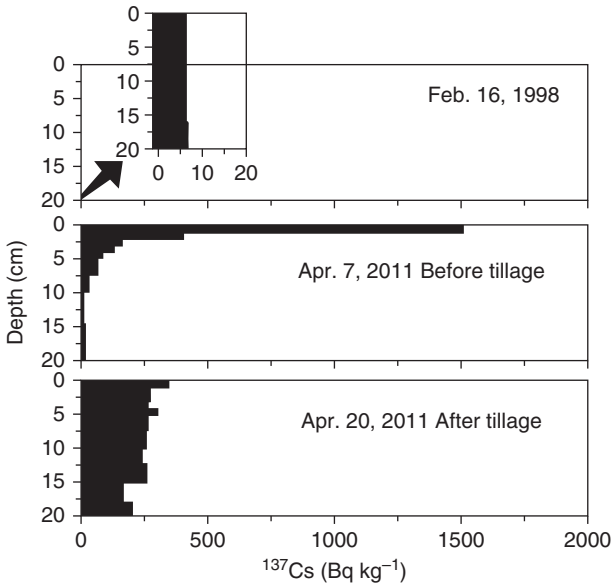

FIGURE 79.6 Radioactive Cs accumulation at the surface volcanic ash soil in Tsukuba, Japan after the accident at the Fukushima atomic power plant on March 11, 2011 [7].

leach. Therefore, sulfate application to the crop fields is not recommended in allophanic andisol, because it accelerates NO_3^- discharge [6].

Figure 79.6 shows radioactive cesium (Cs) accumulation in surface volcanic ash soil in Tsukuba, Japan after the accident at the Fukushima atomic power plant on March 11, 2011 [7]. Because the selectivity of Cs is about 1000 times larger than that of K at the frayed edge sites of some clay minerals, radioactive Cs was fixed strongly at the surface soil [8]. Such strong fixation occurs at the frayed edge of clays having a 2:1 layer structure and negative charges in Si tetrahedral layers such as vermiculite and illite [9]. Figure 79.7 shows the Cs fixation in the frayed edge of

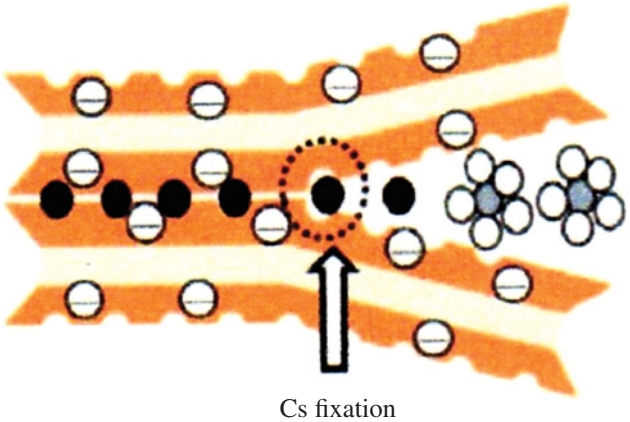

FIGURE 79.7 Cesium fixation in a frayed edge of vermiculite or illite [6].

vermiculite or illite [7]. Because the half-life of the radioactive Cs is 30.2 years, the soil contamination continues for a long time unless it is removed.

The electric charge density significantly influences ion transport in soils. Because ions are important nutrients for crops and sometimes harmful contaminants for living organisms, understanding the electric charge characteristics of soils is important when we consider effective nutrient use in agriculture and environmental conservation.

79.2.2 Influence of Selectivity Coefficient, Distribution Ratio, and Peclet Number on Ion Transport

The shape of the breakthrough curve is determined by the Peclet number for mass transfer, Pe, the selectivity coefficient, $k_{1/2}$, and the distribution ratio, D_g, as is shown in the following advective–dispersive equation with ion exchange [10]. The Peclet number is defined by

$$Pe = \frac{uL}{D} \tag{79.2}$$

where u is the mean pore water velocity (m/s), L is the soil length (m), D is the dispersion coefficient (m^2/s), and $k_{1/2}$ is a coefficient that indicates the distribution of Ions 1 and 2 between solution and adsorbed phases. Thus

$$\frac{q_1}{q_2} = k_{1/2}\frac{c_1}{c_2} \tag{79.3}$$

where q_1 and q_2 are the amounts of ions 1 and 2, respectively, in the exchange phase (mol_c/kg), and c_1 and c_2 are the concentrations of ions 1 and 2, respectively, in the soil solution (mol_c/m^3) [11, 12]. The input ion concentration, which is equal to the total ion concentration, c_0, is

$$c_0 = c_1 + c_2 \tag{79.4}$$

We assume that the total ion concentration is time-invariant in this binary system and that the two ions have the same valence in order to indicate basic transport phenomena. The ion exchange capacity, q_0 (mol_c/kg), is

$$q_0 = q_1 + q_2 \tag{79.5}$$

From Eqs. (79.3)–(79.5), we obtain

$$Q_1 = \frac{k_{1/2}C_1}{(k_{1/2}-1)C_1 + 1} \tag{79.6}$$

where Q_1 is the relative amount of ion 1 in the exchange phase and C_1 is the relative concentration of ion 1 in the soil solution [12]. They are represented as

$$Q_1 = q_1/q_0 \tag{79.7}$$

$$C_1 = c_1/c_0 \tag{79.8}$$

The one-dimensional advective–dispersive equation with ion exchange in a soil is

$$R_f\frac{\partial C_1}{\partial t} = D\frac{\partial^2 C_1}{\partial x^2} - u\frac{\partial C_1}{\partial x} \tag{79.9}$$

where t is time (s) and x is distance (m) [13]. R_f is defined by

$$R_f = 1 + D_g\frac{\partial Q_1}{\partial C_1} \tag{79.10}$$

Equation (79.9) can be expressed in dimensionless form by introducing the following dimensionless variables [10,14]:

$$X = x/L \tag{79.11}$$

$$T = \frac{ut}{(D_g+1)L} \tag{79.12}$$

The dimensionless time T equals the ratio of the real time to the mean time required for ion 1 to move through the distance $x = L$. We define the effluent volume at $T = 1$ as the apparent pore volume [15]. Given these data, we can rewite Eq. (79.9) in dimensionless form

$$\frac{\partial C_1}{\partial T} = \frac{1}{fPe}\frac{\partial^2 C_1}{\partial X^2} - \frac{1}{f}\frac{\partial C_1}{\partial X} \tag{79.13}$$

where f is

$$f = \frac{R_f}{D_g+1} = \frac{1}{D_g+1} + \frac{D_g}{D_g+1}\frac{\partial Q_1}{\partial C_1} \tag{79.14}$$

The derivative $\partial Q_1/\partial C_1$ in Eq. (79.14) is determined by the exchange isotherm. Differentiating Eq. (79.6) by C_1, we obtain

$$\frac{\partial Q_1}{\partial C_1} = \frac{k_{1/2}}{[(k_{1/2}-1)C_1 + 1]^2} \tag{79.15}$$

When the selectivity coefficient $k_{1/2}$ equals 1.0, that is, when the adsorption energy of ion 1 is the same as that of ion 2, f becomes 1 and the dimensionless advective–dispersive equation [Eq. (79.13)] becomes

$$\frac{\partial C_1}{\partial T} = \frac{1}{Pe}\frac{\partial^2 C_1}{\partial X^2} - \frac{\partial C_1}{\partial X} \tag{79.16}$$

which is similar to the equation for nonreactive solute. In this case, the normalized breakthrough curve can be determined by Pe as shown in Fig. 79.8 [16]. When Pe becomes larger, the breakthrough curve becomes steeper.

Figure 79.9 shows numerically calculated breakthrough curves of ion 1 using Eq. (79.13). When $k_{1/2}$ is smaller than 1.0, the ion 1 breakthrough curve is flatter than that for $k_{1/2} =$ 1.0 (Fig. 79.9a), because the displaced ion, ion 2, is preferred to the input ion, ion 1. When $k_{1/2}$ is larger than 1.0,

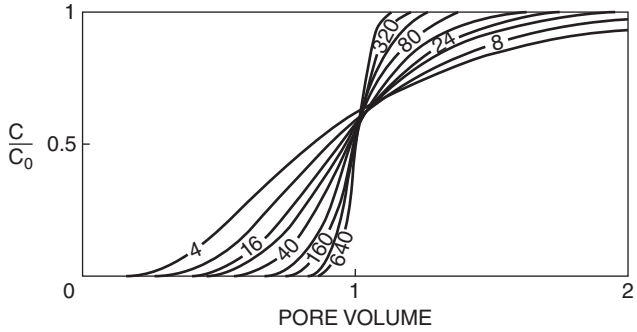

FIGURE 79.8 Breakthrough curves derived from one-dimensional advective–dispersive equation. The numbers on the curves denote Peclet numbers [16].

the ion 1 breakthrough curve is steeper than that for $k_{1/2} = 1.0$ (Fig. 79.9b), because ion 1 is preferred to ion 2.When D_g becomes larger, the breakthrough curve for $k_{1/2} < 1.0$ becomes flatter (Fig. 79.9a) and that for $k_{1/2} > 1.0$ becomes steeper (Fig. 79.9b). However, when D_g is much larger than 1.0, the breakthrough curves are almost the same; the breakthrough curves for $D_g = 10$ are almost same as those for $D_g = 50$, as shown in Fig. 79.9 [10].

Figure 79.10 shows the measured breakthrough curves and calculated breakthrough curves fitted using the measured exchange isotherm data shown in Fig. 79.11. The abscissa of the figure is the normalized cumulative volume, which is the same as T in Eq. (79.12), and is defined by

$$\frac{1}{D_g + 1}\frac{\text{outflow water volume}}{\text{water volume in the soil column}}$$

(unit; apparent pore volume)

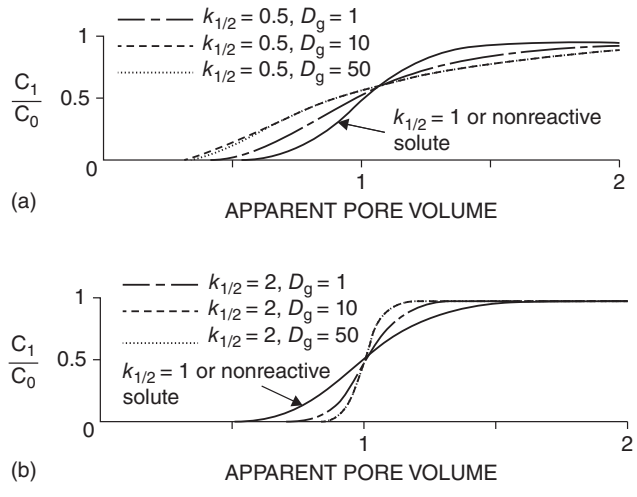

FIGURE 79.9 Effect of distribution ratio and selectivity coefficient on the breakthrough curve: (a) $k_{1/2} = 0.5$; (b) $k_{1/2} = 2$; Pe = 50 [10].

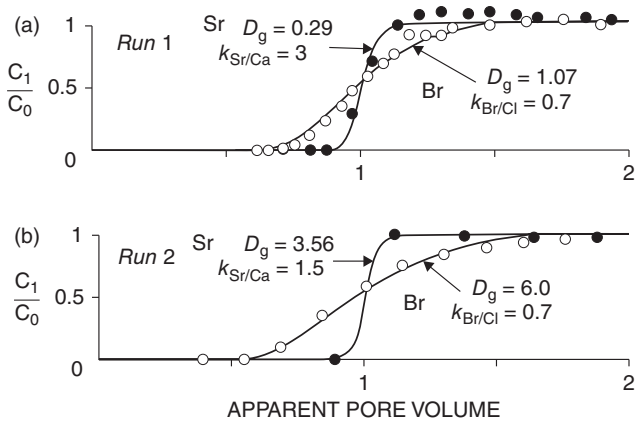

FIGURE 79.10 Comparison of measured breakthrough curves (symbols) and calculated breakthrough curves (solid lines): (a) run 1—pH 4.2, 100 mol_c/L; (b) run 2—pH 5.05, 10 mol_c/L [10].

We can confirm that when $k_{1/2}$ becomes larger, the breakthrough curve is steeper [10], as mentioned before.

79.3 SOIL DISPERSION AND FLOCCULATION

Figure 79.12 shows the result of a dispersion flocculation experiment for allophanic andisol in an Na-H-Cl-OH system at 1 $mmol_c$/L. The ordinate indicates the *dispersion ratio*, which is the ratio of the turbidity of the soil suspension after standing for 12 h to that just after shaking. When pH was lower (pH $\leq$ 4) or higher (pH $\geq$ 10), the soil suspension dispersed well. This is because the positive charge dominates at a lower pH and the negative charge dominates at a higher pH (Fig. 79.2). When the pH was in between, it flocculated well because considerable numbers of both negative and positive charges were present [17].

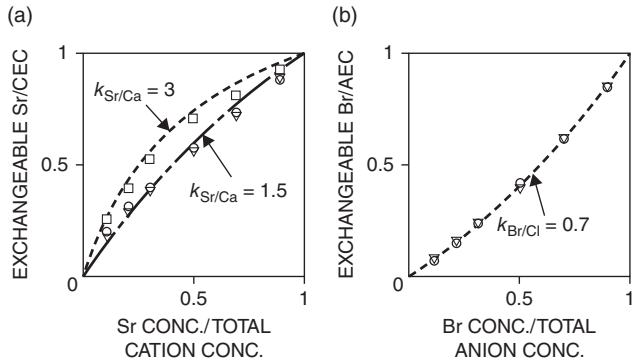

FIGURE 79.11 Measured exchange isotherms (symbols) and the isotherms calculated from Eq. (79.6) (dotted lines): (a) Sr-Ca exchange isotherms; (b) Br-Cl exchange isotherms (□ pH 4.55 and 100 mol_c/L; ○ pH 4.9 and 10 mol_c/L; ▽ pH 5.5 and 10 mol_c/L) [10].

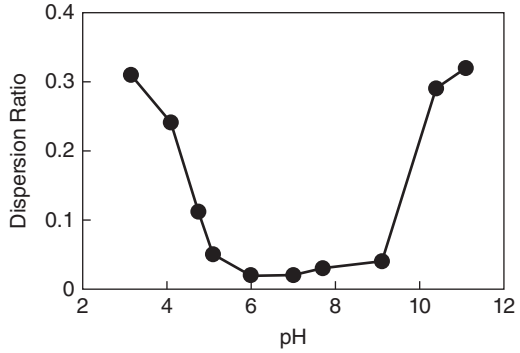

FIGURE 79.12 Influence of pH on dispersion and flocculation of allophanic andisol at 1 $mmol_c/L$ for Na-H-Cl-OH system [17]. Dispersion ratio = (turbidity of soil suspension for 12 h standing) / (turbidity of soil suspension just after shaking).

Figure 79.13 shows the result of the dispersion–flocculation experiments for SO_4^{2-} and NO_3^-solutions at 1 $mmol_c/L$ using allophanic andisol. The solutions were an Na-H-SO_4-OH system and an Na-H-NO_3-OH system. The soil dispersed well at lower pH for the NO_3^- solution. However, it flocculated at lower pH for SO_4^{2-} solution [18]. Zeta-potentials of the soil in the mixture of H_2SO_4 and HNO_3 at pH 3 and pH 4 are shown in Fig. 79.14. The ζ-potential was smaller when the SO_4^{2-} ratio was larger. It was larger when the NO_3^- ratio was larger. Figure 79.15 shows the repulsive potential energy when two soil particles come closer to each ζ-potential plane in the dilute acid. The following equations and ζ-potential obtained were used for the calculation:

$$V_\varsigma = -2\int_b^0 \Pi dD \tag{79.17}$$

$$\Pi = RT\sum(C_i - C_{0,i}) \tag{79.18}$$

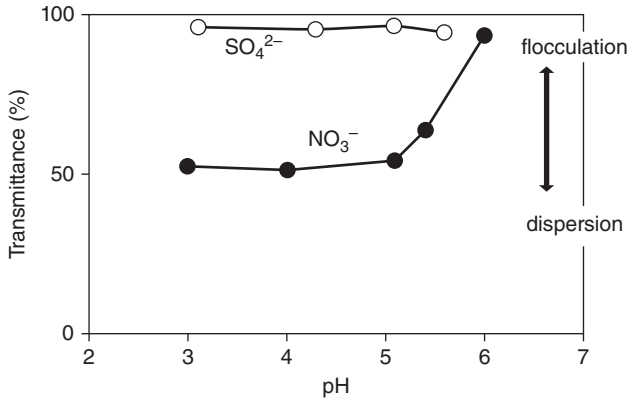

FIGURE 79.13 Effect of anion species on dispersion / flocculation of allophanic andisol at low pH [18].

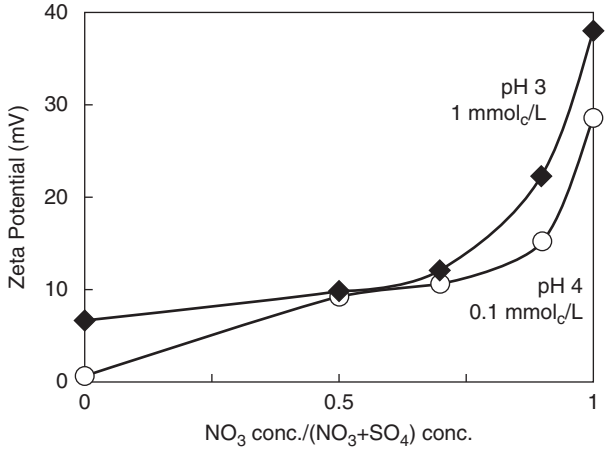

FIGURE 79.14 Zeta-potentials of allophanic andisol in dilute acids [17].

$$C_i(x) = C_{0,i}\exp\left(-\frac{z_i F\Psi_m}{RT}\right) \tag{79.19}$$

$$\Psi_m = 2\Psi \tag{79.20}$$

Here, V_ζ is the repulsive potential energy, D is the distance from the ζ-potential plane to the midpoint between the two soil particles, and b is the distance from the ζ-potential plane to the boundary of the bulk solution. The point at which the repulsive potential energy is equal to 0 is given in the bulk solution. Π is the osmotic pressure difference for each D, R is the gas constant, T the absolute temperature, C_i is the concentration of ion i at the midpoint between the soil particles, $C_{0,i}$ is the concentration of ion i in the bulk solution, z_i the valence of ion i, F is the Faraday constant, Ψ_m is the potential at the midpoint, and Ψ is the potential at the midpoint when the particle exists alone, as calculated by the Gouy–Chapman

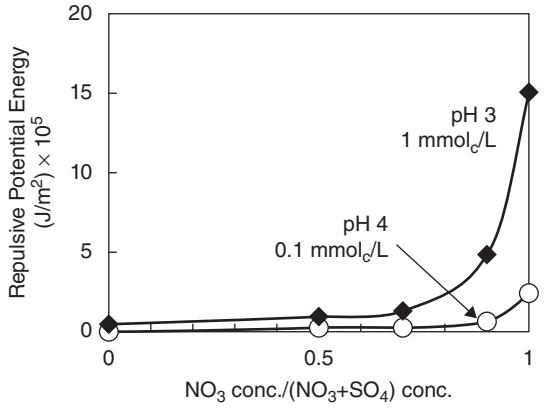

FIGURE 79.15 Calculated electrical repulsive potential energy between particles of allophanic andisol when they approach the ζ-potential plane [19].

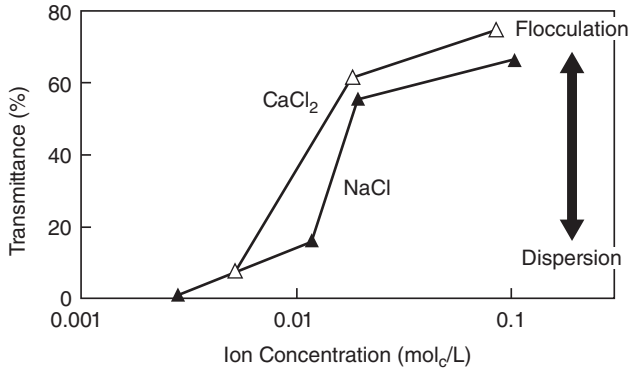

FIGURE 79.16 Effect of ion concentration and cation species on dispersion–flocculation of sediment soil in Lake Kojima; the solutions are at pH 7 [20].

theory. The repulsive potential energy is larger when the NO_3^- ratio in the acid mixture solution is larger (Fig. 79.15). This confirms the result that the soil dispersed well in NO_3^- solution at lower pH and flocculated well in SO_4^{2-} solution (Fig. 79.13) [19]. The behavior of dispersion or flocculation is caused by the difference of adsorption state between the anions because the positive charge is predominant at lower soil pH. Most SO_4^{2-} is strongly adsorbed on the soil surface (Fig. 79.4), while NO_3^- is adsorbed in a diffuse layer, as mentioned before. When most of the anions are adsorbed only on the positively charged soil surface, a diffuse layer does not develop. Then, the soil flocculates well because the electric repulsive potential between the soil particles is small (Fig. 79.15).

Figure 79.16 shows the result of the dispersion–flocculation experiment for the sediment soil of Lake Kojima at pH 7. A well-mixed soil suspension was settled for 8.3 h. Then, the soil suspension was sampled at 3 cm in depth from the water surface and the light transmittance through it at 500 nm wavelength was measured. The soil under an Na^+ system dispersed more than did soil under a Ca^{2+} system because Na^+ is a monovalent cation while Ca^{2+} is a divalent cation, which corresponds to the Shulze–Hardy rule. Cation species influence the dispersion flocculation because the negative charge is predominant in this soil. The soil flocculated well when the ion concentration increased, because the diffuse layer became thin and the repulsive force between soil particles became smaller at a higher ion concentration, due to the shielding of the electric field [20]. This phenomenon is observed at seashore estuaries. Dispersed soil suspensions that adsorb nutrients flow down from rivers. They flocculate and deposit at estuaries because of their high salt concentrations. These regions provide good fisheries as nutrients are accumulated. The fate of radioactive Cs is similarly affected by this phenomenon. Accumulation of radioactive Cs was observed at the mouth of the Arakawa River in Tokyo Bay after the nuclear accident at the Fukushima atomic power plant on March 11, 2011, as shown in Fig. 79.17. The distribution in the sediments above 5 cm in depth sampled from August 2011 to November 2012 was observed. Part of the radioactive Cs that was scattered into the air from the Fukushima atomic power plant flowed down to the Kanto region. The radioactive Cs was fixed to clays in the surface soil, as mentioned earlier. The dispersed clays on which Cs was strongly adsorbed were conveyed by water and gathered in the Arakawa estuary. They flocculated and deposited at that estuary [21]. The discharge of dispersed soil suspensions from paddy fields to the water environment can also cause environmental problems because soil suspensions contain nutrients. Discharge after fertilizer application before transplanting is especially problematic. Plans for appropriate water contaminant mitigation have been proposed [22–25]. Soil dispersion and flocculation are key processes in material cycles in nature; understanding these processes is crucial to addressing environmental contamination associated with agriculture and industry.

79.4 INFLUENCE OF DISPERSION ON SOIL PERMEABILITY

Figure 79.18 shows the change of saturated hydraulic conductivity of allophanic andisol during the percolation of solutions at different pH levels in a 1-$mmol_c$/L Na-H-Cl-OH system. The hydraulic conductivity decreased at lower ($pH \leq 4$) and higher ($pH \geq 10$) levels. The positive charge predominated at more acidic levels and the negative charge, at more alkaline levels, as mentioned before (see also Fig. 79.2). Therefore, the soil dispersed well at lower and higher pH (Fig. 79.12) because the electric repulsive potential energy increased. This led to a decrease in the hydraulic conductivity because macropores in the soil became narrower as a result of swelling of the soil and clogging in the macropores [17]. Figure 79.19 shows the surface of the soil sample before and after percolation of the HCl solution at pH 3. Before the dilute HCl percolation, many aggregates were observed; after the percolation, the aggregates were dispersed. Figure 79.20 shows a vertical cross section of the soil sample after dilute HCl percolation at pH 3. The soil structure of the surface layer changed by soil swelling and macropore clogging [3]. The influence of the electric repulsive force was clearly observed [3,17].

Figure 79.21 shows the change in saturated hydraulic conductivity of allophanic andisol during percolation of dilute HNO_3 and H_2SO_4. While the hydraulic conductivity decreased during HNO_3 percolation, that during H_2SO_4 percolation did not decrease but rather increased [18]. The result corresponds to the results of the dispersion flocculation experiment in Fig. 79.13 and the calculated repulsive potential energy in Fig. 79.15. The repulsive potential energy for HNO_3 was significant, and the soil dispersed well. Therefore,

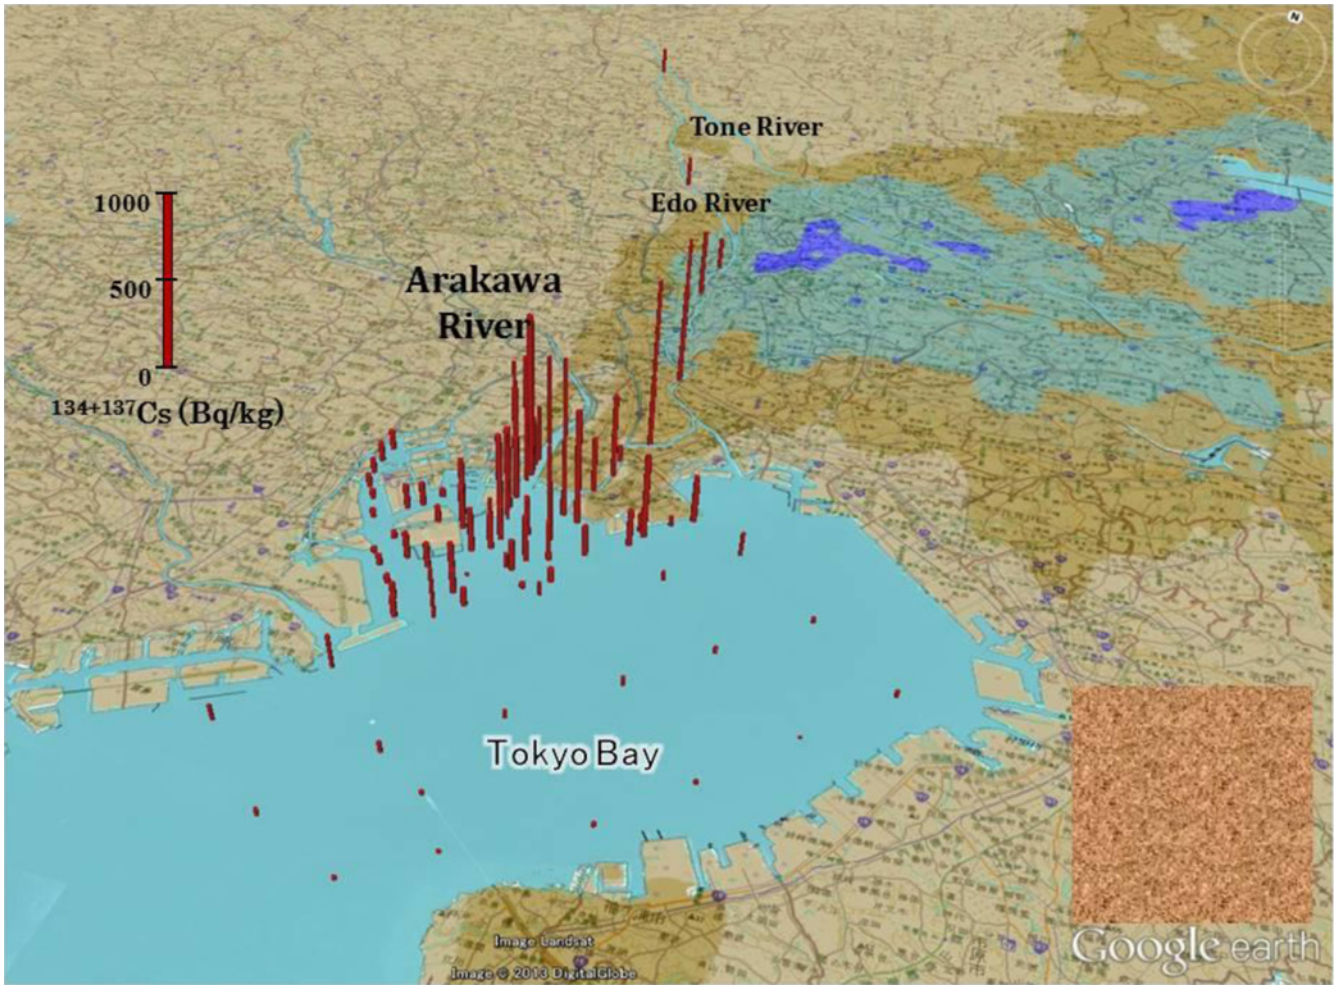

FIGURE 79.17 Radioactive cesium distribution in Tokyo Bay. Cs accumulated at the mouth of Arakawa river [21]. (Map data: Google, DigitalGlobe.)

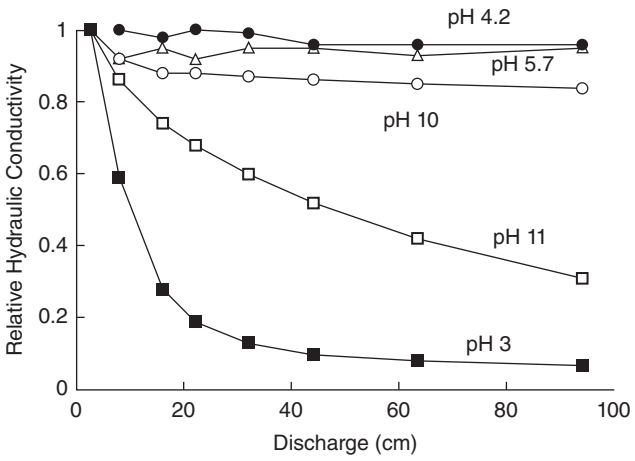

FIGURE 79.18 Effect of pH on saturated hydraulic conductivity of allophanic andisol. The electrolyte concentration was 1 mol_c/L for Na-H-Cl-OH system [3].

the hydraulic conductivity decreased as a result of swelling and dispersion. The hydraulic conductivity for HNO_3 at pH 3 decreased more than that at pH 4, because the repulsive potential energy at pH 3 was greater than that at pH 4. The hydraulic conductivity for H_2SO_4 did not decrease because the repulsive potential energy was smaller and the soil was well flocculated [19]. The difference is due to the variation in adsorption state; NO_3^- is adsorbed into the diffuse layer while SO_4^{2-} is strongly adsorbed just on the soil surface. The adsorption state also influences soil structure and permeability.

Figure 79.22a shows the changes in saturated hydraulic conductivity of the sediment soil in Lake Kojima at different pH levels in a Na system. The soil was initially equilibrated with a 0.1 mol_c/L NaCl solution at the prescribed pH. Then, the NaCl solution was percolated by decreasing the concentration ($0.1 \rightarrow 0.01 \rightarrow 0.001 \rightarrow 0$ mol_c/L) stepwise. The hydraulic conductivity decreased with increase in pH and

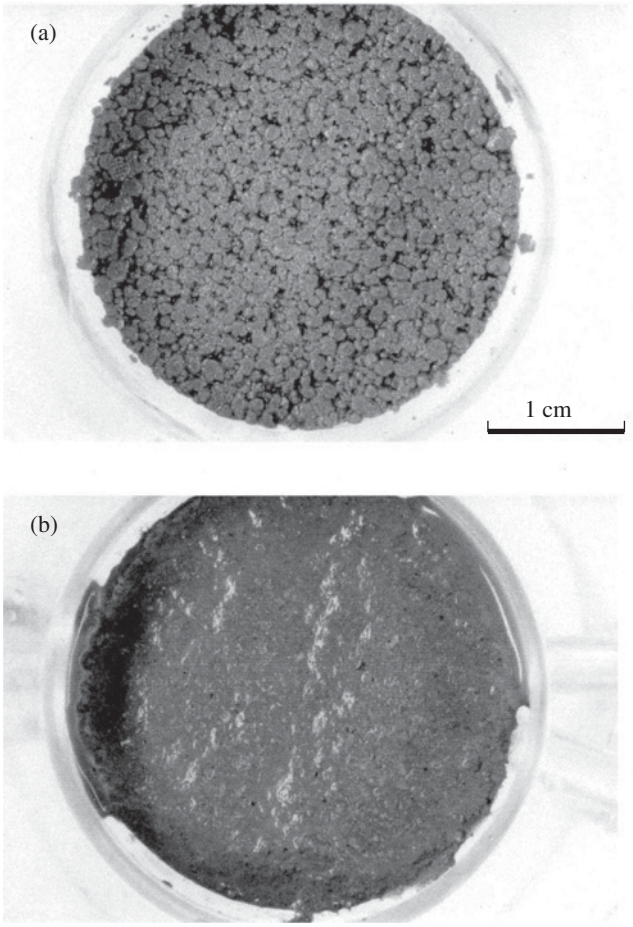

FIGURE 79.19 Surface soil structure of the allophanic andisol (a) before and (b) after HCl at pH 3 percolation (1.33 m) [3].

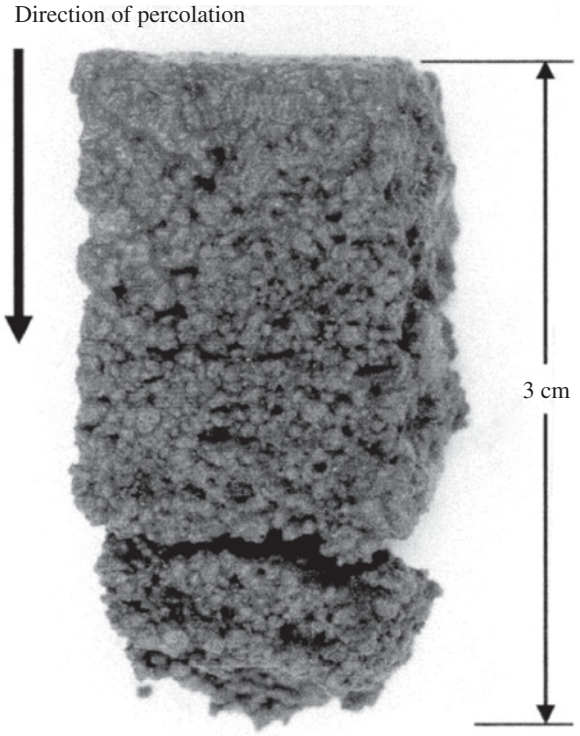

FIGURE 79.20 Vertical cross section of allophanic andisol sample after percolation of HCl solution at pH 3 (1.33 m) [3].

decrease in ion concentration. When the pH increases, the negative charge of the soil increases and the repulsive potential energy between soil particles increases. Then, the soil disperses well and the hydraulic conductivity decreases. When the ion concentration decreases, the diffuse layer becomes thicker and the repulsive potential energy between soil particles increases. Therefore, the soil disperses well, as mentioned before, and the hydraulic conductivity decreases. Figure 79.22b shows the same experiment conducted in a Ca system. The decrease in hydraulic conductivity in the Ca system with the decrease of ion concentration was smaller than that in Na system, because Ca^{2+} is divalent while Na^{+} is monovalent and the soil in a Ca system is more flocculative, as mentioned before. The hydraulic conductivity in a Ca system at pH 11 only slightly decreased with the decrease in ion concentration and was greater than that at pH 9. This was because the soil structure stabilized at pH 11 in a Ca system, due to the chemical reaction between Ca and the soil under alkaline conditions. Historically, reflecting this reaction, a method that consisted in using lime to improve ground stability was used in road construction during the ancient Roman era [20].

When the soil contains Na^{+}, the permeability tends to decrease and the discharge from the soil proceeds very slowly. This condition corresponds to the land reclaimed from below seawater level, such as the Na-salt-accumulated land damaged by tsunami seawater. Because the soil permeability required to wash out Na salt decreases when land is irrigated, a proper drainage plan must be considered. In

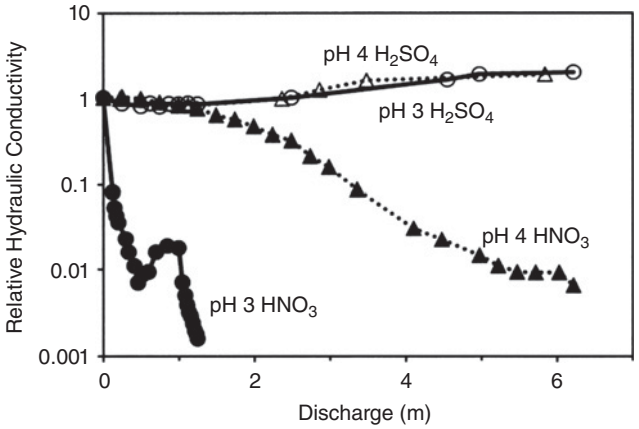

FIGURE 79.21 Effect of anion species of acid solution on saturated hydraulic conductivity of allophanic andisol [18].

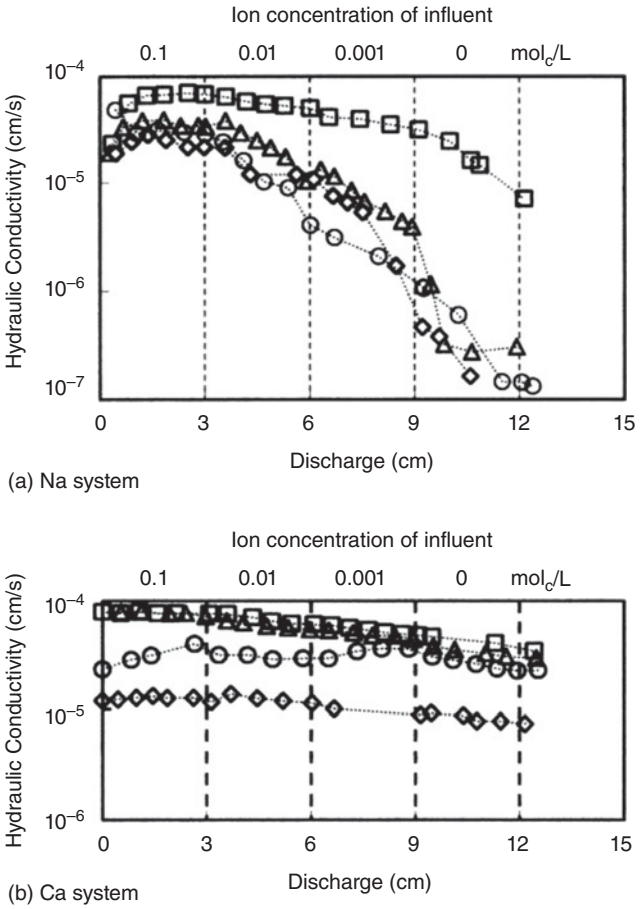

FIGURE 79.22 Effect of soil pH on saturated hydraulic conductivity of the sediment soil of Lake Kojima: (a) Na system; (b) Ca system (□ pH 5; △ pH 7; ◇ pH 9; ○ pH 11) [20].

particular, the permeability decreases at higher pH. Research of this type has been conducted since ancient times because damage due to salt accumulation in crop fields easily occurs in semiarid regions. One theory for the collapse of ancient civilizations is that crop fields were damaged by salt accumulation [26]. Although this theory is not new, current research is focusing on similar problems generated in many areas in the world.

79.5 SURFACTANT ADSORPTION

Surfactants are used for many purposes such as in domestic, industrial, and agricultural applications. When they are discharged into the environment, they can damage the ecosystem, because they can destroy the cells of living organisms. On the other hand, they are sometimes used for remediation of contaminated soils. Because surfactants can change the characteristics of solid surfaces, they affect the physicochemical nature of the soils into which they are introduced.

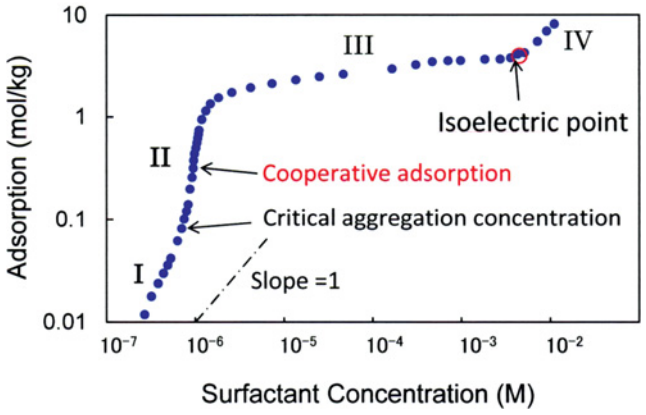

FIGURE 79.23 Cationic surfactant adsorption on anionic polymer in a 5-mmol/L NaCl solution [27].

Before showing the adsorption on soils, it is appropriate to discuss the adsorption on a simple polymer because the fundamental phenomena can be introduced using the polymer adsorption as an example; soils themselves consist of many kinds of materials, and the phenomena are more complicated. Figure 79.23 shows the adsorption of a cationic surfactant, dodecylpyridinium chloride, on an anionic polymer, sodium polystyrene sulfonate. The adsorption isotherm, which is plotted in double-logarithmic scale, is divided into four regions. In *region I*, representing very low adsorption, each monomer surfactant is adsorbed independently on the polymer chain as a result of electrostatic attraction. The slope is close to one unit, the *Henry slope*, which indicates adsorption on isolated *equal-energy sites*. In *region II*, the slope is much larger than one. This indicates cooperative adsorption by which surfactants gather and are adsorbed together because surfactant hydrophobic chains attract each other by hydrophobic interaction. The crosspoint of regions I and II is called the *critical aggregation concentration* (CAC), where surfactants begin to aggregate into polymer chains. In *region III*, the slope gradually becomes smaller because the negative-charge sites decrease. In *region IV*, the net charge becomes positive because the adsorption of surfactant exceeds the negative charge of the polymer as a result of hydrophobic attraction [27].

Humic substances are one of the important components of soils. They characterize soils and play important roles in the material cycle in Nature. Humic substances can be classified into three types: *fulvic acids*, which are soluble in water; *humic acids*, which are soluble in water at pH > 3; and *humins*, which are insoluble in water. Figure 79.24 shows the adsorption of the cationic surfactant, dodecylpyridinium chloride, on three kinds of humic acid and two kinds of fulvic acid. They adsorb the cationic surfactant by electrostatic attractive force as they have negative charges. Cooperative adsorption is not observed because their structures are complicated and surfactants do not aggregate easily. The

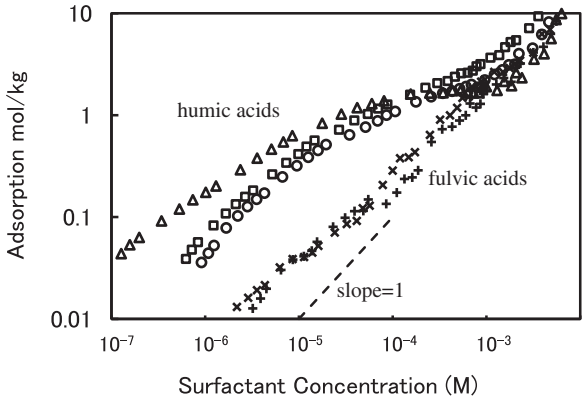

FIGURE 79.24 Cationic surfactant adsorption on fulvic acids and humic acids in a 5 mmol/L NaCl solution (△ Aldrich humic acid; □ Inogashira humic acid; ○ Dando humic acid; × Strichen fulvic acid; + Laurentian fulvic acid) [29].

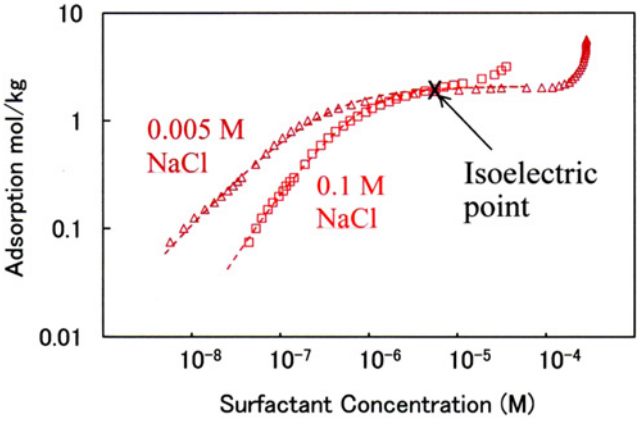

FIGURE 79.26 Effect of ion concentration on surfactant, cetylpyridinium chloride, adsorption in Aldrich humic acid [29].

surfactant begins to adsorb on the humic acids at lower surfactant concentration compared to the fulvic acids, which reflects the difference in hydrophobicity. Figure 79.25 shows the influence of carbon chain length on surfactant adsorption. The effect of hydrophobic chain length of the surfactant on adsorption on Aldrich humic acid is clear. The longer-linear-chain surfactant, cetylpyridinium chloride, has 16 carbons. The shorter-linear-chain surfactant, dodecylpyridinium chloride, has 12 carbons. Both surfactants are positively charged, but the surfactant with longer carbon chain is more hydrophobic. The longer-chain surfactant is adsorbed at lower surfactant concentration. This reflects the stronger adsorption that was caused by the lateral hydrophobic interaction among the carbon chains of the surfactant. One research team [28] indicated that the chain length dependence of the free energy of adsorption per CH_2 group amounts to approximately 3.1 kJ/mol in an alkylpyridinium fulvic acid system and 2.3 kJ/mol in an alkylpyridinium humic acid system. Figure 79.26 shows the effect of ion concentration on the adsorption of the surfactant, cetylpyridinium chloride, on Aldrich humic acid. The surfactant adsorption at 0.1 M NaCl is less than that at 0.005 M NaCl at lower surfactant concentration where the humic acid–surfactant complex is negatively charged. On the other hand, the surfactant adsorption at 0.1 M NaCl is greater than that at 0.005 M NaCl at higher surfactant concentration where the humic acid–surfactant complex is positively charged. This result was induced by the screening effect of the higher ion concentration. As a result of the screening effect at the higher ion concentration, the attractive electric force on the negatively charged surface becomes smaller at lower surfactant concentration, and the repulsive electric force on the positively charged surface becomes smaller at higher surfactant concentrations. Therefore, the adsorption decreased in the former case and increased in the latter case [29].

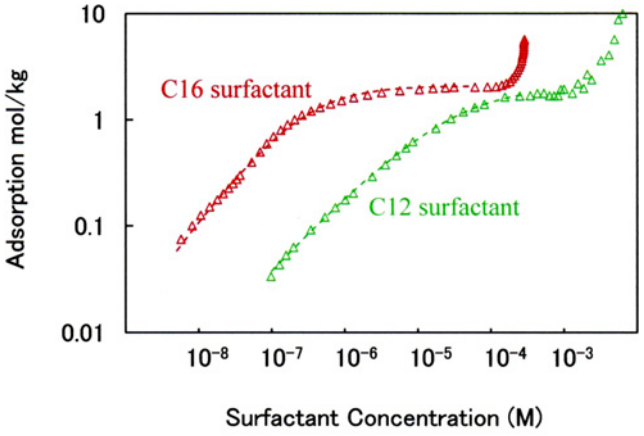

FIGURE 79.25 Effect of surfactant chain length on adsorption in Aldrich humic acid in a 5 mmol/L NaCl solution (C16 surfactant = cetylpyridinium chloride, C12 surfactant = dodecylpyridinium chloride) [29].

When a surfactant is adsorbed on a solid surface, the surface characteristics completely change, because a surfactant is a surface-active agent. Figure 79.27 shows the influence of adsorption of the cationic surfactant dodecylpyridinium chloride on silica stability and the contact angle of water on the silica surface. When the surfactant is adsorbed on the silica, the negative-charge sites of the silica are covered with the surfactant. The stability decreases and the silica gradually becomes flocculative. When the surfactant is adsorbed on more than only the negative-charge sites of the silica, the silica–surfactant complex becomes positively charged. The complex becomes dispersive when the surfactant adsorption is sufficient. When the surfactant covers all negative charge sites and the charge is canceled, the contact angle of water on the silica is largest because the silica surface is covered with the hydrophobic carbon chain of the surfactant [30].

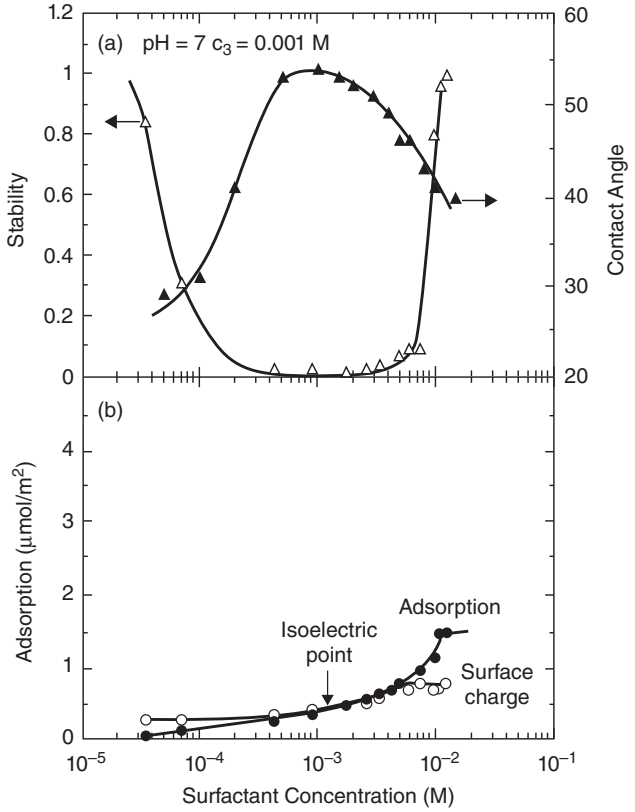

FIGURE 79.27 Stability, contact angle, cationic surfactant adsorption, and surface charge of silica [30].

Figure 79.28 shows the effect of pH on anionic surfactant adsorption in highly humic soil at 100 mM NaCl. The anionic surfactant is sodium dodecylbenzene sulfonate. The highly humic soil has only a negative charge. Therefore, an electric repulsive force is generated between the surfactant and the soil. However, the anionic surfactant is adsorbed by hydrophobic attraction. The adsorption decreases with

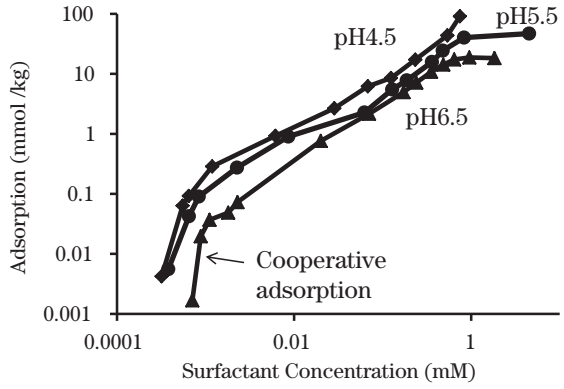

FIGURE 79.28 Effect of pH on anionic surfactant adsorption in highly humic soil [31].

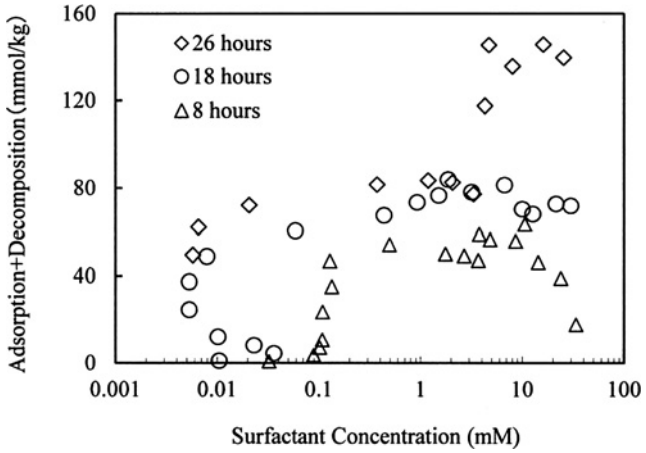

FIGURE 79.29 Sodium dodecyl sulfate (SDS) adsorption and decomposition in highly humic soil. The number denotes the elapsed time after mixing the surfactant and the soil [39].

increasing pH because the negative charge of the soil increases and the repulsive force increases with increasing pH. The increase in negative charge can be detected by the increase in magnitude of the ζ-potential of the soil particles. At lower surfactant concentrations, cooperative adsorption is observed where the slope is larger than one in a double-logarithmic plot [31]. Surfactant adsorption correlates positively with the organic matter content of the soils [32–37] and increases with increasing alkyl chain length [38].

Sodium dodecyl sulfate (SDS) is an anionic surfactant that has a simple linear carbon chain. It decomposes well in humic soil. Figure 79.29 shows the SDS adsorption decomposition in highly humic soil. The number in the figure denotes the elapsed time after mixing the surfactant and the soil. The adsorption–decomposition amount increases with time as a result of decomposition. Surfactants with such simple carbon chains decompose easily in humic soil. At lower surfactant concentrations, the slopes of the curves are steep or skewed, which indicates cooperative adsorption. Figure 79.30 shows the SDS breakthrough curve and the saturated hydraulic conductivity for highly humic soil. After the soil was saturated with a 1 mM NaCl solution, an SDS solution at 5 mM was continuously percolated into the 30-cm-height, 5-cm-diameter soil column. The effluent surfactant concentration initially increased, but after the initial small peak, it gradually decreased to zero—even though the surfactant was continuously percolated. This indicates the process of adsorption and decomposition of the surfactant in the soil. The saturated hydraulic conductivity of the soil decreased gradually with decrease of the breakthrough curve. Because the negative charge of the soil increased as the surfactant adsorption increased, the repulsive force among soil particles increased during the surfactant percolation. This caused a change in

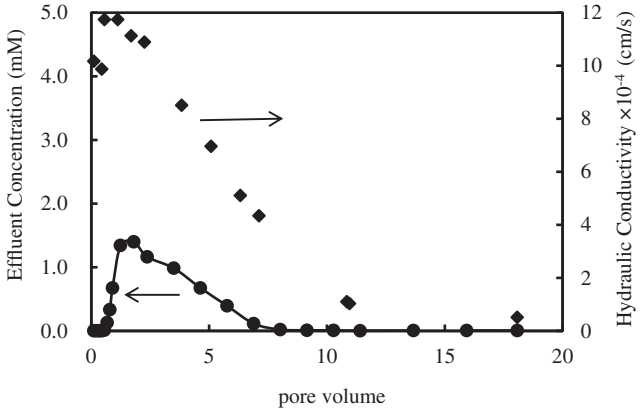

FIGURE 79.30 Sodium dodecyl sulfate (SDS) breakthrough curve and saturated hydraulic conductivity for the highly humic soil; SDS solution at 5 mM was continuously percolated [39].

the soil structure and a decrease in hydraulic conductivity. The surfactant adsorption clearly affects transport phenomena [39].

79.6 ION EXCLUSION AND SALT SIEVING

Ions having same-sign electric charges with the soil itself are excluded from the diffuse layer of the soil. The ions are not only excluded from the diffuse layer but also excluded from the larger pores surrounded by the narrow pores in which diffuse layers overlap. Such ion exclusion affects the ion transport in soils [40–45]. Figure 79.31 shows the NO_3^- breakthrough curve during percolation of 1-mol_c/L NO_3^- solution for the A horizon of allophanic andisol; the soil has negative charge and no positive charge. Because of the anion exclusion, NO_3^- flowed out slightly faster than a nonreactive solute. If there is no interaction with the soil surface, the solute breakthrough curve shows an increase at around 1 pore volume and the relative effluent concentration becomes 0.5

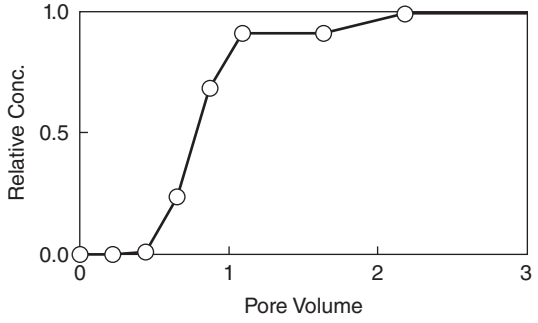

FIGURE 79.31 NO_3^- breakthrough curve during percolation of 1-mol_c/L NO_3^- solution for soil that has a negative charge and no positive charge [6].

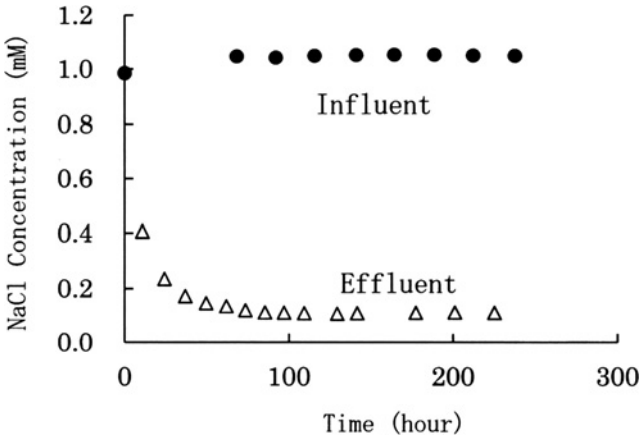

FIGURE 79.32 Salt sieving of montmorillonite membrane.

at 1 pore volume [6]. The NO_3^- breakthrough curve shifted slightly to the left compared to that for the nonreactive solute.

Figure 79.32 shows the salt-sieving effect of a montmorillonite membrane 0.5 mm in thickness. Because montmorillonite is a clay mineral that has a large cation exchange capacity (80–150 $cmol_c$/kg) and specific surface (600–800 m^2/g) [46], its diffuse layer can develop well and the clay is heaviy influenced by its electric charge; it disperses and swells effectively under low electrolyte concentration. When its diffuse double layer overlaps, salts are sieved by it, as shown in Fig. 79.32. The effluent NaCl concentration became 10% of the influent NaCl concentration of 1 $mmol_c$/L [47]. The clay membrane shows the characteristics of a reverse-osmosis membrane.

Transport phenomena in a clay layer are restricted by the water pressure difference ΔP, the osmotic pressure difference $\Delta\pi$, and the electric potential difference ΔV between both ends of the layer under isothermal conditions. Figure 79.33 shows those measured values of a thin montmorillonite clay subject to different NaCl concentrations of 1 $mmol_c$/L and 0.1 $mmol_c$/L under the condition of zero net flux of liquid [48]. The concentration difference between the clay layer induced a pressure difference and an electric potential difference . Groenevelt et al. [49] applied the following phenomenological equations derived from irreversible thermodynamics and evaluated the results:

$$j_V = L_V F_V + L_{VD} F_D + L_{VE} F_E \tag{79.21}$$

$$j_D = L_{VD} F_V + L_D F_D + L_{DE} F_E \tag{79.22}$$

$$I = L_{VE} F_V + L_{DE} F_D + L_E F_E, \tag{79.23}$$

In these equations, j_V is the water flux, j_D is the salt flux, I is the electric current, L represents the phenomenological coefficients, $F_V = -\Delta P/\Delta X$, $F_D = -\Delta\pi/\Delta X$, $F_E = -\Delta V/\Delta X$, and ΔX denotes the thickness of the thin clay layer. Such

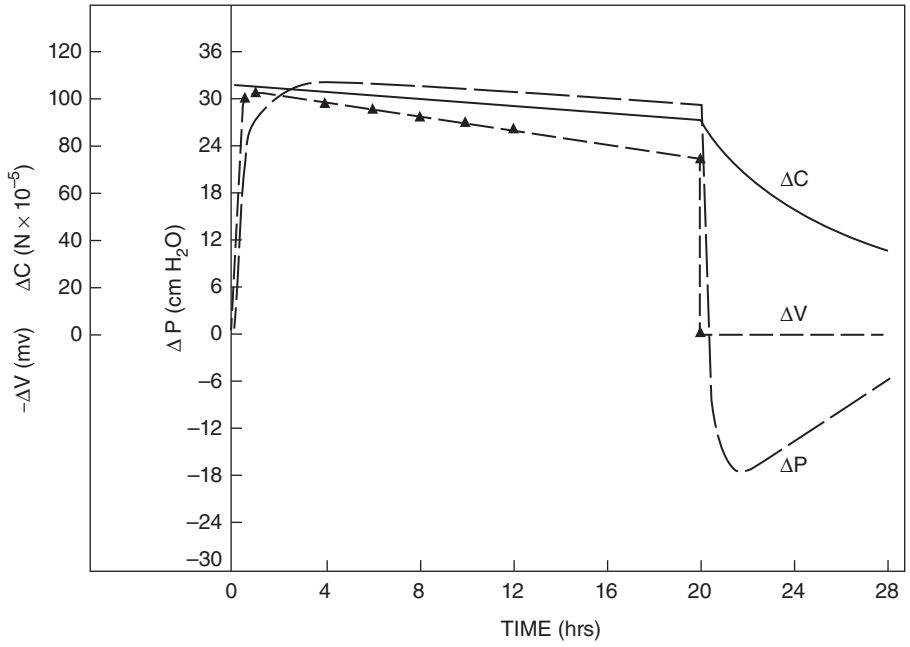

FIGURE 79.33 Changes in concentration difference ΔC, pressure difference ΔP, and voltage difference ΔV, with time for a thin clay layer [48].

coupling phenomena occur during salt sieving and transport in clayey soils [45]. Further research efforts are required to evaluate these interesting phenomena that will relate to environmental technology.

PHARMACEUTICAL SOLID–WATER INTERFACE PHENOMENA MEASURED BY NEAR-INFRARED SPECTROSCOPY

YUSUKE HATTORI AND MAKOTO OTSUKA

Research Institute of Pharmaceutical Sciences, Musashino University, 1-1-20, Shin machi, Nishitokyo, Tokyo 202-8585, Japan

80.1 INTRODUCTION

Because of its portability, countability, and ease of administration, solid dosage is one of the most popular drug formulations. In the more recent decades, the large-scale manufacturing process has significantly improved. New drug additives have been developed for suitable in vivo dissolution of active ingredients. Dissolution and controlled release of active ingredients are critical to an efficient drug delivery, and both have been the object of active investigations [1–7].

On oral administration of a solid dosage, drug absorption rate depends on (1) the release rate of the drug substance from the product, (2) the dissolution rate of the active ingredient under physiological conditions, and (3) the permeability across the gastrointestinal tract. In vitro studies investigating the process of dissolution can bring significant insight into predicting the properties of solid formulations in vivo. Thus, in vitro dissolution tests for solid dosage forms, such as tablets and capsules, are conducted in order to ensure lot-to-lot reproducibility and product quality [2, 8]. When drug formulations, manufacturing processes, or manufacturing sites are changed, in vitro dissolution tests provide useful information to ensure continued quality.

The theory on the dissolution of solids was first introduced by Noyes and Whitney [9], while Nernst presented a diffusion-controlled dissolution model based on Fick's first law [10]. The in vitro dissolution of active ingredients from solid dosage forms is classically interpreted by the Noyes–Whitney–Nernst dissolution model. In this model, the dissolution rate $\mathrm{d}C/\mathrm{d}t$ of a substance from a solid state is calculated as

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{DS}{Vh}(C_s - C) \tag{80.1}$$

where C_s and C represent its solubility concentration and the concentration of the dissolved substance in the bulk solution at a time t, respectively; D, V, and S are the diffusion coefficients of the dissolved substance in the bulk solution, the volume of the solution, and the exposed surface of the solid, respectively. Additionally, Nernst described a zone of nonequilibrium concentration gradient commonly known as the *diffusion layer*, at the interface between the solid and the bulk solution. At the surface of a solid, the concentration of a substance reaches saturation and then decreases toward the bulk concentration. The thickness of the diffusion layer is represented by h in Eq. (80.1).

The diffusion of particles at nonequilibrium is described by Fick's second law:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} = \frac{\partial}{\partial x}\left(D\frac{\partial C}{\partial x}\right) \tag{80.2}$$

In the dissolution theory proposed by Nernst, it is assumed that the diffusion layer of thickness h exists at the solid surface undergoing dissolution; thus, the concentration gradient at the interface is calculated as follows:

$$\frac{\mathrm{d}C}{\mathrm{d}x} = \frac{C_s - C}{h} \tag{80.3}$$

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

By substituting Eq. (80.3) into the diffusion equation Eq. (80.2), the equation thus becomes

$$\frac{\mathrm{dC}}{\mathrm{dt}} = \frac{D}{xh}(C_s - C) \tag{80.4}$$

When a partial, flat, and small area of a solid surface is being considered, the solid surface area S and the volume of the solution V may be substituted by x, which is the distance from a solid surface, with $x = V/S$ in Eq. (80.1). Finally, given h, the thickness of the diffusion layer, the dissolution equation [Eq. (80.1)] is derived from the diffusion equation as presented in Fick's second law.

On oral administration, drug release and dissolution rates from a solid dosage form coincide with its disintegration into particles or granules [11–13]. The total surface area of disintegrated granules may become 10^3 times larger than that of a tablet. At microscopic scale, the distance x from a solid surface is used, instead of S and V, as constant surface area. However, the surface area has a significant contribution in controlling the macroscopic dissolution of active ingredients from a solid dosage form.

The process of disintegration and dissolution of an active ingredient from solid dosages has been empirically characterized by several models such as first-order [14], Hixson–Crowell [15], Higuchi [1], Weibull [16–18], and Korsmeyer–Peppas [19] functions.

A first-order dissolution kinetics represents a dissolution model similar to the one described in the Noyes–Whitney equation, with a constant surface area. Expression of the drug dissolution rate of uniformly sized particles is based on the cube root of the particle weight in accordance with the Hixson–Crowell cube root law.

Higuchi developed theoretical models of drug release from semisolid and solid matrixes, such as ointments and polymer matrices. In the Higuchi model, the amount of released drug is proportional to the square root of time, and the matrix surface is assumed to be constant.

Another model to describe dissolution profiles is the empirical use of the Weibull function

$$C(t) = 1 - \exp(-at^b) \tag{80.5}$$

where a and b are constants. However, there is currently a lack of meaning in these parameters, and this is a pending issue [4, 16]. Recently, this empirical model nicely described the dissolution profiles in both Euclidian and fractal spaces, and the relation between the exponent b and the fractal geometry of its solid structure has been investigated [16, 20, 21]. One research team [20, 21] reported the results of Monte Carlo simulation illustrating the relationship between b and the drug release substrate structure as follows: (1) when $0.35 < b < 0.69$, the drug is released from fractal or disordered substrate; (2) when $0.69 < b < 1$, the drug is released from Euclidian substrate; (3) and when $b = 1$, there is a first-order drug release in accordance with Fick's first law of diffusion [20, 21].

Earlier, another team reported a method that predicts the specific surface area of solid dosages during diffusion and disintegration-controlled dissolution using a model-dependent function [22]. According to this method, the surface area at a given time t may be obtained using the function for area variations during dissolution. According to the authors, the calculated profiles are in good agreement with experimental profiles in describing drug dissolution using the Weibull function.

Another team proposed a model-free function based on the Noyes–Whitney–Nernst equation [23]

$$C(t) = C_s \int_0^{\tau} KS(t) \exp\{-KS(t)t\}\, dt \tag{80.6}$$

where $K = D/Vh$. The cumulative concentration at time τ is expressed using an integral equation, where the surface area of solid exposed to bulk solution is a function of time. Thus the concept of this function is that $S(t)$ can be calculated from the dissolution profile. While a thick diffusion layer slows down the dissolution process, a thinner layer provides a faster dissolution. However, what defines a thick or a thin diffusion layer? If the diffusion layer does exist, what are the dissolution mechanisms within this layer? In this review, we explore the phenomena associated with the initial dissolution of solids based on the Noyes–Whitney–Nernst dissolution model using near-infrared spectroscopic measurements.

80.2 EXPLORATION OF INTERFACE PHENOMENA USING NEAR-INFRARED SPECTROSCOPY

Macroscopic dissolution phenomena were empirically or semiempirically described using multiple models [4]. These models mat be classified into two groups: (1) the models based on Fick's law and (2) those based on a power law. As described above, the power-law models are applicable for solids such as polymeric matrices without a disintegration process. Classically, solid dosage is presented as a compressed solid incorporating monomer additives such as lactose, polymer additives such as cellulose, and a small amount of the active ingredient. In this chapter, we focus on the dissolution of solid dosages.

The Noyes–Whitney–Nernst dissolution model is based on the assumption that the formation of a diffusion layer between the solid and the bulk solution occurs. This layer may be formed prior to the dissolution process. A number of studies have been conducted to investigate the interfacial phenomena by means of contact angle between solid and water [24–29], water adsorption [30–34], microcalorimetry

[25], and inverse gas chromatography [24, 27] methods. These methods evaluate the surface energy of solids on the basis of macroscopic measurements. Microscopic interactions between solids and water molecules have not been investigated using these methods.

Spectroscopic measurements are widely used for measuring molecular interactions. In particular, in situ vibrational spectroscopic measurements, such as Raman [35–37], infrared (IR) [38, 39], and near-infrared (NIR) [40–44] spectroscopy, are noninvasive tools that may provide useful information without any prior sample treatments. IR and NIR spectroscopic measurements are more sensitive to water molecules than Raman spectroscopy; however, IR spectroscopy is too sensitive to measure water rich sample in situ. Although it remains difficult to use NIR spectroscopy to measure sample completely dissolved in water, it is a sufficiently sensitive method for in situ measurements of the initial stages of the dissolution process, when the amount of water is low.

80.2.1 Initial Dissolution of Compressed Solids

Figure 80.1 shows the in situ NIR spectra of compressed lactose with penetrating water. In the initial spectrum (before water penetration), a strong band at 4730 cm^{-1} and a sharp peak at 5170 cm^{-1} can be observed. These two peaks are assigned to the combination of O–H stretching and C–O–H bending modes of disaccharide molecules and the combination of H–O–H stretching and bending modes of water, respectively. Interdependently, the former peak is reduced and the latter peak is enhanced and broadens with water penetration. Several sharp and weak peaks in the 5900–5500 cm^{-1} region and broad peaks in the 6500–6000 cm^{-1} region are assigned to the first overtones of the C–H stretching O–H stretching modes, respectively.

The peaks in the 4800–5200 cm^{-1} and 6500–7200 cm^{-1} regions are due to a combination of O–H stretching and bending modes and first overtone of O–H stretching mode of water molecules, respectively. These bands involve several species of water molecules with different grades of hydrogen bonds [42, 45]. The multiple bands cause a complex overlap of spectra. The differential spectrum is one of the analytical methods used to extract spectral changes from peak-overlapped spectra.

Differential spectra of the in situ NIR spectra of lactose tablets are shown at various times of water penetration in Fig. 80.2a–c. There are bands due to different water species at 5245 and 5108 cm^{-1} and a shoulder at 4921 cm^{-1} involving both of water and a C–O–H combination band of lactose. In Fig. 80.2b,c, these spectra indicate secondary change at around 20 min and 45 min, respectively. The secondary change was not observed with the higher-porosity tablets

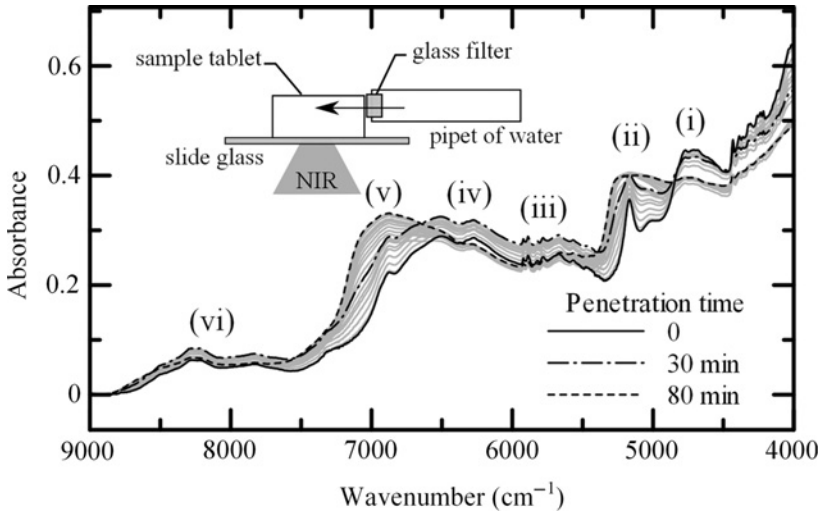

FIGURE 80.1 In situ diffuse reflectance NIR spectra of lactose tablet with penetrating water. The tablet was compressed under 189 MPa. Its dimensions were 8 mm in diameter and 3.1 mm in thickness. The spectra were collected using a FT-NIR spectrophotometer (MPA, Bruker Optics, Ettlingen, Germany). Each spectrum was accumulated 32 times between 4000 cm^{-1} and 9000 cm^{-1} with a 4 cm^{-1} spectral resolution. The spectral measurements were performed at 1-min intervals after the start of water penetration from the glass tube into the tablet via a glass filter (pore size 10–16 μm). The collected spectra were processed using multiplicative scatter to correct the baseline. The bands were assigned to (1) a combination of O–H stretching and C–O–H bending modes, (2) a combination of O–H stretching and H–O–H bending modes, (3) first overtone of C–H stretching, (4) first overtone of O–H stretching (lactose), (5) first overtone of O–H stretching (water), and (6) second overtone of C–H stretching.

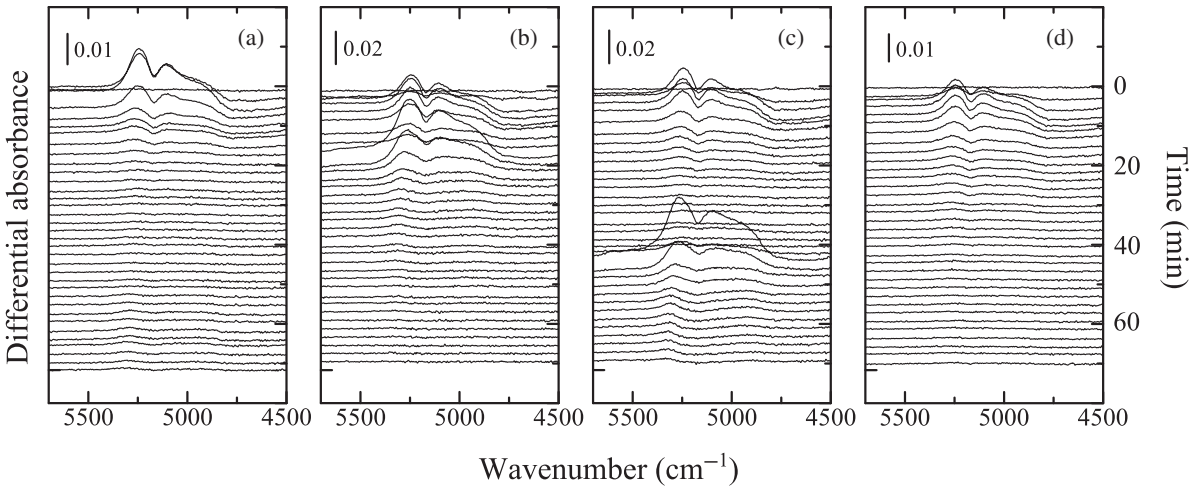

FIGURE 80.2 Differential NIR spectra in the range of bands due to a combination of O–H stretching and bending modes with a time series of penetrating water (a–c) and lactose-saturated solution (d). The tablets were compressed under 118 (a), 189 (b,c), and 243 (c) MPa. The void fractions were 0.149, 0.113, and 0.0898, respectively. The spectral difference was calculated at intervals of 2 min. The two-stage changes were observed in (b) and (c). The time of onset of the second change was delayed when the void fraction of tablets decreased. It is assumed that the second change occurred too rapidly to be detected in the tablet with the highest void fraction (a). The second change disappeared on penetration of lactose-saturated solution (d).

because the fast secondary change coincided with the prior change.

The first change is assigned to the increment of water due to penetration. The time of onset of the secondary change is delayed by the decreasing porosity of tablets. The secondary change may due to the formation of a diffusion layer between lactose solids and the bulk solution.

Figure 80.2d shows the differential spectra of a lactose tablet with penetrating lactose-saturated solution. The porosity of the tablet is shown in Fig. 80.2b; however, the secondary change failed to occur.

In the diffusion layer, the substance concentration decreases from a saturated concentration to a bulk concentration as a function of distance from the solid surface. Therefore, if the bulk concentration is already saturated, the diffusion layer should be absent. In Fig. 80.2d, the disappearance of the secondary change in the differential spectra indicates that it occurred independently of the diffusion layer, and the secondary change indicates the formation of a diffusion layer.

The peak decomposition of spectra provides quantitative information on water molecules, with their different grades of hydrogen bonding, as shown in Fig. 80.3. The decomposition was modelled using a Gaussian function:

$$\Delta A(\nu) = \sum_{i=1}^{n} \Delta A_i(\nu) \exp\left\{ -B \frac{(\nu - \nu_{i,max})^2}{\Gamma_i^2} \right\} \qquad (80.7)$$

Here, $A(\nu)$ is the absorbance at a wavenumber ν; n is the number of components; $\nu_{i,\max}$ and Γ_i are the peak

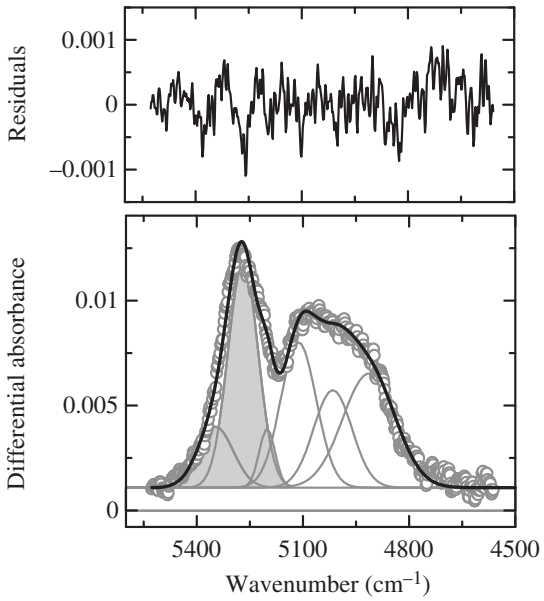

FIGURE 80.3 Spectral decomposition of differential NIR spectrum between 22 and 20 min by nonlinear least-squares method according to Eq. (80.7) and with fitting residuals. The open circles and the solid line represent the experimental and calculated spectra, respectively. The calculation was performed using six Gaussian components (solid gray lines), and the filled components at higher wavenumber indicate free or loosely binding species of water molecules. The other nonfilled components are due to strongly binding water molecules.

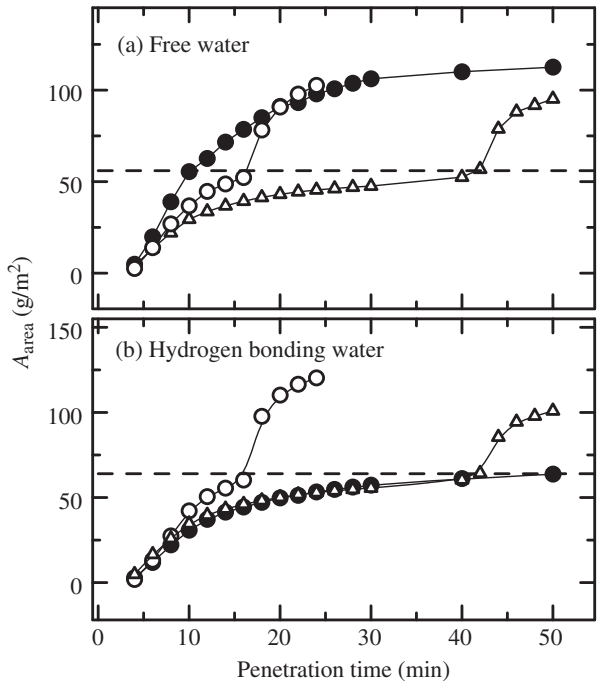

FIGURE 80.4 Surface-area-normalized absorbance (A_{area}) profiles of free/loosely binding water (a) and strongly binding water molecules (b) as a function of water penetration time. The open and closed circles represent the profiles of compressed solids under 189 MPa pressure with penetrating water and saturated lactose solution, respectively. The triangles indicate the profile of the solid compressed under 243 MPa with penetrating water. The values of A_{area} were obtained as the sum of the peak area for each component and normalized by the specific surface area of a compressed solid. The specific surface area was measured using a surface area analyzer (Monosorb, Quantachrom Instruments, FL) and a bulk solid cell (QS-620).

wavenumber and the half-width of a component, respectively; and B is a constant. In this study, six components were used to decompose the spectra because the calculated curve showed an excellent fit to the experimental spectrum. In fact, determination of the number of components should be considered carefully. Here, the meaning of decomposition is the quantitative separation between free (or loosely hydrogen bonding) water and hydrogen bonding water species.

Figure 80.4 shows the peak area profiles of hydrogen bonding and free species of water, which are normalized by the solid surface area of compressed lactose solid. The secondary changes in both hydrogen bonding and free species are simultaneously induced at 16 min and 42 min for highly and loosely compressed tablets, respectively. Noticeably, the threshold area intensity, which relates to the amount of hydration water, necessary to induce the formation of diffusion layer, is independent of tablet porosity.

When a lactose-saturated solution is used, a corresponding increase in free water species occurs with the profiles of secondary change in water penetration. On the other hand, hydrogen-bonded water exhibits the same profile as in the prior change. As a consequence of the spectral decomposition, an initial dissolution model was proposed and is shown in Fig. 80.5. In the early stage, free water molecules attach to the solid surface, and saturation of the attached water molecules induces the formation of a diffusion layer. This represents the initial dissolution of the solid.

80.2.2 Hydration and Swelling of Disintegrating Agents: Two-Dimensional Correlation Spectroscopy (2DCOS)

Disintegrating agents are used in order to accelerate tablet dissolution, as the dissolution rate of an active ingredient is controlled by the disintegration rate of the tablet [23, 31]. Thus the disintegrating properties of tablets depend on the loaded amount and the efficiency of the agent. Starch and microcrystalline cellulose (MCC) are traditionally used as disintegrating agents, while carboxymethyl cellulose sodium (CMC) [46–48] and polyvinilpyrrolidone (crospovidone) [31, 49, 50] are widely employed as "superdisintegrating agents," as they confer a very high efficiency of disintegration. Both traditional and superdisintegrating agents swell up on contact with water. The swelling rate drives the disintegration rate of the tablet, and the swelling rate of superagents is much higher than that of traditional agents [46, 48, 49]. A high swelling rate with a low amount of water creates pores in the tablet to allow water penetration, which, in turn, induces rapid tablet disintegration.

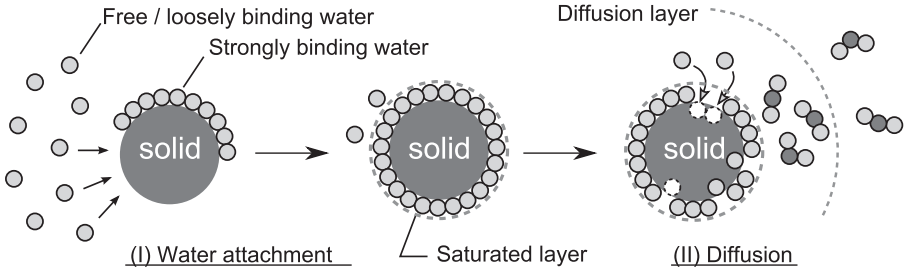

FIGURE 80.5 The dissolution model based on in situ NIR spectroscopy and decomposition. In the first stage, water molecules bind to the solid surface followed by a second stage of diffusion.

The characteristics of disintegrating agents have been macroscopically evaluated by water absorption rate [31, 32, 51] and disintegration force [12]. One team described the linear relationship between disintegration force and the amount of absorbed water [12]. CMC exhibited a high water absorption rate compared to other agents [48]. Microscopic interactions between disintegrating agents and water molecules have been investigated via sorption isotherms [52, 53]. One research group described a model of hydrogen bonding between cellulose and water using moisture sorption isotherms [52]. According to this model, water interacts with cellulose through three stages: (1) strong binding of water to cellulose with two binding sites per water molecule, (2) dissociation of some hydrogen bonds between water and cellulose, and (3) loose hydrogen bonding between water molecules. Both starch and MCC obey this three-stage swelling process upon contact with water.

Figure 80.6 shows the in situ reflectance NIR spectra of cellulose powder with vapor flowing and the differential spectra (i.e., difference between two consecutive spectra). The bands due to the combination between stretching and bending modes of water molecules increased. The differential spectra were decomposed into two species on the basis of strong versus loosely hydrogen-bonded water molecules, as shown in Fig. 80.7. The bands at lower and higher wavenumbers can be assigned to the strongly and loosely bonded water, respectively.

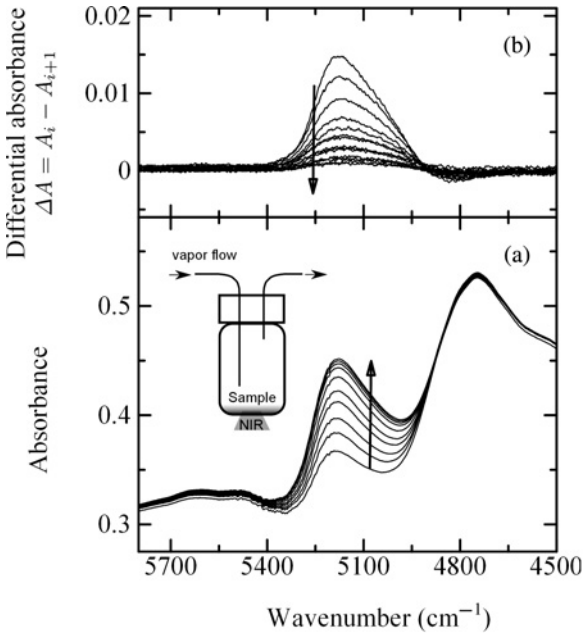

FIGURE 80.6 In situ diffuse reflectance NIR spectra (a) and differential spectra (b) of powder samples in the wavenumber range of O–H combination between stretching and bending modes. The spectra were collected by accumulation of 32 scans and collected at intervals of 60 s for 2 h with flowing vapor at 100 mL/min. Before measurement, the powders were dehydrated for 2 h under reduced pressure. The dehydrated sample (1.0 g) was placed into a glass sample cell, as shown in the figure.

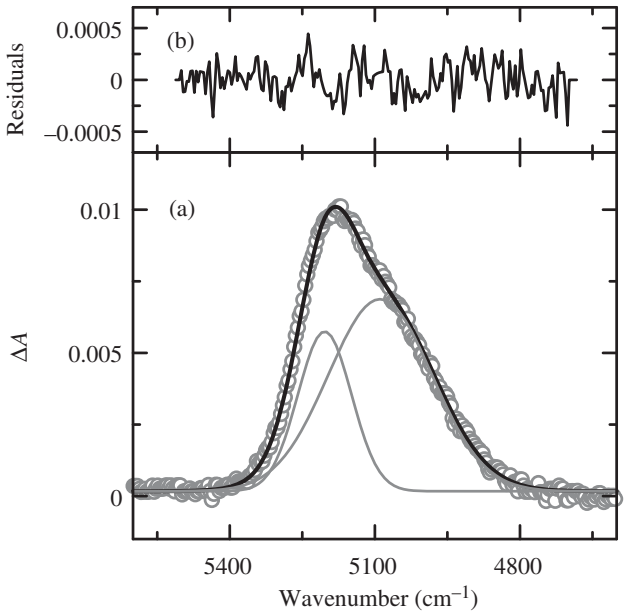

FIGURE 80.7 The decomposition of a differential NIR spectrum into two components of loosely (indicated in gray) and strongly binding water species by nonlinear least-squares method using Eq. (80.7) (a) and with residuals (b). The circles and solid lines indicate the experimental and calculated profiles, respectively. Gray lines indicate the decomposed spectra of each component. The decomposition was performed for all the collected spectra.

The peak area profiles of the two species calculated by the decomposition are shown in Fig. 80.8. The MCC and CMC powder samples denote a faster increment of strongly bonded water compared to that of loosely bonded water, while starch exhibited a reversed profile. In line with the water–cellulose interaction model [52], water molecules bind to cellulose with strong bonding first, followed by the dissociation of some hydrogen bonds. Thus, CMC and MCC feature similar water bonding kinetics.

Next, the wetting process of disintegrating agents was demonstrated by in situ measurements of NIR spectra using a transmittance attachment, as shown in Fig. 80.9. Approximately 20 mg of sample was loaded to the cell and water was added via a syringe pump at a rate of 2.3 μL/min.

Figure 80.10 shows synchronous 2DCOS maps of in situ NIR spectra of wetted powder of MCC, starch, and CMC. 2DCOS is an analytical method employed to visualize spectral changes as a correlation between spectral intensities at the spectral variables of ν_1 and ν_2 for N number of spectra [54, 55]. In the spectral data set of $y(\nu, p)$, ν and p are the wavenumber and the perturbation variable, respectively. The synchronous $\Phi(\nu_1, \nu_2)$ and asynchronous $\Psi(\nu_1, \nu_2)$ 2D correlation spectra between $y(\nu_1, p)$ and $y(\nu_2, p)$ are calculated

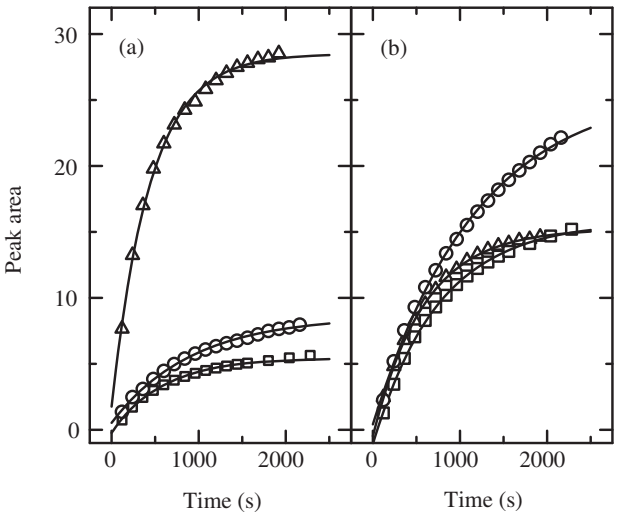

FIGURE 80.8 Profiles of decomposed peak area of loosely (a) and strongly (b) binding water species in starch (triangles), MCC (squares), and CMC (circles) as a function of flowing time. These profiles were fitted using $A = A_{max}(1 - e^{-kt}) + A_0$, where A is the peak area at time t and A_{max}, A_0, and k are the area of maximum, area at $t = 0$, and the rate constant, respectively. The rate constants obtained were 0.00226 s^{-1} (starch), 0.00170 s^{-1} (MCC), and 0.00109 s^{-1} (CMC) for loose component (a), and 0.00171 s^{-1} (starch), 0.00132 s^{-1} (MCC), and 0.000840 s^{-1} (CMC) for strong component (b).

from the mean-centered dynamic spectra $\tilde{y}(\nu, p)$ as detailed in the following equations:

$$\Phi(\nu_1, \nu_2) = \frac{1}{N-1} \sum_{j=1}^{N} \tilde{y}(\nu_1, p_j) \cdot \tilde{y}(y_2, p_j)$$
$$\Psi(\nu_1, \nu_2) = \frac{1}{N-1} \sum_{j=1}^{N} \tilde{y}(\nu_1, p_j) \cdot \sum_{k=1}^{N} M_{jk} \cdot \tilde{y}(\nu_2, p_k) \quad (80.8)$$

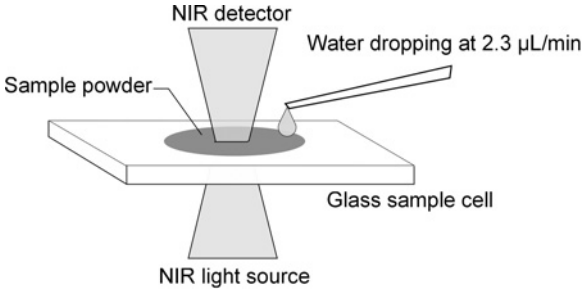

FIGURE 80.9 Transmittance attachment setup for in situ NIR measurements (MPA) of the powder wetting process. Approximately 20 mg of sample was loaded and water was dropped via a syringe pump at 2.3 μL/min. Spectra were repeatedly collected in the range from 10,000 to 5800 cm^{-1} with a spectral resolution of 8 cm^{-1}. The collection interval was 30 s, and spectra were accumulated with 16 scans.

where

$$\tilde{y}(\nu, p) = y(\nu, p) - \frac{1}{N} \sum_{j=1}^{N} y(\nu, p_j) \quad (80.9)$$

and M_{jk} is the element of the discrete Hilbert–Noda transformation matrix. The NIR spectrum of water indicates an overlap in the broad range with several water species of different hydrogen-bonding levels. 2DCOS allows a good visualization of spectral changes, without the effect of spectral overlap.

The autocorrelation spectra can be obtained, as the correlation intensity profiles are equal at ν_1 and ν_2. All synchronous maps indicated similar patterns, with a single autocorrelation peak at ~7200–6800 cm^{-1} due to the first overtone of O–H stretching mode of water. The autocorrelation peak indicates whether the corresponding band changes

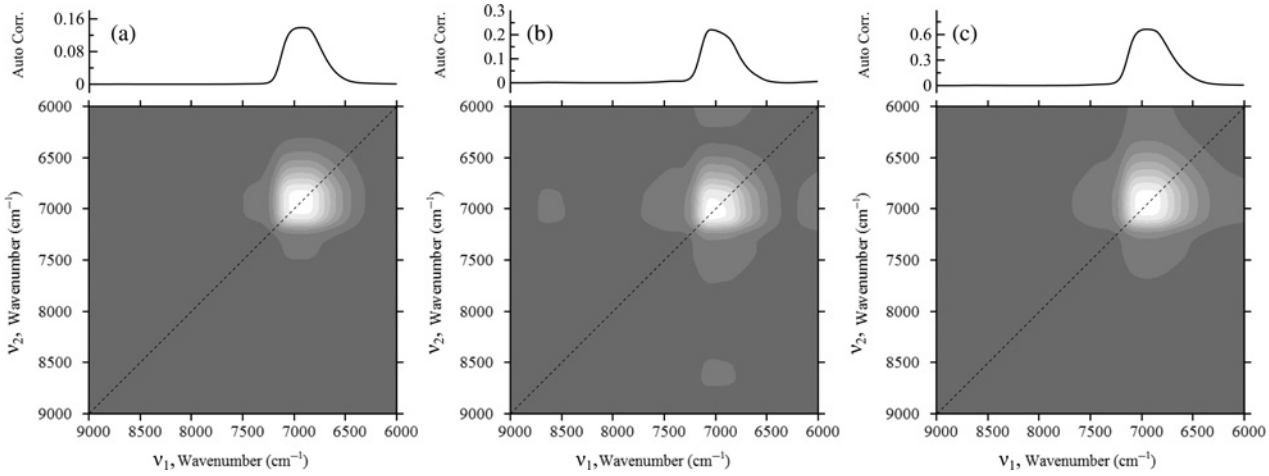

FIGURE 80.10 Synchronous 2DCOS maps of in situ transmittance NIR spectra of starch (a), MCC (b), and CMC (c) with wetting. Autocorrelation spectra correspond to the diagonal line on the 2D map.

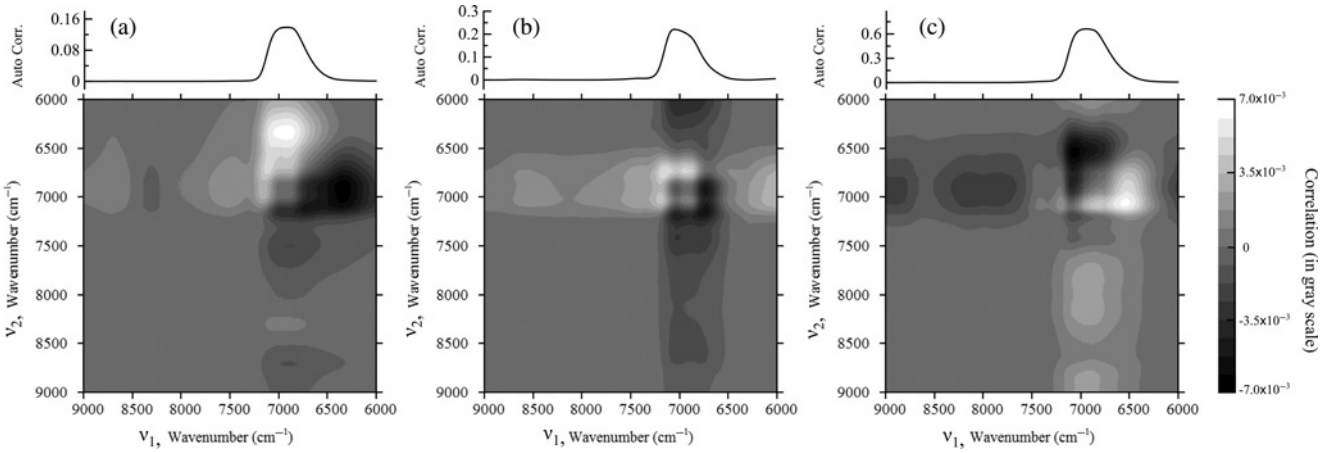

FIGURE 80.11 Asynchronous 2DCOS maps of in situ transmittance NIR spectra corresponding to the synchronous maps, shown in Fig. 80.10.

as a result of perturbation. When the band changes, there is a positive peak in the autocorrelation. In all samples, simply, the first overtone of O–H increased with the addition of water.

In the asynchronous 2DCOS maps shown in Fig. 80.11, several cross-correlation peaks were observed. In the MCC, triple peaks were found at (7021, 7193), (6743, 7153), (6721, 6924), which were due to the first overtone of O–H stretching mode of water in different hydrogen bonding forces. Starch denotes a broad peak at (6908, 6331), unlike MCC. Similarly, CMC denotes a band around (7066, 6541). The two peaks observed at 6331 and 6541 cm^{-1} are due to the first overtone of O–H stretching mode of the associating polymer with water or interpolymer. Thus, the addition of water induced changes in the interaction within the polymer; however, the interactions within MCC were affected by water to a lesser degree. The interpolymer association corresponds to gel formation.

The key information provided by asynchronous 2DCOS maps is the sequence of changes in band intensity. The positive and negative cross-correlation peaks indicate which peak at ν_1 or ν_2 changes prior to the other. The synchronous maps shown in Fig. 80.10a indicate positive cross-correlation in the range 7250–6500 cm^{-1} for both ν_1 and ν_2; thus, the positive cross-correlation in the asynchronous maps indicates that the peak at ν_2 changes prior to the peak at ν_1. Conversely, negative cross-correlation indicates that the peak at ν_1 changes prior to the peak at ν_2. In Fig. 80.11, cross-correlation peaks at around (7100–7000, 7000–6700) are positive for MCC and starch; however, those of CMC are negative. Thus, MCC and starch indicated that the band in the range of 7100–7000 cm^{-1} changes prior to the band in the 7000–6700 cm^{-1} range, and the map of CMC denotes an opposite sequence of events in the spectral changes. These spectral changes are due to water molecules of different hydrogen bonding components. The loosely bound water is assigned to the band at 7100–7000 cm^{-1} and the bands at lower wavenumber are due to strongly bound water. CMC displayed an increment in strongly bound water followed by an increment in loosely bound water. As shown in the asynchronous 2DCOS maps, starch and MCC both showed an increment in loosely bound water prior to that of strongly bound water.

The interaction process of starch and MCC with water molecules has been reported in a number of studies [40, 52, 53,56]. Given the results obtained in the in situ NIR measurements of MCC with vapor flowing and the 2DCOS analysis of MCC powder wetting process, it may be concluded that, initially, water strongly binds to the cellulose ensued by loose water penetration. In the case of CMC, water initially binds to the polymer in a manner similar to MCC; however, the number of bound water molecules is much larger than that of CMC. In the wetting process, an increase in strongly bound water to MCC occurs prior to an increase in loose water. The swelling process of CMC is reminiscent of the gel formation process. Starch exhibits a loose water increment in both the vapor flowing and the wetting processes. Hygroscopic starch contains a much larger amount of water molecules in the absence of strong hydrogen bonds. If starch binds strongly to water molecules, it may form a gel state similarly to CMC.

80.3 CONCLUSION

Current understanding of the interactions between water molecules and solids such as lactose, starch, cellulose, and carboxymethyl cellulose sodium, was reviewed in the context of NIR spectroscopic investigations. In pharmaceuticals, these materials are used not only to dilute a solid dosage but also to control the dissolution of an active ingredient, thus ensuring the mechanical strength of the tablet. The dissolution process has been well described using the Noyes–Whitney–Nernst dissolution model from a macroscopic perspective. One of the key aspects in this theory is the

assumption that a diffusion layer exists between the solid and the bulk solution. It is important to investigate the existence of a miscroscopic diffusion layer. In situ NIR measurements of the initial dissolution of lactose demonstrated a two-stage behavior. In a first stage, water molecules bind onto solid surface followed by diffusion of lactose in a subsequent stage. NIR spectroscopy and 2DCOS analyses revealed that starch, MCC, and CMC act as disintegrating agents according to different processes. The specific mode of interaction with water is strongly related to the swelling characteristics of the materials.

Finally, NIR spectroscopy provides quantitative and qualitative information at the molecular level. NIR spectroscopy is particularly useful for measuring water molecule interactions because of its high sensitivity to water. In this review, analytical techniques such as differential spectroscopy, decomposition, and 2DCOS were described to further elucidate the interaction between water with solids. NIR spectroscopy has been utilized in many fields such as agriculture, food science, medical science, and pharmaceuticals; however, its potential remains to be fully uncovered. We thus hope that a more advanced use of NIR spectroscopy occurs in both fundamental and applied research contexts.

COLLOID STABILITY OF BIOCOLLOIDAL DISPERSIONS

Tharwat Tadros
89 Nash Grove Lane, Wokingham, Berkshire RG40 4HE, United Kingdom

81.1 INTRODUCTION

Colloid and interface science plays a major role in most biocolloidal dispersions [1]. For example, all biocolloidal dispersions such as nanoemulsions, nanosuspensions, and liposomes require application of colloid and interface science phenomena. Section 81.2 deals with the colloid stability of these dispersions by considering the balance between repulsive and attractive forces. Both electrostatic (produced by the presence of electrical double layers) and steric (produced by adsorbed surfactant and polymer layers) forces will be considered. Combination of repulsive and attractive forces results in a quantitative description of colloid stability/instability of biological dispersions. Application of these principles for nanoemulsions such as those used for drug delivery will be considered. This is followed by application to nanobiodegradable dispersions that are used for targeted delivery of drugs. A third example where the colloid and interface principles are applied is in the field of liposomes and vesicles that are used for solubilization of lipophilic and hydrophilic drugs. Stabilization of liposomes by using block and graft copolymers is also described.

81.2 KINETIC STABILITY OF BIOCOLLOIDAL DISPERSION SYSTEMS AND GENERAL STABILIZATION MECHANISMS

Disperse systems lack thermodynamic stability and tend to reduce their surface energy by aggregation and/or coalescence of the particles or droplets. The main driving force for the aggregation process is the universal van der Waals attraction, which will be discussed in subsequent sections. To overcome the aggregation and/or coalescence processes, one must overcome the van der Waals attraction by some repulsive mechanism, and this will give the system kinetic stability with an adequate shelf life. Normally one requires a shelf life of 2–3 years under various storage conditions (e.g., temperature variation). Several stabilization mechanisms are encountered with disperse systems, and these are summarized below.

81.2.1 Electrostatic Stabilization

In this case a repulsive energy is produced by formation of electrical double layers, for example, by adsorption of ionic surfactants. This repulsive energy increases with increase in the surface (or zeta-) potential and decrease of electrolyte concentration. The repulsive energy counteracts the van der Waals attraction at intermediate distance of separation, thus producing an energy barrier that prevents flocculation of the dispersion. A summary of the van der Waals attraction and electrostatic repulsion as well as their combination is given below.

81.2.1.1 Van der Waals Attraction. For two particles or droplets with equal radius R, and surface-to-surface separation h, the van der Waals attractive energy G_A (when $h \ll R$) is given by [2]

$$G_A = -\frac{AR}{12h} \tag{81.1}$$

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

where A is the effective Hamaker constant, which is given by

$$A = \left(A_{11}^{1/2} - A_{22}^{1/2}\right)^2 \tag{81.2}$$

where A_{11} is the Hamaker constant of the particles or droplets and A_{22} is the Hamaker constant of the medium. The Hamaker constant of any material depends on the number of atoms per unit volume q and the London dispersion constant β:

$$A = \pi^2 q^2 \beta \tag{81.3}$$

It can be seen that G_A increases very sharply with decrease in h when the latter reaches small values. In the absence of any repulsion between the particles or droplets, the latter will aggregate (flocculate) by simple diffusion through the medium. This leads to rapid flocculation kinetics. The rate constant for the process k_0 has been calculated by Smolulokowski [3] as

$$k_0 = \frac{4kT}{3\eta} = 5.5 \times 10^{-18}\ \mathrm{m^3 s^{-1}} \tag{81.4}$$

where k is the Boltzmann constant, T is the absolute temperature, and η is the viscosity of the medium.

81.2.1.2 Double-Layer Repulsion. An electrical double layer can be created at the solid–liquid or liquid–liquid interface by charge separation due to the presence of ionogenic groups (e.g., –OH, –COOH) or by adsorption of ionic surfactants at the interface. The double layer is characterized by the following parameters [4]: (surface charge σ_0) – (charge in Stern layer σ_s) – (carge of diffusion layer σ_d). Note that $\sigma_0 = \sigma_s + \sigma_d$ – (surface potential ψ_0) – (Stern potential ψ_d) ($\sim$ zeta-potential). The double-layer extension is determined by the electrolyte concentration, and the valence of the counterions is given by the reciprocal of the Debye–Hückel parameter ($1/\kappa$), referred to as the *thickness of the double layer*

$$\left(\frac{1}{\kappa}\right) = \left(\frac{\varepsilon_r \varepsilon_0 kT}{2n_0 Z_i^2 e^2}\right) \tag{81.5}$$

where ε_r is the permittivity (dielectric constant) of the medium, ε_0 is the permittivity of free space, k is the Boltzmann constant, T is the absolute temperature, n_0 is the number of ions per unit volume of each type present in bulk solution, Z_i is the valence of the ions, and e is the electronic charge. The double-layer thickness increases with decrease in electrolyte concentration: 10^{-5} mol dm^{-3} NaCl ($1/\kappa$) = 100 nm, 10^{-3} mol dm^{-3} NaCl ($1/\kappa$) = 10 nm.

When two particles or droplets with double layers of the same sign approach at a distance of separation h that is smaller than twice the double-layer thickness, double-layer repulsion occurs, since the two double layers cannot be fully extended in the confined space. This leads to repulsion energy G_{el} that is given by the following expression [5]:

$$G_{el} = \frac{[4\pi\varepsilon_r\varepsilon_0 R^2 \psi_0^2 \exp(-\kappa h)]}{[2R + h]} \tag{81.6}$$

This expression shows that G_{el} decreases exponentially with increase in h, and the rate of this decrease depends on electrolyte concentration.

81.2.1.3 Total Energy of Interaction. Combination of G_A with G_{el} at various values of h results in the total energy G_T–distance curve illustrated in Fig. 81.1. This presentation forms the basis of the theory of colloid stability due to Deryaguin–Landau–Verwey–Overbeek (DLVO) theory [5, 6]. The G_T/h curve shows two minima and one maximum: a shallow minimum (of the order of few kT) units at large distances of separation. This may result in weak and reversible flocculation. A deep primary minimum (several 100 kT units) at short distances of separation. This results in strong flocculation (coagulation). An energy maximum G_{max} at intermediate distances prevents flocculation into the primary minimum.

To ensure adequate colloid stability, G_{max} has to be greater than 25 kT. The height of the maximum depends on the surface (or zeta-) potential, electrolyte concentration, particle radius, and Hamaker constant. When the zeta-potential is higher than 40 mV and the electrolyte concentration is $<10^{-2}$ mol dm^{-3} for 1:1 electrolyte, $G_{max} > 25\ kT$.

In the presence of an energy barrier one can define a slow rate of flocculation k [7], which is related to the fast flocculation rate k_0 by the stability ratio W as

$$W = \frac{k_0}{k} \tag{81.7}$$

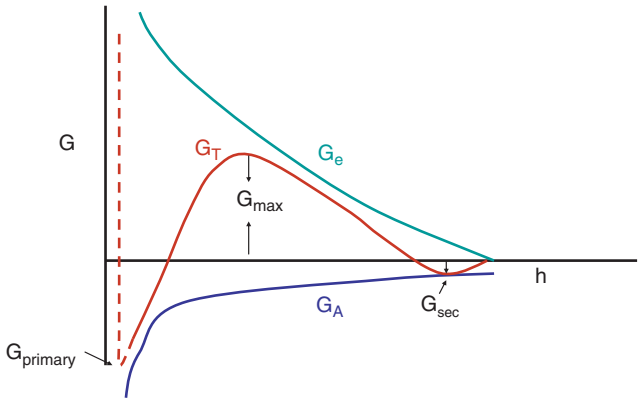

FIGURE 81.1 Energy–distance curves according to the DLVO theory [5, 6].

where W is related to the energy maximum G_{max} by [8]

$$W = \frac{1}{2}k \exp\left(\frac{G_{max}}{kT}\right) \tag{81.8}$$

For maintenance of colloid stability over a long period of time (i.e., 2–3 years), one needs to ensure the following conditions: (1) high ζ-potential by ensuring adequate coverage of the particles or droplets by ionic surfactant, (2) low electrolyte concentration, and (3) low valence of the electrolyte (multivalent ions should be avoided)

81.2.2 Steric Stabilization

Many polymers are used for the preparation of disperse systems (suspensions and emulsions) in pharmaceutical formulations. An example of such systems is the A-B-A block copolymer of poly(ethylene oxide)—poly(propylene oxide)—poly(ethylene oxide) (PEO-PPO-PEO), commercially available as poloxamers and pluronics (BASF). On hydrophobic drug particles or oil droplets, the polymer adsorbs with the B hydrophobic chain (PPO) close to the surface, leaving the two hydrophilic A chains dangling in solution. These nonionic polymers provide stabilization against flocculation and/or coalescence by a mechanism, usually referred to as *steric stabilization* [9]. In order to understand the principles of steric stabilization, one must first consider the adsorption and conformation of the polymer at the solid–liquid or liquid–liquid interface. The PPO chain adsorbs on the surface with many attachment points forming small "loops," whereas the A chains (sometimes referred to as "tails" extend to some distance (a few nanometers) from the surface [10].

The adsorption of polymers at interfaces differ significantly from that of simple surfactant molecules. The adsorption isotherm is of the high-affinity type; that is, the first added molecules are almost completely adsorbed and the plateau adsorption is reached at low equilibrium concentration. Adsorption is practically irreversible, because the molecule is attached by several segments to the surface.

The adsorption isotherm depends on the structure, molecular weight, and environment (temperature, electrolyte) for the chains. To fully characterize polymer adsorption, one needs to obtain information on the following parameters: (1) the amount of adsorption Γ; (2) the fraction of segments in "trains" and the adsorption energy per segment; and (3) extension of the A chains in bulk solution, usually described as *segment density distribution* $\rho(z)$, or *hydrodynamic thickness* δ_h. It is essential to know how these parameters vary with system parameters such as proportion of hydrophobic to hydrophilic chains, molecular weight, flexibility, temperature, and addition of electrolyte.

The most important parameters for steric stabilization are the strong "anchoring" of the B chain to the surface and the extension of the A chains (adsorbed layer thickness δ_h) and its solvation by the molecules of the medium.

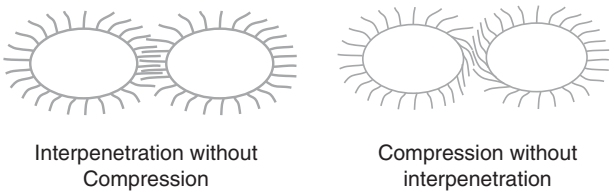

FIGURE 81.2 Schematic representation of interaction between adsorbed layers.

When two particles or droplets each with a radius R and containing an adsorbed surfactant or polymer layer with a hydrodynamic thickness δ_h, approach each other at a surface–surface separation distance of separation h that is smaller than $2\delta_h$, the surfactant or polymer layers interact with each other, resulting in one or both of two main scenarios: (1) the polymer chains may overlap with each other, or (2) the polymer layers may undergo compression. In either case, there will be an increase in the local segment density of the chains in the interaction region. This is schematically illustrated in Fig. 81.2.

The real situation is perhaps in between the two abovementioned cases; specifically, the polymer chains may undergo some interpenetration and some compression. Provided the dangling chains (A chains) are in good solvent (i.e., strongly solvated by the solvent molecules), this local increase in segment density will result in strong repulsion as a results of two main effects.

Two main repulsive energies can be defined: (1) osmotic repulsion arising from the (tnfavourable mixing of the stabilising A chains when these are in good solvent conditions (this is referred to as *mixing interaction* G_{mix}) and (2) entropic, volume restriction or elastic interaction resulting from the loss of configurational entropy of the chains on considerable overlap (this is referred to as *elastic interaction* G_{el}).

As a result of the unfavorable mixing of the chains, when these are in good solvent, an increase in the osmotic pressure in the interaction zone occurs, and G_{mix} is given by the following expression [9] as

$$\frac{G_{mix}}{kT} = \left(\frac{2V_2^2}{V_1}\right)\nu^2\left(\frac{1}{2} - \chi\right)\left(\delta - \frac{h}{2}\right)\left(3R + 2\delta + \frac{h}{2}\right) \tag{81.9}$$

where k is the Boltzmann constant, T is the absolute temperature, V_2 is the molar volume of polymer, V_1 is the molar volume of solvent, ν_2 is the number of polymer chains per unit area, and χ is the Flory–Huggins interaction parameter.

The sign of G_{mix} depends on the value of the Flory–Huggins interaction parameter. When the chains are under favorable solvent conditions (strongly solvated by the

molecules of the medium), $\chi < {}^1/_2$ and G_{mix} is positive; that is, the mixing interaction free energy is positive, and this leads to strong repulsion as soon as $h < 2\delta$. Clearly, to maintain stability of a suspension or emulsion, one must ensure that χ is less than ${}^1/_2$ under all conditions of storage (temperature variation, addition of electrolyte, etc.).

The coefficient G_{el} may be given by the following simple expression (assuming the chains to be represented by simple rods that rotate in a circle with a radius δ)

$$\frac{G_{el}}{kT} = 2kTv^2 \ln\left[\frac{\Omega(h)}{\Omega(\infty)}\right] \tag{81.10}$$

where $\Omega(h)$ is the number of chain configuration after overlap ($h < \delta$), and $\Omega(\infty)$ is the number of chain configurations before overlap ($h > 2\delta$).

The elastic interaction G_{el} is always positive and could play a major role in steric stabilization. The steric free energy of interaction G_s is given by the sum of G_{mix} and G_{el}, and when this is added to the van der Waals attraction, we obtain the total interaction energy G_T:

$$G_T = G_s + G_A = G_{mix} + G_{el} + G_A \tag{81.11}$$

A schematic representation of the variation of G_{mix}, G_{el}, G_A, and G_T with h is given in Fig. 81.3.

The mixing interaction G_{mix} increases very sharply with decrease of h when $h < 2\delta$. G_{el} increases very sharply with decrease of h when $h < \delta$. G_T versus h shows a minimum, G_{min}, at separation distances comparable to 2δ; G_T shows a rapid increase with further decrease in h [9]. Unlike the G_T/h curve predicted by the DLVO theory (which shows two minima and one energy maximum), the G_T/h curve for systems that are sterically stabilized dispersions shows only one minimum G_{min}, followed by a sharp increase in G_T when $h < 2\delta$. The depth of the minimum depends on the Hamaker constant A, particle radius R, and adsorbed layer thickness. At a given A and R, G_{min} increases with decrease of δ. When δ is small (say, <5 nm), G_{min} may reach sufficient depth (a few kT units) for weak flocculation to occur. However, this flocculation is reversible, and by gentle shaking of the container, the suspension or emulsion can be easily redispersed.

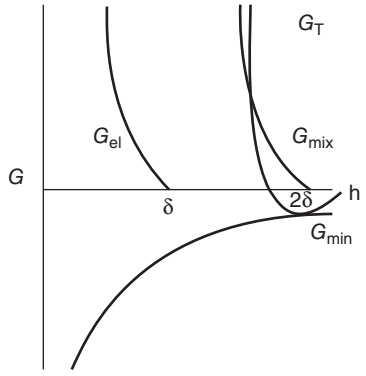

FIGURE 81.3 Variation of G_{mix}, G_{el}, G_A, and G_T with surface–surface distance between the particles.

When δ is sufficiently large (e.g., > 10 nm), G_{min} may become so small that no flocculation will occur. In this case the suspension or emulsion approach thermodynamic stability and no aggregation occurs over very long periods (>2 years). Clearly the particle radius also plays a major role. The larger the particles, the deeper G_{min} becomes (at a given δ value).

Several criteria for effective steric stabilization can be defined:

1. The particles or droplets should be completely covered by the surfactant or polymer (the amount should correspond to the plateau value). Any bare patches may cause flocculation either by van der Waals attraction (between the bare patches) or by bridging flocculation (where a polymer molecule will become simultaneously adsorbed on two or more particles or droplets).
2. The polymer should be strongly anchored to the particles or droplets surface, to prevent any displacement during particle approach. This is particularly important for concentrated suspensions or emulsions. With an A-B-A block copolymer, the B chain is chosen to be highly insoluble in the medium and has a strong affinity to the surface.
3. The stabilizing chain(s) A should be highly soluble in the medium and strongly solvated by its molecules. In other words, the Flory–Huggins interaction parameter for the A chains should always be less than ${}^1/_2$. The most commonly used A chains are those based on PEO (e.g., with poloxamers).
4. The adsorbed layer thickness δ should be sufficiently large (> 5–10 nm) to prevent weak flocculation. This is particularly the case with concentrated suspensions and emulsions, since such flocculation may cause increase in the viscosity of the system and makes it difficult to redisperse on shaking.

81.3 NANOEMULSIONS

Nanoemulsions are transparent or translucent systems mostly covering the size range 20–200 nm [11, 12]. Nanoemulsions are also referred to as *miniemulsions* [13–15]. Unlike microemulsions (which are also transparent or translucent and thermodynamically stable), nanoemulsions are only kinetically stable. However, the long-term physical stability of nanoemulsions (with no apparent flocculation or coalescence) make them unique, and they are sometimes referred to as *approaching thermodynamic stability*.

The inherently high colloid stability of nanoemulsions can be well understood from a consideration of their steric stabilisation (when using nonionic surfactants and/or polymers) and how this is affected by the ratio of the adsorbed layer thickness to droplet radius, as will be discussed below.

Unless adequately prepared (to control the droplet size distribution) and stabilized against Ostwald ripening (which occurs when the oil has some finite solubility in the continuous medium), nanoemulsions may lose their transparency with time as a result of increase in droplet size.

The attraction of nano-emulsions for application in drug delivery is due to the following advantages:

1. The very small droplet size causes a large reduction in the gravity force, and the Brownian motion may be sufficient for overcoming gravity. This means that no creaming or sedimentation occurs on storage.
2. The small droplet size also prevents any flocculation of the droplets. Weak flocculation is prevented, and this enables the system to remain dispersed with no separation.
3. The small droplets also prevent their coalescence, since these droplets are nondeformable and hence surface fluctuations are prevented. In addition, the significant surfactant film thickness (relative to droplet radius) prevents any thinning or disruption of the liquid film between the droplets.
4. The transparent nature of the system, their fluidity (at reasonable oil concentrations) as well as the absence of any thickeners, give them an advantage in application, in particular for intravenous injection.
5. Nanoemulsions can be applied for delivery of lipophilic drugs.
6. Nanoemulsions may be applied as a substitute for liposomes and vesicles (which are much less stable).

81.3.1 Preparation of Nanoemulsions

Two methods may be applied for the preparation of nanoemulsions (covering the droplet radius size range 20–200 nm): (1) use of high-pressure homogenizers (aided by appropriate choice of surfactants and cosurfactants) or (2) application of the phase inversion temperature (PIT) concept. The production of small droplets (<1 μm) requires application of high energy; the process of emulsification is generally inefficient. Simple calculations show that the mechanical energy required for emulsification exceeds the interfacial energy by several orders of magnitude. For example, to produce an emulsion at a volume fraction $\phi = 0.1$ with a Sauter diameter $d_{32} = 0.6$ μm, using a surfactant that gives an interfacial tension $\gamma = 10$ mN m^{-1}, the net increase in surface free energy is $A\gamma = 6\phi\gamma/d_{32} = 10^4$ J m^{-3}. The mechanical energy required in a homogenizer is 10^7 J m^{-3}, that is, an efficiency of 0.1%. The remainder of the energy (99.9%) is dissipated as heat.

The intensity of the process or the effectiveness in making small droplets is often governed by the net power density $[\varepsilon(t)]$ as

$$p = \varepsilon(t)dt \tag{81.12}$$

where t is the time during which emulsification occurs.

Breakup of droplets will only occur at high ε values, which means that the energy dissipated at low ε levels is wasted. Batch processes are generally less efficient than continuous processes. This shows why, with a stirrer in a large vessel, most of the energy applied at low intensity is dissipated as heat. In a homogenizer, p is simply equal to the homogenizer pressure.

Several procedures may be applied to enhance the efficiency of emulsification when producing nanoemulsions; for instance, one should optimize the efficiency of agitation by increasing ε and decreasing dissipation time. The emulsion is preferably prepared at high volume fraction of the disperse phase and diluted afterward. However, very high ϕ values may result in coalescence during emulsification. The addition of more surfactant may result in a smaller γ_{eff} and possibly diminishing recoalescence. It may be desirable to use a surfactant mixture that shows more reduction in the individual components. If possible, dissolve the surfactant in the disperse phase rather than the continuous phase; this often leads to smaller droplets. It may be useful to emulsify in steps of increasing intensity, particularly with emulsions having highly viscous disperse phase.

The phase inversion principle for preparation of nanoemulsions is based on the concepts introduced by Shinoda and coworkers [16–18], who showed that by increasing the temperature of an oil-in-water (o/w) emulsion prepared using a nonionic surfactant of poly(ethylene oxide) type, inversion to a w/o emulsion occurs at a critical temperature that is defined as the phase inversion temperature (PIT). At the PIT the interfacial tension reaches a minimum and very small droplets are produced. By rapid cooling the system near the PIT nanoemulsion droplets are produced.

81.3.2 Steric Stabilisation and Role of Adsorbed Layer Thickness

Since most nanoemulsions are prepared using nonionic and/or polymeric surfactants, it is necessary to consider the interaction forces between droplets containing adsorbed layers (steric stabilization). This was described earlier, and only a summary is given here. When two droplets, each containing an adsorbed layer of thickness δ, approach at a distance of separation h, whereby h becomes less than 2δ, repulsion occurs as a result of two main effects: (1) unfavorable mixing of the stabilizing chains A of the adsorbed layers,

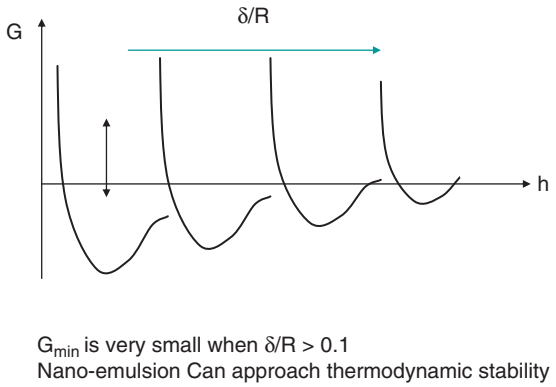

FIGURE 81.4 Importance of adsorbed layer thickness to particle size ratio (δ/R).

when these are in good solvent conditions—referred to as the *mixing* [osmotic interaction G_{mix}, given by Eq. (81.9)] and (2) reduction in configurational entropy of the chains on significant overlap—referred to as *elastic* (entropic) *interaction*, given by Eq. (81.10). Combination of G_{mix} and G_{el} with the van der Waals attraction G_A gives the total energy of interaction G_T, as given by Eq. (81.11)

Figure 81.3 gave a schematic representation of the variation of G_{mix}, G_{el}, G_A, and G_T with h. As can be seen form Fig. 81.3, G_{mix} increases very rapidly with decrease of h as soon as $h < 2\delta$, G_{el} increase very rapidly with decrease of h when $h < \delta$. G_T shows one minimum, G_{min}, and it increases very rapidly with decrease of h when $h < 2\delta$. The magnitude of G_{min} depends on the following parameters: (1) the particle radius R, (2) the Hamaker constant A, and (3) the adsorbed layer thickness δ. Figure 81.4 shows the variation of G_T with h at various ratios of δ/R. It can be seen from the figure that the depth of the minimum decreases with increasing δ/R. This is the basis of the high kinetic stability of nanoemulsions. With nanoemulsions having a radius in the region of 50 nm and an adsorbed layer thickness of, say, 10 nm, the value of δ/R is 0.2. This high value (when compared with situations in macroemulsions where δ/R is at least an order of magnitude lower) results in a very shallow minimum (which could be less than kT). This situation results in very high stability with no flocculation (weak or strong). In addition, the very small size of the droplets and the dense adsorbed layers ensures lack of deformation of the interface, lack of thinning, and disruption of the liquid film between the droplets, and hence coalescence is also prevented. The only instability problem with nanoemulsions is Ostwald ripening, which is discussed below.

81.3.3 Ostwald Ripening

One of the main problems with nanoemulsions is *Ostwald ripening*, which results from the difference in solubility between small and large droplets. The difference in chemical potential of dispersed phase droplets between different sized droplets as given by Lord Kelvin [19]

$$c(r) = c(\infty) \exp\left(\frac{2\gamma V_m}{rRT}\right) \tag{81.13}$$

where $c(r)$ is the solubility surrounding a particle of radius r, $c(\infty)$ is the bulk phase solubility and V_m is the molar volume of the dispersed phase.

The quantity ($2\gamma V_m$/RT) is termed the characteristic length. It has an order of ~1 nm or less, indicating that the difference in solubility of a 1-μm droplet is of the order of ≤0.1%. Theoretically, Ostwald ripening should lead to condensation of all droplets into a single drop (i.e. phase separation). This does not occur in practice since the rate of growth decreases with increase of droplet size.

For two droplets of radii r_1 and r_2 (where $r_1 < r_2$), we obtain

$$\left(\frac{RT}{V_m}\right) \ln\left[\frac{c(r_1)}{c(r_2)}\right] = 2\gamma\left(\frac{1}{r_1} - \frac{1}{r_2}\right) \tag{81.14}$$

This equation shows that the larger the difference between r_1 and r_2, the higher the rate of Ostwald ripening.

Ostwald ripening can be quantitatively assessed from plots of the cube of the radius versus time; this is known as the *Lifshitz–Slesov–Wagner* (LSW) *theory* [20, 21]

$$r^3 = \frac{8}{9}\left[\frac{c(\infty)\gamma V_m D}{\rho RT}\right] t \tag{81.15}$$

where D is the diffusion coefficient of the disperse phase in the continuous phase and ρ is the density of the disperse phase.

Several methods may be applied to reduce Ostwald ripening [22–25]:

1. Addition of a second disperse phase component that is insoluble in the continuous phase (e.g., squalane). In this case significant partitioning between different droplets occurs, with the component having low solubility in the continuous phase expected to be concentrated in the smaller droplets. During Ostwald ripening in two component disperse phase system, equilibrium is established when the difference in chemical potential between different size droplets (which results from curvature effects) is balanced by the difference in chemical potential resulting from partioning of the two components. If the secondary component has zero solubility in the continuous phase, the size distribution will not deviate from the initial one (the growth rate is equal to zero). In the case of limited solubility of the secondary component, the distribution is the same as governed by Eq. (81.15); that is, a mixture growth rate is obtained that is still lower than that of the more soluble

component. This method is of limited application since one requires a highly insoluble oil as the second phase which is miscible with the primary phase.

2. Modification of the Interfacial film at the o/w interface. According to Eq. (81.15), reduction in γ results in reduction of Ostwald ripening. However, this alone is not sufficient since one has to reduce γ by several orders of magnitude. One author [25] suggested that by using surfactants that are strongly adsorbed at the o/w interface (i.e. polymeric surfactants) and that do not desorb during ripening, the rate could be significantly reduced. An increase in the surface dilational modulus and decrease in γ would be observed for the shrinking drops. The difference in γ between the droplets would balance the difference in capillary pressure (i.e., curvature effects).

To achieve this effect it is useful to use A-B-A block copolymers that are soluble in the oil phase and insoluble in the continuous phase. The polymeric surfactant should enhance the lowering of γ by the emulsifier. In other words, the emulsifier and the polymeric surfactant should show synergy in lowering γ.

81.4 NANOBIODEGRADABLE DISPERSIONS

Nanobiodegradable dispersions offer a potentially attractive method for targeted delivery of drugs to its pharmacologically site of action in a controlled manner [26–32]: (1) protection of the drug against metabolism or recognition by the immune system; (2) reduction of toxic side effects, especially for potent chemotherapeutic drugs and poor tissue specificity; and (3) improved patient compliance by avoiding repetitive administration.

Polymeric nanoparticles have some advantages in terms of their long-term physical stability and also their stability in vivo. Both model nondegradable and biodegradable particulate drug carriers have been investigated. The main problem that needs to be overcome is their removal by phagocytic cells (macrophages) of the reticuloendothelial system (RES) and in particular the Kupffer cells of the liver. The main target of any research on nanoparticles is to modify the surface of the particles in such a way to avoid RES recognition.

The above approach has been investigated for both nonbiodegradable polymer particles (such as polystyrene or cyanoacrylate) and biodegradable particles (such as poly(lactic acid)/poly(lactic acid-*co*-glycolic acid) [25].

Several particle characteristics play a major role in controlled delivery:

1. *Particle Size*. Particles >7 μm are larger than blood capillaries (∼ 6 μm) and become entrapped in the capillary beds of the lungs (which may have fatal effects). The majority of particles that pass the lung capillary bed accumulate in the elements of the RES (spleen, liver, and bone marrow). The degree of splenic uptake increases with particle size. Removal of particles >200 nm is due to nonphagocytic process (physical filtration) in the spleen and phagocytosis (by Kupffer cells) by the liver. Particles < 200 nm decrease splenic uptake and are cleared by the liver and bone marrow. Colloidal particles not cleared by the RES can potentially exit the blood circulation via the sinusoidal fenestration of the liver and bone marrow.
2. *Surface Charge*. Surface charges only influence particle–protein or particle–macrophage interactions at very short distances. The surface charge may affect the surface hydrophobicity, which can affect protein adsorption.
3. *Surface Hydrophobicity*. Serum components adsorb on the surface of colloidal particles via their hydrophobic sites. Increase in surface hydrophobicity increases opsonization. To reduce opsonization, a predominantly hydrophilic surface is required. This has led to the conclusion that by adsorption of poly(ethylene glycol (PEG)-type block copolymers on the surface of the particles should reduce the opsonisation process. This will be discussed in the next section.

Polystyrene nanoparticles have been used as model systems for investigation of the effect of surface modification in the various processes of phagocytosis, opsonization, and dysopsonization. It was possible to modify the surface of polystyrene particles either by adsorption of block copolymers containing PEG or by grafting PEG chains on the surface of the particles. PEG has the advantage of being nontoxic and approved by the FDA. Earlier work using liposomes containing PEG-phospholipid derivatives showed prolonged circulation times and prevention of phagocytic clearance. The PEG chains act as a barrier towards adsorption of proteins thus preventing phagocytic clearance.

Two methods for surface modification could be applied:

1. Adsorption of block copolymers of PEO-PPO-PEO, namely, poloxamers, or poloxamines that are made of polyethylene diamine with four branches of PEG chains. The molecular weight of the PEG chain and hence the adsorbed layer thickness was crucial in preventing phagocytosis. For example, Poloxamer 338 (with PEG chains of $M_w = 5600$) was more efficient in preventing phagocytosis when compared with Poloxamer 108 (with PEG $M_w = 1800$). A long PPO chain was also important to ensure anchoring of the block copolymer to the surface. The particle size of the polystyrene particles was also important. For example, 60- and 150-nm particles coated with

Poloxamer 407 were not sequestered by the macrophages in the bone marrow (they avoided capture by the Kupffer cells). In contrast to the 250-nm particles (also coated with Poloxamer 207), which were absorbed by the spleen and liver, only a small portion of the smaller particles reached the bone marrow.

2. Chemically grafting the PEG chains. Particles with different surface densities of PEG were prepared by copolymerization of styrene with methoxy(PEG) acrylate macromonomer. Particle uptake by the Kupffer cells (in rat studies) showed a decrease with increase in graft density. Only particles with a very low PEG density resulted in considerable liver deposition. However, the higher PEG density achieved with grafting did not improve the blood circulation time when compared with particles containing adsorbed block copolymers.

Several biodegradable polymers have been investigated as drug carriers [26]: (1) poly(lactic acid)/poly(lactic acid-*co*-glycolic acid), (2) poly(anhydrides), (3) poly(*ortho*-esters), (4) poly(β-malic acid-*co*-benzyl malate), and (5) poly(alkylcyanoacrylates). The most widely used biodegradable polymer was poly(lactic) (PLA)/poly(lactic acid-*co*-glycolic acid) (PLGA), which have been used to produce a wide range of drug delivery formulations (microparticles, implants, and fibers). To avoid contamination, the nanoparticles were produced by precipitation by mixing acetone solution with water. PLGA nanoparticles < 150 nm in diameter were produced. The surface of the PLGA particles was modified by adsorption of water-soluble PLA-PEG block copolymer or Poloxamine 908 (forming an adsorbed layer thickness ~ 10 nm). Block copolymer micelles were also used as drug carriers; the A-B or A-B-A block copolymers can produce micelles with aggregation numbers of several tens or hundreds of molecules (10–30 nm diameter). The hydrophobic core can be used to solubilise insoluble drugs (lipophilic molecules), whereas the hydrophilic chains provide the steric barrier, preventing protein adsorption and phagocytosis.

The most systematically studied micelle forming block copolymers are those based on PLA-PEG assemblies. The structure of the PLA-PEG micelles depend on the copolymer composition, including the PLA to PEG ratio. With a fixed PEG block ($M = 5000$), the size of the PLA-PEG micelle increases with increase in the PLA molecular weight. The characteristics of the corona, in a good solvent, are determined by the aggregation number and surface curvature. PLA-PEG nanoparticles prepared from a copolymer with PLA molecular weight ≤ 15,000 are colloidally stable with a reasonable high surface coverage of stabilizing PEG chain. The grafting density of PEG chains appears to increase as the molecular weight of the PLA block increases from 2000 to 15,000, which results in increase in the thickness of the steric layer. As the PEG chains become radially more extended, they become less compressible. As the PLA molecular weight increases above 15,000, the colloid stability of the nanoparticles is impaired, suggesting a reduction in PEG surface coverage. For PLA-PEG copolymer with a PLA block $M >$ 45000, it is possible to increase the aggregation number and particle size. To produce long-circulating particulate carriers (i.e., to reduce opsonisation), one has to enhance the surface coverage of the brushlike PEG chains; copolymers with intermediate PLA to PEG ratio (e.g., PLA-PEG 15: 5) appear to give optimal protein-resistant surface properties. To study the effect of nanoparticle structure on blood circulation, a hydrophobic radiolabeled γ-emitter ^{111}In-oxine (8-hydroxy quinoline) was incorporated within PLA and PLA-PEG nanoparticles [27, 28]. The PLA nanoparticles (~125 nm) were rapidly cleared from blood circulation with only 13% of the injected dose still circulating after 5 min. After 3 h, 70% of the nanoparticles were removed by the liver. The rate and extent of release of the radiolabeled compound (using in vitro studies with rat serum) was higher for nanoparticles produced from the PLA-PEG copolymers with a lower M PLA. After 3 h, 77% and 88% radiolabeled compound remained associated with the PLA-PEG 6: 5 and 30: 5.

In vivo studies showed that free radiolabeled compound remained in the blood at moderate levels after 3 h, and there was low liver accumulation. Contrary to expectation, it was found that smaller micelles of PLA-PEG copolymers did accumulate in the liver. It was necessary to have micelles with size > 100 nm to evade phagocytosis. By optimizing the size of the micelles and controlling the surface characteristics, it is possible to produce nanoparticles that can be applied as drug carriers.

81.5 LIPOSOMES AND VESICLES IN PHARMACEUTICALS

Liposomes are multilamellar structures consisting of several bilayers of lipids (several micrometers). They are produced by simply shaking an aqueous solutions of phospholipids, such as egg lecithin. When sonicated, these multilayer structures produce unilamellar structures (with size range of 25–50 nm) that are referred to as *liposomes*. A schematic representation of liposomes and vesicles is given in Fig. 81.5.

Glycerol-containing phospholipids are used for the preparation of liposomes and vesicles: phosphatidylcholine→phosphatidylserine→phosphatidylethanolamine→phosphatidylanisitol→phosphatidylglycerol→phosphatidic acid→cholesterol. The chemical structures of some of these lipids were given earlier. In most preparations, a mixture of lipids is used to obtain the most optimum structure.

Liposomes and vesicles are ideal systems for drug delivery, due to their high degree of biocompatability, in particular for intravenous delivery [33]. For effective application, larger unilamellar vesicles are preferred (diameter

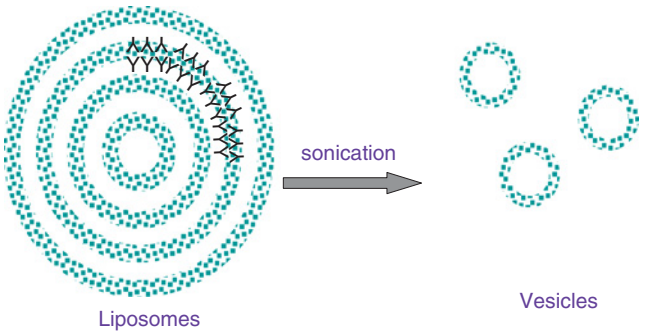

FIGURE 81.5 Schematic representation of liposomes and vesicles.

100–500 nm). In addition to drug delivery, liposomes have been used as model membranes, as carriers of drugs, DNA, ATP, enzymes, and diagnostic agents. Both water-soluble and water-insoluble drugs can be incorporated by encapsulation in the aqueous space or intercalation into the lipid bilayer.

Liposomes are capable of solubilizing both water-soluble and lipid-soluble drugs. The amount and location of a drug within a liposome are dependent on a number of factors: (1) the location of a drug within a liposome is based on the partition coefficient of the drug between aqueous compartments and lipid bilayers, (2) the maximum amount of drug that can be entrapped within a liposome is dependent on its total solubility in each phase, (3) drugs with limited solubility in polar and nonpolar solvents cannot be encapsulated in liposomes, and (4) efficient capture depends on the use of drugs at concentrations that do not exceed the saturation limit in the aqueous compartment (for polar drugs) or the lipid bilayers (for nonpolar drugs).

If liposomes are prepared by mixing the drug with the lipids, the drug will eventually partition to an extent depending on the partition coefficient of the drug and the phase volume ratio of water to bilayer. Release rates are highest when the drug has intermediate partition coefficient.

The bilayer/aqueous compartment partition coefficient is usually estimated by determining the partition coefficient between octanol and water (the log P number). Drug solubilization in liposomes has important biological effects: (1) the ultimate efficacy of a liposomal dosage depends on the control of the amount of free drug that can reach the exact *site of action*; (2) generally, the exact site of action is not known, and one must rely on attaining reproducible blood levels of the drug; (3) with nonparenteral dosage forms, only the free drug is absorbed and hence one can measure the amount of drug that enters the blood as a function of time.

With parenteral, especially intravenous, administration of drugs encapsulated in liposomes requires control of the pharmacokinetics of the drug and this requires control of the following factors: (1) concentration of the free drug in the blood, (2) concentration of liposomes and their entrapped drug in blood, (3) leakage rate of drug from liposome in the blood, and (4) disposition of the intact drug-carrying liposomes in the blood.

To control the pharmacokinetics of these complex systems, one must separate out the leakage rate of the drug from the liposome in the blood and the disposition of the intact carrying liposomes in the blood.

One of the major problems with application of liposomes for drug delivery is their interaction with high-molecular-weight substances such as albumin. The instability of liposomes in plasma appears to be the result of transfer of bilayer lipids to albumin and high-density lipoproteins (HDLs). Some protein is also transferred from the lipoprotein to the liposome. Both lecithin and cholesterol can exchange with membranes of red blood cells. The susceptibility of liposomal phospholipid and phspholipase is strongly dependent on liposome size and type. Generally MLVs are most stable and SUVs are least stable. Liposomes prepared with higher chain length phospholipids are more stable in buffer and in plasma. Cholesterol and sphingomyelin are very effective in reducing instability. As we will see later, incorporation of block copolymers such as poloxamers can enhance the stability of liposomes.

Despite the above limitations, the therapeutic promise of liposomes as a drug delivery system is becoming a reality in the following applications: (1) parenteral administration, (2) inhalation treatment, (3) percutaneous administration, (4) ophthalmics, (5) cancer treatment, and (6) controlled-release formulations.

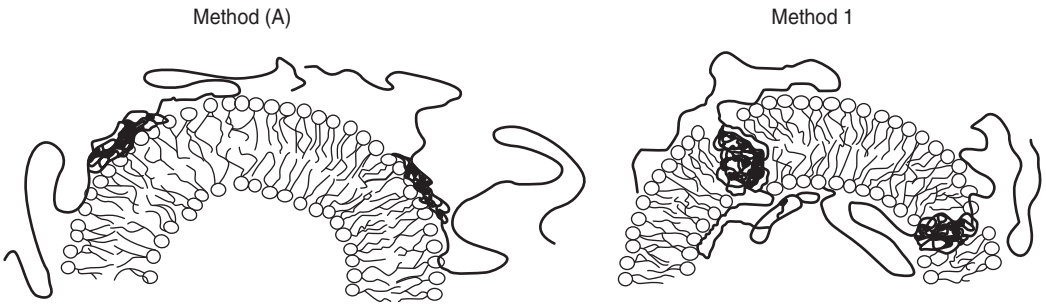

FIGURE 81.6 Schematic representation of vesicle structure in the presence of block copolymers.

The preparation of sterically stabilized vesicles with the addition of triblock copolymers of the polyethylene oxide (PEO)- polypropylene oxide (PPO) type, Namely, poloxamers or pluronics (PEO-PPO-PEO) have been shown to enhance stabilization [34]. The steric stabilization of phospholipid vesicles by the copolymer molecules was attempted by following two different techniques: (1) addition of the block copolymer to performed vesicles (denoted as method A) and (2) addition of the block copolymer to the lipid before formation of the vesicles (denoted as method I). In this case both the lipid and copolymer participate in the construction of the vesicle. A schematic representation of the resulting vesicle structure for both methods is given in Fig. 81.6. Vesicles prepared according to method I are more stable than those prepared according to method A for the following reasons: Association of the block copolymer as an integral part of the bilayer (method I) gives better "anchor" to the bilayer when compared to those prepared by simple adsorption (method A). Increased rigidity of the lipid-polymer bilayer structure (for method I). The increased rigidity decreases the interaction with HDL. The (I) vesicles do not exhibit osmotic swelling.

STABILITY RATIO AND EARLY-STAGE AGGREGATION KINETICS OF COLLOIDAL DISPERSIONS

HIROYUKI OHSHIMA

Faculty of Pharmaceutical Sciences, Tokyo University of Science, 2641 Yamazaki Noda, Chiba 278-8510, Japan

82.1 INTRODUCTION

The stability of dispersions of colloidal particles can be analyzed by the DLVO (Derjaguin–Landau–Verwey–Overbeek) theory of colloid stability [1, 2]. This theory factors in the repulsive electrostatic interaction and the attractive van der Waals interaction between colloidal particles [3–12]. There are a number of theoretical studies on colloidal aggregation kinetics [13–33]. A quantitative measure of the stability of colloidal dispersions based on the DLVO theory is the stability ratio, which is expressed by the ratio of the rapid and slow aggregation rates of colloidal particles. The rapid aggregation process is caused only by the van der Waals attractive interaction in the absence of the electrostatic repulsion. In the presence of the electrostatic repulsion, under certain conditions, the potential curve for the interparticle interaction can exhibit a maximum, a primary deep minimum, and a secondary shallow minimum. The slow aggregation rate is related to the height of a maximum on the potential curve of the interaction energy between two approaching particles. The aggregation kinetics of colloidal particles is usually analyzed via the probability that association of two single-particle monomers occurs at the primary minimum to form an irreversibly aggregated dimer after overcoming the potential energy barrier at the potential maximum. Behrens and Borkovec [25], in particular, considered a set of coupled nonlinear differential rate equations for the early-stage aggregation kinetics of colloidal particles by taking into account the influence of the secondary minimum. In this chapter we derive a simple analytic solution to these rate equations.

82.2 DLVO THEORY OF COLLOID STABILITY AND THE STABILITY RATIO

Following the DLVO theory of colloid stability [1, 2], we consider the interaction between two identical spherical particles of radius a carrying unperturbed surface potential ψ_0 at separation H between their surfaces immersed in a symmetric electrolyte solution of valence z and bulk concentration (number density) n. The interaction energy $V(H)$ between the two spheres can be given by the sum of the repulsive electrostatic interaction energy $V_R(H)$ and the attractive van der Waals interaction energy $V_A(H)$, namely, $V(H) = V_R(H) + V_A(H)$.

The most widely employed expressions for $V_R(H)$ and $V_A(H)$ are given by

$$V_R(H) = \frac{64\pi ankT\gamma^2}{\kappa^2} e^{-\kappa H} = \frac{G\kappa akT}{12} e^{-\kappa H} \tag{82.1}$$

$$V_A(H) = -\frac{Aa}{12H} \tag{82.2}$$

with

$$\kappa = \sqrt{\frac{2z^2e^2n}{\varepsilon_r\varepsilon_0 kT}} \tag{82.3}$$

$$\gamma = \tanh\left(\frac{ze\psi_0}{kT}\right) \tag{82.4}$$

$$G = \frac{12 \times 64\pi\gamma^2 n}{\kappa^3} = \frac{384\pi\gamma^2\varepsilon_r\varepsilon_0 kT}{(ze)^2\kappa} \tag{82.5}$$

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.

where κ is the Debye–Hückel parameter, e is the elementary electric charge, ε_r is the relative permittivity of the electrolyte solution, ε_0 is the permittivity of a vacuum, k is Boltzmann's constant, T is the absolute temperature, and A is the Hamaker constant.

The total interaction energy $V(H) = V_R(H) + V_A(H)$ between the two spheres is thus given by

$$V(H) = \frac{64\pi ankT\gamma^2}{\kappa^2} e^{-\kappa H} - \frac{Aa}{12H} \tag{82.6}$$

which can be rewritten as

$$V(H) = \frac{A\kappa a}{12}\left(\frac{GkT}{A} e^{-\kappa H} - \frac{1}{\kappa H}\right) \tag{82.7}$$

The potential curves of $V_R(H)$, $V_A(H)$, and $V(H) = V_R(H) + V_A(H)$ are schematically given as function of the separation H between the two spheres in Fig. 82.1 for the case where there exists a potential maximum V_{max} at $H = H_m$. Figure 82.1 gives the scaled interaction energy $V^*(H) = V(H)/(\kappa aA/12)$ as a function of the scaled separation κH for various values of GkT/A [33].

The following three types of the stability ratio have been proposed for a dispersion of colloidal particles of radius a with the inter-particle interaction potential $V(H) = V_R(H) + V_A(H)$:

$$W = q \tag{82.8}$$

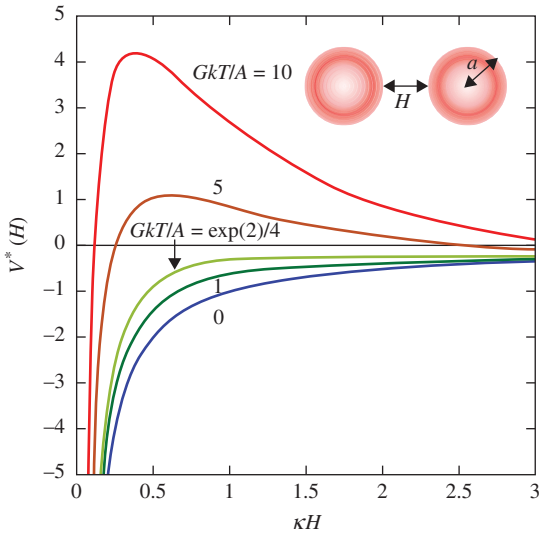

FIGURE 82.1 The scaled potential energy $V^*(H) = V(H)/(\kappa aA/12)$ as a function of the scaled separation κH for several values of GkT/A. The potential curve exhibits a maximum if $GkT/A >$ exp(2)/4, while there is no maximum if $0 \le GkT/A \le$ exp(2)/4 [33].

$$W = \frac{q}{q^o} \tag{82.9}$$

$$W_{visc} = \frac{q_{visc}}{q^o_{visc}} \tag{82.10}$$

In these three equations

$$q = 2a\int_0^\infty \frac{e^{V(H)}}{(2a+H)^2} dH = 2\int_0^\infty \frac{e^{V(u)}}{(2+u)^2} du \tag{82.11}$$

$$q^o = 2a\int_0^\infty \frac{e^{V_A(H)}}{(2a+H)^2} dH = 2\int_0^\infty \frac{e^{V_A(u)}}{(2+u)^2} du \tag{82.12}$$

$$q_{visc} = 2\int_0^\infty \beta(u)\frac{e^{V(u)}}{(2+u)^2} du \tag{82.13}$$

$$q^o_{visc} = 2\int_0^\infty \beta(u)\frac{e^{V_A(u)}}{(2+u)^2} du \tag{82.14}$$

with

$$\beta(u) = \frac{6u^2+13u+2}{6u^2+4u} = \frac{(6u+1)(u+2)}{2u(3u+2)} \tag{82.15}$$

where $u = H/a$. Equation (82.8) is Fuch's stability formula [13], in which the rapid coagulation is considered to be a pure diffusion-limited process. Equation (82.9), which is the stability ratio modified by McGown and Parfitt [15], accounts for the fact that the rapid coagulation is caused by the attractive van der Waals interaction (which is neglected in Fuch's formula). Further improvement was made by Spielman [16] and Honig et al. [17], who derived Eq. (82.10), in which a function $\beta(u)$ is introduced to account for viscous interactions between particles. Also Honig et al. [17] provide the following analytic expressions q^o and q^o_{visc}:

$$q^o = 1 - \frac{A}{24kT}\exp\left(\frac{A}{24kT}\right) E_1\left(\frac{A}{24kT}\right) \tag{82.16}$$

$$q^o_{visc} = \frac{11}{8}\exp\left(\frac{A}{24kT}\right) E_1\left(\frac{A}{24kT}\right) - \frac{9}{8}\exp\left(\frac{A}{8kT}\right) E_1\left(\frac{A}{8kT}\right) \tag{82.17}$$

where $E_1(z)$ is the first-order exponential integral, defined by

$$E_1(z) = \int_1^\infty \frac{e^{-zt}}{t} dt \tag{82.18}$$

82.3 APPROXIMATE ANALYTIC EXPRESSIONS FOR THE STABILITY RATIO *W*

We present a novel method in which $\exp[V_R(H)/kT]$ is expanded in a Tylor series:

$$\begin{aligned} q &= 2\int_0^\infty \frac{e^{V(u)/kT}}{(u+2)^2}du = 2\int_0^\infty \frac{1}{(u+2)^2}e^{V_R(u)/kT}e^{V_A(u)/kT}du \\ &= 2\int_0^\infty \frac{1}{(u+2)^2}e^{V_A(u)/kT}\left\{1+\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{V_R(u)}{kT}\right)^m\right\}du \\ &= q^o + 2\int_0^\infty \frac{1}{(u+2)^2}e^{-A/12kTu} \\ &\quad\times\left\{\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{G\kappa a e^{-\kappa a u}}{12}\right)^m\right\}du \\ &\approx q^o + \frac{1}{2}\int_0^\infty e^{-A/12kTu}\left\{\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{G\kappa a e^{-\kappa a u}}{12}\right)^m\right\}du \end{aligned} \tag{82.19}$$

Here, $2/(u+2)^2$ in the integrand has approximately been replaced by $^1/_2$. Further, Eq. (82.19) becomes

$$q = q^o + \sqrt{\frac{A}{12kT\kappa a}}\sum_{m=1}^{\infty}\frac{1}{m!\sqrt{m}}\left(\frac{\kappa a G}{12}\right)^m K_1\left(\sqrt{\frac{A\kappa a m}{3kT}}\right) \tag{82.20}$$

where $K_1(z)$ is the first-order Bessel function of the second kind and the following relation has been employed:

$$\int_0^\infty e^{-C_1u-C_2/u}du = 2\sqrt{\frac{C_2}{C_1}}K_1(2\sqrt{C_1C_2}) \tag{82.21}$$

We thus obtain

$$W = \frac{q}{q^o} = 1 + \frac{1}{q^o}\sqrt{\frac{A}{12kT\kappa a}}\sum_{m=1}^{\infty}\frac{1}{m!\sqrt{m}}\left(\frac{G\kappa a}{12}\right)^m \times K_1\left(\sqrt{\frac{A\kappa a m}{3kT}}\right) \tag{82.22}$$

This is the required expression for the stability ratio W without viscous interactions between particles [33].

Similarly, we obtain the stability ratio W_{visc} with viscous interaction as follows:

$$\begin{aligned} q_{visc} &= 2\int_0^\infty \beta(u)\frac{e^{V(u)/kT}}{(u+2)^2}du \\ &= 2\int_0^\infty \frac{\beta(u)}{(u+2)^2}e^{V_R(u)/kT}e^{V_A(u)/kT}du \\ &= 2\int_0^\infty \frac{\beta(u)}{(u+2)^2}e^{V_A(u)/kT}\left\{1+\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{V_R(u)}{kT}\right)^m\right\}du \\ &= q^o_{visc} + 2\int_0^\infty \frac{\beta(u)}{(u+2)^2}e^{-A/12kTu} \\ &\quad\times\left\{\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{G\kappa a e^{-\kappa a u}}{12}\right)^m\right\}du \\ &\approx q^o_{visc} + \frac{1}{4}\int_0^\infty \frac{e^{-A/12kTu}}{u} \\ &\quad\times\left\{\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{G\kappa a e^{-\kappa a u}}{12}\right)^m\right\}du \end{aligned} \tag{82.23}$$

Here, $2\beta(u)/(u+2)^2$ in the integrand has approximately been replaced by $^1/_4u$. We thus obtain

$$q_{visc} = q^o_{visc} + \frac{1}{2}\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{G\kappa a}{12}\right)^m K_0\left(\sqrt{\frac{A\kappa a m}{3kT}}\right) \tag{82.24}$$

where $K_0(z)$ is the zeroth-order Bessel function of the second kind and the following relation has been employed:

$$\int_0^\infty \frac{1}{u}e^{-C_1u-C_2/u}du = 2K_0(2\sqrt{C_1C_2}) \tag{82.25}$$

We thus obtain

$$W_{visc} = \frac{q_{visc}}{q^o_{visc}} = 1 + \frac{1}{2q^o_{visc}}\sum_{m=1}^{\infty}\frac{1}{m!}\left(\frac{\kappa a G}{12}\right)^m \times K_0\left(\sqrt{\frac{A\kappa a m}{3kT}}\right) \tag{82.26}$$

This is the required expression for the stability ratio W_{visc} with viscous interactions between particles [33]. Note that in Eqs. (82.22) and (82.26), q^o and q^o_{visc} are given by Eqs. (82.16) and (82.17), respectively.

The expressions obtained [Eqs. (82.22) and (82.26) as combined with Eqs. (82.16) and (82.17)] involve modified Bessel functions K_0(z), K_1(z) and an exponential integral E_1(z), which can easily be calculated via programs such as Mathematica. It is found that the present results are in excellent agreement with the exact numerical results obtained directly from Eqs. (82.11)–(82.14). Examples are shown in Fig. 82.2, which compares the exact numerical results and the stability expressions obtained [Eq. (82.22) as combined with Eq. (82.16) for W and Eq. (82.26) as combined with Eq. (82.17) for W_{visc}] calculated at $A/kT = 1$ and $\kappa a = 50$.

We see that the approximate stability expressions obtained are in excellent agreement with the exact numerical results within the line width for all values of G/AkT.

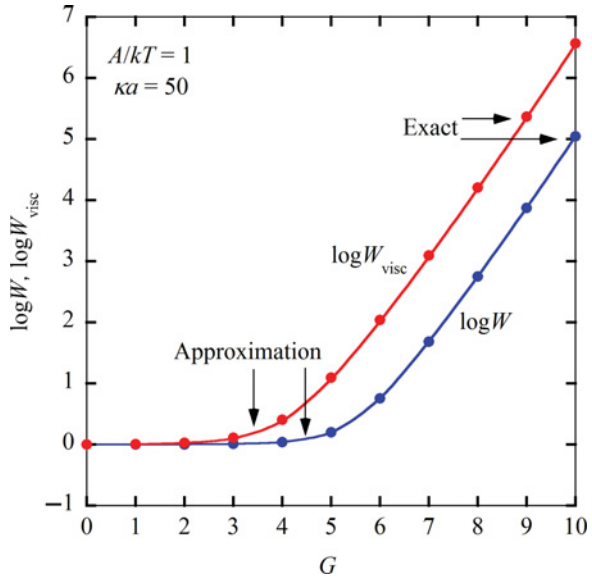

FIGURE 82.2 Logarithm of the stability ratio without viscous interaction between particles (log W) and that with viscous interactions (log W_{visc}) as function of G at $A/kT = 1$ and $\kappa a = 50$. The solid line represents the approximate results [Eqs. (82.22) and (82.26) as combined with Eq. (82.16) and (82.17)], which agree with exact numerical results represented by • within the line width [33].

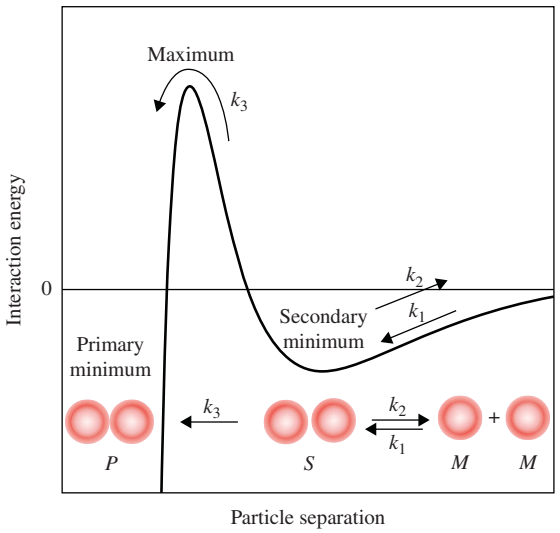

FIGURE 82.3 A typical interaction energy profile leading to the association of two single-particle monomers M to form both irreversibly aggregated dimes P (primary aggregated dimers) and reversibly aggregated dimers S (secondary aggregated dimers). (Adapted from Behrens and Borkovec 2000 [25], Fig. 1.)

82.4 RATE EQUATIONS FOR EARLY-STAGE AGGREGATION KINETICS OF COLLOIDAL PARTICLES

The potential energy of the interaction between two approaching colloidal particles obtained by the DLVO theory can exhibit a maximum, a primary minimum, and a secondary minimum on the potential curve of the interparticle interaction energy. Behrens and Borkovec [25] considered a set of coupled nonlinear differential rate equations for the early-stage aggregation kinetics of colloidal particles by factoring in the influence of the secondary minimum.

Following Behrens and Borcovec [25], we consider a dilute suspension of colloidal particles for the case in which the interaction energy between two approaching particles has a maximum, a primary minimum, and a secondary minimum (Fig. 82.3).

We assume two-step early-stage aggregation kinetics, in which association of two single-particle monomers M forms a reversibly aggregated dimer S in the secondary minimum (secondary aggregated dimer) before an irreversibly aggregated dimer P in the primary minimum (primary aggregated dimer) is formed:

$$2M \underset{k_2}{\overset{k_1}{\rightleftharpoons}} S \xrightarrow{k_3} P \tag{82.27}$$

Here, k_1 is the rate constant for association of two single-particle monomers M into a secondary aggregated dimer S, k_2 is the rate constant for dissociation of a secondary aggregated dimer S into two single-particle monomers M, and k_3 is the date constant of a secondary aggregated dimer S into a primary aggregated dimer P after overcoming the potential energy maximum. These rate constants are related to the potential energy of the interparticle interaction [25]. We assume that initially at time $t = 0$ there exist only single-particle monomers. Equation (82.27) holds good for the early stage of the aggregation kinetics, in which formation of higher-order aggregates can be neglected (early-stage approximation).

We denote the concentrations of single-particle monomers M, secondary aggregated dimers S, and primary aggregated dimers P at time t by $n_1(t)$, $n_{2S}(t)$, and $n_{2P}(t)$, respectively. The time evolution of the concentrations $n_1(t)$, $n_{2S}(t)$, and $n_{2P}(t)$ for the two-step reaction [Eq. (82.27)] is thus governed by [25]

$$\frac{dn_1(t)}{dt} = -k_1 n_1^2(t) + 2k_2 n_{2S}(t) \tag{82.28}$$

$$\frac{dn_{2S}(t)}{dt} = \frac{1}{2}k_1 n_1^2(t) - (k_2 + k_3) n_{2S}(t) \tag{82.29}$$

$$\frac{dn_{2P}(t)}{dt} = k_3 n_{2S}(t) \tag{82.30}$$

which are subject to the following boundary conditions

$$n_1(0) = n_0,\ n_{2S}(0) = 0,\ n_{2P}(0) = 0 \tag{82.31}$$

where n_0 is the initial concentration of the single-particle monomers. Note that the above set of rate equations satisfies the conservation law: $n_1(t) + 2\{n_2\mathrm{S}(t)+n_2\mathrm{P}(t)\} = n_0$. These rate equations [Eqs. (82.28)–(82.30)], which neglect higher-order aggregates, can be applicable only when the concentration of aggregated dimers is much smaller than the concentration of monomers. Since the above coupled rate equations [Eqs. (82.28)–(82.30)] are nonlinear with respect to $n_1(t)$, they can be solved only numerically.

82.5 APPROXIMATE SOLUTION TO THE RATE EQUATION

In order to obtain an approximate solution to Eqs. (82.28)–(82.30), we put

$$n_1(t) = n_0\{1 + \Delta(t)\} \tag{82.32}$$

where $\Delta(t)$ is a small quantity and linearize ${n_1}^2(t)$ in Eqs. (82.28) and (82.30) as

$$n_1^2(t) = n_0^2\{1 + \Delta(t)\}^2 \approx n_0^2\{1 + 2\Delta(t)\} \tag{82.33}$$

The rate equations [Eqs. (82.28)–(82.30)] thus become

$$\frac{d\Delta(t)}{dt} = -k_1 n_0^2\{1 + 2\Delta(t)\} + 2k_2 n_{2S}(t) \tag{82.34}$$

$$\frac{dn_{2S}(t)}{dt} = \frac{1}{2}k_1 n_0^2\{1 + 2\Delta(t)\} - (k_2 + k_3)n_{2S}(t) \tag{82.35}$$

$$\frac{dn_{2P}(t)}{dt} = k_3 n_{2S}(t) \tag{82.36}$$

which are subject to the following boundary conditions:

$$\Delta(0) = 0,\ n_{2S}(0) = 0,\ n_{2P}(0) = 0 \tag{82.37}$$

Note that the above set of rate equations satisfies the conservation law: $n_1(t) + 2\{n_2\mathrm{S}(t)+n_2\mathrm{P}(t)\} = n_0$. Equations (82.34)–(82.36), subject to Eq. (82.37), which are linear, can easily be solved to give

$$\begin{aligned} n_1(t) &= n_0\{1 + \Delta(t)\} \\ &= \frac{n_0}{2}\left\{1 + \left(\frac{K_\mathrm{a} + K_\mathrm{b} - 2k_1 n_0}{2K_\mathrm{b}}\right) e^{-(K_\mathrm{a}-K_\mathrm{b})t}\right. \\ &\quad \left. - \left(\frac{K_\mathrm{a} - K_\mathrm{b} - 2k_1 n_0}{2K_\mathrm{b}}\right) e^{-(K_\mathrm{a}+K_\mathrm{b})t}\right\} \end{aligned} \tag{82.38}$$

$$n_{2S}(t) = \frac{k_1 n_0^2}{4K_\mathrm{b}}\{e^{-(K_\mathrm{a}-K_\mathrm{b})t} - e^{-(K_\mathrm{a}+K_\mathrm{b})t}\} \tag{82.39}$$

$$\begin{aligned} n_{2P}(t) &= \frac{n_0}{4}\left\{1 - \left(\frac{K_\mathrm{a} + K_\mathrm{b}}{2K_\mathrm{b}}\right) e^{-(K_\mathrm{a}-K_\mathrm{b})t}\right. \\ &\quad \left. + \left(\frac{K_\mathrm{a} - K_\mathrm{b}}{2K_\mathrm{b}}\right) e^{-(K_\mathrm{a}+K_\mathrm{b})t}\right\} \end{aligned} \tag{82.40}$$

and

$$\begin{aligned} n_2(t) &= n_{2S}(t) + n_{2P}(t) \\ &= \frac{n_0}{4}\left\{1 - \left(\frac{K_\mathrm{a} + K_\mathrm{b} - 2k_1 n_0}{2K_\mathrm{b}}\right) e^{-(K_\mathrm{a}-K_\mathrm{b})t}\right. \\ &\quad \left. + \left(\frac{K_\mathrm{a} - K_\mathrm{b} - 2k_1 n_0}{2K_\mathrm{b}}\right) e^{-(K_\mathrm{a}+K_\mathrm{b})t}\right\} \end{aligned} \tag{82.41}$$

where

$$K_\mathrm{a} = \frac{k_2 + k_3}{2} + k_1 n_0 \tag{82.42}$$

$$K_\mathrm{b} = \left(K_\mathrm{a}^2 - 2k_1 k_3 n_0\right)^{1/2} \tag{82.43}$$

Note here that $K_\mathrm{a} > K_\mathrm{b}$. Equations (82.38)–(82.41) are the required results for the time evolution of the concentrations $n_1(t)$, $n_{2\mathrm{S}}(t)$, $n_{2\mathrm{P}}(t)$, and $n_2(t) = n_{2\mathrm{S}}(t) + n_{2\mathrm{P}}(t)$ [32].

In Fig. 82.4, we compare two results for the concentration $n2(t)$ of the total aggregated dimers $(S + P)$, that is, the analytic result [Eq. (82.41)] and exact numerical solutions.

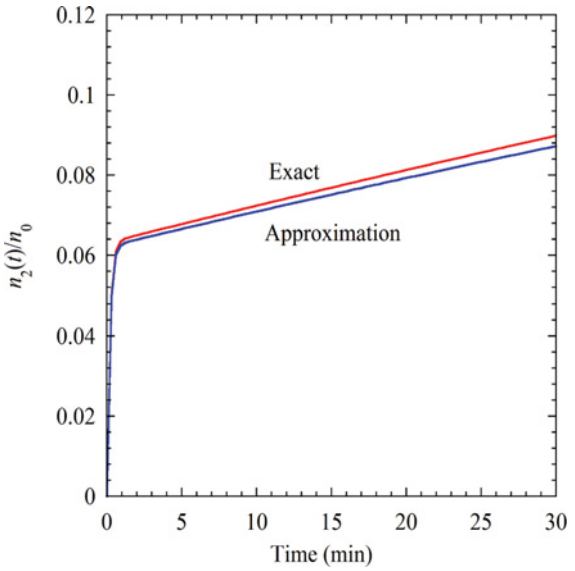

FIGURE 82.4 Comparison of results for the time evolution of concentration $n_2(t)$ of the total aggregated dimers $(S + P)$, that is, the analytic approximate result [Eq. (82.41)] [32] and exact numerical solutions to Eqs. (82.2)–(82.4). Calculated with $n_0 = 10^{15}$ m^{-3}, $k_1 = 1.1 \times 10^{-17}$ m^3 s^{-1}, $k_2 = 6.6 \times 10^{-2}$ s^{-1}, and $k_3 = 3.2 \times 10^{-4}$ s^{-1} from Behrens and Borkovec [25].

Following Behrens and Borkovec [25], we have used the following parameter values: $n_0 = 10^{15}$ m^{-3}, $k_1 = 1.1 \times 10^{-17}$ m^3 s^{-1}, $k_2 = 6.6 \times 10^{-2}$ s^{-1}, and $k_3 = 3.2 \times 10^{-4}$ s^{-1}, which are considered to be a suitable example for real colloidal dispersions showing an appreciable secondary minimum on the potential energy of the interparticle interaction.

We see that the analytic results are in excellent agreement with the numerical results. The relative error is found to be less than ∼3% for $t \leq 30$ min.

The most remarkable feature of the time evolution of $n_2(t)$ shown in Fig. 82.4 is that $n_2(t)$ increases almost linearly with time t after its initial sharp increase with a transient time $\tau_1 = 1/(K_a + K_b)$. Indeed, for the time region $t \ll \tau_2 = 1/(K_a - K_b)$, Eq. (82.41) tends to

$$n_2(t) \approx \frac{n_0}{4}\left[\left\{\frac{k_1 n_0 (k_3 - K_a + K_b)}{K_b}\right\} t - \left(\frac{K_a - K_b - 2k_1 n_0}{2K_b}\right)\{1 - e^{-(K_a + K_b)t}\}\right] \quad (82.44)$$

It follows from Eq. (82.44) that the slope of linear increase in $n_2(t)$ is given by

$$\frac{k_1 n_0^2 (k_3 - K_a + K_b)}{4K_b} \quad (82.45)$$

which agrees well with the exact numerical results.

CATANIONIC SURFACTANTS: NOVEL SURROGATES OF PHOSPHOLIPIDS

Kausik Manna and Amiya Kumar Panda
Department of Chemistry, University of North Bengal, Darjeeling 734 013, West Bengal, India

83.1 INTRODUCTION

Because of the complications in isolation, purification, and characterization as well as their stability, it has been necessary to develop phospholipid mimetic synthetic amphiphiles in order to understand their various biophysical properties at the molecular level. Recently, a new class of bipolar amphiphiles has been developed that consists of two oppositely charged long-chain surfactants and thus are named as *catanionic surfactants*. The various aggregates formed by synthetic catanionic surfactants in aqueous media are considered to serve as feasible substitutes of phospholipids in comparison with the high cost, stability, and ease of preparation of liposomes [1–8]. Besides, they can serve as novel drug–DNA delivery agents [9–13] and templates for the synthesis of nanomaterials [14–17]. The ease of availability and low cost of single-chain surfactants, compared to the double-tailed phospholipids, provide significant motivation in using catanionic surfactants as neoteric materials for the synthesis of vesicles. Structure of the catanionic surfactants resembles that of the zwitterionic phospholipids (Fig. 83.1), although their polar head moieties are generally composed of two oppositely charged groups bound electrostatically. Despite their structural differences, the aggregates they form in the bulk solution exhibit the same rich diversity of morphologies that are also observed in phospholipids; these range from stable vesicles to liquid crystals, depending on the composition, temperature, and ionic strength of the medium [9, 18]. The designation *catanionic surfactant* was first coined in 1987 by Jokela et al. [19]. It may be noted that the studies on such systems started earlier; in 1943, Scott et al. [20] prepared the crystalline surfactants octyltrimethylammonium–octanesulfonate and decyltrimethylammonium–decylsulfonate for the first time and termed those as *double long-chain salts*. They investigated the colloidal electrolytic properties of those synthesized catanionic surfactants in aqueous media. In 1987, Jokela et al. [19] synthesized four different catanionic surfactants: dodecylammonium–dodecanoate, dodecylammonium–dodecyl sulfate, dodecyltrimethylammonium–dodecyl sulfate and dodecylethyldimethylammonium–dodecyl sulfate, and they studied the detailed phase equilibria of those systems. For the first time such a study revealed the existence of various phases, including isotropic micellar, lamellar (Fig. 83.2), and liquid crystalline phases. They noticed the structural and behavioral similarity between the prepared catanionic surfactants and naturally occurring zwitterionic phospholipids (Fig. 83.3) and proposed that the catanionic surfactant–water systems can be used as suitable theoretical models for studies to identify and clarify the properties of phospholipids.

In the last few decades catanionic surfactants have attracted the attention of scientists throughout the world and have been studied with focus on several aspects. Among them, the most striking outcome is the formation of vesicles by catanionic surfactants and its successful

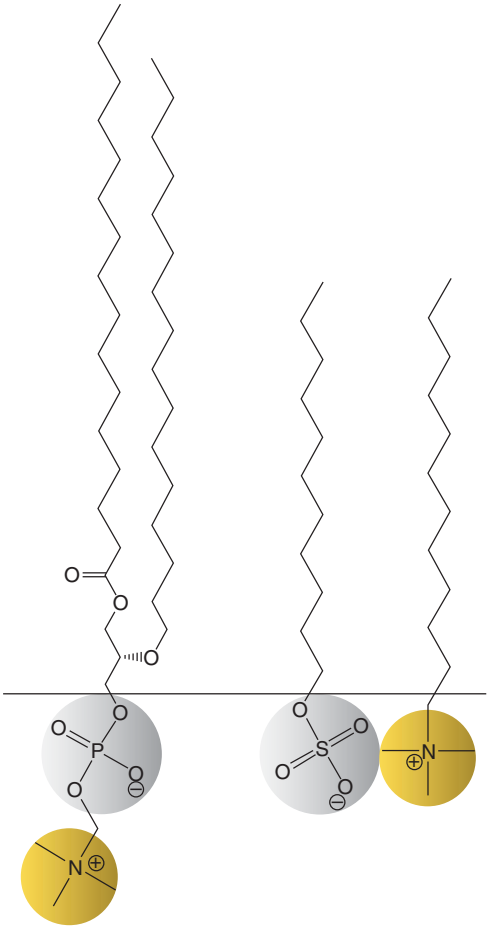

FIGURE 83.1 Structural comparison between a phospholipid (DPPC, shown on left) and a typical catanionic surfactant molecule (shown on right).

application in drug or DNA delivery [9–13, 21]. Besides, the other aggregates of catanionic surfactants such as liquid crystalline phase [22–27], monolayer at air–water interface [24,28–34], micelles [23,26,31,35–38], have also fascinated scientists for their resemblance to phospholipids. They can be considered as a new class of pseudo-double-chained surfactants, which have been developed with a potential as the

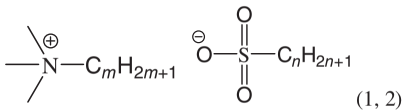
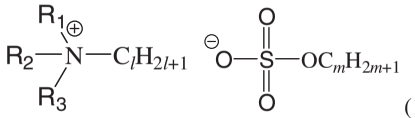
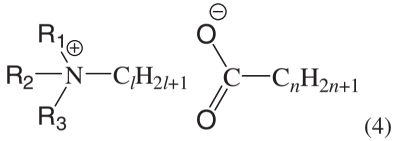
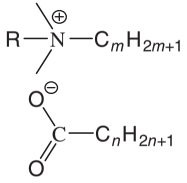
substitute of phospholipids for the study of various biophysical phenomena [5, 39, 40].

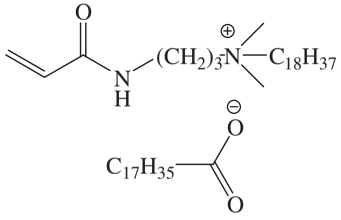
It should be noted that the synthesis, properties, and applications of catanionic surfactants cover a vast area of colloid science, so in this chapter we briefly discuss the synthesis of catanionic surfactants and its characterization procedures, the properties of catanionic surfactants of various compositions and fixed compositions (isolated IPA) in aqueous media, and its applications based on the aqueous media and pure molecular state of IPA.

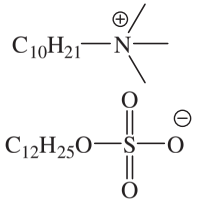




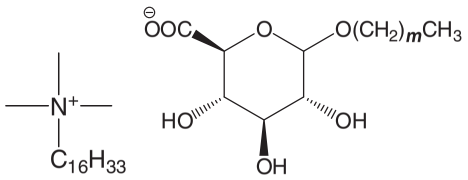




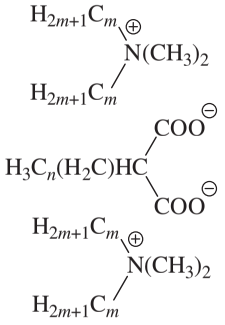


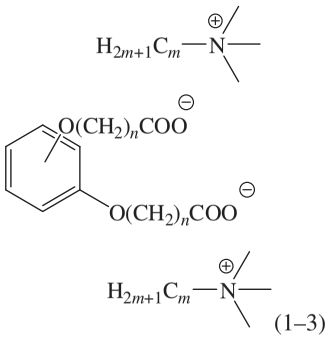


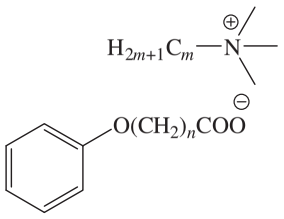
83.2 CLASSIFICATIONS

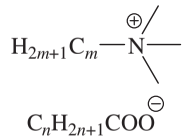


On the basis of their differences in precursors, structure, properties, and applicability, catanionic surfactants can be divided into four main categories:





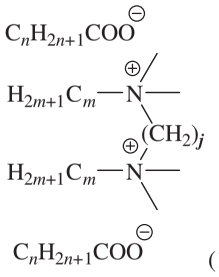


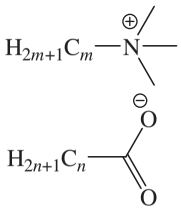


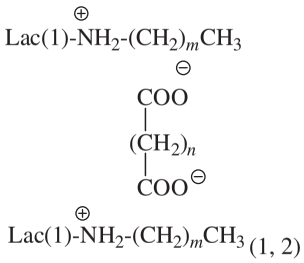
1. *Pseudo-double-chain catanionic surfactants*–the simplest class of catanionic surfactants, obtained by the combination of two oppositely charged single- chain surfactants
2. *Pseudo-triple- and quadruple-chained catanionic surfactants*–combination of two oppositely charged multiple-chain or multiple-head surfactants (gemini surfactants, bolaamphiphiles)
3. *Polymerizable catanionic surfactants*–combination of surfactants containing a polymerizable group
4. *Amino acid–and amino sugar–derived catanionic surfactants*–synthesized by either cationic or anionic surfactants, both derived from amino acid and sugar.

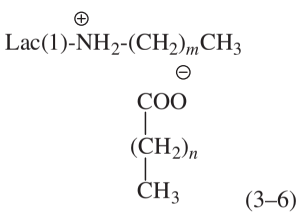
Details on the structure, synthetic methods, and investigated properties of these four types of surfactants are listed in Table 83.1. Each individual catanionic surfactant serves a unique purpose. Table 83.1 also lists the various IPA systems synthesized and studied by various research groups in chronological order.

TABLE 83.1 Chronological Order of Some IPA Systems Synthesized, Isolated, and Investigated and Available in the Literature









IPA system	Chain length	Synthetic method(s)	Investigation highlights	Ref. (year of report)

83.3 PREPARATION AND ISOLATION

Catanionic surfactants are also known as *ion pair amphiphiles* (IPA) as they are synthesized by mixing two oppositely charged amphiphiles. It is worth mentioning that the catanionic surfactants are generated only when an equimolar amount of two oppositely charged surfactants are mixed. It should be kept in mind that as a catanionic surfactant is generally a neutral molecule, the term *ionic equivalence* is more appropriate than *equimolar* in some cases where either of the ionic surfactants holds two headgroups (e.g., gemini surfactants, bolaamphiphiles). Therefore, in such cases one mole equivalence of double-headed ionic surfactant should be mixed with two mole equivalence of single-headed oppositely charged surfactants to obtain neutral catanionic surfactant or IPA. Several methods have been used to synthesize catanionic surfactants or IPA by several research groups [41–44]. Among those, five distinguished methods can be described in general. T

83.3.1 Extraction Method

This method consists in mixing oppositely charged surfactants in water whereby the precipitate of the IPA is formed; the formed IPA is then extracted using suitable organic solvents and the salts remaining in the aqueous phase.

83.3.2 Precipitation Method

Surfactants prepared by this method can be processed in one of two ways:

(a) Precipitation of the potassium, sodium, or lithium salt of the anionic surfactant with silver ions in the aqueous phase. After purification of the precipitate, it is dissolved in a mixture of water and organic solvent, and an equivalent amount of the cationic surfactant with a chloride or bromide counterion is then added to the solution. The pure catanionic surfactant is finally b

(b) Preparation of IPA generated by mixing of supersaturated aqueous solution of two oppositely charged surfactants. The IPA precipitates are removed by filtration or centrifugation where the residual salts remain in solution.

83.3.3 Ion Exchange Method

In this method the cationic surfactant is converted into its hydroxide form and the anionic surfactant into its protonated form by passing through suitable ion exchange resin. The two surfactant solutions are then mixed to produce the pure catanionic surfactant through an acid–base reaction.

83.3.4 Evaporation Method

In this method constituent cationic and anionic surfactants are dissolved in low-boiling-point organic solvents and are mixed in ionic equivalent ratio. The solvents are then evaporated out, leaving solid IPA molecules.

83.3.5 Proton Exchange Method

This method consists in mixing an equimolar quantity of an amino sugar–derived surfactant with an amphiphile bearing an acidic function in water. By a simple acid–base reaction, equimolar catanionic amphiphiles are obtained without residual salts.

83.4 CHARACTERIZATION OF ISOLATED IPA

Since the catanionic surfactants are formed by means of electrostatic attraction between the oppositely charged headgroups of the cationic and the anionic species, characterization of the catanionic surfactants is based on the headgroups and their surrounding environments. Isolated catanionic surfactants are generally characterized by ^{1}H-NMR, FT-IR, or XRD analysis. It may be mentioned that each and every method has its own advantages and disadvantages. The methods are described below, with examples.

83.4.1 ^{1}H-NMR Spectroscopy

In ^{1}H-NMR spectra of catanionic surfactants significant changes in the chemical shift (δ) values of the protons near the headgroups (α and β protons) are observed and compared to those of the precursors [1, 2, 24, 25, 58, 59]. Symmetric and asymmetric chain catanionic surfactants show different δ values for the same headgroups [24]. Results on the NMR studies for a catanionic surfactant comprising hexadecyltrimethylammonium cation and the dodecylsulfate anion are mentioned here in as catanionic surfactants represent one of the simplest systems. The different protons for the IPA can be assigned as shown in Fig. 83.4.

It is obvious that for the IPA, the peaks for the α,α', β,β', and γ γ' protons will be shifted because of the proximity of the charged headgroups. On the other hand, the NMR peak for the terminal protons as well and the other protons will not be significantly changed. Such an observation was reported by Maiti et al. [24]. According to that team of researchers, the following peaks are representative for the IPA: $C_{16}TA^+$ DS^- : 0.87 (t, 6H, ω,$\acute{\omega}$), 1.25 [s, 40H, (CH2)12, 8], 1.33 (s, br, 4H γ, γ'), 1.62–1.72 (q, 2H, β'), 1.89 (s, br, 2H, β), 3.27 [s, 9H,N(CH_3)$_3$], 3.37-)3.42 (t, 2H, α), 3.99 (t, 2H, $\acute{\alpha}$) (where the abbreviations s, d, t ,q, br, etc. have their usual meanings). The same research group described the structural characterization of ion pair amphiphiles formed between hexadecyl pyridinium ion and dodecyl sulfate ion in another report [25].

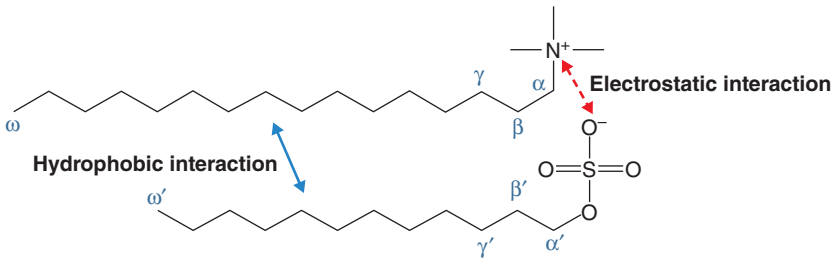

FIGURE 83.4 Cetyltrimethylammonium dodecylsulfate (CTA^+DS^-) molecule.

83.4.2 FT-IR Spectroscopy

The stretching and bending modes of vibration of the various bonds with and around the headgroups are affected by the electrostatic attraction in catanionic surfactants [24, 25, 31]. Vibrational spectroscopy is a very simple yet informative tool used to characterize catanionic surfactants by means of the changes in those vibrational frequencies with respect to the individual precursors. Table 83.2 summarizes the FTIR vibrational frequencies of the individual C–H bonds of an isolated catanionic surfactant, octadecyltrimethylammonium–dodecylsulfate ($C_{18}TA^+DS^-$), and its precursors. Data show that the vibrational frequencies of headgroups and the methylene groups near them change significantly during formation of the catanionic surfactant.

83.4.3 X-Ray Diffraction Study

X-ray diffraction studies on catanionic surfactants can provide useful information on the surfactants' crystal lattice structures [24, 25, 59]. Usually they remain in the form of interdigitated bilayers. The headgroups remain separated by two paraffinic layers with an equimolar mixing of the alkyl chains of the cationic and anionic surfactants and remain in *trans* configuration [59]. Figure 83.5 illustrates the powder XRD pattern of hexadecylylpyridinium–dodecylsulfate (CP^+DS^-).

Characteristic XRD diffraction lines confirm the bilayer lamellar structure of catanionic surfactants [24, 25]. Size and nature of the headgroup plays an important role in describing the structure of crystal lattice. Electrostatic interaction between two oppositely charged headgroups and the hydrophobic–hydrophobic interaction between their alkyl chains are key factors in the packing arrangements of the crystal lattice of the catanionic surfactants. Interlamellar electrostatic interactions between headgroups neutralize the surface charge density and thus help to form closely packed ion pairs, while the van der Waals interaction between their hydrophobic tails forces their alkyl chains into a compact packing arrangement.

83.5 PROPERTIES

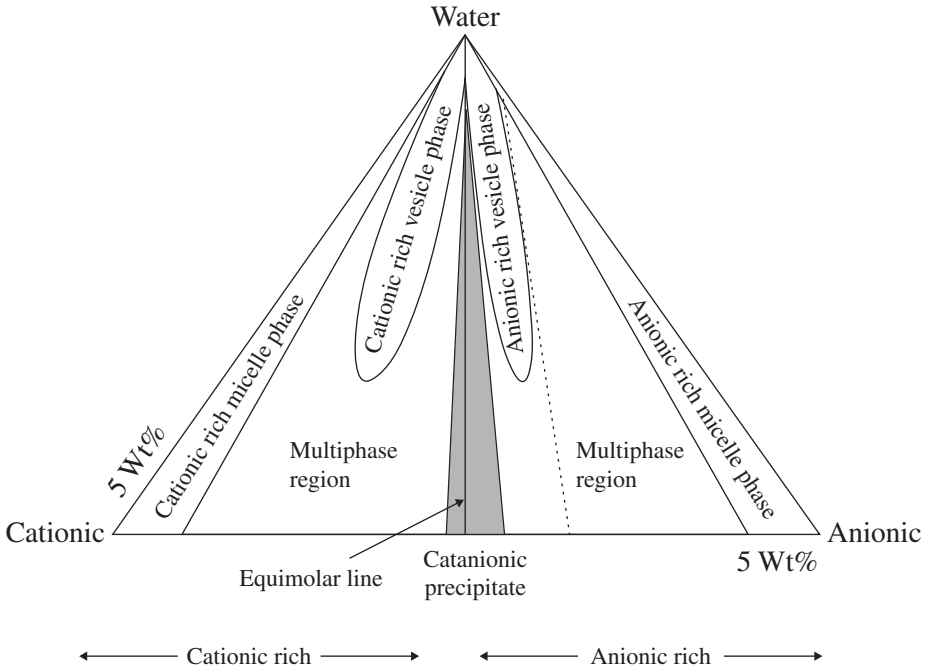
The properties of catanionic surfactant systems have been grouped into two main categories according to surfactant composition and synthesis and how they are studied:

1. Solutions of oppositely charged surfactant solutions are mixed as a function of variable composition in a wide range surfactant concentration. The compositional and total surfactant concentration effects on phase equilibria and aggregation behavior are studied mainly in this way. However, catanionic surfactant systems are accompanied by impurities of either of the constituent surfactants and counterions, which influence the properties of such systems.
2. The catanionic surfactant is synthesized at fixed compositions, isolated, purified, and studied. The selective and targeted study of catanionic surfactants or IPA thus can be performed in an impurity-free environment.

83.5.1 Properties of Catanionic Surfactants as Functions of Composition and Concentration

83.5.1.1 Phase Equilibria. A single-chain cationic or anionic surfactant exhibits only one (isotropic micellar) phase in water. The combination of two oppositely charged surfactants in aqueous media introduces more components of the surfactant–water systems. In addition to that, the synergism between opposite charges and dissimilarity in structure and some other physicochemical properties between two kinds of surfactants introduce both complexity and versatility in the phase behavior of catanionic surfactant systems. The packing parameter, defined as $p = v/al$ (where v is volume of the hydrocarbon chain, l is optimal length close to the fully extended chain length, and a is surfactant headgroup area), is expected to play a major role in the aggregation pattern of surfactants. The assembly of two surfactants with different structures can result in a variety of curvatures of amphiphilic films and, therefore, a wide variety of aggregates and hence various phases. Owing to the suppleness of their structure, catanionic surfactants reveal various phases in semidilute and concentrated aqueous solutions such as micelle, gel, vesicle, lamella, and liquid crystal [21,24,26,27,35,60,61]. The concurrence of two inverted hexagonal phases in different systems has also been observed. Precipitation or coacervation is one of the most significant features of the phase behavior for most catanionic surfactant systems at the equimolar region, which occurs irrespective of the overall surfactant concentration [24, 35].

In the high-concentration region the phase behavior of catanionic surfactants is more diverse than in the semidilute and dilute regions. Liquid crystalline phases, such as normal and cubic hexagonal, normal cubic, and lamellar, dominate over other phases in the higher-concentration region [27, 62]. Vesicles are seldom formed in the extremely high concentration range. Figure 83.6 represents the ternary phase diagram for the sodium deoxycholate (NaDOC)/hexadecyltrimethylammonium bromide (C_{16}TABr)/water system. The phase diagram shows occurrence of normal hexagonal, normal cubic phases at high concentration range, while the gel and isotropic micellar phases are formed in the semidilute region of the surfactants. Formation of the precipitates or coacervates at equimolar composition generally take place in the dilute or semidilute region.



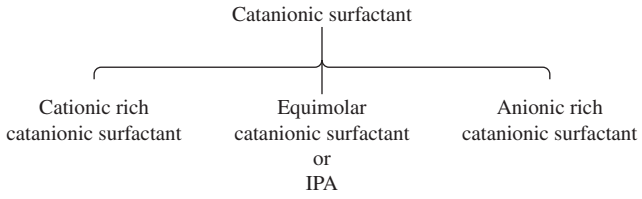


FIGURE 83.7 Schematic phase diagram of symmetric pseudo-double-tail catanionic surfactant mixture, single-chain cationic (12-carbon)–single-chain anionic (12-carbon)–water system, in the very dilute region of the pseudoternary system. Compositions are in wt%. (Adapted from Khan et al. 1996 [63], pp. 614–623.)

The phase behavior is equally diverse even in the semidilute and dilute regions [24, 35]. Figure 83.7 is a schematic phase diagram of a symmetric pseudo-double-chain catanionic surfactant. Catanionic precipitates are formed in the equimolar region, and in the cationic and anionic surfactant–rich regions, the precipitates are redissolved to form the stable vesicle phase. On further increase in the parent surfactant concentration, transition from vesicle to micellar phase occurs. Reports on the formation of rodlike and wormlike micelles in cationic- or anionic-rich regions are also available in the literature [26, 35]. The vesicle phase remains in equilibrium with multiphase regions and with catanionic precipitate. The phase behavior is predominantly dependent on the surfactant structure: number of alkyl chains, chain length, and alkyl chain symmetry; however, the surfactant polar headgroups were found to have minor effects on the phase behavior in the dilute region (e.g., the asymmetric pair hexadecyltrimethylammonium bromide and sodium octylsulfate [64]). One of the most interesting findings of the phase manifestation of catanionic surfactants is the concurrence of precipitate and vesicle phases near the equimolar region. Cationic- and anionic-rich mixed surfactants form vesicles very near to the equimolar region, which led scientists to believe that the formation of pseudo-double-chain surfactants in the equimolar region explains why the surfactants are insoluble in aqueous medium as a result of enhanced hydrophobicity.

All combinations of oppositely charged surfactants do not exhibit phase variation. Occurrence of the different phases depend mainly on the nature of the surfactants, apart from the other physicochemical conditions. According to the report of Panda et al. [35], sodium cholate (NaC) exhibits only one (isotropic micellar) phase in combination with alkyltrimethylammoniumbromhides (C_nTABr), whereas in the case of its derivative sodium deoxycholate (NaDC), various phases are observed in aqueous media. Interestingly, only slight variation in the structure of bile slats (NaC and NaDC) abruptly changes the macroscopic phase behavior. Formation of only small micelles by catanionic surfactants of NaC and C_nTABr implies that the spontaneous curvature of the aggregates is sufficiently higher. Although the NaDC-C_nTABr catanionic surfactants exhibit various phases and form various aggregates (normal micelles, wormlike micelles, and vesicle), the radii of the vesicles formed are shorter than those of vesicles formed by conventional long-chain catanionic surfactants.

Review of the above mentioned phase manifestations clearly implies that the different phases in catanionic surfactants lie in three main regions: cationic-rich, anionic-rich, and equimolar catanionic surfactants. In both the cationic- and anionic-rich regions, various phases are observed and in the equimolar region the complete precipitation of catanionic surfactant occurs; therefore, this can be considered as a signature composition where formation of catanionic surfactants are confirmed. The mixture thus formed at equimolar cationic

and anionic surfactant ratio is often known as *coacervate* or *ion pair amphiphile* (IPA):

The separation of IPA from the bulk phase through precipitation completely frees the IPA from counterions. The removal of counterions further strengthens the electrostatic interactions between the two surfactants, which changes the total area occupied by these polar headgroups and subsequently the packing parameter (p). As a result, IPA is significantly different from the catanionic surfactants at nonequimolar compositions in various physicochemical aspects.

83.5.1.2 Electrical Properties. Replacement of small counterions from the individual surfactants by long-chain oppositely charged ionic surfactants can abruptly change the electrical property of aqueous cationic surfactants owing to the strong synergism between oppositely charged surfactants. In the first report on catanionic surfactants [20], the electrical behaviors of two synthesized catanionic surfactants were studied by means of electrical conductance. The appearance of sharp breakpoints in the conductance–surfactant concentration profiles implied that the change in the strong long-chain noncolloidal electrolytes in the premicellar region might be due to the weak colloidal electrolytes (micelle) in the postmicellar region (Fig. 83.8). In this study the bulk as well as micellar compositions were quantified by means of electrical conductometry. The unexpected nonneutrality of micelles of catanionic surfactants, as indicated by the increase in conductance of catanionic surfactants (Fig. 83.8) after micellization, revealed the stoichiometric inequality of the oppositely charged surfactants in their mixed micelles. Either anionic or cationic excess exists in the micelles even at equimolar composition. Similar results were also found by Panda and his coworkers [35] in the zeta-potential (ZP) measurements of catanionic surfactants of alkyltrimethylammonium bromide and bile salts (Fig. 83.9). The ZP values were found to be nonzero at equimolar composition of cataionic surfactants. The results again prove that micellar composition differs from that of bulk depending on the nature of the surfactants.

Conductometric titrations can also conveniently sense the pulse of the formation of different phases in the aqueous catanionic surfactant solutions. Onset of the formation of different phases and various aggregates lead to the change in conductivity of catanionic surfactant systems ranging from

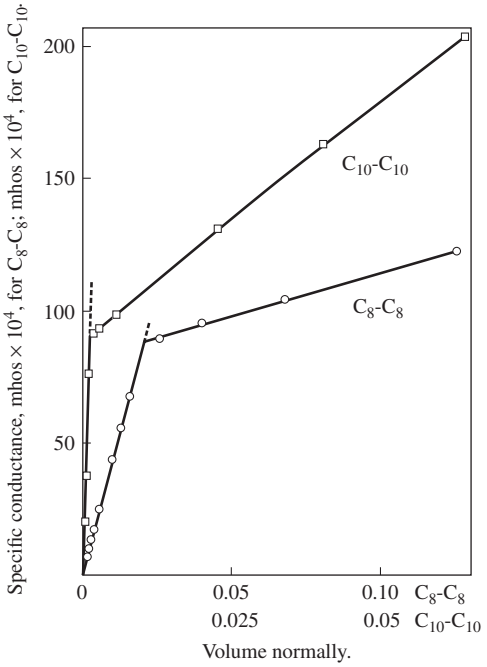

FIGURE 83.8 Specific conductance of aqueous solutions decyltrimethylammonium decanesulfonate (at 40°C) and octyltrimethylammonium octanesulfonate (at 25°C). (Adapted from Scott et al. 1943 [20], pp. 698–701.)

cationic rich to anionic rich region. Some catanionic surfactant systems have been studied conductometrically at a wide range of concentrations by Panda et al. [24,35]. In those studies the onset of various phases could be identified for both variable and fixed total surfactant concentrations (Fig. 83.10). Like phase behavior, the conductance behavior of catanionic surfactants also changes from dilute to concentrate region as a function of overall surfactant concentration (Fig. 83.10). The conductance behavior just reversed from dilute to concentrate region. The onset of micellization or formation of aggregates can clearly be predicted from the breakpoints.

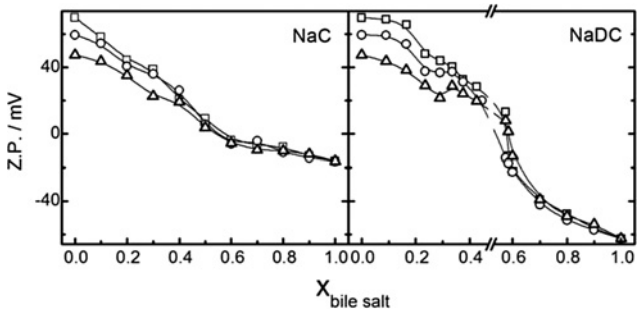

FIGURE 83.9 Variation in zeta-potential (ZP) with the mole fraction of bile salt ($x_{\text{bile salt}}$) at 25°C; bile salts are labeled in the figure (symbols: □ C_{16}TABr; ∘: C_{14}TABr; Δ C_{12}TABr; total surfactant concentration = 50 mM) [35].

(IV) SDS–C_{12}TABr system [24] (*A* indicates onset of coacervation; *B*, onset of gel formation; *C*, onset of clear solution formation). Temperature: 25°C.

83.5.1.3 Aggregation Behavior in Water. Spontaneous aggregation (like normal surfactants in solution) of IPA is hindered because of its poor solubility in water. Strategies to stabilize IPA suspensions have been suggested by introducing additives [8, 24, 40, 65]. The aqueous solubility of IPA decreases with the increase of hydrophobic chain length of the individual surfactants. Besides, the aqueous solubility or insolubility of IPA resembles that of the phospholipids. Although additives such as cholesterol or bile salts themselves are poorly soluble in water, their presence enhances the aqueous solubility of IPA. Only a small amount of cholesterol (3.5–7.0 mol%) acts most effectively as solubilizing agent; an excess amount of it can have an adverse effect on the solubilization, due to an antagonistic effect. Similar phenomena are also common in living cell membranes; the presence of a trace amount of cholesterol facilitates the solubilization of lipids and hence lipid bilayer formation [66]. In mammalian bile, bile salts help in the solubilization of cholesterol. Through the formation of mixed micelles with lecithin, it increases the water solubility of IPA as well. It is

found that bile salts are better solubilizers at their postmicellar concentrations [24].

Introduction of cosolvents such as alcohol additives enhance the solubility of IPAs in water [40, 65]. It has been found that the cosolvent effect on the enhancement of the solubility of IPA in water follows the order 1-butanol→1-propanol→ethanol→methanol for a given IPA. For a particular cosolvent, the solubility of IPA increases with the concentration of cosolvent, and at sufficiently higher concentration, IPAs prefer to remain in the molecular dispersion state instead of forming aggregates [40].

83.5.2 Properties of Isolated IPA

83.5.2.1 Special Features of IPA: Liquid Crystalline Behavior. The ability to pass through the liquid crystalline (LC) phase in case of catanionic surfactants at aqueous cationic or anionic rich regions were discussed in a previous section. In the aqueous cationic- and anionic-rich regions, the formed LCs are lyotropic, formed due to the amphiphilic aggregation in solvents. Several reports [67–72] are available on the liquid crystalline behavior exhibited by phospholipids. But those lamellae, hexagonal liquid crystalline phases are observed for hydrated phospholipids, which are also lyotropic in nature. However, the liquid crystalline behavior of pure isolated IPA has recently been explored with some unique observations that are typical for IPA. IPA shows thermotropic LC behavior [24, 25, 44, 47, 56, 73] at higher temperatures. It may be noted that catanionic surfactants coomprising quaternary ammonium/pyridinium as cationic headgroups and sulfate/sulfonate as anionic headgroups show thermotropic LC (shown in Table 83.1). Smectic phases are observed for such catanionic surfactants in the majority of cases except the hexagonal columner (discotic) [52, 57] and nematic phases [57]. Some of them show liquid crystalline behavior even at room temperature [57]. Variation in the phase transition temperature depends on the hydrocarbon of the catanionic surfactant systems. It has been observed that double-chain catanionic surfactants exhibit smectic phases and triple- and quadruple-chain catanionic surfactants exhibit hexagonal and nematic phases. The existence of smectic phases is an outcome of the formation of layered structure by the pseudo-double-chain catanionic surfactants and their orientation. Figure 83.11 shows various LC textures observed for some synthesized catanionic surfactants.

83.5.2.2 Insoluble Monolayer at Air–Water Interface. Catanionic surfactants form a two-dimensional (2D) insoluble monolayers at the air–water interface that are considered to be similar to those of the phospholipid monolayers. Decoration of the ensuing monolayer depends on the balance of a competition between hydrophilic and lipophilic groups among the surfactant molecules at the interface through intermolecular interactions; therefore, intermolecular hydrophilic–lipophilic balance (HLB) among the surfactant molecules plays an important role in such cases. Although this fact is similarly applicable to the bulk solution, the nature of this competition is not so prominent in bulk as in Langmuir monolayers. This is because the surfactant molecules are limited to orientation at the 2D interface. Configuration of the monolayer depends mainly on three parameters: (1) tilting of the surfactant chains, (2) minimum area per surfactant molecule, and (3) relative distance between them and their penetration into the bulk phase. All these parameters are governed by the nature of the hydrophilic head and hydrophobic chain of the surfactants [32]. On compression and expansion of the monolayer film, the surfactant molecules reorganize themselves into lower- and higher-energy states, respectively, by changing these structural parameters.

The selective preparation of insoluble IPA monolayer is generally performed by following the same procedure as in case of phospholipids [33, 34]. The IPA monolayer is formed at the air–water interface by spreading a solution of IPA (generally prepared in pure or mixed organic solvents) dropwise at the interface. The films are then characterized by following a procedure similar to that adapted for phospholipid monolayers. While the functionality of the monolayer is generally investigated by surface pressure measurements, structure of the monomolecular films of the IPA are characterized by different techniques, such as fluorescence microscopy, Brewster angle microscopy (BAM), IR spectral analysis, ellipsometry, and atomic force microscopy (AFM). The equilibrium surface tension of IPA dispersions is characteristically lower than those of the solutions of each ionic surfactant separately [29] even at higher concentrations of their CMCs. This demonstrates two factors: (1) that the 2D interface covered by the catanionic surfactant is higher than the area covered by a single-chain surfactant and (2) the existence of strong synergism. The interfacial behavior of IPA monolayer is best understood in surface pressure measurement using the Langmuir technique. Figure 83.12 plots the surface pressure (π)–area (A) behavior of various IPAs at the air–water interface for different catanionic surfactants prepared from alkyltrimethylammonium bromide and sodium dodecyl sulfate. The π–A isotherm for pure DPPC has also been shown in the figure for comparison of the surface activity of the IPA.

Individual components of the IPA are individually highly soluble in water and less likely to form Langmuir monolayer at the air–water interface; instead, they prefer to remain in the bulk through micellization. With the variation in hydrocarbon chain length, IPAs are inclined to exhibit variances in π– A isotherm behavior that are governed by the relative strength of intramonolayer hydrophobic interactions. An IPA with a longer hydrophobic chain prefers to stay at the air–water interface compared to the IPA of shorter hydrocarbon chain. On compression, a 2D monolayer is formed with various

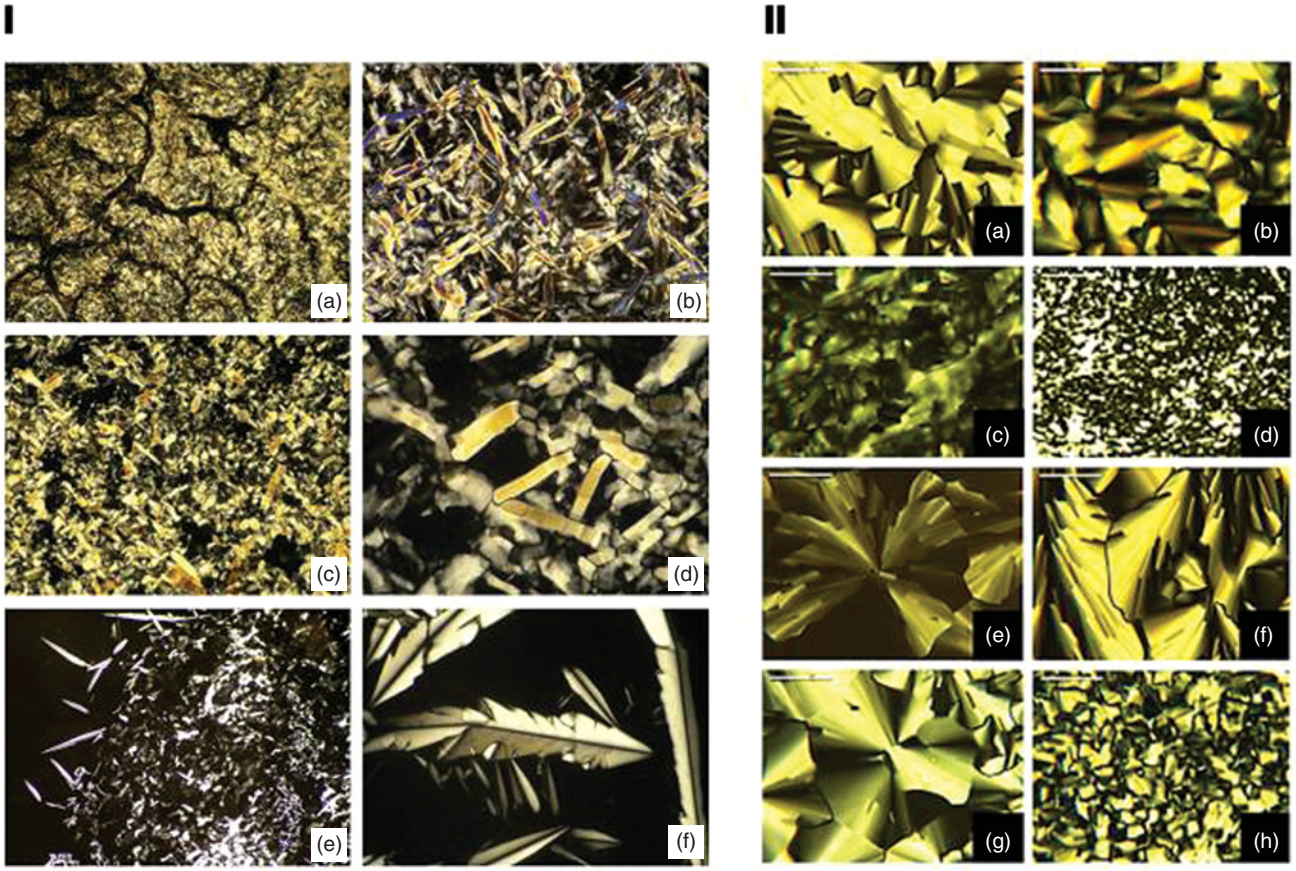

FIGURE 83.11 Optical microscopic texture of liquid crystal phases exhibited by catanionic surfactants: (I) smectic phases—mosaic and featherlike lancet textures (from Matos et al. 2013 [56], reproduced with permission of Elsevier); (II) hexagonal and nematic (D) phases—fan-shaped and nematic textures (from Jose et al. 2013 [57], reproduced with permission of Elsevier).

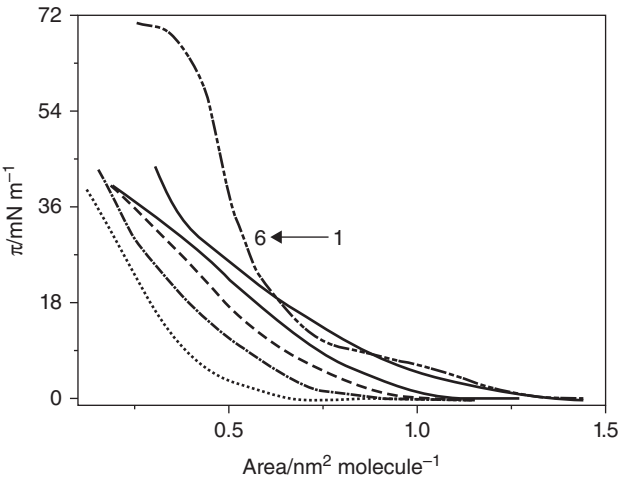

FIGURE 83.12 $\pi - A$ isotherms of IPA at the air–water interface at 298 K. Curves: (1) DPPC; (2) $C_{10}TA^+DS^-$; (3) $C_{12}TA^+$ DS^- ; (4) $C_{14}TA^+$ DS^- ; (5) $C_{16}TA^+$ DS^- ; (6) $C_{18}TA^+DS^-$. (Adapted from Maiti et al. 2010 [24], pp. 867–879.)

patterns depending on surface pressure. Thus the IPAs could be considered to have potentials to act as novel substitutes for the conventional phospholipids. However, the cytotoxicity of the IPA needs to be explored for a particular formulation.

83.6 CATANIONIC MICELLES

The CMC for a binary mixed surfactant system can be theoretically calculated according to the Clint formalism [74]:

$$\frac{1}{CMC} = \frac{x_1}{CMC_1} + \frac{1 - x_1}{CMC_2} \tag{83.1}$$

where, CMC, CMC_1, CMC_2, and x_1 are the CMCs of mixed micelle, surfactant 1, surfactant 2, and mole fraction of cationic surfactant, respectively. The rationale could simply be made applicable to the catanionic surfactants also. Interaction among the constituent surfactants are defined and evaluated by employing the Rubnigh's *regular solution*

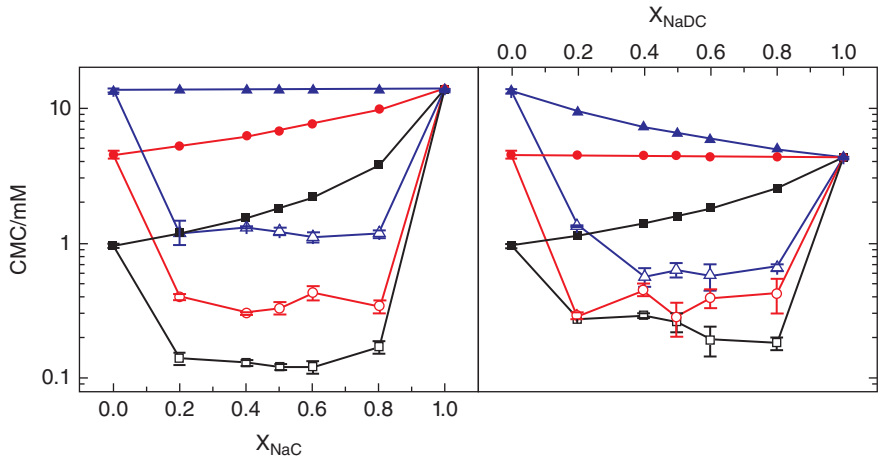

FIGURE 83.13 Variation of CMC for C_nTABr-NaC (left panel) and C_nTABr-NaDC (right panel) mixed surfactant systems with the mole fraction of bile salt ($X_{\text{bile salt}}$). Systems: -□- C_{16}TABr; -○- C_{14}TABr; -Δ- C_{12}TABr. (From Manna et al. 2012 [35], pp. 10–21.)

theory (RST) [75]. The interaction parameter (β) can be evaluated according to the following equation

$$\beta = \frac{\ln(x_1 CMC / x_1^R CMC_1)}{(1 - x_1^R)^2} \tag{83.2}$$

where x_1^R is the micellar mole fraction of component 1 (herein the cationic surfactants, C_nTABr). x_1^Rcan be obtained from the following equation:

$$\frac{\left(x_2^R\right)^2 \ln\left(\dfrac{CMCx_1}{CMC_1 x_1^R}\right)}{\left(1 - x_1^R\right)^2 \ln\left[\dfrac{CMC\left(1 - x_1\right)}{CMC_2\left(1 - x_1^R\right)}\right]} = 1 \tag{83.3}$$

The equation is repeatedly solved for x_1^R using a computer program by iterative method. The activity coefficient (f^{R}) also reflects the nonideality of a multicomponent mixed micellar system. The f^{R} values of both the surfactants in their mixture can respectively be evaluated using the following equations:

$$\begin{aligned} f_1^R &= \exp[\beta_i (x_1^R)] \\ f_2^R &= \exp[\beta_i (1 - x_1^R)] \end{aligned} \tag{83.4}$$

where subscripts 1 and 2 denote surfactant 1 and surfactant 2, respectively. $f^{\mathrm{R}} = 1$ indicates an ideal mixed system. Several reports [26,31,35–38,76,77] are available on micellization of catanionic surfactants, where remarkable differences in micellization parameters of catanionic surfactants, with significant negative deviation from the ideal values, were noticed. These were attributed to change in both hydrophilic and hydrophobic environments. Abrupt lowering of experimental CMC is found to occur with respect to theoretical values. Figure 83.13 describes the variation in CMC of the mixed micellar systems of alkyltrimethylammonium bromide and bile salts [sodium cholate (NaC) and sodium deoxycholate (NaDC)] with the composition. Significant negative deviations from the ideal values (calculated by the Clint equation) were due to strong synergism between the oppositely charged surfactants.

83.7 CATANIONIC VESICLES: CATANOSOMES

Because of their structural similarities, catanionic surfactants can form liposomelike ensembles, which are known as *catanosomes*.

83.7.1 Preparation Methods

Catanionic vesicles are generally prepared by spontaneous, semispontaneous, or mechanical disruption approaches [45, 78, 79] (see Fig. 83.14).

83.7.1.1 Spontaneous Process. Vesicle dispersion of IPA is prepared by gentle mixing of the cationic and anionic surfactant solutions for several hours at room temperature. All solutions are then left to stand at room temperature to attain equilibrium for 24 h.

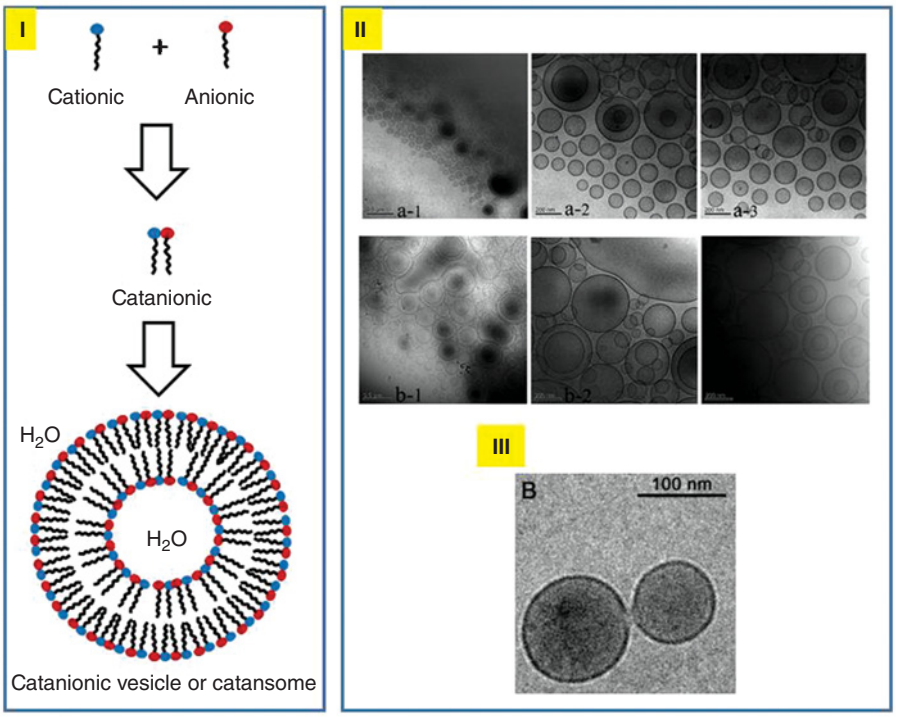

FIGURE 83.14 Schematic representation of catanosome preparation: (I) cryo-TEM images of C_nDMAO/C_7F_{15}CF=CHCOOH catanosomes; (II) [80], Cryo-TEM image of liposome (III) [81]. [Panel (II) is from Li et al. 2009 [80], from the journal *Soft Matter* (published by Royal Society of Chemistry); panel (III) is from Urbán et al. 2011 [81], from the journal *Nanoscale Research Letters* (published by Springer).]

83.7.1.2 Semispontaneous Method. In this method [8], the aid of cosolvent addition is applied. In a typical experiment of vesicle preparation, a suitable amount of IPA is dissolved in the alcohol. Water is then added and the solution sample is passed through a homogenizer for few minutes at room temperature in a sealed container specially designed for this vesicle preparation process.

83.7.1.3 Mechanical Disruption Process. In this method [8], an appropriate amount of IPA is dissolved in suitable organic (easily vaporizable) solvent and dried to form thin films on the surfaces of glass beads in a test vessel by blowing of nitrogen gas. The resulting films are then hydrated in absence or presence of additives and vortexed for a few minutes. A heterogeneous suspension is generated, which is then exposed to ultrasonic dispersion. The translucent solution is then extruded under nitrogen pressure through a membrane filter sequentially at higher temperature (above the phase transition temperature) whereby a stable vesicular diepersion is obtained.

83.7.1.4 Modified Reversed-Phase Evaporation. This method can also be applied for the preparation of vesicles from catanionic surfactants. IPA, dissolved in a small volume of suitable organic solvent, was added to large amount of water, and the two-phase mixture was briefly bath-sonicated (for 15–20 min) at ambient temperature to produce a stable emulsion. The organic solvent from this emulsion was gradually evaporated under reduced pressure. The resulting suspension was then subjected to freeze–thaw cycles several times. Then a brief bath sonication (5 min) above 70°C (well above the chain melting temperature) afforded a stable, translucent suspension of the catanosomes.

83.7.2 Stability of Catanosomes

Some recent investigations revealed that through the dispersion of IPA in aqueous medium, stable IPA vesicles can also be prepared by introducing double-chain ionic surfactants. In consideration of intravesicle interaction, addition of cholesterol or fatty alcohol can modify the molecular packing or intermolecular interaction within the bilayer. For the intervesicle aspect, additional ionic surfactant can increase the electrostatic repulsion to prevent the vesicle fusion or aggregation. Consequently, an appropriate amount of additives can effectively enhance the physical stability of the vesicles.

83.8 APPLICATIONS OF IPA/CATANIONIC SURFACTANTS

Their versatile phase behaviors and their tunability in enabling different desired formulations have opened doors to multifaceted applications of catanionic surfactants in various fields, especially in drug delivery, synthesis of nanomaterials, and liquid crystalline systems. In addition, researchers are investigating the applications of catanionic surfactant systems in ion sensing, molecular recognition, and catalysis. Such applications of catanionic surfactant systems are relatively recent phenomena in the progress of colloidal science. Some of the applications of catanionic surfactants are mentioned below.

83.8.1 Drug Delivery

Liposomes have attracted the attention of different research groups in various interdisciplinary fields because of their biomimetic cell membrane like structures. However, because of the high cost, difficulties in isolation and purification, and biological stability of the naturally occurring phosopholipids, catanionic surfactants have emerged as an important substitute because of their phospholipidlike structure and easy preparation, isolation, and purification and because of the low cost of their precursors. Because of their liposomelike structure, catanionic vesicles are now good biomimetic systems for researchers in biophysical chemistry and pharmaceutics. Encapsulation or entrapment efficiency of the drug carrier and vectorization, or the specific delivery of drugs, are the major challenges in pharmaceutical research. Several research groups have investigated the encapsulation ability of hydrophilic probes of catanionic vesicles. However, vectorization using catansomes is still limited. Major hurdles of such entities are their cytotoxicity, which are still in infancy stage.

In 1989, Kaler et al. [78] found that glucose could be efficiently encapsulated in CTAT/SDBS vesicles (T = tosylate), which remained stable for at least 1 year. Caillet et al. [82] studied the encapsulation of riboflavine and glucose in CTAB/SOS vesicles as well as in the corresponding IPA vesicles. The encapsulation was extremely low (<0.01%), which was attributed to the ionic character of the probe, which might destabilize the vesicles. The release of glucose was rapid, complete, and independent of the presence or absence of a membrane disrupting agent, indicating that the amphiphilic membrane has a very dynamic and permeable nature. Fischer et al. [51] investigated CTAT/SDBS systems, in which three vesicle compositions were used: a vesicle with an excess of CTAT, a vesicle with an excess of SDBS, and pure IPA vesicles without counterions. The CTAT-rich vesicles were the least efficient in entrapping glucose, whereas the SDBS-rich and the pure IPA vesicles were approximately equivalent in efficiency. The intrinsic encapsulated volume, even at very low surfactant concentrations, was greatest for the IPA vesicles, but in the long term the IPA vesicles seemed to be less stable than the SDBS-rich. Therefore, the entrapment capacity is better in the IPA vesicles where all counterions had been removed, provided, that the IPA system is allowed to age for 24 h. In 1990, Fukuda et al. [45] investigated the riboflavin encapsulation ability of the vesicles formed by the catanionic surfactant (Table 83.1) in water for the first time. They found that the catanionic vesicles were able to encapsulate 0.9 % riboflavin. A similar study by Bhattacharya et al. [2] in their synthesized catanionic vesicles of bolaamphiphile and long-chain quaternary ammonium hydroxide (Table 83.1) showed 2.28% encapsulation efficiency. Tondre et al. [9] were able to encapsulate 2.5% glucose in their catansomes. A glucose retention stability study revealed that after 24 h only 8% of the initially encapsulated glucose was retained in the hydrophilic core of the catanionic vesicles, which indicates the high permeability of this system.

Polymerization of the ion pair amphiphiles is another approach that can be adopted to increase the encapsulation efficiency and the tightness of the bilayer membrane of the vesicles. Chung et al. [3] tried to polymerize different combinations of ion pair amphiphiles using an amphiphile with ammonium headgroup and carboxylate chain amphiphile (Table 83.1) with a lipoyl group at the chain end, to study the encapsulation and release of fluorescent markers. Their study revealed that the uncharged polymerized catansomes prepared from an anionic surfactant with two carboxylic groups with the same cationic surfactant showed an almost complete encapsulation, while the negatively charged vesicles (made from one ammonium and one dicarboxylate surfactant) only partially encapsulated the fluorescence markers. The release also differed between the two vesicles, with the uncharged vesicle showing a much slower release than the negatively charged one.

Vectorization using catanionic vesicles has remarkably improved with studies involving the vesicles of nontoxic amino acid– [11, 83] or amino sugar– [41, 42] derived catanionic surfactants. Such entities are found to be highly efficient as drug and DNA delivery systems. Studies by Blanzat et al. [41, 42] revealed that the aminoglucose-derived gemini catanionic analog possesses both low toxicity and strong anti-HIV activity. The low toxicity of the gemini analog compared with the other catanionic analogs was attributed to its unique aggregation characteristics. Further studies by Brun et al. [84] suggested that the gemini analog would probably not penetrate into a biological membrane. In a more recent study, Blanzat et al. [54] showed an 8% encapsulation efficiency and very good drug entrapment stability (30 h) of the catanionic vesicles of amino sugar–derived catanionic surfactants, regardless of medium used (water or phosphate buffer), and this is the highest encapsulation efficiency by the catanionic vesicles reported to date.

[14]; (ii) different-shaped copper oxide nanocrystals at different catanionic surfactant (SDS/CTAOH) compositions: 1:0 (A), 7:1 (B), 7:2 (C), 7:3, (D), 7:4 (E), 4:7 (F), 3:7 (G), 2:7 (H), 1:7 (I) and 0:1 (J) Shen et al. [15]; (iii) mesoporous alumina [16] and (iv) gold nanorods synthesized by CTAB/NaOL catanionic templates [17].

83.8.2 Templates for Nanomaterial Synthesis

Surfactant-mediated nanomaterial synthesis has given a new direction to nanochemistry. In the last two decades several approaches have been made by several research groups to synthesize nanomaterials using micelles and reverse micelles as templates. But those most of the synthesized materials are spherical in shape. Surfactant-templated controlled syntheses of nanoparticles are limited and are mainly performed using microemulsions, whereas the fabrication of synthesized nanoparticles is still absent. In the last few years, catanionic aggregates have been used for that purpose and found capable of fabricating the nanomaterials in various shapes and geometry in a controlled manner in aqueous media. Various stable aggregates formed by catanionic surfactants in aqueous media have added a further dimension and velocity in surfactant mediated nanomaterial synthesis.

In 2003 Kaler et al. [14] synthesized silica hollow spheres of size 60–120 nm, using catanionic vesicles as templates from tetramethoxysilane (TMOS). They used two different catanionic surfactant formulations, CTAB/SDBS and CTAT/SDBS, for the preparation of vesicle dispersions. The reaction was performed at room temperature and acidic condition (pH = 3) whereby fairly monodispersed nanocrystalline materials could be synthesized [Fig. 83.15(i)].

The catanionic surfactants CTAOH/SDS were introduced as shape and size modifiers by Shen et al. [15] for the syntheses of cuprous oxide (Cu_2O) nanocrystals. The presence of SDS-rich catanionic surfactants could induce the formation of polyhedral Cu_2O structures with eight triangular structures. The presence of SDS-rich catanionic surfactants could induce the formation of polyhedral Cu_2O structures, while the CTAOH-rich catanionic surfactants led to the generation of hexapod-shaped Cu_2O mesostructures with tiny nanoparticles on these symmetrical branches [Fig. 83.15(ii)].

Wang et al. [16] synthesized mesoporous γ-alumina nanoparticles using CTAB/SDS catanionic micelles as templates. The synthesized materials consisted mainly of nanoparticles with length about 50–100 nm, high specific surface area (261 $m^2\ g^{-1}$), large pore volume (0.79 $cm^3\ g^{-1}$), and large pore size (12.1 nm) [Fig. 83.15(iii)].

In a very recent study Murray et al. [17] showed a dramatically improved synthesis of colloidal gold nanorods using catanionic surfactants CTAB/NaOL. Both thin (diameter < 25 nm) and thicker (diameter > 30 nm) gold nanorods with exceptional monodispersity and broadly tunable longitudinal surface plasmon resonance could be synthesized using seeded growth at reduced CTAB concentrations (as low as 0.037 M). The CTAB/NaOL catanionic surfactants helped to overcome the difficulty of growth of the nanomaterials,

which is often associated with the single-component CTAB system.

83.9 CHALLENGES AND FUTURE PERSPECTIVES

In terms of drug delivery, *toxicity* is a major concern. Assurance of nontoxicity or negligible toxicity of the catansomes is one of the most important factors before developing such systems. The involvement of toxic cationic surfactants increases the cytotoxicity of catansomes since they increase the generation of reactive oxygen species (ROS). One team [53] investigated the cytotoxic effect of positively charged catansomes of HTMADS/DTDAB/cholesterol on a wide range of concentration on the U-937 human macrophages. At sufficiently low concentration (40– 80 nM), catansome dispersions were found to be nontoxic.

PHASE BEHAVIOR OF NATURAL-SOURCED SURFACTANT SYSTEMS

KENJI ARAMAKI

Graduate School of Environment and Information Sciences, Yokohama National University, Yokohama, Japan

84.1 INTRODUCTION

Surfactants is widely used in many industrial fields. In terms of performance and cost, synthetic surfactants obtained from petrochemical materials are commonly used in most industries. However, growing demands for low environmental impacts and low toxicity allow people to consider employing surfactants produced by/from natural-sourced materials. Phospholipids are one of the most important natural-sourced surfactants and are already used in pharmaceutical and cosmetic products. Recently biosurfactants produced by microorganisms have expanded application fields because of their characteristic properties and the development of low-cost production processes [1]. Contrary to those naturally produced surfactants, there are several synthetic surfactants from natural-sourced materials such as sugar, glycerol, amino acids, and fatty acids. In this chapter, such surfactants are called *natural-sourced surfactants*. Advantages for these surfactants can be obtained at relatively low cost and flexibility of molecular architecture to meet demands regarding physicochemical properties such as cmc, Krafft point, and HLB.

84.2 SUGAR-BASED SURFACTANTS

Sugars are natural and renewable materials and are used for the surfactant hydrophilic group because of their strong hydrogen-bonding ability. Alkyl glucosides are nonionic surfactants with a glucose headgroup. One team studied the phase behavior of aqueous dodecyl glucoside ($C_{12}G_1$) in a composition-temperature diagram (Fig. 84.1) [2, 3].

The aqueous $C_{12}G_1$ system gives a Krafft point at ~40°C, while poly(oxyethylene) lauryl ethers do not give any Krafft point. Above the Krafft point, a lamellar phase (L_α) and an isotropic phase (L_2) are formed, and the composition range for those phase regions are temperature-insensitive. The same group also reported the effect of chain branching for the hydrophobic chain with the same carbon number, showing that the Krafft point vanishes for $C_{12}G_1$ with a branched hydrophobic chain [2]. Another group studied the aqueous phase bahavior of octyl, nonyl, and decyl glucosides (C_8G_1, C_9G_1, and $C_{10}G_1$) as shown in Fig. 84.2. C_8G_1 and C_9G_1 give micelles at low concentration, and no Krafft and cloud points are apparent. $C_{10}G_1$ also give micelles, but phase separation occurs in the dilute region [4, 5].

Phase separation in the dilute region of the water/$C_{10}G_1$ system is due to the LCST-type phase separation or the clouding phenomena commonly observed in poly(oxyethylene)-type surfactant systems, which was suggested by earlier work for a mixed $C_9G_1/C_{10}G_1$ system [6]. The C_8G_1 and C_9G_1 systems give a hexagonal phase, a bicontinuous cubic phase, and a lamellar phase in the concentrated region.

Sucrose alkanoates or sucrose fatty-acid esters are also a type of sugar-based surfactant and are sysnthesized from sucrose and fatty acids. They are approved as a food-grade emulsifier or solubilizer in most countries. Because of the stronger hydrogen- bonding ability of sucrose compared to glucose, the monoester-type sucrose fatty-acid ester is a more hydrophilic surfactant than alkyl glucoside with the same hydrophobic chain length. One team of researchers reported aqueous phase diagrams of sucrose monooctanoate,

monodecanoate, monododecanoate, and monohexadecanoate (C_8SE, C_{10}SE, C_{12}SE, and C_{16}SE) as shown in Fig. 84.3 [7].

As described previousely, both $C_{10}G_1$ and $C_{12}G_1$ behave as hydrophobic surfactants while C_{12}SE and even C_{16}SE give micelles in the dilute region. A Krafft point appears at around 20°C in the water/C_{16}SE systems, but no cloud points appear in any of the systems studied. A discontinuous cubic phase is formed in the C_8SE and C_{10}SE systems but in a limited composition and temperature range. A hexagonal phase is formed at a high-concentration region for all the systems, and the hexagonal region continues to >100°C, which is again similar to the temperature-insensitive behavior found in the alkyl glucoside systems. Although no full phase behavior has not been shown, one team [8] reported micellar formation in an aqueous sucrose monooleate ($C_{18:1}$SE) system at 25°C, indicating that the Krafft point is below this temperature for this sugar surfactant with an unsaturated hydrophobic chain. They also reported that 10 wt% of the aqueous solution of $C_{18:1}$SE gives relatively high viscosity, approximately 100 Pa • s, and shows a viscoelastic nature, suggesting the formation of wormlike micelles in a binary water/surfactant system. Sucrose fatty-acid esters are more suitable surfactants compared to poly(oxyethylene)-type surfactants in terms of the formation of wormlike micelles as the former combine monoglycerides [9], fatty alcohols [10], and fatty acids [11]. Strong hydrogen-bonding ability of the sucrose fatty-acid esters also allows for the formation of reverse wormlike micelles in alkanes [12].

As found in the mixture of nonyl- and decyl glucosides (C_9G_1 and $C_{10}G_1$) [6], cloud points are found in a mixed sucrose laurate system [13]. In this literature, authors studied the dependence of cloud points against the surfactant HLB number for the sucrose laurate systems and compared then with that for the poly(oxyethylene) dodecyl ether ($C_{12}EO_n$) systems as shown in Fig. 84.4.

Contrary to moderate increase in cloud points for the $C_{12}EO_n$ systems, cloud points of the sucrose laurate systems drastically increase, indicating that the clouding phenomenon is observed only in a limited HLB number range. The authors pointed that this is the reason for a common observation of "no clouding phenomenon for polyol-type nonionic surfactants," which is actually incorrect.

A sucrose molecule contains eight hydroxyl groups, and therefore hydrophile–lipophile balance (HLB) of the sucrose fatty-acid esters can be tuned by the relative degree of

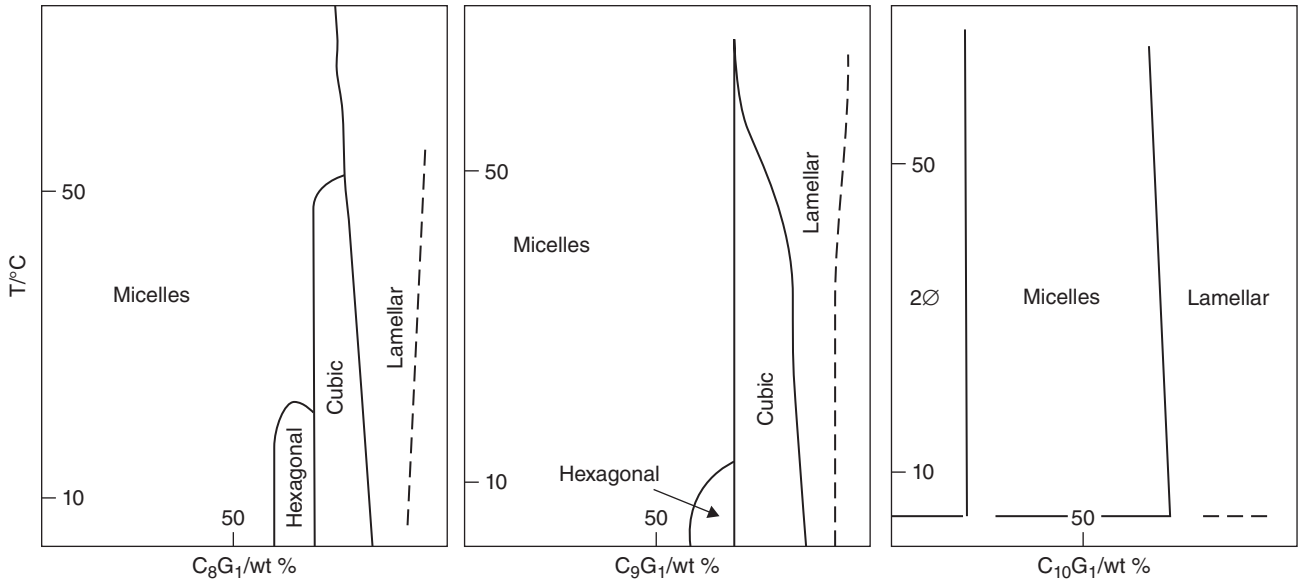

FIGURE 84.2 Phase diagram of binary aqueous systems of *n*-octyl β-D-glucopyranoside (C_8G_1), *n*-nonyl β-D-glucopyranoside (C_9G_1) and *n*-decyl β-D-glucopyranoside ($C_{10}G_1$).

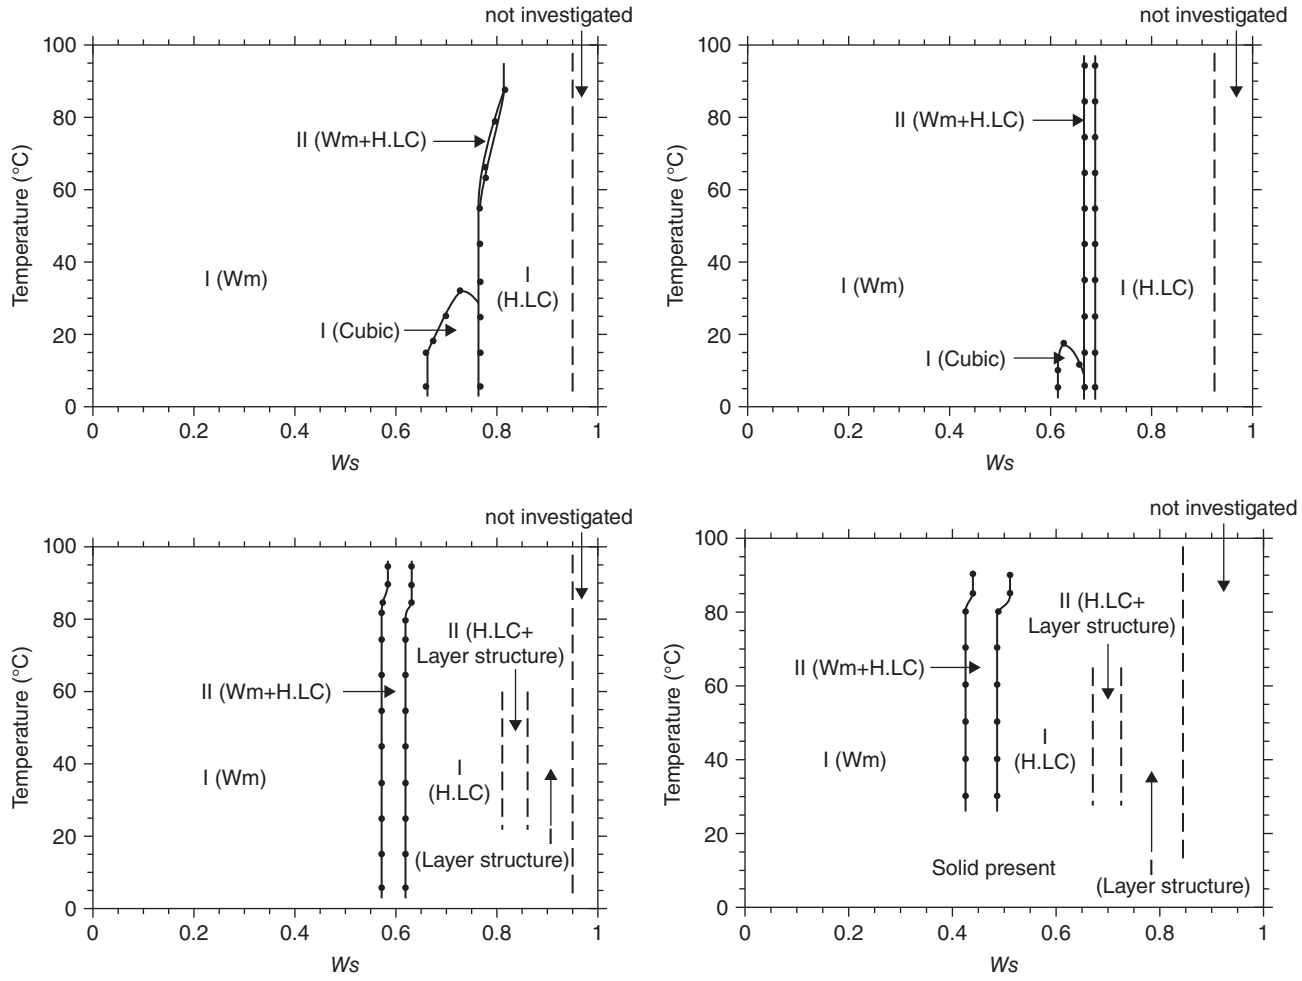

FIGURE 84.3 Phase diagram of binary aqueous systems of C_8SE (upper left), C_{10}SE (upper right), C_{12}SE (lower left), and C_{16}SE (lower right). W_S indicates weight fraction of surfactant.

esterification. As mentioned previously, the monoesters are hydrophilic but diesters are already hydrophobic and form lamellar liquid crystal [14], which is similar to the behavior of other double-tailed amphiphiles such as phospolipids and dialkyl dimethyl ammonium halides. As shown in Fig. 84.5, mixing sucrose mono- and dilaurates induces curvature change of a self-assembled structure from a highly positive one (micelle and hexagonal phase) to zero curvature (lamellar phase), but the phase behavior is rather simple compared to that of other mixed amphiphile systems.

However, as shown in Fig. 84.6, adding oils expands the variety of phases as found in the same study cited above [14], in which a phase transition occurs from lamellar to hexagonal and discontinuous cubic phases occur by solubilization of *n*-dexadecane. Also, the solubilized content of oil in the discontinuous cubic phase is reached with almost the same composition of water, and the authors referred to this cubic phase as *cubic-phase microemulsions*.

General microemulsion, especially the bicontinuous type, formation, and phase behavior have been reported in a sucrose fatty-acid mixture system [15] and also by combining cosurfactants such as fatty alcohols [16–18] and diethyleneglycol mono ethyl ether [19]. Formulation of food-grade microemulsions is also attempted [20, 21]. Similar to high thermal stability of liquid crystalline phases as described previously, thermal stability of bicontinuous microemulsions in sucrose fatty-acid ester systems is relatively high [15,16]. As shown in Fig. 84.7, a abicontinuous phase region (I) exists in a wide temperature range above $X = 0.1$.

84.3 GLYCEROL-BASED SURFACTANTS

Glycerol fatty-acid esters or monoglycerides are one of the most popular food additives for emulsifying or foaming. Since only two hydroxyl groups exist in a

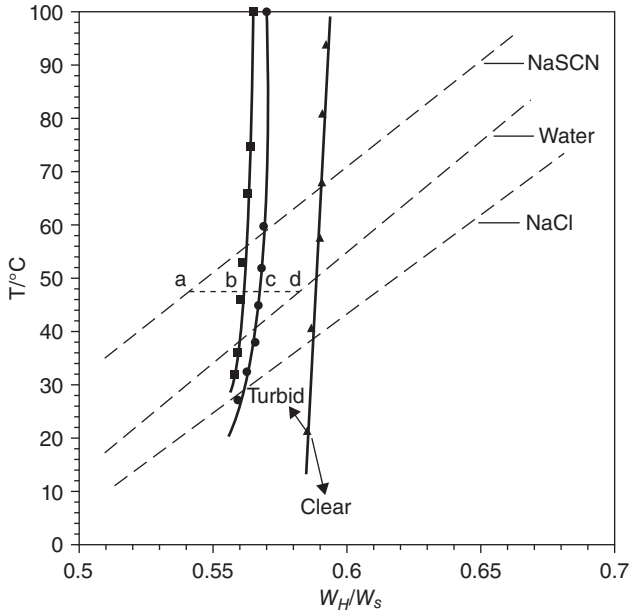

FIGURE 84.4 Cloud points of aqueous sucrose laurate system at 2 wt% without salt (circles) and with 5 wt% of NaCl (triangles) and NaSCN (squares). Dotted lines indicate loci of cloud points for aqueous poly(oxyethylene) lauryl ether ($C_{12}EO_n$) systems.

monoglyceride molecule, the nature of monoglycerides as a surfactant is hydrophobic. Therefore monoglycerides with a long acyl chain generally form lamellar (L_α), reverse hexagonal (H_2), and reverse bicontinuous cubic (V_2) phases

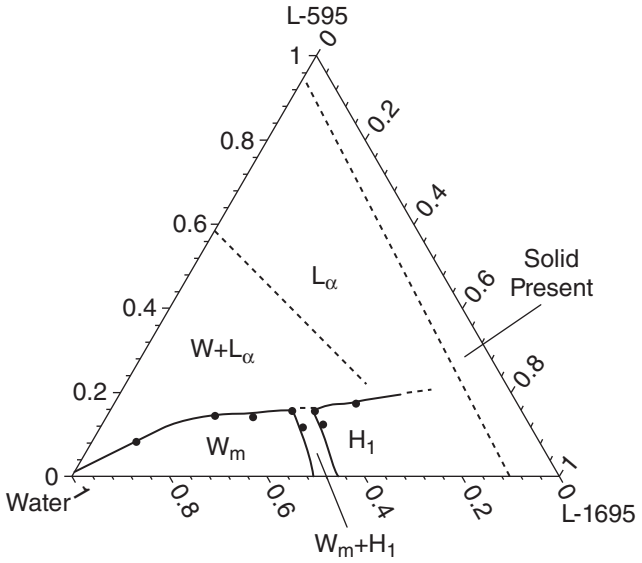

FIGURE 84.5 Phase diagram of the ternary water/L-1695/L-595 system at 30°C. L-1695 and L-595 are sucrose laurate mixture containing mono-, di-, and trilaurates. Averaged esterification degree is 1.16 for L-1695 and 1.79 for L-595. W_m indicates aqueous micellar phase.

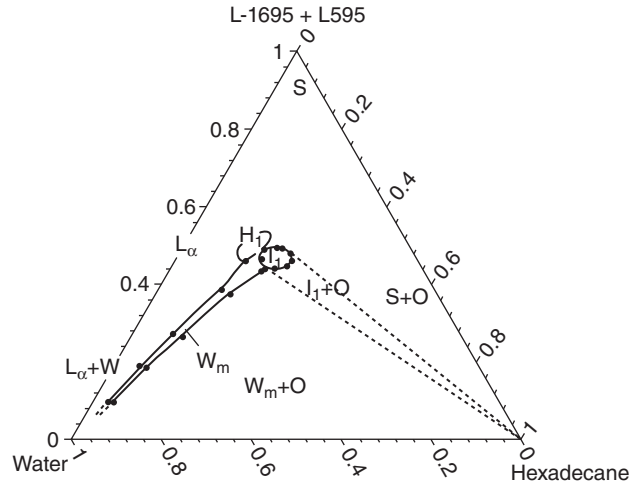

FIGURE 84.6 Phase map of quaternary water/L-1695/L-595/hexadecane system with equiweight mixture of L-1695 and L595 at 30°C.

with low contents of water. For this reason, temperature–composition phase diagrams in a binary water/surfactant system have normally been drawn as a function of water concentration in spite of surfactant concentration in conventional surfactant systems. Another team reported a series of temperature-composition phase diagrams of monoglycerides

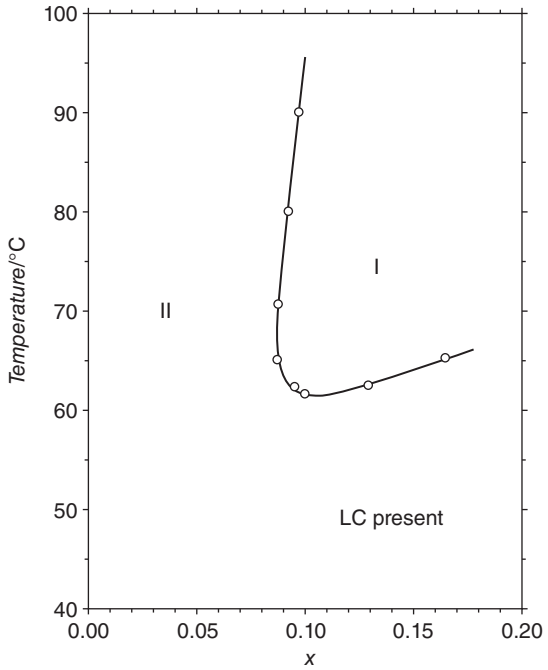

FIGURE 84.7 Phase map of quaternary water/L-1695/L-595/heptane system with a constant weight ratios water/oil = 1/1 and L-1695/L-595 = 2/8. *X* indicates the weight fraction of sucrose ester mixture in the whole system.

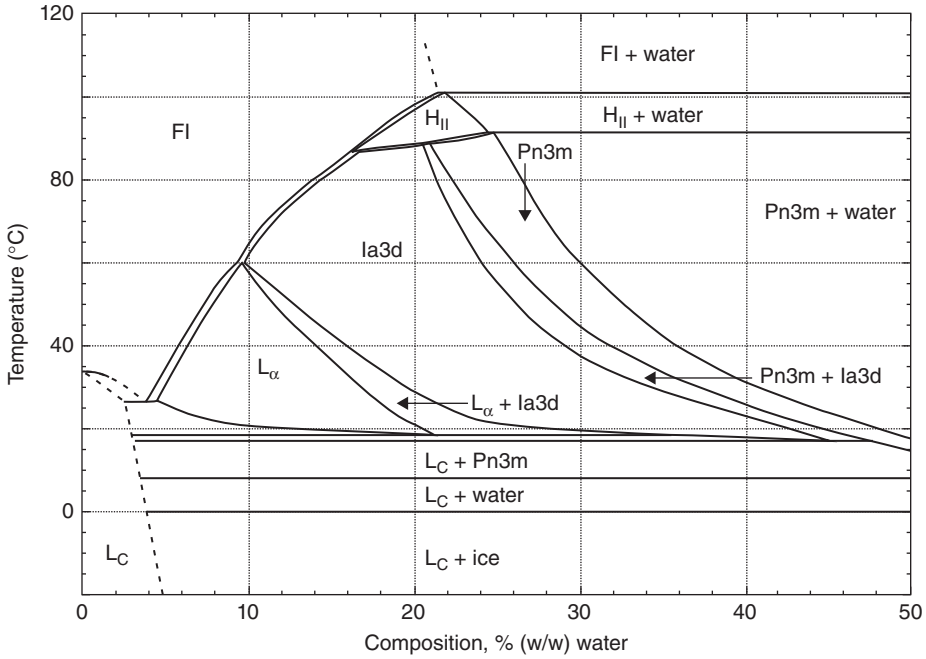

FIGURE 84.8 Phase diagram of binary water/monoolein system. L_C, *FI*, and H_{II} indicate hydrated crystalline, fluid isotropic, and reverse hexagonal phases, respectively. Two different space groups (*Ia3d* and *Pn3m*) for bicontinuous cubic phases are characterized.

with saturated (monolaurin, monomyristin, monopalmitin, monostearin, monoarachidin, monobehenin) and unsaturated (monoolein, monolinolein, monoelaidin, monoerucin) acyl chain [22]. Formation of the V_2 phase in some aqueous monoglycerides systems have been paid people's attention since dispersion of the V_2 phase in excess water with a dispersant was found to formulate fine particles called cubosome which is a potential nanocarrier of drugs and active molecules. Particle size of cubosomes is typically several tens to a few hundreds of nanometer and each particle has the V_2 phase structure in the interior. The most well-known system forming cubosomes are water/monoolein system in which Pn3m-type V_2 phase is equilibrated with water between 20 and 90°C as shown in Fig. 84.8 [23].

Monolinolein, which has one more unsaturated bond in the acyl chain than monoolein, also forms the *Pn3m*-type V_2 phase but in a narrow temperature range between 20°C and 40°C; instead, it forms the H_2 phase between

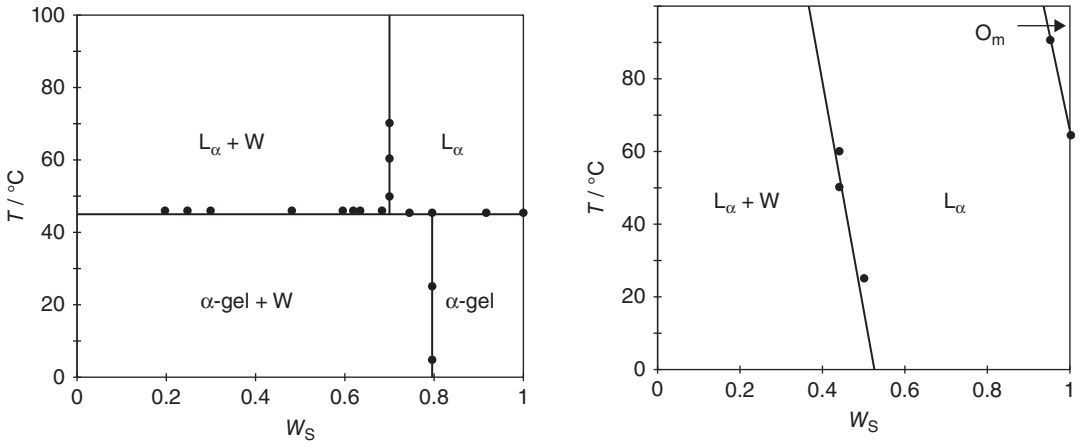

FIGURE 84.9 Phase diagrams of binary water/pentaglycerol monostearate ($C_{18}G_5$, left) and water/monooleate ($C_{18:1}G_5$, right) systems; α-gel indicates a hydrated α-type crystalline phase.

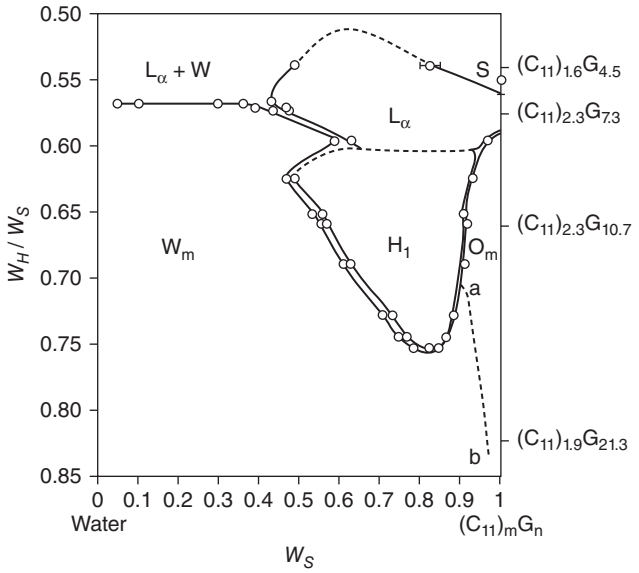

FIGURE 84.10 Phase diagrams of binary water/polyglycerol laurate, $(C_{11})_mG_n$, system as a function of weight ratio of polyglycerol group (W_H) to whole surfactant molecule (W_S) at 25°C.

40°C and 90°C, whose nanoparticles are called *hexosomes* [24].

Polyglycerol fatty acid esters are also used as food additives in some countries but basic phase study had not been done before Ishitobi and Kunieda in 2000 [25]. Similar to the sucrose fatty-acid esters, an advantage of this surfactant is availability of various HLBs by changing polymerization degree of the polyglycerol. Diglycerol monomyristate ($C_{14}G_2$) and monopalmitate ($C_{16}G_2$) are still hydrophobic, and their aqueous phase behavior is similar to that of monoglycerides such as monolaurin and monomyristin, in which an L_α phase is formed at high surfactant concentration and above Krafft points, 25°C for $C_{14}G_2$ and 45°C for $C_{16}G_2$ [26]. Pentaglycerol monostearate ($C_{18}G_5$) and monooleate ($C_{18:1}G_5$) are still hydrophobic, and an L_α phase is formed above 45°C for $C_{18}G_5$ and above 0°C for $C_{18:1}G_5$ as shown in Fig. 84.9 [27].

Another group studied aqueous phase bahavior of polyglycerol dilaurate as a function of weight ratio of polyglycerol in a surfactant molecule (W_H/W_S) [28]. As shown in Fig. 84.10, a phase transition from lamellar to micelle takes place at $W_H/W_S = 0.57$ with an increase in the polymerization degree of polyglycerol.

In another study the same group also observed cloud points for the same surfactant and showed very sensitive cloud-point change against the W_H/W_S value, which is similar to the behavior found in the sucrose fatty-acid esters described before (see Fig. 84.4) [29].

Another group reported several phase diagrams of mono- and diglycerol fatty-acid esters in nonpolar solvents. Monoglycerides such as monocaprylin (glycerol monooctanoate), monocaprin (glycerol monodecanoate), and monolaurin (glycerol monolaurate) do not form any liquid crystalline phases in liquid paraffin, squalene, and squalene as shown in Fig. 84.11 [30]. Instead of ordered phases, an isotropic phase with reverse micelles is formed in a wide composition range above a melting temperature of a solid phase. In the squalane system, the isotropic phase is separated into two liquid phases, while no phase separation is observed in the other systems. This clouding curve in the squalane system shows an UCST-type miscibility gap and is caused by increasing lipophilicity of the monoglyceride. Therefore the phase separation takes place in all oil systems with monocaprylin but not in those with monolaurin.

In diglycerol fatty-acid ester/oil systems, phase behavior becomes more complicated, as shown in Fig. 84.12 [31]. The single-phase region of the lamellar phase (L_α) appears at high surfactant concentration, and an oil phase is separated out in lower surfactant concentration. However, the variety of

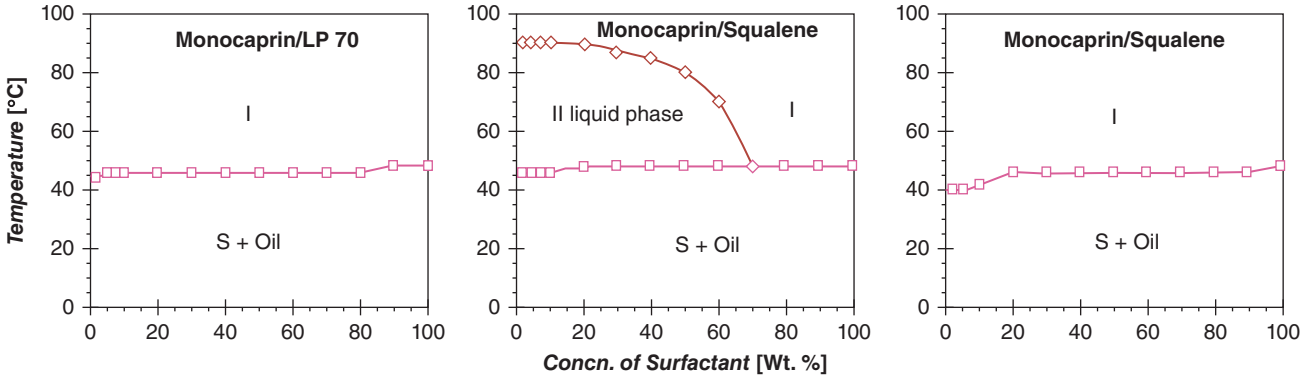

FIGURE 84.11 Composition–temperature phase diagrams of monocaprin/oil system. LP 70 indicates a liquid paraffin (hydrocarbon mixture). I indicates an isotropic phase in which reverse micelles are formed.

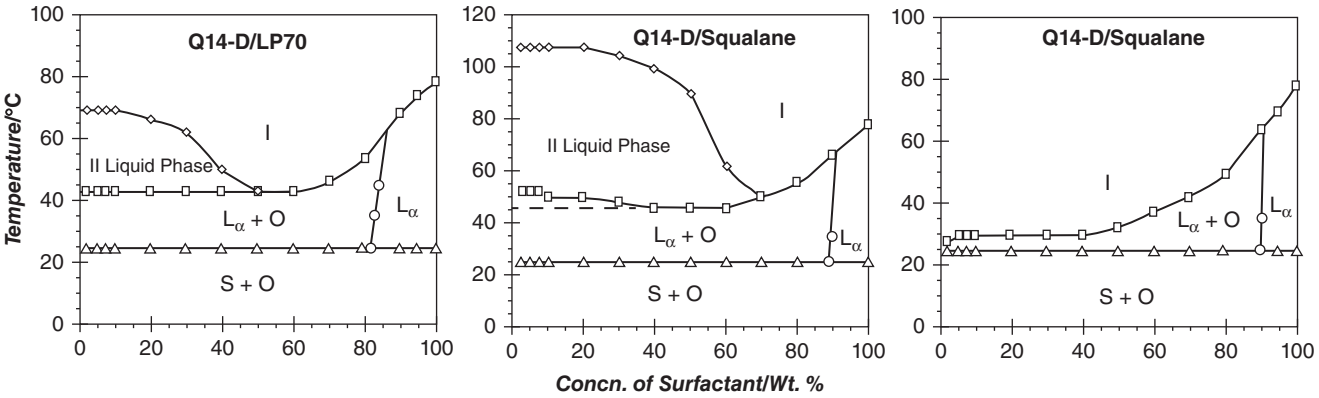

FIGURE 84.12 Composition–temperature phase diagrams of diglycerol monomylistate.

phases is narrower than that of aqueous surfactant systems. Again, a UCST-type miscibility gap appeared in the liquid paraffin and squalane systems.

SURFACTANTS AND BIOSURFACTANTS

YOUICHI TAKATA

Department of Chemical and Biological Engineering, Ube National College of Technology, Ube, Yamaguchi, Japan

85.1 INTRODUCTION

The surfactant molecule is composed of hydrophilic and hydrophobic groups. Hydrophilic groups are attracted to ("like") water, whereas hydrophobic groups are repelled by ("dislike") water (or are attracted to oil). In this respect, a surfactant molecule possesses two totally different groups. This causes interesting phenomena characteristic of surfactant, such as surface adsorption and micelle formation in the solution.

The various kinds of groups are well known for both hydrophilic and hydrophobic characteristics. The wide global variety of surfactants is due to the fact that the surfactant molecule is structurally fixed by the combination of hydrophilic and hydrophobic groups. Such versatility in surfactant synthesis is useful for designing a novel surfactant applied for a specific purpose. The function of synthetic surfactants has also been improved to meet demands based on the needs of society. More recent developments in surfactant preparation also reflect the "greening effect" or the need to produce surfactants that are ergonomic or compatible with the natural environment (i.e., that are "environmentally friendly").

In this chapter, the basic structure and properties of general surfactants are first reviewed. Next, the novel surfactants that have been widely studied recently are discussed. The chapter concludes with an introduction to the surfactants associated with the field of biology, the so-called biosurfactant.

85.2 GENERAL SURFACTANTS

Surfactants are usually classified into four basic types, according to the charge on the hydrophilic groups: cationic, anionic, zwitterionic, and nonionic. The typical hydrophilic groups in each type are shown below, after some information on the hydrophobic groups is mentioned.

85.2.1 Hydrophobic Group

The term *hydrophobic* means to be repelled by or to "dislike" water. In other words, hydrophobic groups prefer oil to water. Therefore, the hydrophobic groups have structures similar to those of organic compounds. In general, the hydrophobic groups are actually alkyl groups composed of hydrogen and carbon atoms, which are often called *hydrocarbon chains* (Fig. 85.1).

In order to exert the function of surfactant, the length of the hydrocarbon chain is important. If its length is too short, the molecules indicate fairly strong water-soluble properties and their hydrophobic properties are hardly observed. This results in a loss of driving force for the adsorption to the interface, the micelle formation in solution, and so on. On the contrary, when the hydrocarbon chain is too long, the molecules become insoluble in water because of their strong hydrophobic properties. It is usually assumed that the 8–18 carbon atoms in the hydrocarbon chain are suitable for the surfactant.

In some cases, one surfactant molecule has two hydrocarbon chains (Fig. 85.2).

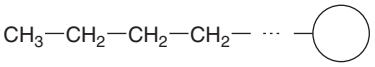

FIGURE 85.1 Example of hydrocarbon chain. Circle shows hydrophilic group.

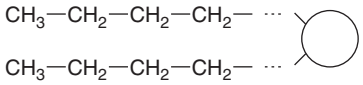

FIGURE 85.2 Example of surfactant with two hydrocarbon chains. Circle shows hydrophilic group.

Obviously, the hydrophobic property of a surfactant with two hydrocarbon chains increases in comparison to a surfactant with one hydrocarbon chain. Also, this modification affects the aggregate formation in the solution. The packing parameter, which is determined by the geometry of one surfactant molecule [1], of the typical surfactant is about $1/3$, and this suggests the formation of a spherical micelle. When the number of the hydrocarbon chain varies from one to two, the hydrophobic group becomes bulky and as a result its packing paramater approaches 1. Therefore the surfactant with two hydrocarbon chains tends to form a vesicle or lamellar structure rather than the spherical micelle.

Fluorocarbon chains composed of fluorine and carbon atoms are known as the other hydrophobic groups (Fig. 85.3).

It is well known that fluorine compounds show a high water repellency. This fact reveals that fluorocarbon chains have a strong hydrophobic property. Furthermore, the hydrocarbon and fluorocarbon compounds do not mix with each other and are separated into two phases [2]. This is because the interaction between hydrocarbon and fluorocarbon compounds is very week, and therefore the same species are condensable. This immiscible effect brings about an interesting behavior regarding the adsorbed film and micelles of the hydrocarbon and fluorocarbon surfactant mixture system. For example, the mixed micelle in the binary system of hydrocarbon surfactants is formed at any micelle composition by adjusting the bulk composition. On the other hand, the mixed micelle in the hydrocarbon–fluorocarbon surfactant mixture system is not formed at any micelle composition, and either hydrocarbon-rich micelles or fluorocarbon-rich ones appear in the aqueous solution [3]. This is due to the very weak interaction between hydrocarbon and fluorocarbon chains.

The unique properties of surfactants are produced by including two totally different groups, namely, hydrophilic and hydrophobic groups, in one molecule. At this point, the research on surfactants having both hydrocarbon and fluorocarbon chains as hydrophobic groups becomes

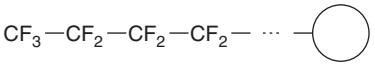

FIGURE 85.3 Example of fluorocarbon chain. Circle shows hydrophilic group.

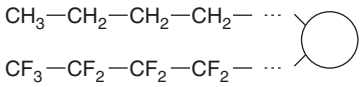

FIGURE 85.4 Example of hybrid surfactant. Circle shows hydrophilic group.

interesting. Such surfactants are called *hybrid surfactants* (Fig. 85.4).

As expected, hybrid surfactants exhibit unusual properties (critical micelle concentration, morphology of micelle, viscosity and so on) that are different from those of general surfactants [4]. It is anticipated that the hybrid surfactants will be applied in new fields in the future.

85.2.2 Hydrophilic Group

The term *hydrophilic* means to be attracted to or "like" water. The hydrophilic groups are divided into four types on the basis of their charges. As each hydrophilic group exhibits an inherent property, we can choose the surfactants depending on the purpose.

Ionic surfactants dissociate into cations and anions in water. The ion that has a charge opposite to that of the hydrophilic group is called a *counterion*. Even if both hydrophobic and hydrophilic groups of surfactants are the same, the different counterions greatly affect the properties of their surfactants [5]. Although the existence of counterions is not negligible, we omit further discussions here.

85.2.2.1 Cationic Surfactant. The hydrophilic group of cationic surfactant has a positive charge. The representative cationic group is the ammonium one. The substitution of hydrogen atom for methyl group leads to a series of ammonium groups, namely, (mono)methylammonium, dimethylammonium, and trimethylammonium groups (Fig. 85.5).

The properties of cationic surfactants are highly influenced by a slight change in hydrophilic group due to methylation [6].

In general, the main component of hair rinse is cationic surfactants. This is because the cationic hydrophilic group binds to the negatively charged surface of wet hair and its hydrophobic group provides the lubrication of hair.

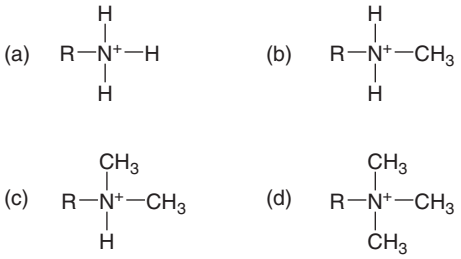

FIGURE 85.5 Example of cationic hydrophilic group: (a) ammonium; (b) monomethylammonium; (c) dimethylammonium; (d) trimethylammonium group (R denotes hydrophobic group).

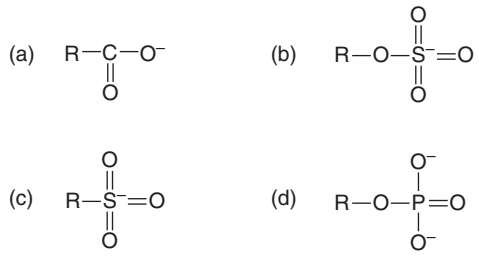

FIGURE 85.6 Example of anionic hydrophilic group: (a) carboxyl; (b) sulfate; (c) sulfonate; (d) phosphate group (R denotes hydrophobic group).

85.2.2.2 Anionic Surfactant. The hydrophilic group of anionic surfactant has a negative charge. There are various kinds of anionic surfactants compared with cationic ones. The most popular anionic surfactant is alkali salt of fatty acid (Fig. 85.6a), which is so-called soap. Sodium dodecyl sulfate (SDS), which contains an anionic sulfate group (Fig. 85.6b), is often utilized not only in ordinary household detergents but also in professional biological experiments such as electrophoresis. Besides, the sulfonate and phosphate groups are included in the typical hydrophilic groups of anionic surfactants (Fig. 85.6c,d).

85.2.2.3 Zwitterionic Surfactant. Amphoteric electrolyte such as amino acid and protein can possess both positive and negative charges in their molecules, depending on the pH. When the positive and negative charges are equal, the pH is defined as the *isoelectric point*. If the pH is less than the isoelectric point (i.e., if the solution is strongly acidic), the amphoteric electrolyte has a positive charge. On the other hand, if the pH is greater than the isoelectric point (i.e., if the solution is strongly basic), the amphoteric electrolyte has a negative charge. Thus the property of the amphoteric electrolyte depends on the pH.

In a similar manner, some surfactants can have both positive and negative charges in their hydrophilic groups. Such surfactants are called *zwitterionic* surfactants. The *critical micelle concentration* (cmc or CMC, depending on context) in the solution and ability of adsorption to the surface of zwitterionic surfactants are changeable by adjusting the pH in analogy with the amphoteric electrolyte because of the alteration in charge of hydrophilic group depending on the pH [7].

The most popular zwitterionic surfactant is alkyldimethyl betaine (Fig. 85.7a).

Phospholipid molecules such as diacylphosphatidyl choline (Fig. 85.7b) are also classified as zwitterionic surfactants. From a biological perspective, it is useful to clarify the pH dependence of the property of phospholipid molecules, which constitute the cell membrane.

85.2.2.4 Nonionic Surfactant. The hydrophilic group of nonionic surfactants has neither positive nor negative charge.

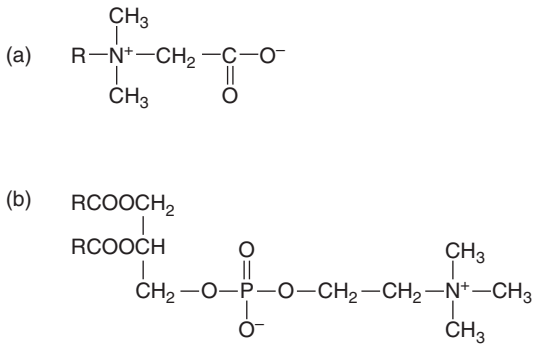

FIGURE 85.7 Example of zwitterionic hydrophilic group: (a) alkyldimethyl betaine; (b) diacylphosphatidyl choline (R denotes hydrophobic group).

FIGURE 85.8 Example of nonionic hydrophilic group (polyoxyethylene group) (R denotes hydrophobic group).

Thus, the cmc is lower in nonionic surfactants than in ionic surfactants because there is no electrostatic repulsive force between the hydrophilic groups of the nonionic surfactant. Therefore, nonionic surfactants play an important role in products such as household detergents.

The most popular nonionic surfactant includes a polyoxyethylene chain (Fig. 85.8) in the hydrophilic group.

The nonionic surfactant polyoxyethylene alkylether is o ften presented as C_iE_j, where i and j denote the numbers of carbon atoms in the alkyl chain and in the oxyethylene group, respectively. The C_iE_j surfactants are available for various commercial purposes because it is possible to adjust their hydrophobicity or hydrophilicity simply by changing the number of i or j. Furthermore the solubility of C_iE_j surfactants into water or oil can change with temperature. For instance, an elevation in temperature causes the dehydration from the oxyethylene group and the C_iE_j surfactants to gradually acquire an oil-soluble property. The temperature at which the phase separation occurs is the *cloud point*.

85.2.3 Novel Surfactants

In addition to the abovementioned conventional surfactants, novel types of surfactants have been developed recently. These novel surfactants have two main advantages: (1) a smaller quantity is needed for use and (2) they are environmentally friendly.

If the surfactants exhibit outstanding performances, the required amount of surfactants decreases. For this reason much research has focused on gemini surfactants. *Gemini surfactants* are those surfactants to which the hydrophilic groups of two surfactant molecules are connected by a spacer composed of a shorter hydrocarbon chain (Fig. 85.9).

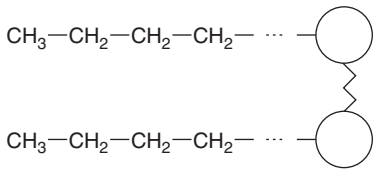

FIGURE 85.9 Example of gemini surfactant. Circle shows hydrophilic group. The shorter hydrocarbon chain between hydrophilic groups is a spacer.

As the gemini surfactants have two hydrophobic chains, the performance of adsorption is high. On the other hand, the solubility of gemini surfactants in water is maintained because of two hydrophilic groups. Therefore the critical micelle concentration of gemini surfactants becomes lower than that of ordinary surfactants [8].

The inherently low degradation power of synthetic surfactants is a major problem. In order to address this problem, sugar-based surfactants have been developed [9]. The hydrophilic group of a sugar-based surfactant is a monosaccharide such as glucose or galactose (Fig. 85.10). It is also suspected that sugar-based surfactants possess a higher degree of biodegradability compared to other synthetic surfactants.

There are several ongoing studies on the other novel surfactants focusing on the control of properties of a surfactant under an external field. As mentioned above, the properties of zwitterionic surfactants depend on the pH. Also the properties of C_iE_j surfactants depend on temperature, and it is possible that the same surfactant can possess both water-soluble and oil-soluble properties at certain temperatures. Research on light-sensitive (or photoresponsive) surfactants is increasing. The light-sensitive surfactant has a group characterized by a chemical structure that varies according to the relative absorption of light. Therefore, the irradiation of light switches the properties of light- sensitive surfactants. For example the irradiation of visible and ultraviolet light results in a change in chemical structure between *cis*- and *trans*-azobenzene (Fig. 85.11). If the hydrophobic group contains azobenzene, the properties of the surfactant depend on the light absorption [10, 11].

85.3 BIOSURFACTANTS

Surfactants are classified into synthetic and natural groups. The surfactants described above are mainly examples of

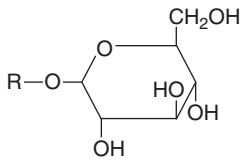

FIGURE 85.10 Example of sugar surfactant (R denotes hydrophobic group).

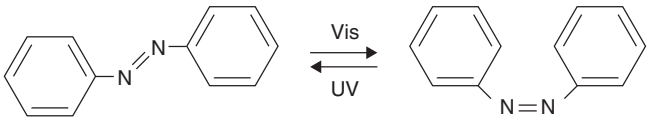

FIGURE 85.11 Change in chemical structure of azobenzene due to the absorption of light. If the hydrophobic group in surfactant molecule contains such a structure, the irradiation of light affects the properties of the surfactant.

synthetic surfactants and those synthesized from organic compounds. On the other hand, natural (i.e., nonsynthetic) surfactants originate from within the human body. The representative natural surfactant is a biosurfactant. More recent the research on biosurfactants has increased because of their environmentally friendly properties, although the ability of their surface activities is not as good as that of synthetic surfactants.

The most popular biosurfactant is a phospholipid, as shown in Fig. 85.7b. The packing parameter of phospholipid is close to 1, and therefore formation of the liposome and lamellar structure is easy. In fact, phospholipids are one of major components of the cell membrane.

Cholesterol constituting the cell membrane may also be regarded as a biosurfactant (Fig. 85.12).

The distinction between hydrophilic and hydrophobic groups in cholesterol molecules is not as clear as that for the usual (ordinary) surfactants, and in addition, the solubility of cholesterol in water is low. However, the interfacial tension acting on the water/oil solution of the cholesterol interface decreases with increasing cholesterol concentration [12]. Therefore, cholesterol has higher surface activity.

Bile acid and its salts are often investigated from the standpoint of surface chemistry [13]. Their chemical structures are similar to those of cholesterol (Fig. 85.13).

The micelle formation of bile acid is related to the function of digestion in the human body, and therefore, its research is important.

Surfactants that assist lung function are called *pulmonary surfactants*. The pulmonary surfactant exists at the surface of alveoli and reduces the surface tension acting at the air–water surface on the alveoli [14]. The pulmonary surfactant is

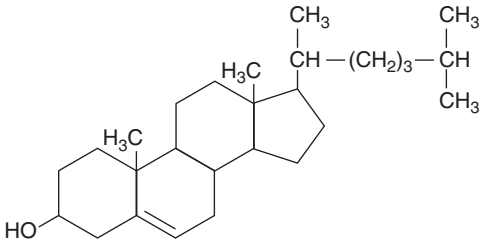

FIGURE 85.12 Chemical structure of cholesterol.

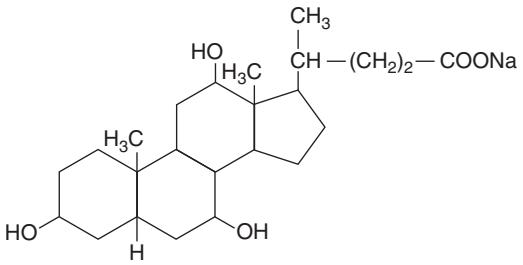

FIGURE 85.13 Chemical structure of sodium cholate.

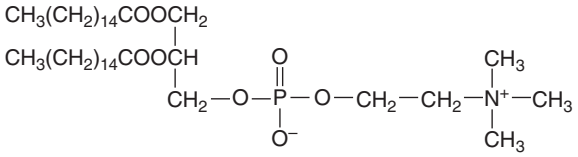

FIGURE 85.14 Chemical structure of dipalmitoylphosphatidylcholine.

composed mainly of phospholipids such as dipalmitoylphosphatidylcholine (Fig. 85.14).

As shown above, the origin of biosurfactants is the human body; therefore, its effect on the natural environment is low. From that perspective, research on biosurfactants, such as improvement of their functions and synthesis of surfactants having structures similar to those of biosurfactants, is widespread globally.

86.1 INTRODUCTION

The amphiphiles are molecules, which contain two parts: (1) oil-preferring or water-hating, referred to as *lipophilic* or *hydrophobic*, respectively, and (2) water-preferring, or *hydrophilic*. In aqueous environments, these molecules, including surfactants [1–24], drugs [25–38], and polymers [39–46], can form a kind of self-organized molecular assembly of thermodynamically stable colloidal dimension above their critical micelle concentrations (cmc's), which are termed *micelles* or *association colloids*. The self-organization and self-assembly are spontaneous and natural processes. They occur mainly through noncovalent interactions such as van der Waals, hydrogen bonding, hydrophobic/hydrophilic, electrostatic, donor and acceptor, and metal–ligand coordination networks [47]. The interests in micelle solutions stem from their potential as functional molecular assemblies for use in various fields of pure and applied sciences. They can be used as models for several biochemical and pharmacological systems. These solutions of amphipathic systems can solubilize water-insoluble substances (including certain medicines/drugs) in their hydrophobic cores [48].

Amphiphilic compounds bear an ionic (anionic, cationic, or zwitterionic) or nonionic polar headgroup and a hydrophobic portion. In aqueous medium, they are able to organize themselves as micelles, bilayers, monolayers, or as hexagonal or cubic phases. The spatial separation between the polar and nonpolar moieties, as well as the molecular shape [49] and the hydrophilic–lipophilic balance (HLB) [50], determine their tendency to form the different structures, which eventually can be interconverted as a function of pH, temperature, ionic strength, and concentration.

Surface-active drugs of quite different chemical structures are reported to self-associate and bind to membranes, causing disruption and solubilization, in a surfactantlike manner. Classes of surface-active drugs include phenothiazine [25–27,51–58] and benzodiazepine [25–27,59] tranquilizers, analgesics [25,60], peptide [61] and nonpeptide [25–27,62, 63] antibiotics, tricyclic antidepressants [25–27,64–66], antihistamines [67], anticholinergics [68], β-blockers [69], local anesthetics [25–27,70–73], nonsteroidal antiinflammatory drugs [74], and anticancer drugs [75]. Many of these drugs contain one or more (condensed or not) aromatic nuclei, while others are of peptide nature. A list of cmc and aggregation number N_{agg} (under specific conditions) of some commonly used nonpeptide surface-active drugs is given in Table 86.1.

The surface-active behavior among many diverse classes of drugs has been reported in order to correlate surface activity with biological activity [25–27]. The aggregation of the drugs listed in Table 86.1 follows same principles as those of

conventional surfactants [25,27]. The "surfactantlike" behavior is due to the presence of an almost planar tricyclic ring system and a short hydrocarbon chain carrying a terminal nitrogen atom (see Scheme 86.1) [25–27]. It is well known that the cmc values of amphiphiles vary in presence of additives, as the interfacial and micellar properties of these compounds in solutions are governed by a subtle balance of hydrophobic and hydrophilic interactions. As additives are known to modify those interactions and drugs that are used in combination with additives (salts, surfactants, excipients, etc.), it is necessary to have some knowledge of the additive's effect on the cmc and the thermodynamics of amphiphilic

SCHEME 86.1 Molecular structure of surface-active drugs used in the present study: (a) 3-(10, 11-dihydro-*5H*-dibenzo[*a*,*d*]cycloheptane-5-ylidene)-*N*,*N*-dimethyl-1-1-propanamine hydrochloride [amitriptyline hydrochloride (AMT)]; (b) 5-[3-(dimethylamino)propyl]-10,11-dihydro-*5H*-dibenz[*b*,*f*]azepine hydrochloride [imipramine hydrochloride (IMP)]; (c) 2-chloro-10-(3-dimethylaminopropyl)phenothiazine hydrochloride [chlorpromazine hydrochloride (CPZ)]; and (d) 10-[2-(dimethylamino)propyl]phenothiazine hydrochloride [promethazine hydrochloride (PMT)].

drugs. Because surfactants have long shelf-lives and their preparation is usually simple, they have been widely used as drug delivery vehicles or drug carriers.

The excellent colloidal properties of amphiphilic drugs are determined largely by the nature of the aromatic ring system of their hydrophobic moieties. Such drugs are useful in probing relationships between the molecular architecture and physicochemical properties [25–27,76]. In pharmaceutical applications, the interaction between small molecules and drugs has been studied extensively. In this respect, it is worthwhile to mention here that many drugs, particularly those with local anesthetic, antidepressant, tranquillizer, and antibiotic actions, exert their activities by interaction with biological membranes, which can be considered as complex forms of amphiphilic bilayers. Thus, a full knowledge of the mechanism of the interactions of drugs with other foreign materials is essential prior to their actual application in the human body. This is so because drugs are always used in presence of a variety of additives (excipients).

Clouding is a well-known phenomenon, which is generally observed in nonionic surfactants. When the temperature is raised, the system becomes cloudy and phase separation occurs at a well-defined temperature, which called the *cloud point* (CP) [77–80]. To the best of our knowledge, the mechanism of clouding in nonionic surfactants is not yet clearly understood, and continues to be a source of controversy among various research groups. This clouding phenomenon rarely occurs in charged micelles, presumably because of the electrostatic repulsions between the micelles in addition to the van der Waals attraction force, which prevents phase separation in most cases [81–83]. The appearance of CPs in ionic surfactant solutions is rare except under certain special conditions [84–93], namely, high salt concentration [84–89], salt-free aqueous solutions of certain surfactants with large headgroups [90, 91] or large counterions [92, 93], and in some mixed cationic–anionic surfactant solutions [93]. The occurrence of CPs in these systems is explained in terms of increased hydrophobic interactions, dehydration of the hydrophilic group [89], and formation of large aggregates or clusters [88,92].

The clouding phenomena of amphiphilic drugs are rare, as are like ionic surfactants. However, under special conditions, they showed clouding phenomena and phase separation occurred [94–111]. The pK_a values of these drugs lie in the range 9.1– 9.4 [112], and, depending on the solution pH, the drug monomers may acquire cationic (i.e., protonated) or neutral (i.e., deprotonated) forms (see Scheme 86.1) [94]. Some surface-active drugs, such as ionic surfactants, undergo phase separation, depending on pH, concentration, and temperature [94=-111]. It was observed that their CP values can vary with additives [94–111]. The thermodynamic parameters of some surface-active drugs in presence of additives have recently been reported [113–119].

The work presented here is aimed at obtaining a better understanding of the role of the presence of additives in the surface properties, micellization or mixed micellization and the thermodynamic quantities of micellization of two basic types of amphiphilic

drugs: (1) tricyclic antidepressants [3-(10, 11-dihydro-*5H*-dibenzo[*a*,*d*]cycloheptane-5-ylidene)-*N*,*N*-dimethyl-1-1-propanamine hydrochloride, i.e., amitriptyline hydrochloride (AMT) and 5-[3-(dimethylamino)propyl]-10 ,11-dihydro-*5H*-dibenz[*b*,*f*]azepine hydrochloride, i.e., imipramine hydrochloride (IMP)] and (2) phenothiazines [2-chloro-10-(3-dimethylaminopropyl)phenothiazine hydrochloride, i.e., chlorpromazine hydrochloride (CPZ) and 10-[2-(dimethylamino)propyl]phenothiazine hydrochloride, i.e., promethazine hydrochloride (PMT)] (see Scheme 86.1). The Gibbs energies at the air–water interface ($G_{\min}^{(s)}$), standard Gibbs energy of micellization (ΔG_{mic}°), standard Gibbs free energy change of adsorption (ΔG_{ads}°), and excess Gibbs energy change of micellization (ΔG_{ex}) are calculated and discussed here.

Clouding phenomena in both absence and presence of additives have also been reported. It was found that the CP of these drugs can vary with additives. It is worthwhile to mention here that the thermodynamics of clouding (phase separation) of the above four amphiphilic drugs—AMT, IMP, CPZ, and PMT—in the presence of additives (electrolytes, surfactants, etc.), with a view to stimulate further studies in drug delivery andmodel drug delivery systems.

86.2 SURFACE PROPERTIES, SELF-ASSOCIATION, AND MIXED MICELLIZATION OF SURFACE-ACTIVE DRUGS WITH AND WITHOUT ADDITIVES

Representative plots of surface tension versus log [drug] for surface-active drugs with different additives are indicated in Fig. 86.1a. The cmc values of all the drugs have been found to decrease in the presence of additives (see representative plot in Fig. 86.1b). On the basis of the spectra of Sudan III in x mM drug (AMT, IMP, CPZ, and PMT) solutions with and without fixed concentrations of additives, the cmc values of the drugs were determined using the dye solubilization method also (Fig. 86.1c) and revealed a similar trend in the cmc values, which decreased in the presence of additives (e.g., NaCl; see Fig. 86.1d). The cmc values for pure drugs are in good agreement with the literature values [25–27,112].

The cmc values of all drugs are found to decrease in the presence of additives. Counterions are bound to micelles primarily not only by the strong electric field created by the headgroups but also by specific interactions that depend on the headgroup and the counterion type. Two mechanisms were proposed: (1) inorganic salts affecting the solvent property of water and (2) ions affecting the micelles directly by adsorbing/desorbing to the headgroup region of the micelles [120, 121]. Counterion binding plays a role in determining the effective charge on the micelles and hence its formation, shape, and mutual interactions [122]. Added Cl^- ions (in the form of NaCl) follow mechanism 2 and adsorb to the cationic headgroup region of the drug monomers. This adsorption decreases the electrostatic repulsion among headgroups, and less electrical work is required to form micelles. The cmc values of the drugs also decreased in the presence of CTAB and TX-100. The concentrations of these surfactants were lower than or equal to their cmc values (which are 1 mM – CTAB and 0.36 mM – TX-100 [124]). Furthermore, these surfactants are known to form mixed micelles with the drugs [31,124].

Rodriguez et al. [31,124] studied the effect of dodecyltrimethylammonium bromide concentration on the cmc of AMT in aqueous solution using conductivity and static fluorescence measurements. They explained their results on the basis of mixed micelle formation. Theoretical calculations of their results predict an apparent ideal but nonsynergistic behavior of the mixed micelles. Our results also suggest mixed micelle formation, although the slope of cmc decrease is lower in the case of CTAB.

The values of the surface pressure at the cmc (Π_{cmc}) were obtained using the following equation

$$\Pi_{cmc} = \gamma_0 - \gamma_{cmc} \tag{86.1}$$

where $\gamma_{0,}$ and γ_{cmc} are the surface tension of the solvent and the surface tension of the mixture at the cmc, respectively. The values of Π_{cmc} increase, with increase in concentration of the additives, indicating that the efficiency increases.

The surface excess concentration is an effective measure of the Gibbs adsorption at the liquid–air interface, which was calculated by employing Eq. (86.2) [125] as

$$\Gamma_{max} = -\frac{1}{2.303nRT}(d\gamma/\log c)_T \tag{86.2}$$

where γ, R, T, and c are surface tension, gas constant, absolute temperature, and concentration, respectively. The variable n is introduced to allow for the simultaneous adsorption of ions (anions and cations). The expression used in the calculation of n was that proposed by two investigators [126], $n = 1+ m/(m+m_s)$, where m_s is the concentration of the added electrolyte. Hence, n has a value of 2 in water and approaches 1 in the presence of excess inert electrolyte. The slope of the tangent at the given concentration of the γ *vs* log c plot was used to obtain Γ_{max}, and A_{min} and evaluated using the following relation [127]

$$A_{min} = 10^{16}/N_A\Gamma_{max} \tag{86.3}$$

where N_A is the Avogadro number.

A thermodynamic quantity for the evaluation of synergism in mixing, i.e., the free energy of the given air/water interface $G_{min}^{(s)}$, which was proposed by another team [128, 129], is defined as follows:

$$\Delta G_{min}^{(s)} = A_{min}\Pi_{cmc}N_A \tag{86.4}$$

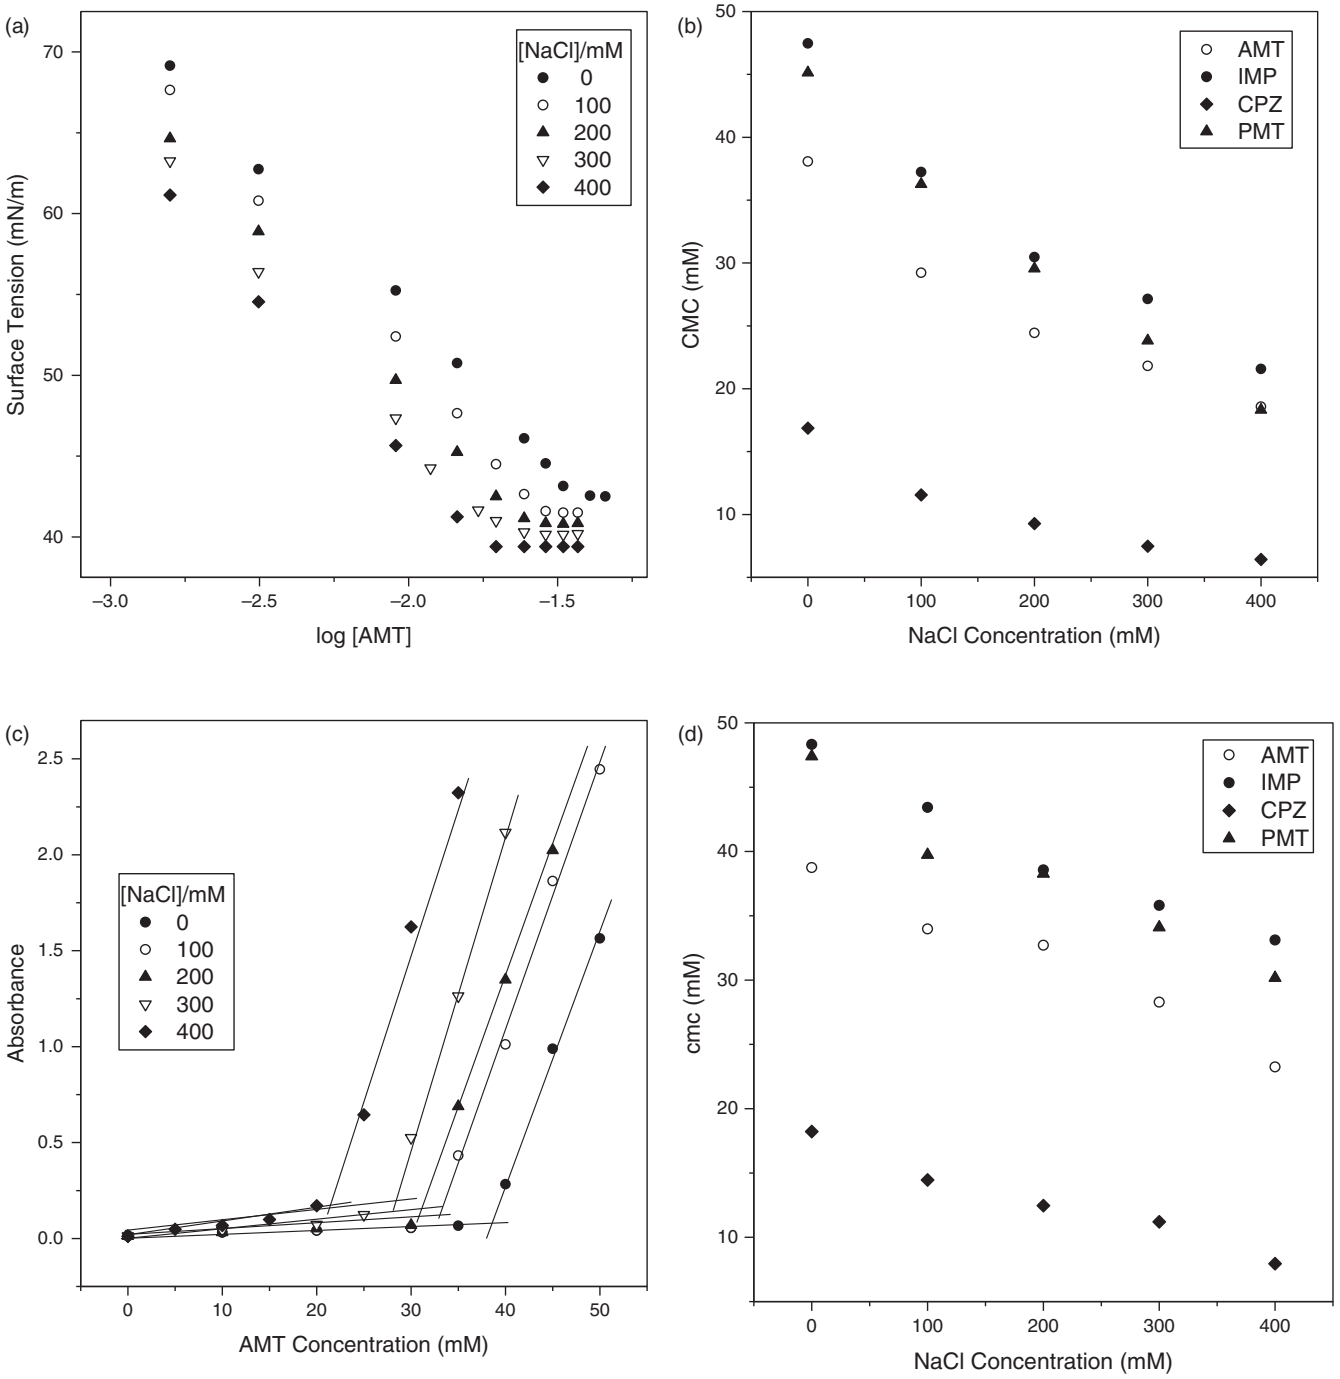

FIGURE 86.1 Plots of surface tension versus logarithm of AMT concentration at different fixed concentrations of NaCl: (a) effect of NaCl concentration on cmc values of drugs in aqueous solutions at ~27°C determined by surface tension measurements; (b) plots of absorbance versus concentration of AMT at different fixed concentrations of NaCl at 510 nm; (c) effect of NaCl concentration on cmc values of drugs in aqueous solutions at ~27°C determined by the dye solubilization method (d).

The Gibbs energy $G_{\min}^{(s)}$ is regarded as the work needed to construct an interface per mole or the free-energy change accompanied by the transition from the bulk phase to the surface phase of the solution components. In other words, the lower the values of $G_{min}^{(s)}$, the more thermodynamically stable surface is obtained. With increase in the additives' concentration/mole fractions, the $G_{\min}^{(s)}$ values are found to decrease (Fig. 86.2a).

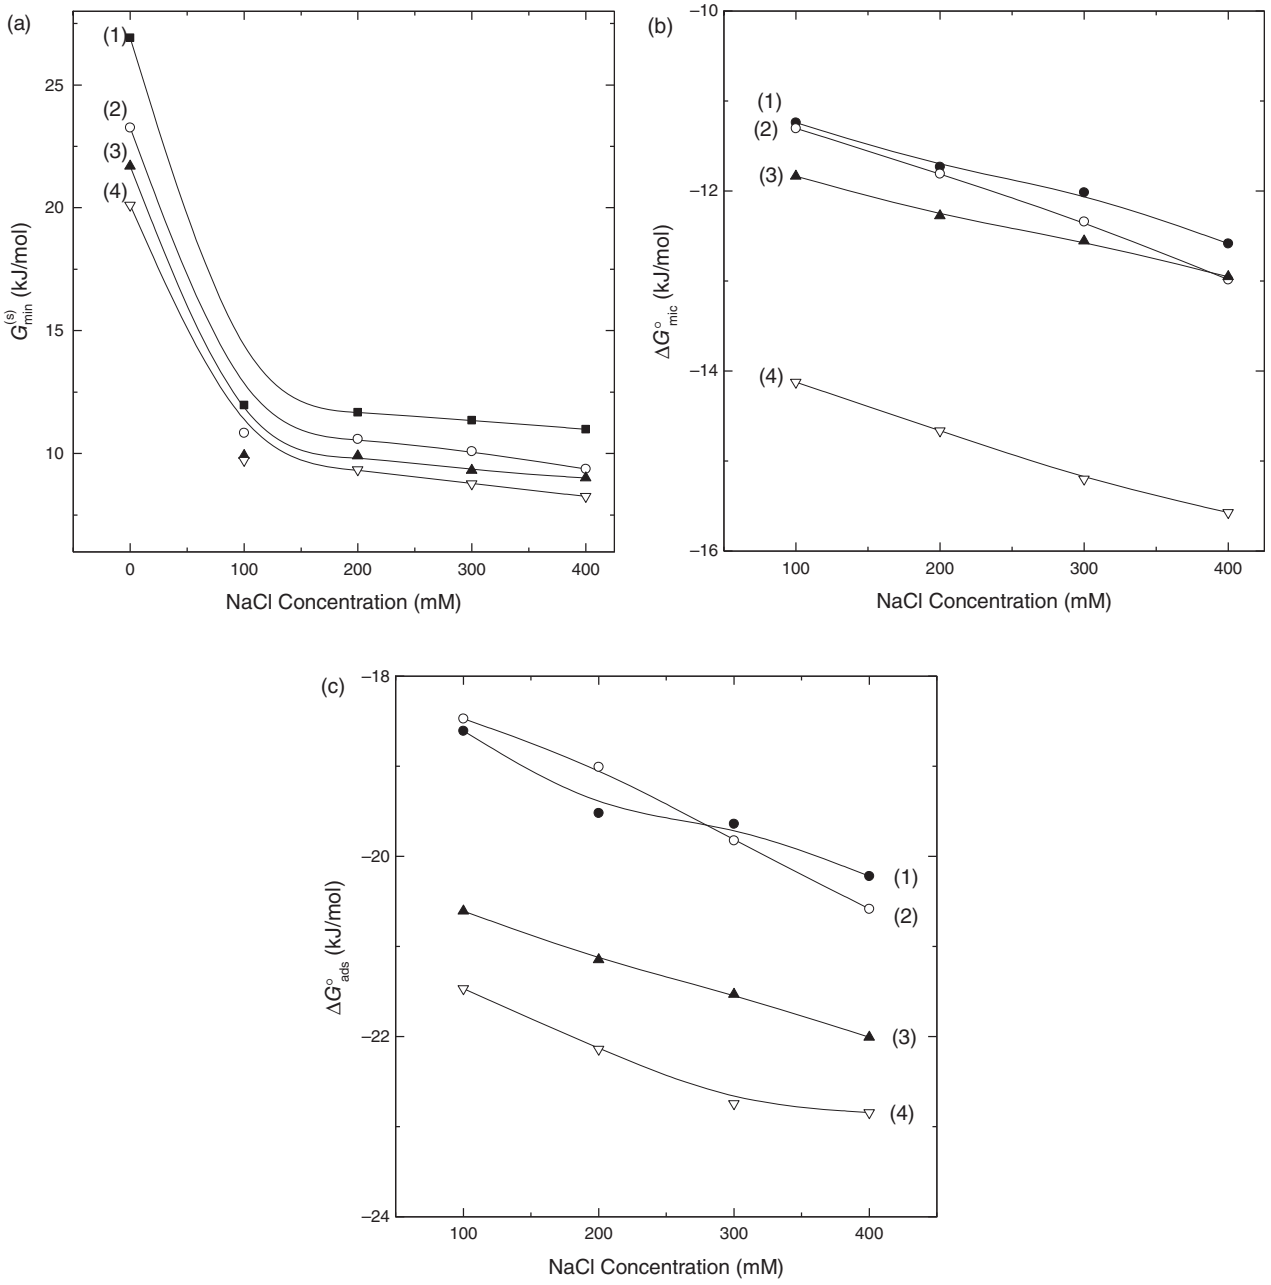

FIGURE 86.2 Variation in Gibbs free energy at the air–water interface: (a) the standard Gibbs energy change of micellization ΔG°_{mic}; (b) Gibbs energy change of micellization, ΔG°_{ads}; (c) surface-active drugs [(1) amitriptyline hydrochloride (AMT), (2) chlorpromazine hydrochloride (CPZ), (3) imipramine hydrochloride (IMP), (4) promathiazine hydrochloride (PMT) at different concentration of NaCl.

In order to quantify the effect of additives in the mixture on the micellization process, the standard Gibbs free-energy change of micellization ΔG°_{mic} and standard Gibbs energy of adsorption ΔG°_{ads} were calculated using Eqs. (86.5) and (86.6) as

$$\Delta G^{\circ}_{mic} = RT \ln \mathrm{cmc}_m \tag{86.5}$$

where cmc_m is the cmc of the mixture of the two components at a given mole fraction.

$$\Delta G^{\circ}_{ads} = \Delta G^{\circ}_{mic} - \Pi_{\mathrm{cmc}}/\Gamma_{\max} \tag{86.6}$$

A decrease in ΔG°_{mic} and ΔG°_{ads} values with increasing additive concentrations was observed (see Fig. 86.2b,c). The

standard state (at zero surface pressure) for the adsorbed surfactant is a hypothetical monolayer at its minimum surface area per molecule. The last term in Eq. (86.6) expresses work involved in transferring the surfactant molecule from a monolayer at zero surface pressure to the micelle. In all the cases (in absence/presence of additives), ΔG°_{mic} values are negative and decreased with increasing additive concentration/mole fraction (Fig. 86.2b). This indicates that the micellization is more spontaneous in presence of the additives (Fig. 86.2b). All the ΔG°_{ads} values were also found to be negative, implying that the adsorption of the surfactants at the air–mixture interface takes place spontaneously (see Fig. 86.2c).

The nature and strength of the interactions between the drugs and surfactants can be determined by finding the values of their β^m parameters [130]. The intermicellar interaction coefficient in the mixed micelles is calculated from the following equations:

$$\frac{\left\{\left(x_1^m\right)^2 \ln(\mathrm{cmc}\alpha_1/\mathrm{cmc}_1 x_1^m\right\}}{\left[\left(1-x_1^m\right)^2 \ln\left\{(\mathrm{cmc}(1-\alpha_1)/\mathrm{cmc}_2(1-x_1^m)\right\}\right]} = 1 \quad (86.7)$$

$$\beta^m = \ln\left(\mathrm{cmc}\alpha_1 x_1^m\right)/\left(1-x_1^m\right)^2 \quad (86.8)$$

Here, x_1^m is the mole fraction of component 1 in the micelles and cmc_1; cmc_2 and cmc are the cmc values for component 1, component 2, and their mixture at mole fraction of component 1, α_1, in the solution.

Equation (86.7) was solved iteratively for x_1^m, which was then substituted into equation (8) to obtain the β^m values.

The activity coefficients f_1 and f_2 are related to β and calculated by Eqs. (86.9) and (86.10):

$$f_1 = \exp\left\{\beta^m\left(1-x_1^m\right)^2\right\} \quad (86.9)$$

$$f_2 = \exp\left\{\beta^m x_1^m\right)^2\right\} \quad (86.10)$$

The excess free-energy change of micellization, ΔG_{ex}, is calculated by using the following equation:

$$\Delta G_{ex} = \left\{x_1^m \ln f_1 + \left(1-x_1^m\right)\ln f_2\right\}RT \quad (86.11)$$

In addition of surfactants (CTAB/TX-100), first they adsorbed and then formed mixed micelles. The negative ΔG_{ex} indicates a positive synergism [128]. The values of ΔG_{ex} are negative for all mole fraction/concentration values of additives, and the magnitude increases (ΔG_{ex}values become more negative) with increase in the additives' mole fractions/concentrations. This negative magnitude increase of ΔG_{ex} indicates stability of the micelles as well as more effective (positive) synergism.

86.3 EFFECT OF ADDITIVES ON CLOUDING BEHAVIOR OF AMPHIPHILIC DRUG SOLUTIONS

86.3.1 Effect of pH

As we have mentioned before, drugs (see Scheme 86.1) used in the present investigations can behave as cationic surfactants at pH < 7, and intermolecular and intermicellar interactions depend on the polar head charge and counterion concentration. Hence, the clouding behavior of surface-active drug solutions should be influenced by both pH and ionic strength. Indeed, maintaining the [drug] fixed [50 mM (or 100 mM for IMP)—all above the cmc of the drugs] and increasing the pH permitted us to observe the clouding phenomenon. We showed that the CP decreases as the pH value of the drug soltions increases (regardless of whether an additive is present); the results are plotted in Fig. 86.3a. In the pH range employed, this decrease in CP implies a significant change in the micellar surface charge. Depending on the solution pH, the hydrophilic *tert*-amine of the drug molecule (see Scheme 86.1) becomes protonated (i.e., cationic) or deprotonated (i.e., neutral). With the increase in solution pH, number of un-ionized (deprotonated) drug molecules in the micelles increases. Thus the observed behavior can be explained in terms of reduction of electrical repulsion due to increased fraction of the deprotonated drug with the concomitant enhancement in micellar aggregation number leading to decrease in the CPs. The behavior remains the same in the presence of additives, except that the CP values (increasing or decreasing as compared to the no-additive case) are dependent on the nature of the additive.

86.3.2 Effect of Electrolytes

86.3.2.1 Inorganic Salts. Figure 86.3b depicts the effect of inorganic counterions (F^-, Cl^- and Br^-) on the CP of drug solutions. Addition of electrolytes causes an increase in CP, and the order of increase is NaF < NaCl < NaBr. As halide ions carry charge opposite to that of the drug micelles (which is cationic), they should interact electrostatically with the micelles. The degree of counterion binding is known to affect the size and shape of the micelles [27,122]. The fluoride ion binding to the cationic headgroup is weak (as F^- is highly hydrated; crystal radius is 1.36 Å and hydrated radius is 3.52 Å) [131]. Therefore, with addition of NaF, micelle shape/size changes slowly and CP increase is slow. For NaBr, Br^- binds strongly to the micelles and increases the size of micelles. However, as Br^- is also hydrated, although less than F^- (crystal radius, 1.95 Å; hydrated radius, 3.30 Å) [131], and it increases micelle hydration as well as CP. The size of Cl^- (crystal radius, 1.81 Å; hydrated radius, 3.32 Å) [131] is in between F^- and Br^-, therefore, CP increase is intermediate to F^- and Br^-. The CP increase with micellar growth has been proposed [94, 95]. Those same authors observed a

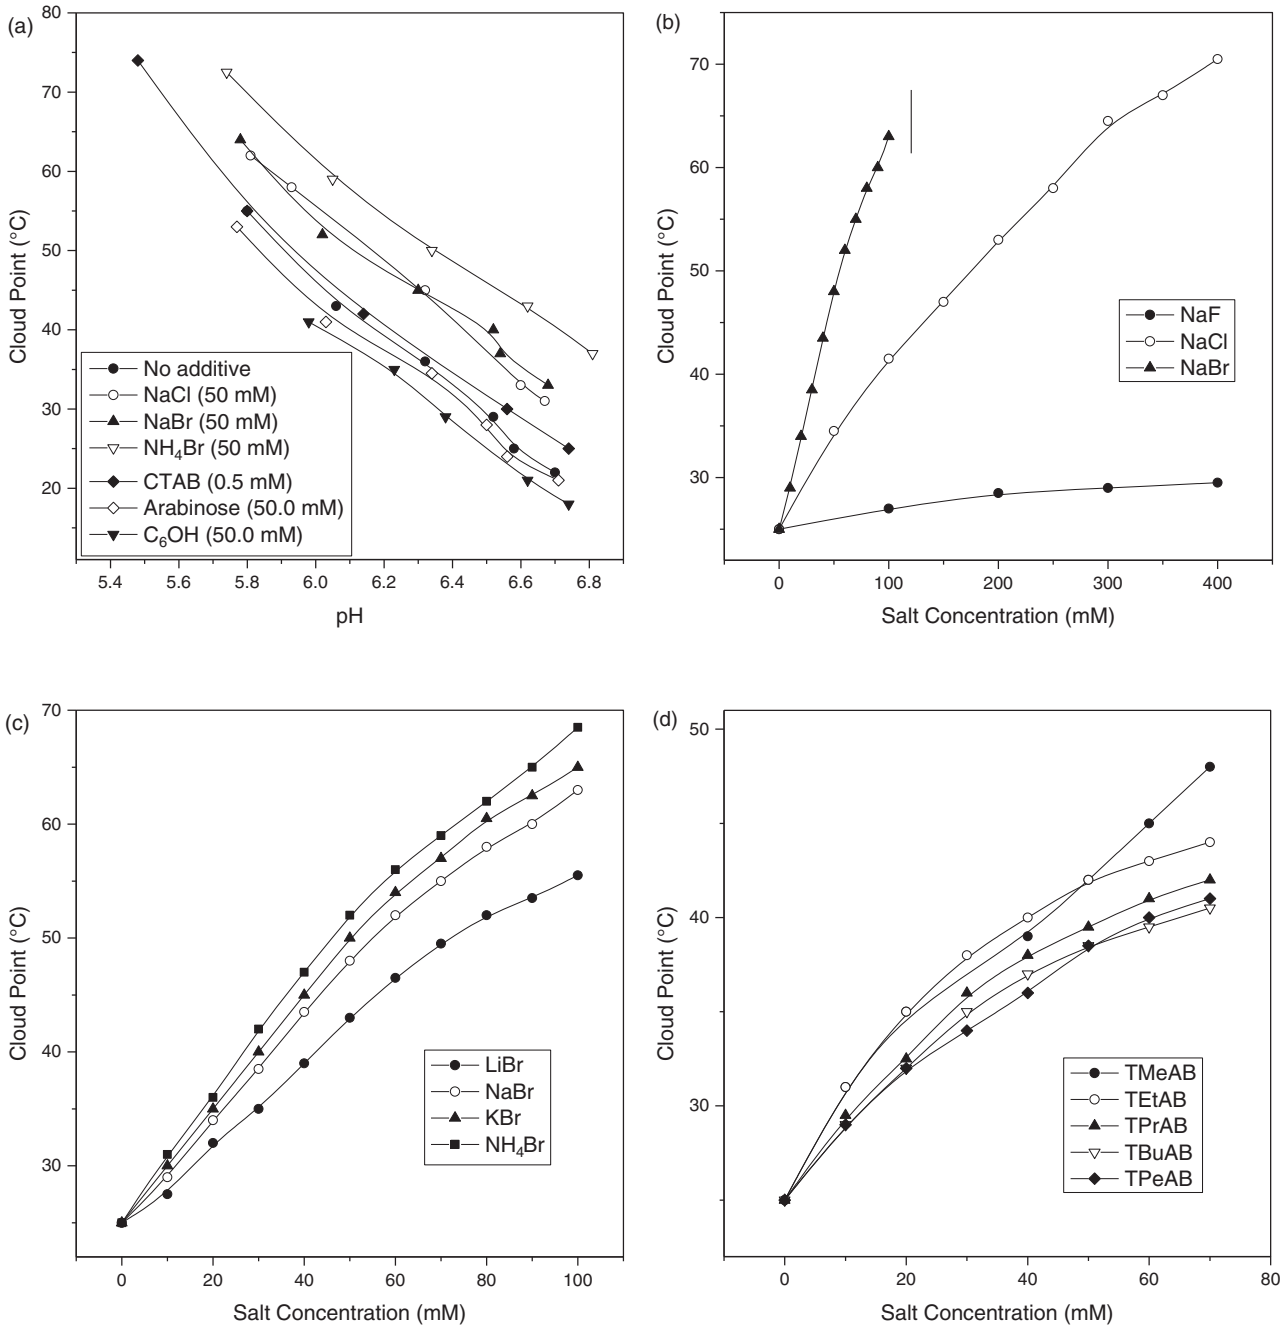

FIGURE 86.3 Effect of pH (containing no or a fixed additive concentration): (a) anionic counterions (| indicates precipitation occurring beyond [NaBr] > 100 mM at room temperature (which could be due to formation of nonmicellar phases); (b) cationic coions; (c) quaternary ammonium bromide salts; (d) concentration on the CP of 50 mM AMT solution, prepared in 10 mM sodium phosphate buffer (pH = 6.7).

larger increase in CP as well as in UV–visible intensity of AMT drug solutions with the addition of NaBr as compared to NaF addition [94, 95].

The variation in cloud points of drug solutions in presence of inorganic coions (Li^+, Na^+, K^+ and NH_4^+) is shown in Fig. 86.3c. The order of CP increase is LiBr < NaBr < KBr < NH_4Br. Ions can be classified into Hofmeister series according to their hydrated radius and salting-out strength [132]: (1) salts on the left-hand side of the series are water-structure makers and decrease the solute solubility; and (2) salts on the right-hand side are considered as water-structure breakers and increase the solute

solubility in water [120]. Another mechanism for Hofmeister series behavior relates salting-in and salting-out phenomena directly to adsorption or desorption of ions to the hydrophilic parts of the organic compounds [133]. In the series of MBr salts, Li^+ is highly hydrated (r_h = 3.82 Å) [131] and would act as a water-structure promoter, decreasing the availability of water to the micelles, which results in a slow increase in CP. Na^+, K^+, or $NH_4{}^+$ are comparatively less hydrated (for Na^+, r_h = 3.58 Å, for K^+ and $NH_4{}^+$, r_h = 3.31 Å) [131] and result in increase in micelle hydration. Hence, CP increases sharply.

86.3.2.2 Quaternary Ammonium Bromides. Figure 86.3d illustrates the variation in CP of drug solutions prepared in 10 mM SP buffer (pH = 6.7) as a function of the concentration of added quaternary ammonium bromides (QABs). All the salts cause an increase in CP. The increase is in the following order: TMeAB>TEtAB>TPrAB>TBuAB>TPeAB. The QABs are less hydrated than the inorganic salts. It was reported that the tetraalkylammonium ions are water-structure formers, and this effect increases with increase in the length of the alkyl group. The CP rising in the case of QA^+ cations is ascribed to adsorption–mixed micelle formation predominating over water-structure formation [134]. In such cases, micelles would experience greater intermicellar repulsions and consequently higher CPs. This, indeed, has been observed experimentally (Fig. 86.3d).

86.3.3 Effect of Surfactants

86.3.3.1 Anionic Surfactants. The effect of anionic surfactants on drug solutions is shown in Fig. 86.4a. In drug solutions, the added anionic surfactants (SDS/SDBS) would behave as counterions to the drug micelles. Also, penetration of dodecyl/dodecylbenzene chain into the micelles is probable. These factors should decrease the CP. However, we observe a different behavior with SDS/SDBS. The CP increases up to a certain surfactant concentration and then decreases (Fig. 86.4a). At low concentrations surfactant molecules adsorb at the micellar interface and inhibit micellization resulting in an increase in CP; whereas, at higher concentrations the added surfactant increases the compactness of the micelles and leads to micellar growth. Intercalation of DS^-/DBS^- anions into the drug micelles would reduce the headgroup repulsions and enhance the hydrophobic interactions. This, in turn, would reduce a_o and increase v. Hencee, R_p increases with anionic surfactants.

The addition of SDBS shows a slight increase and a sharp decrease in CP, which indicates that SDBS is more hydrophobic than SDS. A phenyl group is considered to be equivalent to three or four carbons in a straight chain [135]. This is reflected in a lower cmc value for SDBS [123]. As a result, greater hydrophobic interactions occur between the benzene ring of the SDBS monomer and the hydrophobic portion of the drug molecule. Also, the presence of a benzene ring causes greater electrostatic interaction with cationic drug molecules. All of these factors make SDBS more effective in dehydrating the drug micelles causing a sharper decrease in CP at higher relative concentrations.

86.3.3.2 Cationic Surfactants. The effects of cationic surfactants on the CPs are shown in Fig. 86.4b. The CP increases with addition of all the cationic surfactants. The magnitude of CP increase is found to be dependent on the chain length of the alkyl chain present in the surfactant. Increasing the chain length (longer chain lengths) results in increasing the CP to a higher degree. The presence of a counterion (Br^-) is responsible for the decrease in surface area occupied per drug headgroup, with a simultaneous increase in R_p [136]. An increase in R_p results in micellar growth. The added cationic surfactants exist in the surface-active drug solutions as monomers, micelles, and mixed micelles depending on their cmc values. The addition of CTAB, which forms larger micelles than TTAB, generates stronger electrostatic repulsion between micelles and produces a higher CP (Fig. 86.4b).

86.3.3.3 Nonionic Surfactants. Data on CP variation in surface-active drug solutions in presence of various nonionic surfactants are clearly illustrated in Fig. 86.4c. All the nonionic surfactants cause an increase in CP. All these surfactants contain oxyethylene chains. When the nonionic surfactant-drug mixed micelles are formed, they contain relatively more hydrated water in comparison to that with a micelle of a pure drug. This increase in water hydration provided by oxyethylene chains seems to be the primary cause of CP increase in drug solutions. It can also be seen from figure Fig. 86.4b that the CP increase is highest with TX-100 and lowest with Tween 20. This may be due to the presence of unidentical as well as different numbers of hydrophobic and hydrophilic groups, which would affect the CP behavior of drug solutions in a different manner.

86.3.4 Effect of Additives at Different Fixed pHs

The variation in CP of surface-active drug solutions at different fixed pHs (= 6.5, 6.7 and 6.9) prepared in 10 mM SP buffer (see representative plot, Fig. 86.5a). Additive concentration variations at different fixed pHs (all below pK_a values of the drugs) [112] show that increase/decrease in pH causes a decrease/increase in CP. With all the additives, the trend of CP variation remains exactly the same as observed at pH = 6.7 (for comparison, plots of pH = 6.5, 6.7 and 6.9 are shown in Fig. 86.5a).

86.3.5 Effect of Additives at Different Fixed Drug Concentrations

Figure 86.5b illustrates the effects of additive concentrations on the CPs of drug solutions at different fixed concentrations, prepared in 10 mM sodium phosphate buffer (pH = 6.7). The

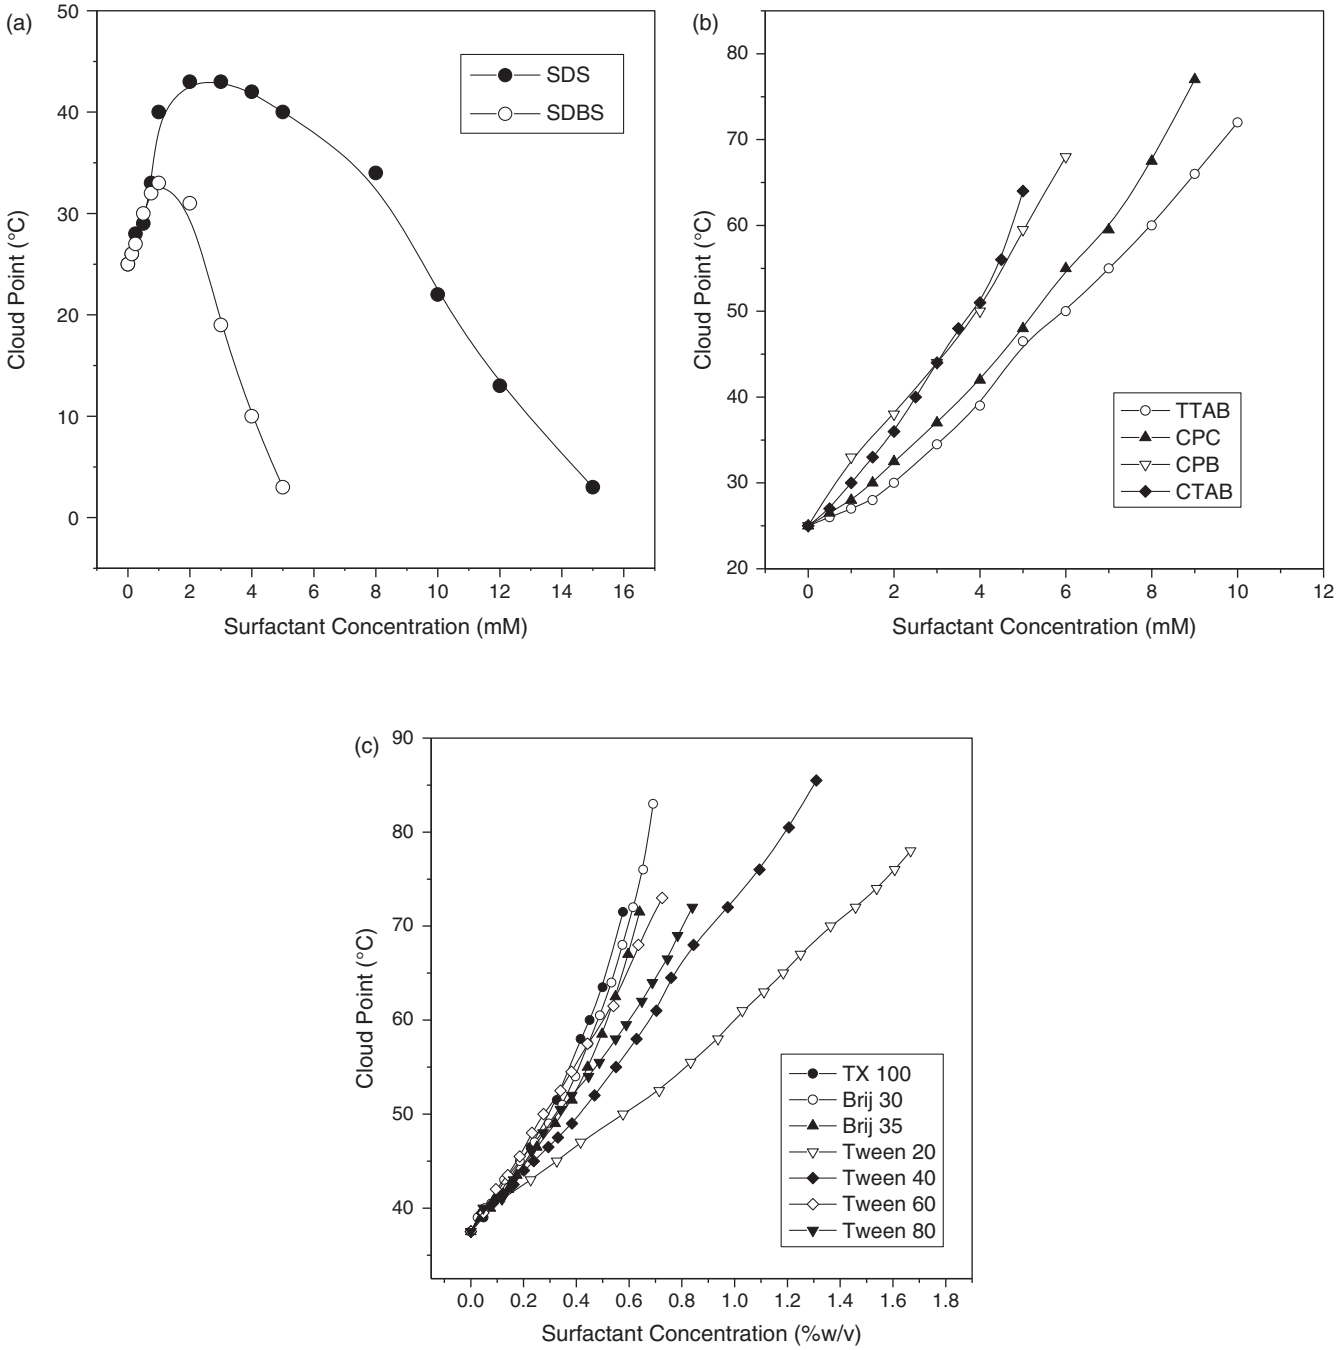

FIGURE 86.4 Effects of anionic (a), cationic (b), and nonionic (c) surfactant concentrations on the CP of 50 mM AMT solution, prepared in 10 mM sodium phosphate buffer (pH = 6.7).

trend in CP variations with different additives is the same as described earlier. With increase in drug concentrations, there is a corresponding increase in the number of micelles (which are charged). This increased number of micelles increases the degrees of intermicellar and intramicellar repulsion, and hence the CP also increases (Fig. 86.5b).

86.4 THERMODYNAMICS AT CP

As the amphiphile phase separates at temperatures above CP, the CP of a given amphiphile can be considered as the limit of its solubility. The clouding components release their solvated water and separate out from the solution. Hence, the standard

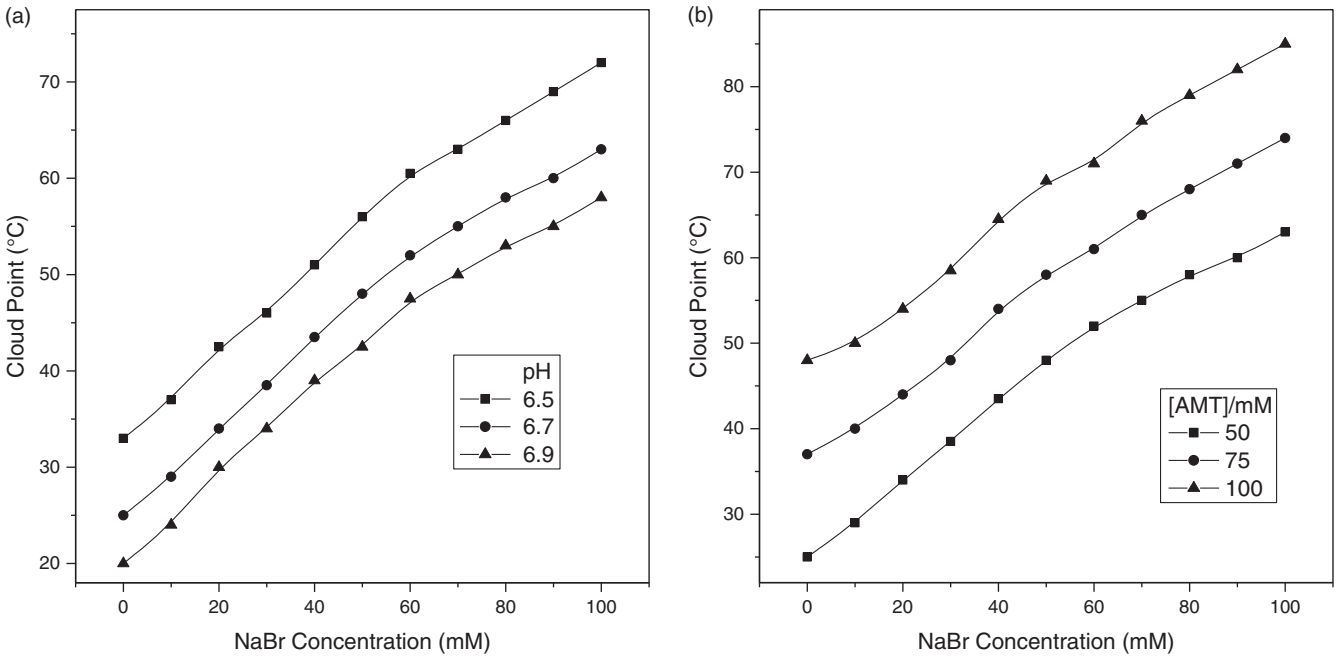

FIGURE 86.5 Effect of NaBr concentration on the CP of 50 mM AMT solution, prepared in 10 mM sodium phosphate buffer at different pH levels (a) and the effect of NaBr concentration on the CP of different fixed concentrations of AMT solutions, prepared in 10 mM sodium phosphate buffer (pH = 6.7) (b).

Gibbs energy of solubilization (ΔG_s°) of the amphiphile can be evaluated from the relation

$$\Delta G_s^\circ = -RT \ln X_s \tag{86.12}$$

where X_s is the mole fraction concentration of additive at CP, R is gas constant, and T is the clouding temperature in Kelvin scale.

The standard enthalpy and entropy of clouding, ΔH_s° and $T\Delta S_s^\circ$, respectively, can be calculated by the following equations:

$$\Delta H_s^\circ = \frac{\delta\left(\Delta G_s^\circ/T\right)}{\delta(1/T)} \tag{86.13}$$

$$T\Delta S_s^\circ = \Delta H_s^\circ - \Delta G_s^\circ \tag{86.14}$$

The thermodynamic parameters were calculated by employing Eqs. (86.12) – (86.14). The $\Delta G_s^\circ/T$ versus $1/T$ curves have two stages (a representative plot is shown in Fig. 86.6): (1) an enthalpy-controlled stage (i.e., $\Delta H_s^\circ > T\Delta S_s^\circ$) and (2) a stage that is controlled by both enthalpy and entropy (i.e., $\Delta H_s^\circ \approx T\Delta S_s^\circ$).

The thermodynamics of clouding data for surface-active drugs in the presence of additives are evaluated. The thermodynamic parameters ΔG_s° are found positive for all additives, whereas ΔH_s° and $T\Delta S_s^\circ$ values are negative or positive depending on the type and nature of the additives.

86.4.1 Effect of Surfactants

86.4.1.1 Anionic Surfactants. In presence of anionic surfactants (both SDS and SDBS), the values of thermodynamics parameters (ΔH_s° and $T\Delta S_s^\circ$) change sign from positive to

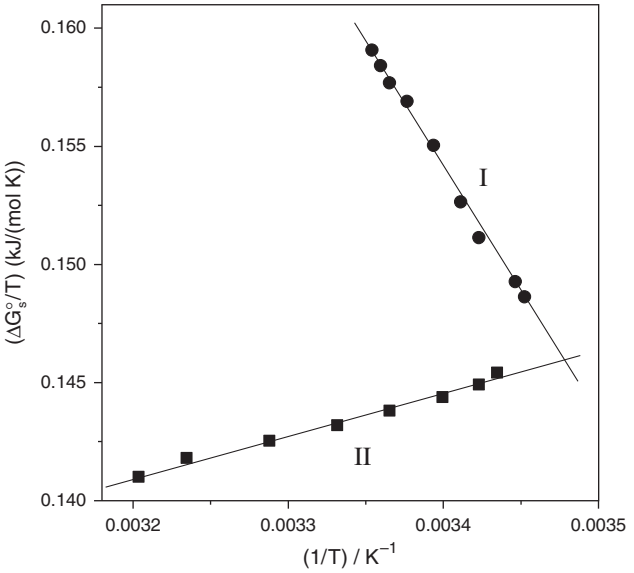

FIGURE 86.6 Plot of $\frac{\Delta G_s^\circ}{T}$ versus $\frac{1}{T}$ of surface-active drug–additive system for derivation of the enthalpy change of clouding (ΔH_s°). The stages are denoted by the labels I and II.

negative in all mole fractions. First they have positive values ΔH_s° and $T\Delta S_s^\circ$; and then after a certain concentration (cmc), the values of ΔH_s° and $T\Delta S_s^\circ$ become negative:

1. At low concentration of anionic surfactants, ΔH_s° and $T\Delta S_s^\circ$ become positive and $\Delta H_s^\circ > T\Delta S_s^\circ$. At low concentrations, these surfactants hinder micelle formation, and the overall system is in a disordered state.
2. As the concentration of surfactant increases, micellar growth increases and large aggregates form and ΔH_s° and $T\Delta S_s^\circ$ become positive with $\Delta H_s^\circ \approx T\Delta S_s^\circ$.

86.4.1.2 Cationic Surfactants. At all mole fractions of cationic surfactants, the thermodynamic parameters, both ΔH_s° and $T\Delta S_s^\circ$ are found to be positive. The added cationic surfactants exist in the solution as monomers, micelles, or mixed micelles [32], which increase the degree of interaggregate repulsion. The longer the alkyl chains of the cationic surfactant, the lower the values of ΔH_s° and $T\Delta S_s^\circ$.

86.4.1.3 Nonionic Surfactants. For all nonionic surfactants, the values of both ΔH_s° and $T\Delta S_s^\circ$are positive. These surfactants possess hydrophilic oxyethylene chains, and they form mixed micelles. Therefore, the drug–surfactant system [32] would be highly hydrated. Undoubtedly, the increase in CP with the addition of nonionic surfactants is due to this headgroup hydration, and the randomness of the systems also increases (i.e., $T\Delta S_s^\circ$ increases).

At standard conditions, the dissolution of one mole of drug in presence of additives releases heat with an overall ordering of the drug–additive system. These additives are only partially soluble in water. Hence, they solubilize more in micelles with their headgroups facing toward the surface and alkyl chain penetrating into the micelles. This results in the formation of larger aggregates that ultimately release heat with overall ordering in the system. It is clear that the exothermicity of the clouding phenomenon is due to the aggregation of weakly solvated amphiphile molecules and their phasing out into the condensed phase. This is a simplified explanation; otherwise, various environmental and structural factors and their combinations (desolvation, solvent modification, micellar growth, morphological transition, intermicellar interactions, etc.) have their due share on the energetics of clouding.

86.5 CONCLUSIONS

Like surfactants, a large number of drug molecules are amphiphilic; that is, they self-associate in aqueous environments to form small aggregates. The effect of additives on self-association, mixed micellization, and clouding phenomena of four surface-active drugs [viz., tricyclic antidepressants—amitriptyline hydrochloride (AMT) and imipramine hydrochloride (IMP) and phenothiazines—chlorpromazine hydrochloride (CPZ) and promethazine hydrochloride (PMT)]. The cmc values of all drugs have been found to decrease in the presence of additives. The thermodynamics of these four surface- active drugs in the absence and presence of additives and evaluated Gibbs energies [at the air–water interface ($\Delta G^s_{\min}$), standard Gibbs energy change of micellization (ΔG°_{mix}), standard Gibbs energy change of adsorption (ΔG°_{ads}), and excess free-energy change of micellization (ΔG_{ex})] were evaluated. In all cases (in absence/presence of additives), these values are negative and decrease with increasing additive concentration/mole fraction. This indicates that the micellization is more spontaneous in presence of the additives. Under special conditions, these surface-active drugs undergo phase separation or cloud point (CP). Like ionic surfactants, these drugs undergo phase separation, which depends on the pH, concentration, and temperature. It was observed that their cloud point (CP) can vary with additives. At cloud point the thermodynamics parameters are evaluated. In all cases standard Gibbs free-energy changes are found to be positive; but the values of ΔH_s° and $T\Delta S_s^\circ$ are found to be positive as well as negative, depending on the nature of the additive. Additives that increase the micelle size decrease the randomness of the system, and hence the $T\Delta S_s^\circ$ value becomes negative. On the other hand, additives that cause breakdown of micelles and are water structure breakers give positive ΔH_s° and $T\Delta S_s^\circ$. The above two points have clearly been demonstrated by studying the cloud points of these drugs in the presence of various additives.

ACKNOWLEDGMENT

The authors are grateful to the Department of Science and Technology (DST), New Delhi, India for financial support (Grant SR/FT/CS-48/2011) and also for financial support from Project CSC0201 of the Council of Scientific and Industrial Research (CSIR), New Delhi, India.

THERMODYNAMIC ANALYSIS OF PARTIAL MOLAR VOLUME IN BIOCOLLOIDAL SYSTEMS

MICHIO YAMANAKA,[1] HIDEYUKI MAEKAWA,[1] TAMAKI YASUI,[1] AND HITOSHI MATSUKI[2]

87.1 INTRODUCTION

It is well known that the partial molar properties provide fundamental, useful information about solute–solute, solute–solvent, and solvent–solvent interactions in solutions [1, 2]. The partial molar quantities such as enthalpy, entropy, and volume are determined by experiments. However, because enthalpy and entropy of a solution are measured relative to some reference system, they are the difference between the values of the partial molar enthalpy and entropy in the solution and in the reference system. In contrast, volume of a solution can be measured, so that the partial molar volume (PMV) in the solution is directly obtained from experiments [3].

Biocolloids such as lipid membrane aggregates and proteins are involved in many biophysical and biochemical processes. The main events in the processes could be the protein–ligand binding and/or the incorporation of biomolecules into membranes. Since PMV of a solute contains information about the interaction of the solute molecule with molecules around it in solution, one can bring out useful information about the processes from PMV measured for the biocolloidal systems [4]. Since, for example, the phenomena of pressure reversal of general anaesthesia [5–8] indicate that general anaesthesia is a process with a volume increase, the analysis of PMVs provides useful information to elucidate the molecular mechanism of general anaesthesia.

In this chapter, we develop thermodynamic approaches to analyze PMVs to obtain the binding parameters of ligand molecules to protein such as the binding constant and the binding number and to obtain information about the miscibility in the mixed vesicle membrane and the partition of water-soluble molecules and ions into the membrane. In Section 87.2, we first review the definition of PMV in a multicomponent solution and elementary thermodynamic equations describing volume behavior of the solution. Section 87.3 concerns a thermodynamic treatment of the binding of protein and ligand in solution from the standpoint of PMVs. A Method for obtaining a binding isotherm from PMV is shown. The application of the treatment to aqueous solutions of globular proteins and short chain alcohols is also described. In Section 87.4, we develop a thermodynamic treatment of PMVs for aqueous solutions of vesicles of binary water-insoluble lipid mixtures and for aqueous solutions of binary vesicles of a water-insoluble lipid and a water-soluble compound. Using the treatment for the former system, we can obtain information about the miscibility of lipids in the bilayer membrane from the analysis of PMVs. On the other hand, for the latter system, the partition of the water-soluble compound into the membrane can be examined using PMVs. The application of the derived equations to the latter system is demonstrated.

87.2 DEFINITION OF PARTIAL MOLAR VOLUME AND ELEMENTARY THERMODYNAMIC EQUATIONS OF THE VOLUME BEHAVIOR OF SOLUTIONS

Let us consider a solution of solute components 1,2, . . . , c dissolved in solvent w. The volume of the solution V' is given as a function of temperature T, pressure p, number of moles of solvent n_w, and number of moles n_i of solute component i (=1,2, . . . , c). The partial molar volume v_i of solute i in the solution is defined as the infinitesimal change of solution volume associated with the addition of an infinitesimal amount of the component i at constant T, p, n_w, and the numbers of moles of all solutes other than component i, $n_{j\neq i}$, and given by

$$v_i = \left(\frac{\partial V'}{\partial n_i}\right)_{T,p,n_w,n_{j\neq i}} = \lim_{\delta n_i \to 0} \frac{V'(T,p,n_w,n_{j\neq i};n_i+\delta n_i) - V'(T,p,n_w,n_{j\neq i};n_i)}{\delta n_i} = \lim_{\delta n_i \to 0} \frac{\delta V}{\delta n_i} \tag{87.1}$$

where the index $j \neq i$ indicates all components other than i and δV is defined by

$$\delta V = V'(T,p,n_w,n_{j\neq i};n_i+\delta n_i) - V'(T,p,n_w,n_{j\neq i};n_i) \tag{87.2}$$

Therefore, PMV of component i includes information about the intrinsic geometric volume of a molecule of component i, the contribution of the solute–solute interactions between molecules of component i and between a molecule of component i and that of other solute components, the solute–solvent interaction (solvation of molecules of solute component i), and change in the solvent structure by the addition of small amounts of component i (see Fig. 87.1). The total differential of the solution volume V' at constant T and p is written in the form

$$dV' = v_w dn_w + \sum_{i=1}^{c} v_i dn_i \tag{87.3}$$

and, according to the Euler's theorem, the solution volume is given by

$$V' = v_w n_w + \sum_{i=1}^{c} v_i n_i \tag{87.4}$$

From an experimental perspective, it is convenient to consider the solution volume per 1 kg of solvent and to adopt

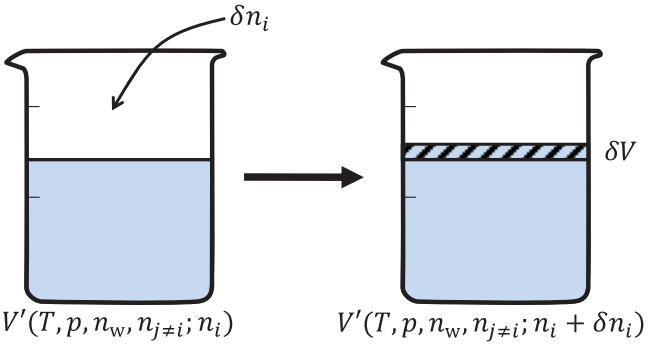

FIGURE 87.1 Schematic illustration of variation in solution volume with the addition of small amount of component i.

molality of solute components as the concentration variables. The solution volume V and the molality m_i of solute component i are defined by

$$V = \frac{V'}{n_w M_w} \tag{87.5}$$

and

$$m_i = \frac{n_i}{n_w M_w} \qquad (i = 1,2,\ldots,c) \tag{87.6}$$

where M_w is the molar mass of solvent in the unit of kg mol^{-1}. The total differential of the solution volume V at constant T and p is written in the following form:

$$dV = \sum_{i=1}^{c} v_i dm_i \tag{87.7}$$

Thus, PMV of component i is redefined by

$$v_i = \left(\frac{\partial V}{\partial m_i}\right)_{T,p,m_{j\neq i}} \tag{87.8}$$

and the solution volume is given by

$$V = \frac{v_w}{M_w} + \sum_{i=1}^{c} v_i m_i. \tag{87.9}$$

The values of PMVs are obtained experimentally from the dependence of V on molality of component i at constant T, p, and molalities of components other than i. V is related to solution density ρ by

$$V = \frac{1 + \sum_{i=1}^{c} m_i M_i}{\rho} \tag{87.10}$$

where M_i is the molar mass of component i (= 1,2, . . . , c) in unit of kg mol^{-1} and density ρ is in kg per unit volume.

Thus, one can obtain PMVs of solute components from density measurements for solutions. In the following sections, we will develop thermodynamic treatments for protein and membrane systems using the molalities.

87.3 PARTIAL MOLAR VOLUMES IN A PROTEIN–LIGAND SYSTEM

In this section, we will derive thermodynamic equations to estimate the binding parameters such as the binding constant between protein and ligand molecules and the maximum number of ligand molecules per protein molecule. Let us consider a solution that contains 1 kg of solvent w, $m_{\mathrm{M}}^{\mathrm{T}}$ moles of protein M, and $m_{\mathrm{X}}^{\mathrm{T}}$ moles of ligand X. The protein M is assumed to have $b_{\max}$ binding sites of ligand X, each site able to bind with only one ligand molecule. Thus, the dissolved species in the solution are free protein M, free ligand X, and protein–ligand complexes MX_i ($i = 1,2,\ldots,b_{\max}$). When the molalities of these dissolved species are represented by m_{M}, m_{X}, and m_i ($i = 1,2,\ldots,b_{\max}$), respectively, the preparation molality of protein $m_{\mathrm{M}}^{\mathrm{T}}$ is given by

$$m_{\mathrm{M}}^{\mathrm{T}} = m_{\mathrm{M}} + \sum_{i=1}^{b_{\max}} m_i \tag{87.11}$$

and the preparation molality of ligand $m_{\mathrm{X}}^{\mathrm{T}}$ by

$$m_{\mathrm{X}}^{\mathrm{T}} = m_{\mathrm{X}} + \sum_{i=1}^{b_{\max}} i m_i. \tag{87.12}$$

The total differential of the solution volume per 1 kg of solvent at constant T and p is given by

$$dV = \upsilon_{\mathrm{M}} dm_{\mathrm{M}} + \upsilon_{\mathrm{X}} dm_{\mathrm{X}} + \sum_{i=1}^{b_{\max}} \upsilon_i dm_i \tag{87.13}$$

where v_{M}, v_{X}, and v_{i} are PMVs of free protein, free ligand, and protein–ligand complexes MX_i ($i = 1,2,\ldots,b_{\max}$). These equations are fundamental to treat volume behavior of protein–ligand system.

According to our thermodynamic treatment of protein–ligand binding [9], Eq. (87.13) is rewritten as a function of the preparation molalities of protein and ligand at constant T and p in the form

$$\mathrm{d}V = (\upsilon_{\mathrm{M}} + b\Delta V)\mathrm{d}m_{\mathrm{M}}^{\mathrm{T}} + \upsilon_{\mathrm{X}}\mathrm{d}m_{\mathrm{X}}^{\mathrm{T}} + m_{\mathrm{M}}^{\mathrm{T}}\Delta V \mathrm{d}b, \tag{87.14}$$

where we have introduced the averaged number of ligand molecules bound to a protein molecule, b, defined by

$$b = \frac{\sum_{i=1}^{b_{\max}} i m_i}{m_{\mathrm{M}} + \sum_{i=1}^{b_{\max}} m_i} = \frac{m_{\mathrm{X}}^{\mathrm{T}} - m_{\mathrm{X}}}{m_{\mathrm{M}}^{\mathrm{T}}} \tag{87.15}$$

and the averaged partial molar volume change of the complex formation per ligand molecule (volume change of binding) ΔV, defined by

$$\begin{aligned}\Delta V &= \frac{\sum_{i=1}^{b_{\max}} i m_i \left(\dfrac{\upsilon_i - \upsilon_{\mathrm{M}} - i\upsilon_{\mathrm{X}}}{i}\right)}{\sum_{i=1}^{b_{\max}} i m_i} \\ &= \frac{\sum_{i=1}^{b_{\max}} i m_i \left(\dfrac{\upsilon_i - \upsilon_{\mathrm{M}}}{i}\right)}{\sum_{i=1}^{b_{\max}} i m_i} - \upsilon_{\mathrm{X}} \\ &= \upsilon_{\mathrm{X}}^{\mathrm{M}} - \upsilon_{\mathrm{X}}\end{aligned} \tag{87.16}$$

where $v_{\mathrm{X}}^{\mathrm{M}}$ is the averaged partial molar volume of ligand binding to protein molecules defined by

$$\upsilon_{\mathrm{X}}^{\mathrm{M}} = \frac{\sum_{i=1}^{b_{\max}} i m_i \left(\dfrac{\upsilon_i - \upsilon_{\mathrm{M}}}{i}\right)}{\sum_{i=1}^{b_{\max}} i m_i}. \tag{87.17}$$

It should be noted that $v_{\mathrm{X}}^{\mathrm{M}}$ includes the contribution of the changes of hydration state and conformation of protein molecule by the binding of ligand molecules. Thus, PMV of total protein $V_{\mathrm{M}}^{\mathrm{T}}$, which is determined experimentally, provides PMV of free protein unbound by ligand molecules, v_{M}, the volume change of ligand binding per mole of protein, $b\Delta V$, and a term relating to the dependence of the binding number on protein molality;

$$\begin{aligned}V_{\mathrm{M}}^{\mathrm{T}} &= \left(\frac{\partial V}{\partial m_{\mathrm{M}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{X}}^{\mathrm{T}}} \\ &= \upsilon_{\mathrm{M}} + b\Delta V + m_{\mathrm{M}}^{\mathrm{T}}\Delta V\left(\frac{\partial b}{\partial m_{\mathrm{M}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{X}}^{\mathrm{T}}}\end{aligned} \tag{87.18}$$

When the V vs. $m_{\mathrm{M}}^{\mathrm{T}}$ plot is almost linear, the third term of the right-hand side (RHS) of Eq. (87.18) is negligible and therefore $V_{\mathrm{M}}^{\mathrm{T}}$ is independent of $m_{\mathrm{M}}^{\mathrm{T}}$. Further, if the value of v_{M} at $m_{\mathrm{X}}^{\mathrm{T}}$ is the same as that of PMV of protein in the solution at $m_{\mathrm{X}}^{\mathrm{T}} = 0$ which is free from ligand, the value of $b\Delta V$ is obtained from the difference between the value of $V_{\mathrm{M}}^{\mathrm{T}}$ at $m_{\mathrm{X}}^{\mathrm{T}}$ and the value at $m_{\mathrm{X}}^{\mathrm{T}} = 0$ on the $V_{\mathrm{M}}^{\mathrm{T}}$ vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve. Since b approaches to $b_{\max}$ and the dependence of b on $m_{\mathrm{M}}^{\mathrm{T}}$ at constant $m_{\mathrm{X}}^{\mathrm{T}}$ becomes very small when $m_{\mathrm{X}}^{\mathrm{T}}/m_{\mathrm{M}}^{\mathrm{T}}$ becomes large, the experimental partial molar volume of total protein

at high ligand molality relative to protein molality is given by

$$V_{\mathrm{M}}^{\mathrm{T}} = v_{\mathrm{M}} + b_{\max}\Delta V \tag{87.19}$$

Thus, we can approximate the value of $b_{\max}\Delta V$ by the value of $(V_{\mathrm{M}}^{\mathrm{T}} - v_{\mathrm{M}})$ obtained from the $V_{\mathrm{M}}^{\mathrm{T}}$ vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve at high $m_{\mathrm{X}}^{\mathrm{T}}$.

On the other hand, PMV of total ligand obtained from the V vs. $m_{\mathrm{X}}^{\mathrm{T}}$ plot provides

$$V_{\mathrm{X}}^{\mathrm{T}} = \left(\frac{\partial V}{\partial m_{\mathrm{X}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{M}}^{\mathrm{T}}} = v_{\mathrm{X}} + m_{\mathrm{M}}^{\mathrm{T}}\Delta V\left(\frac{\partial b}{\partial m_{\mathrm{X}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{M}}^{\mathrm{T}}} \tag{87.20}$$

It may be assumed that v_{X} on the RHS of Eq. (87.20) has the same value as PMV of ligand has at $m_{\mathrm{M}}^{\mathrm{T}} = 0$. Introducing the site occupancy $\theta = b/b_{\max}$, we have

$$V_{\mathrm{X}}^{\mathrm{T}} = v_{\mathrm{X}} + m_{\mathrm{M}}^{\mathrm{T}} b_{\max}\Delta V\left(\frac{\partial \theta}{\partial m_{\mathrm{X}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{M}}^{\mathrm{T}}} \tag{87.21}$$

which gives

$$\left(\frac{\partial \theta}{\partial m_{\mathrm{X}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{M}}^{\mathrm{T}}} = \frac{V_{\mathrm{X}}^{\mathrm{T}} - v_{\mathrm{X}}}{m_{\mathrm{M}}^{\mathrm{T}} b_{\max}\Delta V} \tag{87.22}$$

The value of $(V_{\mathrm{X}}^{\mathrm{T}} - v_{\mathrm{X}})/m_{\mathrm{M}}^{\mathrm{T}}$ on the RHS of this equation is obtained ftom the $V_{\mathrm{X}}^{\mathrm{T}}$ vs. $m_{\mathrm{M}}^{\mathrm{T}}$ curve and the value of $b_{\max}\Delta V$ from the $V_{\mathrm{M}}^{\mathrm{T}}$ vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve using Eq. (87.19). Integration of Eq. (87.22) by $m_{\mathrm{X}}^{\mathrm{T}}$ yields

$$\theta = \int_0^{m_{\mathrm{X}}^{\mathrm{T}}} \frac{V_{\mathrm{X}}^{\mathrm{T}} - v_{\mathrm{X}}}{m_{\mathrm{M}}^{\mathrm{T}} b_{\max}\Delta V}\mathrm{d}m_{\mathrm{X}}^{\mathrm{T}} \tag{87.23}$$

Thus, we can obtain, in principle, the site occupancy as a function of $m_{\mathrm{X}}^{\mathrm{T}}$ at constant T and p from the concentration dependence of PMVs of protein and ligand.

In order to examine in detail the binding behavior, it is necessary to evaluate the maximum binding number $b_{\max}$ and the binding constant K by applying a binding isotherm to the site occupancy data. In this chapter, we adopt a binding isotherm of Langmuir type. The extension of the isotherm to more complex one is quite easy. The Langmuir binding isotherm is expressed by

$$\theta = \frac{b}{b_{\max}} = \frac{Km_{\mathrm{X}}}{1 + Km_{\mathrm{X}}} = \frac{K\left(m_{\mathrm{X}}^{\mathrm{T}} - bm_{\mathrm{M}}^{\mathrm{T}}\right)}{1 + K\left(m_{\mathrm{X}}^{\mathrm{T}} - bm_{\mathrm{M}}^{\mathrm{T}}\right)} \tag{87.24}$$

where we have used Eq. (87.15) on the RHS of this equation. Rearranging this equation, we obtain a quadratic equation of θ:

$$Kb_{\max}m_{\mathrm{M}}^{\mathrm{T}}\theta^2 - \left(1 + Km_{\mathrm{X}}^{\mathrm{T}} + b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}\right)\theta + Km_{\mathrm{X}}^{\mathrm{T}} = 0 \tag{87.25}$$

Solving this equation analytically and accounting for the fact that θ has to be close to 0 in the limit of $m_{\mathrm{X}}^{\mathrm{T}} \to 0$, we obtain the solution as follows:

$$\theta = \frac{\left(1 + Km_{\mathrm{X}}^{\mathrm{T}} + b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}\right) - \sqrt{\left(1 + Km_{\mathrm{X}}^{\mathrm{T}} + b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}\right)^2 - 4b_{\max}K^2m_{\mathrm{M}}^{\mathrm{T}}m_{\mathrm{X}}^{\mathrm{T}}}}{2Kb_{\max}m_{\mathrm{M}}^{\mathrm{T}}} \tag{87.26}$$

By differentiating both sides of this equation by $m_{\mathrm{X}}^{\mathrm{T}}$ at constant T, p, and $m_{\mathrm{M}}^{\mathrm{T}}$, we have

$$\left(\frac{\partial \theta}{\partial m_{\mathrm{X}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{M}}^{\mathrm{T}}} = \frac{\sqrt{\left(1 + Km_{\mathrm{X}}^{\mathrm{T}} + b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}\right)^2 - 4b_{\max}K^2m_{\mathrm{M}}^{\mathrm{T}}m_{\mathrm{X}}^{\mathrm{T}}} - \left(1 + Km_{\mathrm{X}}^{\mathrm{T}} - b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}\right)}{2b_{\max}m_{\mathrm{M}}^{\mathrm{T}}\sqrt{\left(1 + Km_{\mathrm{X}}^{\mathrm{T}} + b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}\right)^2 - 4b_{\max}K^2m_{\mathrm{M}}^{\mathrm{T}}m_{\mathrm{X}}^{\mathrm{T}}}} \tag{87.27}$$

Although this is an exact equation which expresses the slope of the θ vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve as a function of $m_{\mathrm{X}}^{\mathrm{T}}$ and $m_{\mathrm{M}}^{\mathrm{T}}$, it is very difficult to fit this to the experimental values on the RHS of Eq. (87.22) to obtain the values of $b_{\max}$ and K.

Instead, let us consider the initial slope of the θ vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve. When $m_{\mathrm{X}}^{\mathrm{T}}$ approaches zero, Eq. (87.27) gives the initial slope of the θ vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve

$$\left(\frac{\partial \theta}{\partial m_{\mathrm{X}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{M}}^{\mathrm{T}}}^{m_{\mathrm{X}}^{\mathrm{T}} \to 0} = \frac{K}{1 + b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}} \tag{87.28}$$

and Eq. (87.22) is rewritten in the form

$$\left(\frac{\partial \theta}{\partial m_{\mathrm{X}}^{\mathrm{T}}}\right)_{T,p,m_{\mathrm{M}}^{\mathrm{T}}}^{m_{\mathrm{X}}^{\mathrm{T}} \to 0} = \frac{V_{\mathrm{X}}^{\mathrm{T},0} - v_{\mathrm{X}}}{m_{\mathrm{M}}^{\mathrm{T}} b_{\max}\Delta V} \tag{87.29}$$

where $V_{\mathrm{X}}^{\mathrm{T},0}$ is PMV of ligand at its infinite dilution. When the V vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve is linear, the value of $V_{\mathrm{X}}^{\mathrm{T},0}$ is identical to that of $V_{\mathrm{X}}^{\mathrm{T}}$. Thus, Eq. (87.28) says that the initial slope of the θ vs. $m_{\mathrm{X}}^{\mathrm{T}}$ curve, evaluated from the experimental data of PMVs of protein and ligand by using Eq. (87.29), is related to the biding parameters and depends on the preparation molality of protein. At low concentrations of protein where the second term $b_{\max}Km_{\mathrm{M}}^{\mathrm{T}}$ of the denominator on the RHS of

Eq. (87.28) is negligibly smaller than unity, the initial slope of the θ vs. m_X^T curve provides the binding constant K.

Now, let us apply the equations derived above to the experimental data for the systems of globular proteins and short chain alcohols. Proteins used were myoglobin (Mgb, from equine skeletal muscle, Sigma, St. Louis, MO) and lysozyme (Lys, from chicken egg white, Sigma, St. Louis, MO). Mgb is larger in the molar mass, smaller in the surface hydrophilicity, and softer in the rigidity than Lys [10]. Alcohols used were 1-hexanol (C_6OH, Tokyo Chemical Industry, Tokyo, Japan), 1-butanol (C_4OH, Tokyo Chemical Industry, Tokyo, Japan), ethanol (C_2OH, Wako Pure Chemical Industries, Osaka, Japan), and 2,2,2-trifluoroethanol (TFE, Tokyo Chemical Industry, Tokyo, Japan). We measured densities of solutions of the proteins dissolved in dilute aqueous solutions of the alcohols at 298.15 ± 0.02 K under atmospheric pressure using a vibrating tube density meter (DMA 60/602, Anton Paar, Austria). The experimental error in the density was within $\pm 0.002\,\mathrm{kg\,m^{-3}}$. The values of the solution volume per 1 kg of solvent water were calculated by

$$V = \frac{1 + M_M m_M^T + M_X m_X^T}{\rho} \tag{87.30}$$

which is derived from Eq. (87.10). M_M and M_X in Eq. (87.30) are the molar mass of protein and ligand.

In Figs. 87.2 and 87.3, the values of V are plotted against m_M^T at constant m_X^T for the Mgb and Lys systems, respectively. It is observed that, for all of the V vs. m_M^T curves, V increases with increasing m_M^T linearly. The linearity of the curves indicates that the value of PMV of protein V_M^T at m_M^T is identical to that at infinite dilution of protein. The values of V_M^T obtained from Figs. 87.2 and 87.3 are plotted against m_X^T in Fig. 87.4, and the values of PMVs of Mgb and Lys in their aqueous solutions which are free from ligand are listed in Table 87.1. For both proteins, subtracting the v_M values in Table 87.1 from the values of V_M^T at $m_X^T = 100\,\mathrm{mmol\,kg^{-1}}$ for C_4OH, C_2OH, and TFE and at $m_X^T = 50\,\mathrm{mmol\,kg^{-1}}$ for C_6OH from corresponding V_M^T vs. m_X^T curves, we obtained the values of $b_{max}\Delta V$ using Eq. (87.19) and listed them in Table 87.2. It is found that the values of $b_{max}\Delta V$ for Mgb and Lys are positive, i.e., the values of ΔV are positive for the present systems. According to Eq. (87.16), this fact indicates that the averaged partial molar volume of alcohol binding to protein molecules is larger than PMV of alcohol in the bulk solution. Moreover, the magnitude of $b_{max}\Delta V$ increases in the order of $C_6OH < TFE < C_2OH < C_4OH$ for both proteins. The value of ΔV includes the contributions of the changes in the hydration states of alcohol and protein molecules and the conformation change of protein molecule associated with the binding. Therefore, in order to explain in detail the reason of

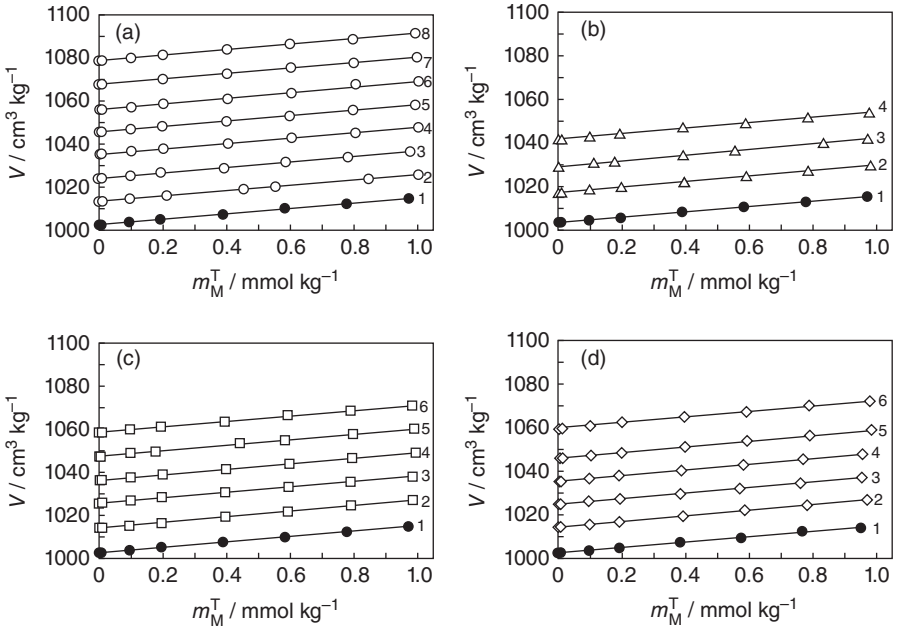

FIGURE 87.2 Solution volume per 1 kg of water versus total protein molality curves for Mgb systems: (a) C_6OH, $m_X^T/\mathrm{mmol\,kg^{-1}}$ = (1) 0, (2) 4.950, (3) 11.61, (4) 20.07, (5) 24.93, (6) 29.94, (7) 40.89, (8) 48.82; (b) C_4OH, (1) 0, (2) 50.54, (3) 75.08, (4) 101.7; (c) C_2OH, (1) 0, (2) 20.17, (3) 49.48, (4) 60.53, (5) 81.64, (6) 101.1; (d) TFE, (1) 0, (2) 20.42, (3) 30.25, (4) 39.77, (5) 50.42, (6) 100.6. In order to avoid overlap of the curves, all curves other than curve 1 in each graph are shifted upward by (2) +10, (3) +20, (4) +30, (5) +40, (6) +50, (7) +60, (8) +70 $\mathrm{mmol\,kg^{-1}}$.

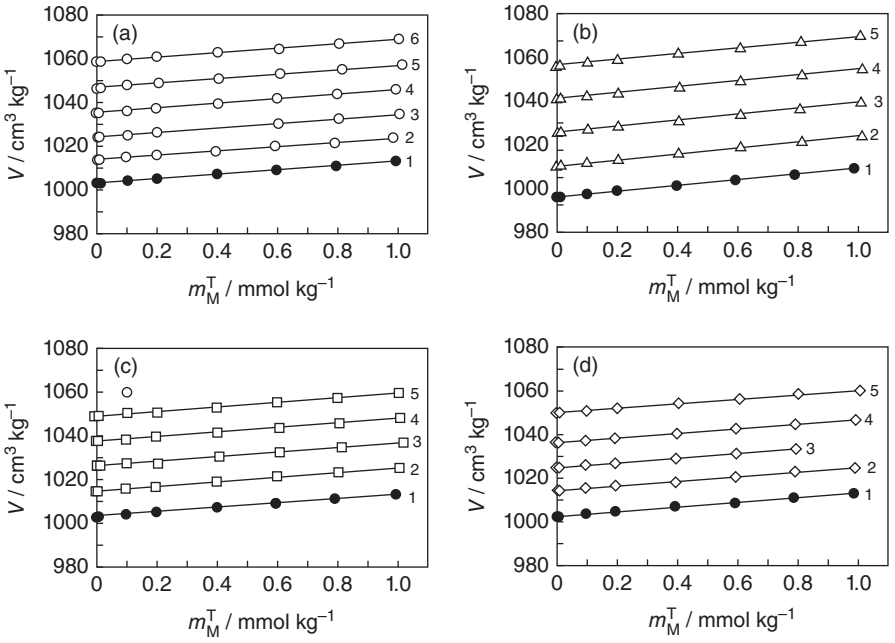

FIGURE 87.3 Solution volume per 1 kg of water versus total protein molality curves for Lys systems: (a) C_6OH, m_X^T/mmol kg^{-1} = (1) 0, (2) 5.011, (3) 10.26, (4) 20.05, (5) 29.87, (6) 49.08; (b) C_4OH, (1) 0, (2) 25.35, (3) 50.03, (4) 75.81, (5) 100.7; (c) C_2OH, (1) 0, (2) 25.47, (3) 50.57, (4) 75.90, (5) 101.5; (d) TFE, (1) 0, (2) 20.68, (3) 30.41, (4) 50.43, (5) 102.1. In order to avoid overlap of the curves, all curves other than curve 1 in each graph are shifted upward by (2) +10, (3) +20, (4) +30, (5) +40, (6) +50 mmol kg^{-1}.

the order of the magnitude of $b_{max}\Delta V$, it is necessary to know the value of b_{max}, the hydrophobicity of the binding sites of the short chain alcohol molecules, effect of the addition on the conformation of the proteins, and the hydration state of protein and alcohol molecules.

Since the influence of the polar group on the hydrophobic hydration around alkyl chains of the solutes becomes more significant for shorter-chain alcohols [11, 12], it may be difficult to compare the order of ethanol and TFE with the order of C_4OH and C_6OH simply. If the binding sites of C_6OH and C_4OH molecules are in the hydrophobic domain, the volume of the hydrophobic process [13] may contribute the smaller value of $b_{max}\Delta V$ for C_6OH than for C_4OH; in other words, the longer the hydrophobic alkyl chain, the larger the volume lost due to the release of hydrating water molecules within the transfer of an alcohol molecule from the bulk solution to the surface of the protein molecules. The volume of the hydrophobic process may also explain the negative value of $b_{max}\Delta V$ for octanol (C_8OH) binding to bovine serum albumin (BSA) (see Fig. 87.9, later) [9]. Further, the value of $b_{max}\Delta V$ is smaller for Lys than for Mgb. This fact may be attributable to the difference in the rigidity and the compactness of the structure between Lys and Mgb.

TABLE 87.1 Partial Molar Volumes of Proteins and Alcohols

	v_M (cm^3 mol^{-1})	v_X (cm^3 mol^{-1})
Mgb	12,440	—
Lys	10,454	—
C_6OH	—	118.1
C_4OH	—	86.4
C_2OH	—	55.1
TFE	—	66.4

The values of V at constant m_M^T taken from the V vs. m_M^T curves in Figs. 87.2 and 87.3 are plotted against m_X^T for the Mgb and Lys systems in Figs. 87.5 and 87.6, respectively. The curves show the linear dependence of V on m_X^T. Thus, the values of V_X^T at m_X^T are identical to those of PMV of alcohol at its infinite dilution, $V_X^{T,0}$. The values of V_X^T obtained from the curves in Figs. 87.5 and 87.6 are plotted against m_M^T in Fig. 87.7, and the PMVs of alcohols in their aqueous solutions free from proteins are listed in Table 87.1. For all alcohols used here, V_X^T increases linearly with increasing m_M^T. According to Eq. (87.21), this fact indicates that the left-hand side (LHS) of Eq. (87.22) is almost constant for the present systems. The slope of the curves in Fig. 87.7 is larger for Mgb than for Lys, corresponding to the difference in the magnitude of $b_{max}\Delta V$.

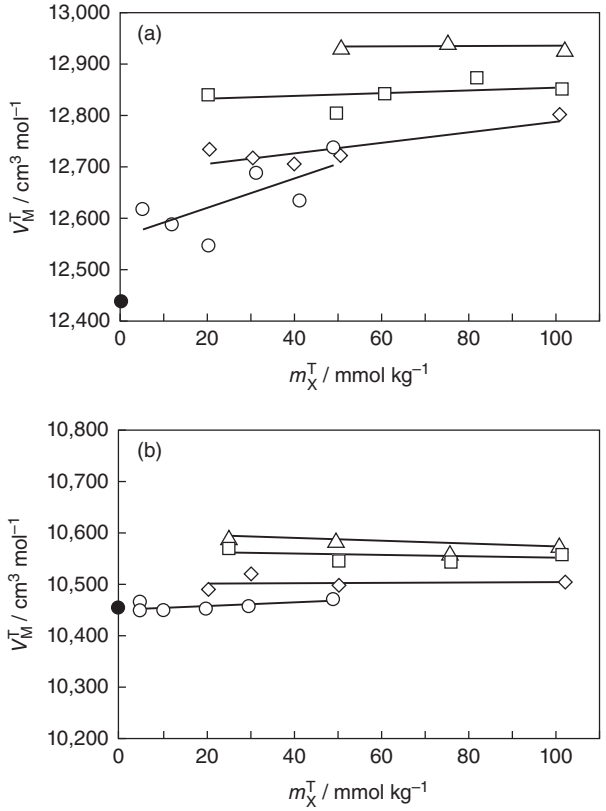

FIGURE 87.4 Partial molar volume of total protein in water (•) and partial molar volume of total protein versus total alcohol molality curves at 298.15 K (a) for Mgb in aqueous solutions of (○) C_6OH, (△) C_4OH, (□) C_2OH, and (◇) TFE and (b) for Lys in aqueous solutions of (○) C_6OH, (△) C_4OH, (□) C_2OH, and (◇) TFE.

Since the V_X^T vs. m_M^T curves of the present systems are linear, the slopes of the curves provide the values of $(V_X^{T,0} - v_X)/m_M^T$ in Eq. (87.29), which are listed in Table 87.2. Combining these values with the values of $b_{max}\Delta V$ and using Eq. (87,29), we obtained the values on the LHS of Eq. (87.28) listed in Table 87.2. Because of the small value of $b_{max}\Delta V$, we excluded the value for the Lys-C_6OH system from the list. Using these values, we calculated the values of K at infinite dilution of alcohols of the present systems for the values of $b_{max}m_M^T = 1$ and 5 mmol kg^{-1} and listed the results in Table 87.2. The values on the LHS of Eq. (87.28) correspond to the K values at $b_{max}m_M^T = 0$. The values of K at different $b_{max}m_M^T$ seem to be in agreement with each other. As compared with the value of the binding constant BSA and C_8OH [14], the magnitude of the K values for the present systems may be reasonable. Further, it is interesting that, contrary to that of C_4OH, the affinity of C_2OH and TFE to protein is stronger for Lys than for Mgb. This fact may be attributable to difference in the size and hardness of the structure between Lys and Mgb.

The procedure described above is a simple one to obtain the binding isotherm and the value of K from PMV data, but it is not able to determine the respective values of b_{max} and ΔV. In order to do this, it is necessary to arrange the procedure a little. From Eqs. (87.28) and (87.29), the following equation is obtained:

$$V_X^{T,0} = v_X + \frac{b_{max}\Delta V K m_M^T}{1 + b_{max}K m_M^T} \tag{87.31}$$

This equation expresses the dependence of the PMV of the ligand at its infinite dilution on the preparation molality of protein, if v_X has the same value with that of PMV of ligand in the solution free from protein. Rearranging Eq. (87.31) further, we obtain the following equation

$$\frac{1}{V_X^{T,0} - v_X} = \frac{1}{b_{max}\Delta V K} \cdot \frac{1}{m_M^T} + \frac{1}{\Delta V} \tag{87.32}$$

which implies that the slope and vertical intercept of the $1/(V_X^{T,0} - v_X)$ vs $1/m_M^T$ plot provide $1/(b_{max}\Delta V K)$ and $1/\Delta V$, respectively. Since the value of $b_{max}\Delta V$ is obtained

TABLE 87.2 Volume and Binding Parameters of Protein-Ligand Systems

Protein	Alcohol	$\frac{b_{max}\Delta V}{cm^3\ mol^{-1}}$	$\frac{(V_X^{T,0}-v_X)/m_M^T}{(cm^3\ mol^{-1})/(mol\ kg^{-1})}$	$\frac{(\partial\theta/\partial m_X^T)_{T,p,m_M^T}^{m_X^T\to 0}}{(mol\ kg^{-1})^{-1}}$	$\frac{K}{(mol\ kg^{-1})^{-1}}$	
Mgb	C_6OH	264[a]	4.08	15.5	15.7[c]	16.8[d]
	C_4OH	495[b]	5.01	10.1	10.2[c]	10.7[d]
	C_2OH	418[b]	3.19	7.6	7.7[c]	7.9[d]
	TFE	350[b]	2.74	7.8	7.9[c]	8.1[d]
Lys	C_6OH	13[a]	0.39	—	—	—
	C_4OH	113[b]	1.02	9.1	9.1[c]	9.5[d]
	C_2OH	93[b]	0.88	9.4	9.5[c]	9.9[d]
	TFE	50[b]	0.50	10.1	10.2[c]	10.6[d]

The values of $b_{max}\Delta V$ were obtained at [a]$m_X^T = 50$ mmol kg^{-1} and at [b]m_X^T=100 mmol kg^{-1}. The values of K were calculated by assuming [c]$b_{max}m_M^T = 1$ mmol kg^{-1} and [d]$b_{max}m_M^T = 5$ mmol kg^{-1}.

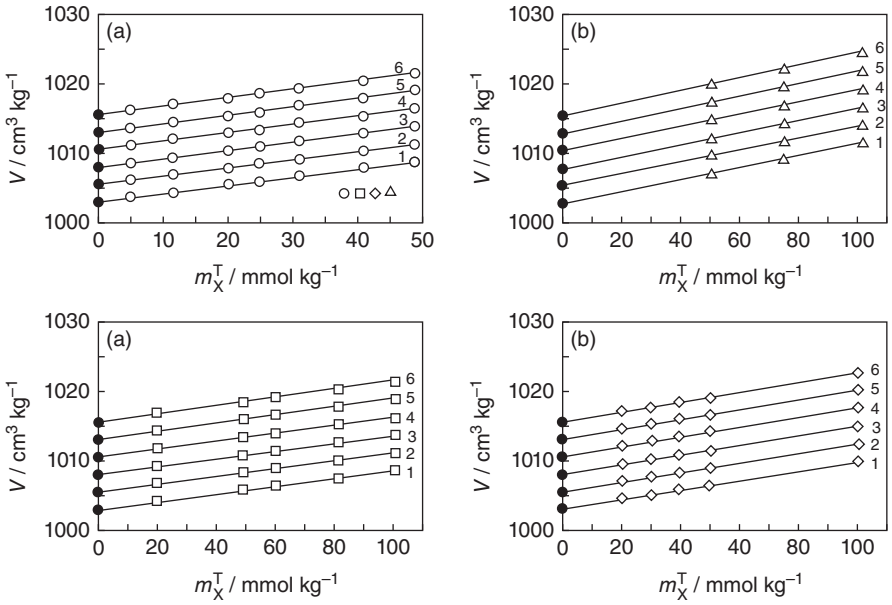

FIGURE 87.5 Solution volume per 1 kg of water versus total alcohol molality curves for Mgb systems: (a) C_6OH; (b) C_4OH; (c) C_2OH; (d) TFE; $m_M^T/\text{mmol kg}^{-1}$ = (1) 0, (2) 0.2, (3) 0.4, (4) 0.6, (5) 0.8, (6) 1.0.

from the V_M^T vs. m_X^T plot, the values of b_{max} and K can be estimated. In the following, we show the application of Eq. (87.32) to the binding between BSA and C_8OH [9].

Figure 87.8 shows the PMV of BSA at infinite dilution $V_M^{T,0}$ as a function of C_8OH molality m_X^T at 298.15 K. Evidently, the value of $b_{max}\Delta V$ is negative for the BSA-C_8OH system. In Fig. 87.9, the PMV of C_8OH $V_X^{T,0}$ is shown as a function of BSA molality m_M^T. The value of $V_X^{T,0}$ decreases with increasing BSA molality. This decrease corresponds to the negative value of $b_{max}\Delta V$. The

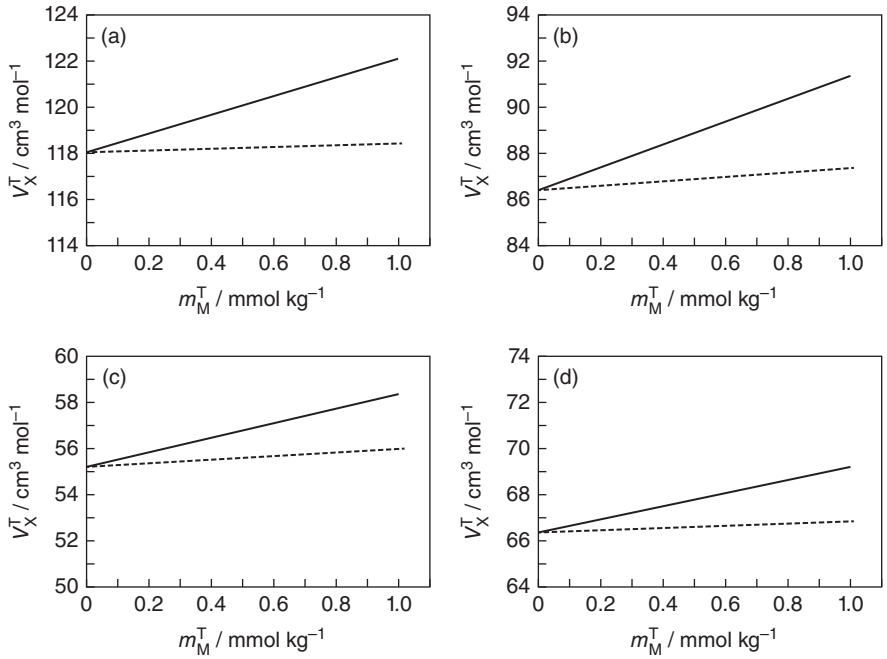

FIGURE 87.7 Partial molar volume of total alcohol versus total protein molality curves at 298.15 K: (a) C_6OH; (b) C_4OH; (c) C_2OH; (d) TFE; (—) Mgb and (- - -) Lys.

values of $V_X^{T,0} - v_X$ at m_M^T were obtained by assuming the value of v_X was equal to PMV of C_8OH in the solution free from BSA. In Fig. 87.10, the values of $1/(V_X^{T,0} - v_X)$ are plotted against $1/m_M^T$. It is found that $1/(V_X^{T,0} - v_X)$ decreases linearly with increasing $1/m_M^T$. This fact indicates that Eq. (87.32) is valid for the BSA-C_8OH system. Using the values of the slope and vertical intercept of the plot and the value of $b_{max}\Delta V$ obtained from Fig. 87.7, the values of $\Delta V = -109\,\text{cm}^3\,\text{mol}^{-1}$, $b_{max} = 1.9$, and $K = 392\,\text{kg mol}^{-1}$ were obtained.

87.4 PARTIAL MOLAR VOLUME IN MIXED MEMBRANE SYSTEMS

Let us consider an aqueous vesicle dispersion composed of n_w moles of solvent water and n_i moles of solute i (= 1,2, . . . , c). It is presumed that n_m moles of vesicles are monodispersed in the solution with volume V'. In a manner similar to that used for the micellar systems [15], the thermodynamic quantities of the bilayer membrane can be defined as the surface excess quantities in reference to two

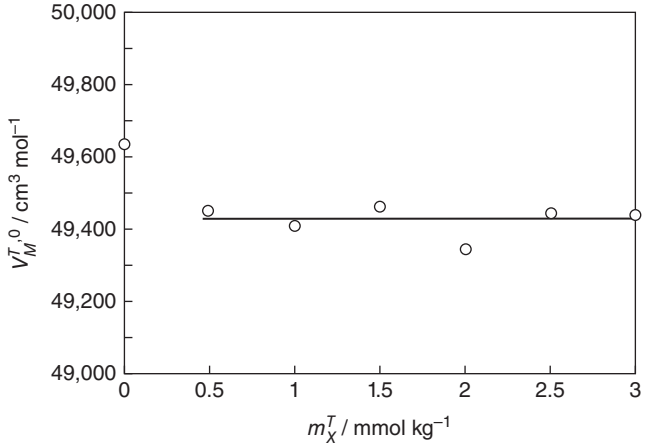

FIGURE 87.8 Partial molar volume of BSA at infinite dilution of BSA versus total molality of C_8OH curve. (Adapted from Yamanaka et al. 2001 [9].)

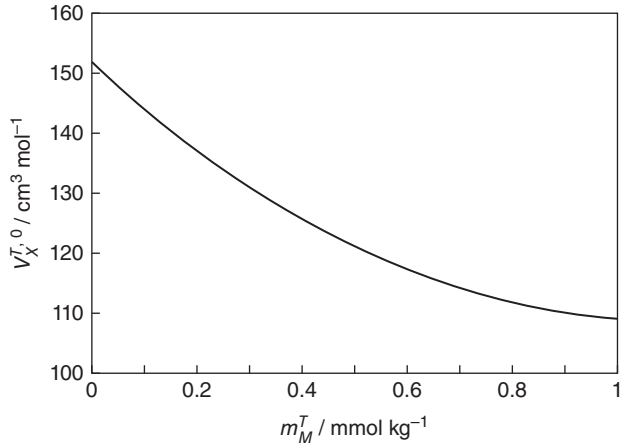

FIGURE 87.9 Partial molar volume of C_8OH at infinite dilution of C_8OH versus total molality of BSA curve. (Adapted from Yamanaka et al. 2001 [9].)

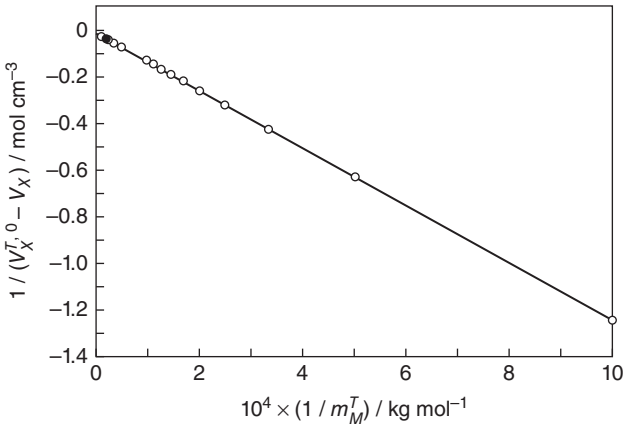

FIGURE 87.10 Reciprocal plot of partial molar volume of C_8OH. (Adapted from Yamanaka et al. 2001 [9].)

curved dividing surfaces at each side of the bilayer membrane. The locations of the dividing surfaces are determined so as to make the surface excess moles of water zero:

$$n_{\mathrm{w}} - c_{\mathrm{w}}^{\mathrm{W,I}} V'^{\mathrm{W,I}} - c_{\mathrm{w}}^{\mathrm{W,O}} V'^{\mathrm{W,O}} = 0 \tag{87.33}$$

Here, $c_{\mathrm{w}}^{\mathrm{W,I}}$ and $c_{\mathrm{w}}^{\mathrm{W,O}}$ are the number of moles of water per unit volume at positions far from the membrane surfaces in the interior and exterior bulk solutions of vesicle particles, respectively, whose volumes are denoted by $V'^{\mathrm{W,I}}$ and $V'^{\mathrm{W,O}}$. (See Fig. 87.11.)

The number of molecules of solute i per mole of vesicle is defined by

$$N_i^{\mathrm{M}} = \frac{n_i - c_i^{\mathrm{W,I}} V'^{\mathrm{W,I}} - c_i^{\mathrm{W,O}} V'^{\mathrm{W,O}}}{n_{\mathrm{m}}} \tag{87.34}$$

where $c_i^{\mathrm{W,I}}$ and $c_i^{\mathrm{W,O}}$ are the number of moles of solute i per unit volume in the interior and exterior bulk solutions, respectively, of the vesicle particles. Similarly, the molar thermodynamic quantity y^{M} of the membrane is defined by

$$y^{\mathrm{M}} = \frac{Y' - c_y^{\mathrm{W,I}} V'^{\mathrm{W,I}} - c_y^{\mathrm{W,O}} V'^{\mathrm{W,O}}}{n_{\mathrm{m}}} \tag{87.35}$$

where Y' is the thermodynamic quantity of the whole solution and $c_y^{\mathrm{W,I}}$ and $c_y^{\mathrm{W,O}}$ the thermodynamic quantity per unit volume in the interior and exterior bulk solutions, respectively. Since $c_v^{\mathrm{W,I}} = c_v^{\mathrm{W,O}} = 1$, the molar volume of the membrane is written in the following form:

$$v^{\mathrm{M}} = \frac{V' - V'^{\mathrm{W,I}} - V'^{\mathrm{W,O}}}{n_{\mathrm{m}}} \tag{87.36}$$

Since it is appropriate to use the molality as a concentration variable in the investigation of the volume properties in solution, let us now consider the solution per 1 kg of water. The molality of solute i in the whole solution and those in the bulk solutions are given by

$$m_i = \frac{n_i}{n_{\mathrm{w}} M_{\mathrm{w}}} \tag{87.37}$$

$$m_i^{\mathrm{W,I}} = \frac{c_i^{\mathrm{W,I}} V'^{\mathrm{W,I}}}{c_{\mathrm{w}}^{\mathrm{W,I}} V'^{\mathrm{W,I}} M_{\mathrm{w}}} \tag{87.38}$$

$$m_i^{\mathrm{W,O}} = \frac{c_i^{\mathrm{W,O}} V'^{\mathrm{W,O}}}{c_{\mathrm{w}}^{\mathrm{W,O}} V'^{\mathrm{W,O}} M_{\mathrm{w}}}, \tag{87.39}$$

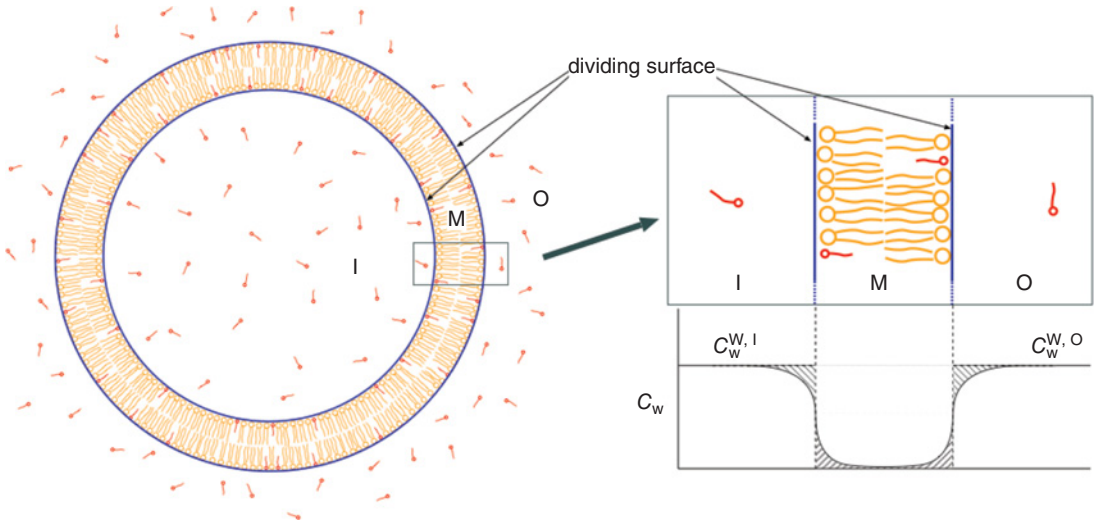

FIGURE 87.11 Schematic illustration of the relation between the variation in the concentration of water and the locations of the dividing surfaces.

respectively, where M_{w} is the molar mass of water. Using these equations, we can rewrite Eq. (87.34) as

$$N_i^{\mathrm{M}} = \frac{m_i - m_i^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} - m_i^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}}}{m_{\mathrm{m}}} \tag{87.40}$$

where $\alpha_{\mathrm{w}}^{\mathrm{W,I}}$ and $\alpha_{\mathrm{w}}^{\mathrm{W,O}}$ are the fractions of the number of moles of water in the interior and exterior solutions, respectively, to the total moles of water of the whole solution defined by

$$\alpha_{\mathrm{w}}^{\mathrm{W,I}} = \frac{c_{\mathrm{w}}^{\mathrm{W,I}} V'^{\mathrm{W,I}}}{n_{\mathrm{w}}} = \frac{c_{\mathrm{w}}^{\mathrm{W,I}} V'^{\mathrm{W,I}}}{c_{\mathrm{w}}^{\mathrm{W,I}} V'^{\mathrm{W,I}} + c_{\mathrm{w}}^{\mathrm{W,O}} V'^{\mathrm{W,O}}} \tag{87.41}$$

$$\alpha_{\mathrm{w}}^{\mathrm{W,O}} = \frac{c_{\mathrm{w}}^{\mathrm{W,O}} V'^{\mathrm{W,O}}}{n_{\mathrm{w}}} = \frac{c_{\mathrm{w}}^{\mathrm{W,O}} V'^{\mathrm{W,O}}}{c_{\mathrm{w}}^{\mathrm{W,I}} V'^{\mathrm{W,I}} + c_{\mathrm{w}}^{\mathrm{W,O}} V'^{\mathrm{W,O}}} \tag{87.42}$$

Similarly to Eqs. (87.37)–(87.39), the volumes per 1 kg of water of the whole solution and of the interior and exterior solutions are given by

$$V = \frac{V'}{n_{\mathrm{w}} M_{\mathrm{w}}} \tag{87.43}$$

$$V^{\mathrm{W,I}} = \frac{V'^{\mathrm{W,I}}}{c_{\mathrm{w}}^{\mathrm{W,I}} V'^{\mathrm{W,I}} M_{\mathrm{w}}} \tag{87.44}$$

$$V^{\mathrm{W,O}} = \frac{V'^{\mathrm{W,O}}}{c_{\mathrm{w}}^{\mathrm{W,O}} V'^{\mathrm{W,O}} M_{\mathrm{w}}} \tag{87.45}$$

respectively. Using Eqs. (87.41)–(87.45), and rearranging Eq. (87.36), we can redefine the molar volume of membrane v^{M} by

$$v^{\mathrm{M}} = \frac{V - V^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} - V^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}}}{m_{\mathrm{m}}} \tag{87.46}$$

Assuming that the vesicle membrane is a solution of film components, we can write

$$v^{\mathrm{M}} = \sum_{l=1}^{\mathrm{c}} v_l^{\mathrm{M}} N_l^{\mathrm{M}} \tag{87.47}$$

$$\mathrm{d}v^{\mathrm{M}} = \sum_{l=1}^{\mathrm{c}} v_l^{\mathrm{M}} \mathrm{d}N_l^{\mathrm{M}} \tag{87.48}$$

where v_l^{M} is PMV of solute l in the vesicle membrane. Using Eq. (87.40), we obtain

$$v^{\mathrm{M}} m_{\mathrm{m}} = \sum_{l=1}^{c} v_l^{\mathrm{M}} \left[m_l - \left(m_l^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + m_l^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right) \right] \tag{87.49}$$

$$\mathrm{d}\left(v^{M} m_{\mathrm{m}}\right) = \sum_{l=1}^{c} v_l^{\mathrm{M}} \mathrm{d}\left[m_l - \left(m_l^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + m_l^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right) \right] \tag{87.50}$$

Rearranging Eq. (87.46) and substituting Eq. (87.49), we obtain the equation for the volume of the whole solution per 1 kg of water in the following form:

$$V = V^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + V^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} + \sum_{l=1}^{c} v_l^{\mathrm{M}} \left[m_l - \left(m_l^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + m_l^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right) \right]. \tag{87.51}$$

Since, because the number of degree of freedom for the whole solution is $c + 2$, the volume V of the whole solution is a function of T, p, and the preparation molalities of solutes, m_1, m_2, …, and m_c, the total differential of V at constant temperature T and pressure p is given by

$$\begin{aligned} \mathrm{d}V &= \mathrm{d}\left(V^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + V^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right) + \mathrm{d}\left(v^{\mathrm{M}} m_{\mathrm{m}} \right) \\ &= \sum_{i=1}^{c} \left\{ \left[\frac{\partial \left(V^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + V^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right)}{\partial m_i} \right]_{T,p,m_{j\neq i}} + v_i^{\mathrm{M}} \right. \\ &\quad \left. - \sum_{l=1}^{c} v_l^{\mathrm{M}} \left[\frac{\partial \left(m_l^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + m_l^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right)}{\partial m_i} \right]_{T,p,m_{j\neq i}} \right\} \mathrm{d}m_i \end{aligned} \tag{87.52}$$

Thus, the PMV of solute i measured experimentally using the preparation molality is given by

$$\begin{aligned} V_i &= \left(\frac{\partial V}{\partial m_i} \right)_{T,p,m_{j\neq i}} \\ &= \left[\frac{\partial \left(V^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + V^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right)}{\partial m_i} \right]_{T,p,m_{j\neq i}} + v_i^{\mathrm{M}} \\ &\quad - \sum_{l=1}^{c} v_l^{\mathrm{M}} \left[\frac{\partial \left(m_l^{\mathrm{W,I}}\alpha_{\mathrm{w}}^{\mathrm{W,I}} + m_l^{\mathrm{W,O}}\alpha_{\mathrm{w}}^{\mathrm{W,O}} \right)}{\partial m_i} \right]_{T,p,m_{j\neq i}} \end{aligned} \tag{87.53}$$

When the interior bulk solution of vesicles has the same composition as the exterior bulk solution, Eqs. (87.51) and (87.52) are rewritten as follows:

$$V = V^{\mathrm{W}} + v^{\mathrm{M}} m_{\mathrm{m}} = \frac{v_{\mathrm{w}}^{\mathrm{W}}}{M_{\mathrm{w}}} + \sum_{i=1}^{c} v_i^{\mathrm{W}} m_i^{\mathrm{W}} + v^{\mathrm{M}} m_{\mathrm{m}} \quad (87.54)$$

The total differential of V at constantan T and p is written in the following form:

$$\begin{aligned} \mathrm{d}V &= \mathrm{d}V^{\mathrm{W}} + \mathrm{d}\left(v^{\mathrm{M}} m_{\mathrm{m}}\right) \\ &= \sum_{i=1}^{c} \left\{ \left(\frac{\partial V^{\mathrm{W}}}{\partial m_i} \right)_{T,p,m_{j\neq i}} + v_i^{\mathrm{M}} - \sum_{l=1}^{c} v_l^{\mathrm{M}} \left(\frac{\partial m_l^{\mathrm{W}}}{\partial m_i} \right)_{T,p,m_{j\neq i}} \right\} \mathrm{d}m_i \end{aligned} \quad (87.55)$$

Therefore, PMV of solute i with respect to the preparation molality, is given by

$$\begin{aligned} V_i = \left(\frac{\partial V}{\partial m_i} \right)_{T,p,m_{j\neq i}} &= \sum_{k=1}^{c} v_k^{\mathrm{W}} \left(\frac{\partial m_k^{\mathrm{W}}}{\partial m_i} \right)_{T,p,m_{j\neq i}} \\ &+ v_i^{\mathrm{M}} - \sum_{l=1}^{c} v_l^{\mathrm{M}} \left(\frac{\partial m_l^{\mathrm{W}}}{\partial m_i} \right)_{T,p,m_{j\neq i}} \end{aligned} \quad (87.56)$$

where the total differential of the volume of the bulk solutions at constant T and p, as

$$\mathrm{d}V^{\mathrm{W}} = \sum_{k=1}^{c} v_k^{\mathrm{W}} \mathrm{d}m_k^{\mathrm{W}} \quad (87.57)$$

has been used. In Sections 87.4.1 and 87.4.2, we will consider application of the above equations to some mixed solute systems whose interior and exterior bulk solution vesicle compositions are the same.

87.4.1 Binary Mixtures of Water-Insoluble Lipids

In this section, we consider binary mixtures of water-insoluble lipids. Since the number of degree of freedom of the system is 4, we can choose two concentration variables other than temperature and pressure as the experimental variables. From the practical point of view on preparing vesicle solutions, it is convenient to adopt the combination of the molality m_{t} of total solutes in the whole solution given by

$$m_{\mathrm{t}} = m_1 + m_2 \quad (87.58)$$

and the mole fraction of solute 2 in the total solutes defined by

$$X_2 = \frac{m_2}{m_{\mathrm{t}}} \quad (87.59)$$

Since both lipids are water-insoluble, the number of molecules of solute $i(= 1, 2)$ per mole of vesicle given by Eq. (87.40) is written in the following form:

$$N_i^{\mathrm{M}} = \frac{m_i}{m_{\mathrm{m}}} \quad (87.60)$$

Thus, the total number of lipids and the mole fraction of solute 2 in the vesicle membrane are given by

$$N_{\mathrm{t}}^{\mathrm{M}} = N_1^{\mathrm{M}} + N_2^{\mathrm{M}} = \frac{m_t}{m_{\mathrm{m}}} \quad (87.61)$$

$$X_2^{\mathrm{M}} = \frac{N_2^{\mathrm{M}}}{N_{\mathrm{t}}^{\mathrm{M}}} = X_2 \quad (87.62)$$

respectively.

From Eq. (87.55), the total differential of V at constant T and p is given by

$$\mathrm{d}V = v_1^{\mathrm{M}} \mathrm{d}m_1 + v_2^{\mathrm{M}} \mathrm{d}m_2 \quad (87.63)$$

Changing the concentration variables from m_1 and m_2 to m_{t} and X_2 using Eqs. (87.58) and (87.59), Eq. (87.63) becomes

$$\mathrm{d}V = \frac{v^{\mathrm{M}}}{N_{\mathrm{t}}^{\mathrm{M}}} \mathrm{d}m_{\mathrm{t}} + m_{\mathrm{t}} \left(v_2^{\mathrm{M}} - v_1^{\mathrm{M}} \right) \mathrm{d}X_2 \quad (87.64)$$

Then, we have

$$\left(\frac{\partial V}{\partial m_{\mathrm{t}}} \right)_{T,p,X_2} = \frac{v^{\mathrm{M}}}{N_{\mathrm{t}}^{\mathrm{M}}} = v_1^{\mathrm{M}} X_1^{\mathrm{M}} + v_2^{\mathrm{M}} X_2^{\mathrm{M}} = v_1^{\mathrm{M}} X_1 + v_2^{\mathrm{M}} X_2 \quad (87.65)$$

$$\left(\frac{\partial V}{\partial X_2} \right)_{T,p,m_{\mathrm{t}}} = m_{\mathrm{t}} \left(v_2^{\mathrm{M}} - v_1^{\mathrm{M}} \right) \quad (87.66)$$

The LHSs of Eqs. (87.65) and (87.66) are obtained experimentally from the V vs. m_{t} curve at constant X_2 and the V vs. X_2 curve at constant m_{t}, respectively. By setting up these equations simultaneously, we can estimate the values of v_1^{M} and v_2^{M}, which provide information about the volume behavior and packing of the vesicle membranes.

The volume of mixing in the vesicle membrane is defined by

$$\Delta_{\mathrm{mix}} v = \frac{v^{\mathrm{M}}}{N_{\mathrm{t}}^{\mathrm{M}}} - \left(v_1^{\mathrm{M},0} X_1 + v_2^{\mathrm{M},0} X_2 \right) \quad (87.67)$$

where $v_i^{M,0}$ $(i = 1, 2)$ is the molar volume of vesicle membrane composed of solute i alone. Applying Eq. (87.67) to the v^M/N_t^M vs. X_2 curve for the mixtures of film-forming lipids, the miscibility and interaction between the lipids in the vesicle membrane can be examined. On the other hand, for mixtures of lipids, one of which, say, solute 2 cannot form vesicles alone like cholesterol [16, 17], Eq. (87.67), which is symmetric for solutes 1 and 2, is not appropriate. It is necessary, for example, to assume that $v_2^{M,0}$ in Eq. (87.67) is approximated by the molar volume of solute 2 in its crystalline state.

87.4.2 Binary Mixtures of a Water-Insoluble Lipid and a Water-Soluble Substance

In this section, we consider the binary mixtures of a water-insoluble lipid (solute 1) and a water-soluble substance (solute 2). Taking $m_1^W \cong 0$ into account, and then applying Eq. (87.56) to the present mixtures, we obtain expressions for PMVs of solute 1 and 2 as

$$V_1 = \left(\frac{\partial V}{\partial m_1}\right)_{T,p,m_2} = v_2^W \left(\frac{\partial m_2^W}{\partial m_1}\right)_{T,p,m_2} + v_1^M - v_2^M \left(\frac{\partial m_2^W}{\partial m_1}\right)_{T,p,m_2} \tag{87.68}$$

$$V_2 = \left(\frac{\partial V}{\partial m_2}\right)_{T,p,m_1} = v_2^W \left(\frac{\partial m_2^W}{\partial m_2}\right)_{T,p,m_1} + v_2^M - v_2^M \left(\frac{\partial m_2^W}{\partial m_2}\right)_{T,p,m_1} \tag{87.69}$$

respectively. Since we can write

$$m_2^W = m_2 - \frac{N_2^M}{N_1^M} m_1 \tag{87.70}$$

using Eq. (87.40), the partial derivatives of m_2^W with respect to m_1 and m_2 are given by

$$\left(\frac{\partial m_2^W}{\partial m_1}\right)_{T,p,m_2} = -\frac{N_2^M}{N_1^M} - m_1 \left[\frac{\partial \left(N_2^M/N_1^M\right)}{\partial m_1}\right]_{T,p,m_2} \tag{87.71}$$

$$\left(\frac{\partial m_2^W}{\partial m_2}\right)_{T,p,m_1} = 1 - m_1 \left[\frac{\partial \left(N_2^M/N_1^M\right)}{\partial m_2}\right]_{T,p,m_1} \tag{87.72}$$

respectively. Substituting Eqs. (87.71) and (87.72) into Eqs. (87.68) and (87.69), respectively, we have

$$V_1 = v_1^M + \left(v_2^M - v_2^W\right) \frac{N_2^M}{N_1^M} + \left(v_2^M - v_2^W\right) m_1 \left[\frac{\partial \left(N_2^M/N_1^M\right)}{\partial m_1}\right]_{T,p,m_2} \tag{87.73}$$

$$V_2 = v_2^W + \left(v_2^M - v_2^W\right) m_1 \left[\frac{\partial \left(N_2^M/N_1^M\right)}{\partial m_2}\right]_{T,p,m_1} \tag{87.74}$$

The value of V_1 can be obtained experimentally from the V vs. m_1 curve at constant m_2 and that of V_2 from the V vs. m_2 curve at constant m_1.

In order to estimate the partial derivatives of N_2^M/N_1^M on the RHSs of Eqs. (87.73) and (87.74), it is necessary to consider the partition equilibrium of water-soluble solute 2 between the membrane phase and the bulk solution using the chemical potentials of solute 2 in the bulk solution and in the bilayer membrane. Assuming that the bulk solution is an ideal-dilute solution of solute 2 in water, we can write the chemical potential of solute 2 in the bulk solution as

$$\mu_2^W = \mu_2^{W,\ominus} + RT \ln m_2^W \tag{87.75}$$

where $\mu_2^{W,\ominus}$ is the standard chemical potential of solute 2 in the bulk solution. Similarly, assuming that the membrane is an ideal-dilute solution of solute 2 in solute 1, we have the chemical potential of solute 2 in the membrane in the form

$$\mu_2^M = \mu_2^{M,\ominus} + RT \ln X_2^M \tag{87.76}$$

where $\mu_2^{M,\ominus}$ is the standard chemical potential of solute 2 in the membrane, X_2^M the mole fraction of amphiphile in the membrane defined by

$$X_2^M = \frac{N_2^M}{N_1^M + N_2^M}. \tag{87.77}$$

The equilibrium constant for the partition of solute 2 between the membrane and the bulk solution is defined by

$$P_{M/W} \equiv \exp\left(-\frac{\mu_2^{M,\ominus} - \mu_2^{W,\ominus}}{RT}\right) = \frac{X_2^M}{m_2^W}. \tag{87.78}$$

and is referred to as the partition coefficient. Accounting for the fact that the number of film-forming lipid molecules in a vesicle is generally very large [18–20] and that solute 2 is very dilute in the membrane, we may replace m_2^W by m_2 and

X_2^{M} by $N_2^{\mathrm{M}}/N_1^{\mathrm{M}}$. Thus, we have the partition coefficient in the form

$$P_{\mathrm{M/W}} = \frac{N_2^{\mathrm{M}}}{m_2 N_1^{\mathrm{M}}} \tag{87.79}$$

which provides the partial derivatives of $N_2^{\mathrm{M}}/N_1^{\mathrm{M}}$ with respect to the preparation molalities of solutes 1 and 2

$$\left[\frac{\partial\left(N_2^{\mathrm{M}}/N_1^{\mathrm{M}}\right)}{\partial m_1}\right]_{T,p,m_2} = 0 \tag{87.80}$$

$$\left[\frac{\partial\left(N_2^{\mathrm{M}}/N_1^{\mathrm{M}}\right)}{\partial m_2}\right]_{T,p,m_1} = P_{\mathrm{M/W}} \tag{87.81}$$

respectively. Substituting Eqs. (87.79)–(87.81) into Eqs. (87.73) and (87.74), we obtain

$$V_1 = v_1^{\mathrm{M}} + \left(v_2^{\mathrm{M}} - v_2^{\mathrm{W}}\right) P_{\mathrm{M/W}} m_2 \tag{87.82}$$

$$V_2 = v_2^{\mathrm{W}} + \left(v_2^{\mathrm{M}} - v_2^{\mathrm{W}}\right) P_{\mathrm{M/W}} m_1 \tag{87.83}$$

respectively. These equations say that the experimental values of PMVs of solutes 1 and 2 with respect to their preparation molalities include the volume change of the transfer of solute 2 from the bulk solution to the membrane.

At low concentrations of solute 2, it may be reasonable to use the molar volume of vesicle membrane composed of solute 1 alone, $v_1^{\mathrm{M},0}$, instead of v_1^{M} , and to introduce the apparent molar volume of solute 2 in the membrane, ϕ_2^{M}, defined by

$$v^{\mathrm{M}} = v_1^{\mathrm{M}} N_1^{\mathrm{M}} + v_2^{\mathrm{M}} N_2^{\mathrm{M}} = v_1^{\mathrm{M},0} N_1^{\mathrm{M}} + \phi_2^{\mathrm{M}} N_2^{\mathrm{M}} \tag{87.84}$$

Further, assuming that v_2^{W} can be replaced by PMV of solute 2 in the solution free from solute 1, $v_2^{\mathrm{W},0}$, we obtain

$$V_1 = v_1^{\mathrm{M},0} + \left(\phi_2^{\mathrm{M}} - v_2^{\mathrm{W},0}\right) P_{\mathrm{M/W}} m_2 \tag{87.85}$$

$$V_2 = v_2^{\mathrm{W},0} + \left(\phi_2^{\mathrm{M}} - v_2^{\mathrm{W},0}\right) P_{\mathrm{M/W}} m_1 \tag{87.86}$$

which are useful for examining the effect of the addition of solute 2 on the molar volume of the vesicle membrane. It is notable that Eq. (87.85) resembles Eq. (87.19) for the protein–ligand binding. Moreover, assuming that ϕ_2^{M} is independent of m_2 in the dilute concentration region, we have

$$\left(\frac{\partial V_1}{\partial m_2}\right)_{T,p,m_1} = \left(\frac{\partial V_2}{\partial m_1}\right)_{T,p,m_2} = \left(\phi_2^{\mathrm{M}} - v_2^{\mathrm{W},0}\right) P_{\mathrm{M/W}} \tag{87.87}$$

which is similar to Maxwell's equations.

TABLE 87.3 Temperature and Volume of Phase Transitions for Bilayer Membranes [21]

Lipid	Transition	T (K)	ΔV ($\mathrm{cm^3\,mol^{-1}}$)
DPPC	$P'_\beta \rightarrow L_\alpha$	315.2	25.4
	$L'_\beta \rightarrow P'_\beta$	307.5	1.9
DMPC	$P'_\beta \rightarrow L_\alpha$	297.1	17.6
	$L'_\beta \rightarrow P'_\beta$	287.1	1.8

Now, let us demonstrate the application of the present treatment to practical systems. In order to do this, we adopted two systems of zwitterionic phospholipids (component 1), 1,2-dipalmitoyl-*sn*-gylycero-3-phosphocholine (DPPC), and 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC), with octanol (C_8OH, nonionic water-soluble component 2). DPPC and DMPC are purchased from Sigma (St. Louis, MO) and C_8OH, 99+ %, anhydrous, from Aldrich (Milwaukee, WI). They were used after further purification. Distilled water was used as solvent. The bilayer membranes of phospholipids exhibit different phases, such as the lamellar gel (L'_β), the liquid crystal (L_α), and the ripple gel (P'_β), depending on the environmental variables such as temperature, pressure, and concentrations of the solutes coexisting with the membranes. In Table 87.3, the temperatures and the volume changes of the phase transitions are listed for DPPC and DMPC [21]. Since the molecular packing of phospholipid is different among these phases, effects of the addition of water-soluble solutes on the volume behavior of the membrane in each phase state may be different.

Densities ρ of aqueous vesicle dispersions were measured as functions of the preparation molality of phospholipid m_1 at constant C_8OH molality m_2 at 303.15 ± 0.02 K under atmospheric pressure using a vibrating-tube density meter (DMA 60/608, Anton Paar, Austria). The experimental error in the density was within $\pm 0.002\,\mathrm{kg\,m^{-3}}$. At 303.15 K, the membrane of DPPC is in the lamellar gel (L'_β) state and that of DMPC in the liquid crystal (L_α) state. The values of solution volume V were calculated from the solution densities using

$$V = \frac{1 + M_1 m_1 + M_2 m_2}{\rho} \tag{87.88}$$

where M_1 and M_2 are molar masses of phospholipid and C_8OH, respectively. In Fig. 87.12a,b, the V vs. m_1 plots are shown for the DPPC and DMPC systems, respectively. All of the curves are linear, which indicates that PMVs of phospholipids are independent of their concentrations.

The values of PMVs V_1 of DPPC and DMPC, estimated by applying $V_1 = (\partial V/\partial m_1)_{T,p,m_2}$ to the V / m_1 curves in Fig. 87.12, are plotted against m_2 in Fig. 87.13. The values of $v_1^{\mathrm{M},0}$ for DPPC and DMPC, given by the V_1 values at $m_2 = 0\,\mathrm{mmol\,kg^{-1}}$, are listed in Table 87.4. It is found that

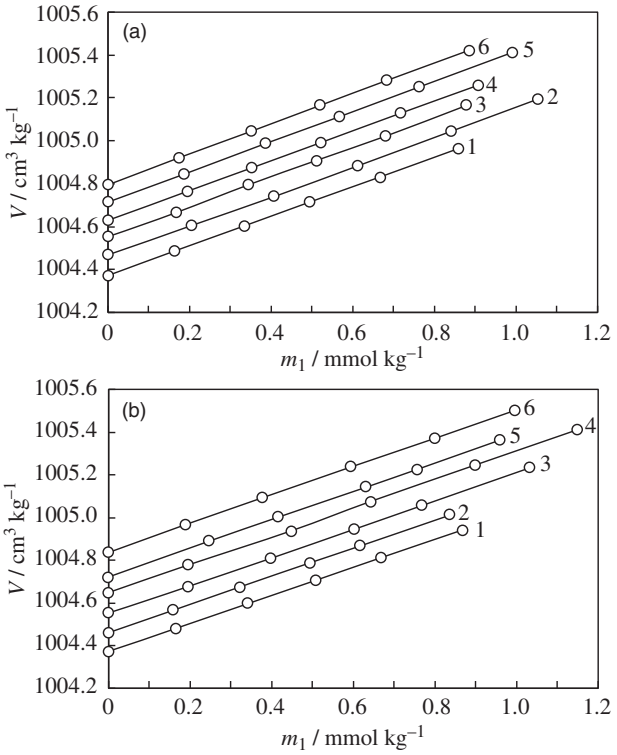

FIGURE 87.12 Solution volume versus phospholipid molality curves for phospholipid-C_8OH systems at 303.15 K: (a) DPPC, m_2/mmol kg^{-1} = (1) 0, (2) 0.548, (3) 1.115, (4) 1.604, (5) 2.184, (6) 2.731; (b) DMPC, m_2/mmol kg^{-1} = (1) 0, (2) 0.561, (3) 1.150, (4) 1.791, (5) 2.330, (6) 2.954.

TABLE 87.4 Volume Parameters of Membrane Systems at 303.15 K

	$v_1^{M,0}$ (cm^3 mol^{-1})	$v_2^{W,0}$ (cm^3 mol^{-1})	$(\partial V_1/\partial m_2)_{T,p,m_1}$ (cm^3 kg mol^{-2})	$(\partial V_2/\partial m_1)_{T,p,m_2}$ (cm^3 kg mol^{-2})
DPPC	688		7509	7507
DMPC	659		3411	3429
C_8OH		155		

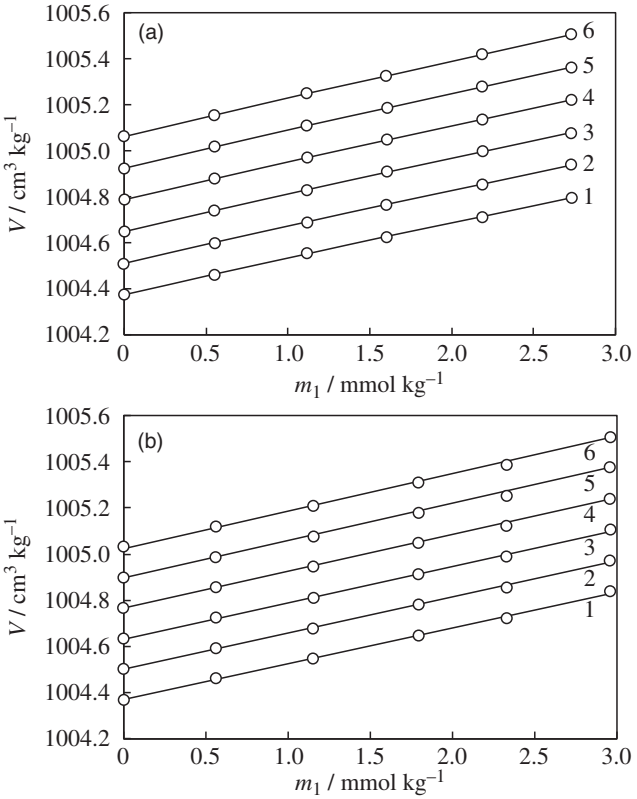

FIGURE 87.14 Solution volume versus phospholipid molality curves for phospholipid-C_8OH systems at 303.15 K: (a) DPPC, m_1/mmol kg^{-1} = (1) 0, (2) 0.2, (3) 0.4, (4) 0.6, (5) 0.8, (6) 1.0; (b) DMPC, m_1/mmol kg^{-1} = (1) 0, (2) 0.2, (3) 0.4, (4) 0.6, (5) 0.8, (6) 1.0.

the values of V_1 of DPPC and DMPC increase linearly with increasing C_8OH molality. The values of the slope of the curve, $(\partial V_1/\partial m_2)_{T,p,m_1}$, are listed in Table 87.4. The value for DPPC is found to be more than twice as large as that for DMPC.

In order to obtain the values of PMV of C_8OH V_2, the values of solution volume V taken from the V vs. m_1 curves in Fig. 87.13 at constant m_2, were plotted against m_2 in Fig. 87.14. The values of V are found to increase linearly with increasing m_2. Applying $V_2 = (\partial V/\partial m_2)_{T,p,m_1}$ to the curves, we determined the values of V_2, plotted against m_1 in Fig. 87.15. The value of $v_2^{W,0}$ of C_8OH in its solution free from phospholipid, given by the V_2 value at $m_1 = 0$ mmol kg^{-1}, is added in Table 87.4. It is observed that the value of V_2 increases linearly with increasing m_1 from the $v_2^{W,0}$ value. The slope of the curve, $(\partial V_2/\partial m_1)_{T,p,m_2}$, listed in Table 87.4, is larger for DPPC than for DMPC. For both DPPC and DMPC, the values of $(\partial V_2/\partial m_1)_{T,p,m_2}$ are in excellent agreement with those of $(\partial V_1/\partial m_2)_{T,p,m_1}$. This fact confirms the validity of Eq. (87.87). Quantitative examination of the value of $(\phi_2^M - v_2^{W,0})P_{M/W}$ requires the

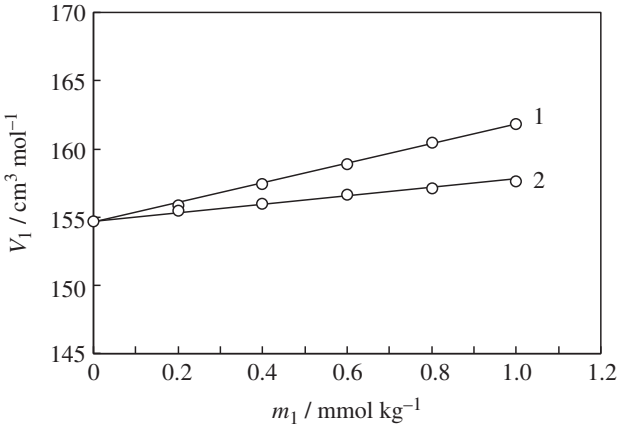

FIGURE 87.15 Partial molar volume of C_8OH versus phospholipid molality curves at 303.15 K: (1) DPPC, (2) DMPC.

numerical values of $P_{M/W}$, which is defined by Eq. (87.78), for the partition of C_8OH between its bulk solution and the bilayer membranes of DMPC and DPPC. The positive value of $(\phi_2^M - v_2^{W,0})P_{M/W}$ indicates that ϕ_2^M is larger than $v_2^{W,0}$ because $P_{M/W}$ assumes a positive value [22–24]. This fact suggests that the packing of the bilayer membranes is loosened by the incorporation of C_8OH molecules. A similar observation was found for the effect of hexanol on the molecular area of adsorbed film of 1,2-dihexanoyl-*sn*-gylycero-3-phosphocholine (DHPC) [25].

VAN DER WAALS INTERACTION BETWEEN COLLOIDAL PARTICLES

HIROYUKI OHSHIMA

Faculty of Pharmaceutical Sciences, Tokyo University of Science, 2641 Yamazaki Noda, Chiba 278-8510, Japan

88.1 INTRODUCTION

The behaviors of colloidal dispersions are determined by the balance of the van der Waals attraction and the electrostatic repulsion acting between particles [1–9]. In this chapter we discuss the van der Waals interaction between colloidal particles. When two molecules are approaching each other, the van der Waals attractive intermolecular forces are acting as a result of interactions between the fluctuating dipoles. A most remarkable characteristic of the van der Waals interaction is that the additivity of interactions approximately holds. The interaction energy between two particles in a vacuum may thus be calculated approximately by a summation (or by an integration) of the interaction energies for all molecular pairs formed by two molecules belonging to different particles [10, 11]. As a result, although the van der Waals interaction energy between two single molecules is small, the interaction energy between two particles consisting of many molecules can be large. In this chapter we start with the van der Waals interaction between two molecules and then we derive analytic expressions for the van der Waals interaction energy between two approaching particles of various geometries.

88.2 VAN DER WAALS INTERACTION BETWEEN TWO MOLECULES

The potential energy $u(r)$ of the van der Waals forces between two similar molecules at separation r between their centers in a vacuum is given by

$$u(r) = -\frac{C}{r^6} \tag{88.1}$$

with

$$C = \frac{3\alpha^2 h\nu}{4(4\pi\varepsilon_0)^2} \tag{88.2}$$

where C is called the *London–van der Waals constant*; α and ν are, respectively, the electronic polarizability and the characteristic frequency of the molecule; and h is the Planck constant. Thus $h\nu$ corresponds to the ionization energy of the molecule. Equation (88.1) holds when the intermolecular distance is shorter than the characteristic wavelength $2\pi/\nu$. At large distances $u(r)$ becomes proportional to $1/r^7$ instead of $1/r^6$ (retardation effect).

For two interacting dissimilar molecules 1 and 2, $u(r)$ is given by

$$u(r) = -\frac{C_{12}}{r^6} \tag{88.3}$$

with

$$C_{12} = \frac{3\alpha_1\alpha_2 h}{2(4\pi\varepsilon_0)^2}\left(\frac{\nu_1\nu_2}{\nu_1+\nu_2}\right) \tag{88.4}$$

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.
© 2016 John Wiley & Sons, Inc. Published 2016 by John Wiley & Sons, Inc.

where α_i and ν_i are, respectively, the electronic polarizability and the characteristic frequency of molecule i ($i = 1,2$). To a good approximation, Eq. (88.4) may be replaced by

$$C_{12} \approx \frac{3\alpha_1\alpha_2 h\sqrt{\nu_1}\sqrt{\nu_2}}{4(4\pi\varepsilon_0)^2} = \sqrt{C_1}\sqrt{C_2} \tag{88.5}$$

with

$$C_1 = \frac{3\alpha_1^2 h\nu_1}{4(4\pi\varepsilon_0)^2},\ C_2 = \frac{3\alpha_2^2 h\nu_2}{4(4\pi\varepsilon_)^2} \tag{88.6}$$

88.3 VAN DER WAALS INTERACTION BETWEEN TWO COLLOIDAL PARTICLES

Since the additivity of the van der Waals interactions holds well, the interaction energy between two particles in a vacuum may thus be calculated approximately by a summation (or by an integration) of the interaction energies for all molecular pairs formed by two molecules belonging to different particles (Fig. 88.1).

In other words, the interaction energy V between two particles 1 and 2, containing N_1 and N_2 molecules per unit volume, respectively, can be obtained by integration of the interaction energy u between two volume elements dV_1 and dV_2 at separation r, containing $N_1 dV_1$ and $N_2 dV_2$ molecules, respectively, over the volumes V_1 and V_2 of particles 1 and 2:

$$V = \int_{V_1}\int_{V_2} u(r)N_1N_2 dV_1 dV_2 \tag{88.7}$$

As a result, although the van der Waals interaction energy between two single molecules is small, the interaction energy between two particles consisting of many molecules can be large.

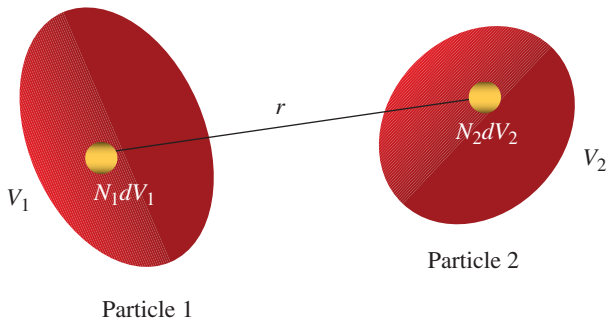

FIGURE 88.1 Integration of the interaction energy between two volume elements dV_1 and dV_2, containing N_1dV_1 and N_2dV_2 molecules, respectively, over the volumes V_1 and V_2 of particles 1 and 2.

88.4 VARIOUS GEOMETRIES

It is not always possible to calculate the van der Waals interaction energy on the basis of Eq. (88.7). In such cases, with the help of Derjaguin's approximation, one can calculate the interaction energy between two spheres or two cylinders of radii a_1 and a_2 at separation H between the closest distance between their surfaces by integrating the interaction energy between the corresponding two parallel plates [12–14]. This approximation holds good at small separations as compared with the particle size. It should also be mentioned that Derjaguin's approximation can be applied not only to the van der Waals interaction between colloidal particles but also to the electrostatic interaction between colloidal particles at small particle separations. Derjaguin's formulas are given here:

$$V_{sp}(H) = \frac{2\pi a_1 a_2}{a_1 + a_2}\int_H^\infty V_{p1}(h)dh \text{ for two spheres} \tag{88.8}$$

$$V_{cy//}(H) = \sqrt{\frac{2a_1a_2}{a_1+a_2}} \times \int_H^\infty V_{p1}(h)\frac{dh}{\sqrt{h-H}} \text{ for two parallel cylinders} \tag{88.9}$$

$$V_{cy\perp}(H) = 2\pi\sqrt{a_1a_2} \times \int_H^\infty V_{p1}(h)dh \text{ for two crossed cylinders} \tag{88.10}$$

We derive approximate analytic expressions for the van der Waals interaction energy between two particles directly on the basis of Eq. (88.7) or by using Derjaguin's approximation [Eqs. (88.8)–(88.10)] in the following sections.

88.4.1 A Molecule and a Plate

The interaction energy $V(h)$ between a pointlike molecule and an infinitely large plate of thickness d and molecular density N separated by a distance h in a vacuum can be calculated via Eq. (88.7) with the result that

$$V(h) = -\frac{\pi C_{12}N}{6}\left[\frac{1}{h^3} - \frac{1}{(h+d)^3}\right] \tag{88.11}$$

where C_{12} is the London–van der Waals constant for the interaction between the single molecule and a molecule within the sphere. In particular, as $d \to \infty$, Eq. (88.11) becomes

$$V(h) = -\frac{\pi C_{12}N}{6h^3} \tag{88.12}$$

which is the interaction energy between a molecule and an infinitely thick plate.

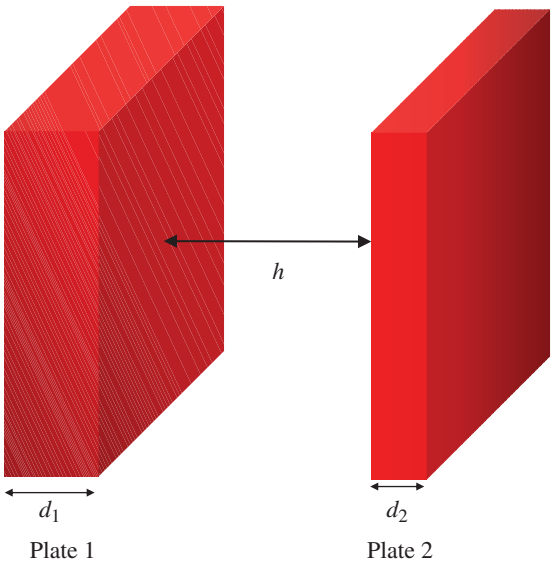

FIGURE 88.2 Two parallel plates of thicknesses d_1 and d_2 separated by a distance h.

88.4.2 Two Parallel Plates

For the interaction energy $V(h)$ per unit area between two parallel similar plates of thickness d separated by distance h between their surfaces in a vacuum (Fig. 88.2), from Eq. (88.7), we have

$$V(h) = -\frac{A}{12\pi}\left[\frac{1}{h^2} - \frac{2}{(h+d)^2} + \frac{1}{(h+2d)^2}\right] \tag{88.13}$$

where

$$A = \pi^2 C N^2 \tag{88.14}$$

is called the *Hamaker constant*.

Note that the Hamaker constant given by Eq. (88.11) can be applied to particles of arbitrary shape (plates, spheres, or cylinders).

Similarly, the interaction energy $V(h)$ between two parallel dissimilar plates 1 and 2 per unit area in a vacuum, which have molecular densities N_1 and N_2, London–van der Waals constants C_1 and C_2, and thicknesses d_1 and d_2, respectively is given by

$$V(h) = -\frac{A_{12}}{12\pi}\left[\frac{1}{h^2} - \frac{1}{(h+d_1)^2} - \frac{1}{(h+d_2)^2} + \frac{1}{(h+d_1+d_2)^2}\right] \tag{88.15}$$

with

$$A_{12} = \sqrt{A_1}\sqrt{A_2} = \pi\sqrt{C_1}\sqrt{C_2}N_1N_2,\ A_1 = \pi^2 C_1 N_1^2,\ A_2 = \pi^2 C_2 N_2^2 \tag{88.16}$$

where A_i is the Hamaker constant for the interaction between similar particles of substance i ($i = 1,2$) and A_{12} is that for dissimilar particles of substances 1 and 2. Equation (88.16) follows from approximate Eq. (88.5).

For small h ($h \ll d_1, d_2$), Eq. (88.15) tends to

$$V(h) = -\frac{A_{12}}{12\pi h^2} \tag{88.17}$$

which is the interaction energy between two infinitely thick plates 1 and 2.

88.4.3 A Molecule and a Sphere

The interaction energy $V(R)$ between a single molecule and a sphere of radius a and molecular density N separated by a distance R between their centers can be calculated via Eq. (88.7) to give

$$V(R) = -\frac{4\pi C_{12} N}{3}\frac{a^3}{(R^2 - a^2)^3} \tag{88.18}$$

where C_{12} is the London–van der Waals constant for the interaction between the single molecule and a molecule within the sphere.

88.4.4 Two Spheres

The interaction energy $V(R)$ between two dissimilar spheres 1 and 2, having radii a_1 and a_2, respectively, separated by a distance R between their centers (Fig. 88.3) can be calculated via Eq. (88.7) to give

$$V(R) = -\frac{A_{12}}{6}\left\{\frac{2a_1a_2}{R^2 - (a_1+a_2)^2} + \frac{2a_1a_2}{R^2 - (a_1-a_2)^2} + \ln\left[\frac{R^2 - (a_1+a_2)^2}{R^2 - (a_1-a_2)^2}\right]\right\} \tag{88.19}$$

where A_{12} is given by Eq. (88.16).

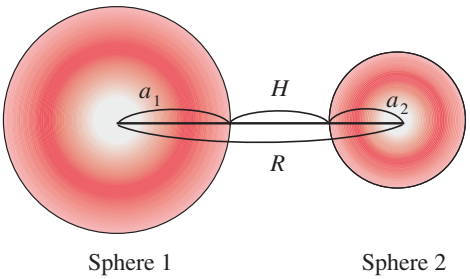

FIGURE 88.3 Two spheres of radii a_1 and a_2 separated by a distance R between their centers.

For the special case of two identical spheres ($a_1 = a_2 = a$, $C_1 = C_2 = C$, and $N_1 = N_2 = N$), Eq. (88.19) becomes

$$V(R) = -\frac{A}{6}\left\{\frac{2a^2}{R^2 - 4a^2} + \frac{2a^2}{R^2} + \ln\left(1 - \frac{4a^2}{R^2}\right)\right\} \quad (88.20)$$

where A is given by Eq. (88.14).

For small H ($H \ll a_1, a_2$), Eq. (88.20) tends to

$$V(H) = -\frac{A_{12}a_1a_2}{6(a_1 + a_2)H} \quad (88.21)$$

with

$$H = R - (a_1 + a_2) \quad (88.22)$$

where H is the closest distance between the surfaces of two spheres 1 and 2. For the special case of two identical spheres, Eq. (88.21) gives

$$V(H) = -\frac{Aa}{12H} \quad (88.23)$$

Equation (88.21) can also be obtained with the help of Derjaguin's approximation, that is, by substituting Eq. (88.17) into Eq. (88.8).

The interaction energy between two dissimilar shells separated by R, having outer radius a and thicknesses d (Fig. 88.4) can be calculated by

$$V(R) = V(a, a, R) - 2V(a, a - d, R) + V(a - d, a - d, R) \quad (88.24)$$

where $V(a_1, a_2, R)$ is given by Eq. (88.19).

88.4.5 A Molecule and a Rod

The interaction energy between a pointlike molecule and an infinitely long thin rod carrying the line density N of molecules along the rod separated by a distance R can be calculated via Eq. (88.7) to give

$$V(R) = -\frac{3\pi NC_{12}}{8R^5} \quad (88.25)$$

where C_{12} is the corresponding London–van der Waals constant for the interaction energy between the single molecule and a molecule within the rod.

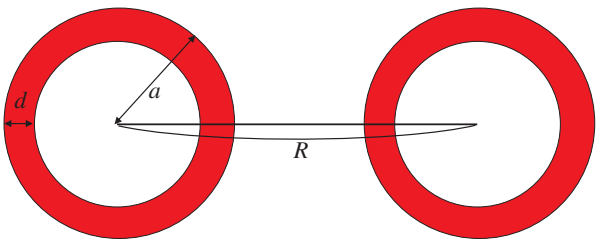

FIGURE 88.4 Interaction between two shells of outer radius a and thickness d separated by a distance R between their centers.

88.4.6 Two Parallel Rods

The interaction energy $V(R)$ per unit length between two dissimilar thin rods 1 and 2, having molecular densities N_1 and N_2, respectively, separated by a distance R between their axes can be calculated via Eq. (88.7) to give

$$V(R) = -\frac{3\pi N_1N_2C_{12}}{8R^5} \quad (88.26)$$

88.4.7 A Molecule and a Cylinder

The interaction energy $V(R)$ between a single molecule and an infinitely long cylinder of radius a and molecular density N separated by a distance R can be calculated via Eq. (88.7) to give [15]

$$V(R) = -\frac{3\pi^2C_{12}Na^2}{8R^5}F\left(\frac{5}{2}, \frac{5}{2}, 2; \left(\frac{a}{R}\right)^2\right) \quad (88.27)$$

with

$$F(\alpha, \beta, \gamma, z) = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\beta)}\sum_{n=0}^{\infty}\frac{\Gamma(\alpha + n)\Gamma(\beta + n)z^n}{\Gamma(\gamma + n)n!} \quad (88.28)$$

where $F(\alpha, \beta, \gamma; x)$ is the *hypergeometric* function and C_{12} is the corresponding London–van der Waals constant.

88.4.8 Two Parallel Cylinders

The interaction energy $V(R)$ per unit length between two parallel dissimilar cylinders 1 and 2, having radii a_1 and a_2, molecular densities N_1 and N_2, respectively, separated by a distance R between their axes (Fig. 88.5), can be calculated via Eq. (88.7) to give [15]

$$V(R) = -\frac{2A_{12}}{3R}\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\frac{\Gamma^2(m + n + 1/2)}{m!n!(m - 1)!(n - 1)!} \times \left(\frac{a_1}{R}\right)^{2m}\left(\frac{a_2}{R}\right)^{2n} \quad (88.29)$$

where A_{12} is given by Eq. (88,16).

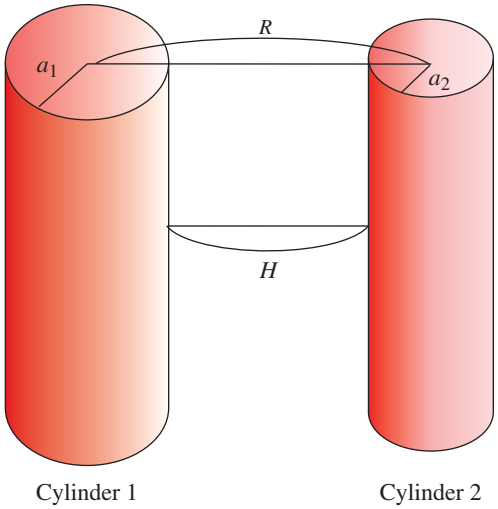

FIGURE 88.5 Two parallel cylinders of radii a_1 and a_2 separated by a distance H.

For the special case of two identical cylinders ($a_1 = a_2 = a$, $C_1 = C_2 = C$, $N_1 = N_2 = N$, and $A_{12} = A$), Eq. (88.29) becomes

$$V(R) = -\frac{2A}{3R}\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\frac{\Gamma^2(m+n+1/2)}{m!n!(m-1)!(n-1)!}\left(\frac{a}{R}\right)^{2(m+n)} \tag{88.30}$$

where A is given by Eq. (88.14).

For small $H = R - (a_1 + a_2)$ ($H \ll a_1$ and a_2), Eq. (88.29) tends to

$$V(H) = -\frac{A_{12}}{12\sqrt{2}H^{3/2}}\left(\frac{a_1 a_2}{a_1 + a_2}\right)^{1/2} \tag{88.31}$$

For the special case of two identical cylinders per unit length, Eq. (88.31) gives

$$V(H) = -\frac{A\sqrt{a}}{24H^{3/2}} \tag{88.32}$$

Equation (88.31) can also be obtained with the help of Derjaguin's approximation, that is, by substituting Eq. (88.17) into Eq. (88.9).

88.4.9 Two Crossed Cylinders

With the help of Derjaguin's approximation, one can derive the van der Waals interaction energy between two crossed cylinders of radii a_1 and a_2 at separation H between their surfaces (Fig. 88.6).

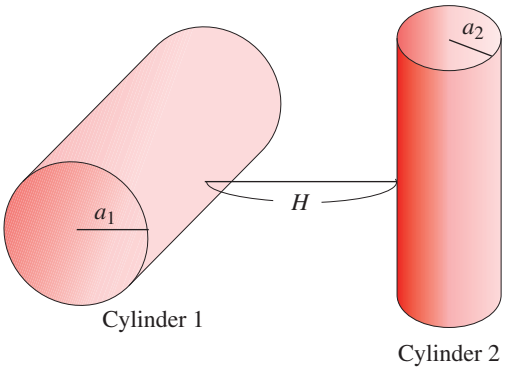

FIGURE 88.6 Two crossed cylinders of radii a_1 and a_2 separated by a distance H.

By substituting Eq. (88.17) into Eq. (88.10), we obtain

$$V(H) = -\frac{A\sqrt{a_1 a_2}}{6H} \tag{88.33}$$

which is applicable for small H ($H \ll a_1, a_2$).

88.4.10 Two Parallel Rings

Consider two parallel rings 1 and 2 of radii r_1 and r_2, respectively, separated by a distance h. The two rings are of the same substance. Let $\tilde{N}$ be the number of molecules on each ring; that is, let $\tilde{N}$ be the line density of molecules on each ring. For the interaction energy between rings 1 and 2, we thus obtain

$$V(r_1, r_2, h) = -\frac{4\pi^2 C\tilde{N}^2 r_1 r_2\left[\left\{h^2 + (r_1 + r_2)^2\right\}\left\{h^2 + (r_1 - r_2)^2\right\} + 6r_1^2 r_2^2\right]}{\left[h^2 + (r_1 + r_2)^2\right]^{5/2}\left[h^2 + (r_1 - r_2)^2\right]^{5/2}} \tag{88.34}$$

Note that for two identical parallel rings ($r_1 = r_2 = r$) in the limit of very small h, Eq. (88.34) becomes

$$V(r_1, r_2, h) = -\frac{3\pi C\tilde{N}^2}{8h^5}\cdot 2\pi r \tag{88.35}$$

It is interesting to note that Eq. (88.35) agrees with the energy between two parallel rods of length $2\pi r$ carrying molecules of line density $\tilde{N}$.

88.4.11 Two Parallel Torus-Shaped Particles

A torus-shaped particle can serve as a model for biocolloids such as biconcave human red blood cells. The interaction between two parallel biconcave-shaped red blood cells can be

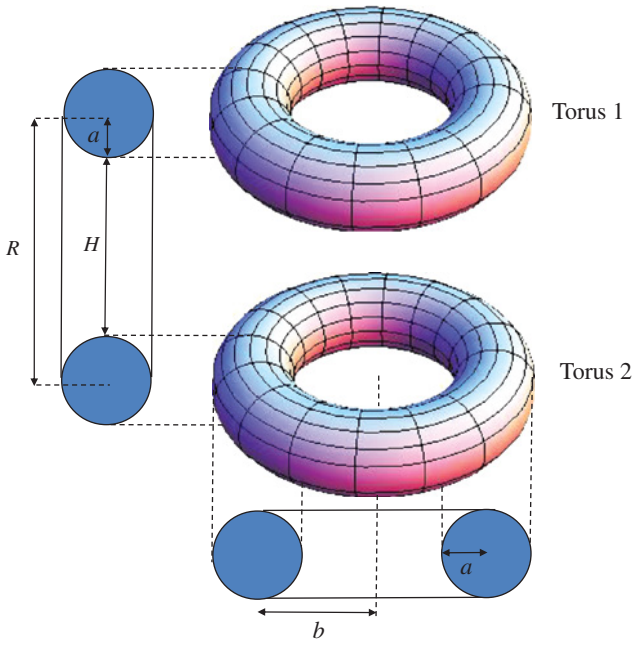

FIGURE 88.7 Two parallel torus-shaped particles at separation R between their centers, where a is the radius of the tube and b is the distance from the center of the tube to the center of the torus. (From Ref. 16.)

approximated by the interaction between two parallel torus-shaped particles.

Consider two parallel similar torus-shaped particles at separation R between their centers (Fig. 88.7) [16].

A torus can be constructed by joining the ends of a cylindrical tube. We denote the radius of the tube by a and the distance from the center of the tube to the center of the torus by b. The length of the cylindrical tube is thus $2\pi b$, and the closest distance H between the surfaces of these tori is $H = R - 2a$. Let N be the number of molecules contained within the particles. The interaction energy $V(R)$ between two parallel tori can be calculated with the help of Eq. (88.34), as

$$V(R) = -4A \int_{\rho_1=0}^{a} \int_{\rho_2=0}^{a} \int_{\phi_1=0}^{2\pi} \int_{\phi_2=0}^{2\pi} \left(\frac{r_1 r_2 \left[\{h^2 + (r_1 + r_2)^2\} \{h^2 + (r_1 - r_2)^2\} + 6r_1^2 r_2^2 \right]}{\left[h^2 + (r_1 + r_2)^2\right]^{5/2} \left[h^2 + (r_1 - r_2)^2\right]^{5/2}} \right) \times \rho_1 \rho_2 d\rho_1 d\rho_2 d\phi_1 d\phi_2 \tag{88.36}$$

with

$$r_1 = b - \rho_1 \cos\phi_1 \tag{88.37}$$

$$r_2 = b - \rho_2 \cos\phi_2 \tag{88.38}$$

$$h = R + \rho_1 \sin\phi_1 - \rho_2 \sin\phi_2 \tag{88.39}$$

As is well known, a torus and the corresponding cylindrical tube of radius a and length $2\pi b$ have the same surface area $(2\pi a \cdot 2\pi b)$ and interior volume $(\pi a^2 \cdot 2\pi b)$ (the Pappus–Guldinus theorem). Therefore, the interaction energy between two parallel tori is expected to be close to that between the corresponding two parallel cylinders. It follows from Eq. (88.36) that the interaction energy $V(R)$ between two parallel similar cylinders of radius a and length $2\pi b$ is given by

$$V(R) = -\frac{2A}{3R} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\Gamma^2(n + m + 1/2)}{m!n!(m-1)!(n-1)!} \left(\frac{a}{R}\right)^{2(m+n)} \times 2\pi b \tag{88.40}$$

For small $H/a < 2$, Eqs. (88.36) and (88.40) give results very close to each other. Indeed, in the limit of small H/a, Eqs. (88.36) and (88.40) both tend to the same limiting value

$$V(R) = -\frac{A\sqrt{a}}{24H^{3/2}} \times 2\pi b \tag{88.41}$$

which also agrees with the results obtained by applying Derjaguin's approximation to the interaction between two parallel cylinders.

88.4.12 Two Particles Immersed in a Medium

The expressions for the interactions between particles derived in this chapter so far are based on the assumption that the interacting particles are interacting in a vacuum. If the medium between the particles is no longer a vacuum, but a second substance (e.g., water), we have to account for the fact that each particle replaces an equal volume of water. It follows from the assumption of the additivity of the van der Waals interaction energies that the Hamaker constant A_{132} for the interaction two different particles of substances 1 and 2 immersed in a medium of substance 3 is

$$A_{132} = \left(\sqrt{A_1} - \sqrt{A_3}\right)\left(\sqrt{A_2} - \sqrt{A_3}\right) \tag{88.42}$$

$$|A_{132}| = \sqrt{A_{131}}\sqrt{A_{232}} \tag{88.43}$$

where A_1 and A_2 are, respectively, the interactions between two similar particles of substances 1 and 2 immersed in a vacuum. In particular, the Hamaker constant for the interaction two similar particles of substance 1 immersed in a medium of substance 3 is

$$A_{131} = \left(\sqrt{A_1} - \sqrt{A_3}\right)^2 \tag{88.44}$$

Note that while A_{131} is always positive, A_{132} may be positive or negative depending the relative magnitudes of A_1, A_2, and

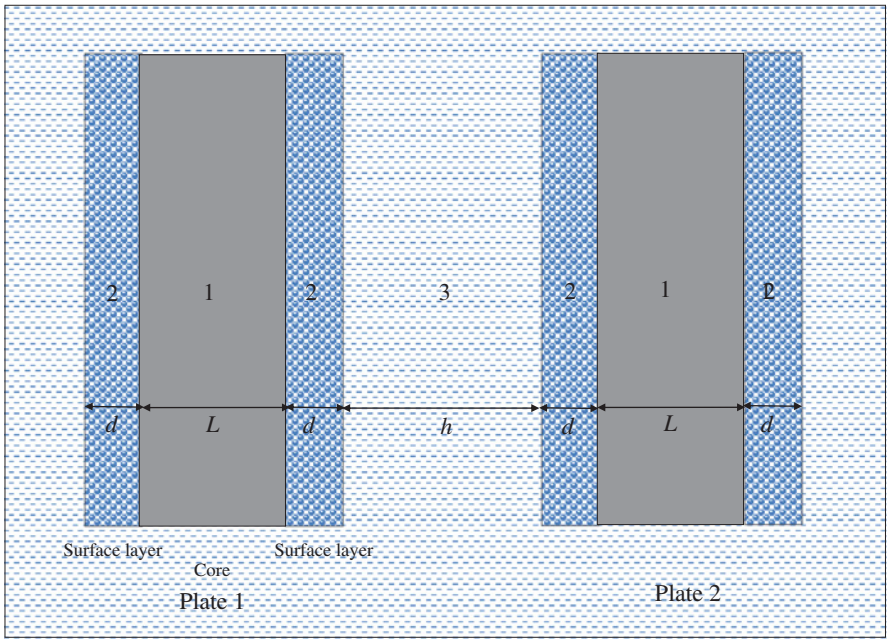

FIGURE 88.8 Two similar parallel plates of substance 1 and thickness L covered by a surface layer of substance 2 and thickness d separated at a separation h in a medium 3.

A_3. Thus, if two particles of substances 1 and 2 are interacting in medium 3, then A_{12} appearing in the expressions given in previous sections must be replaced by A_{132}.

88.4.13 Two Parallel Plates Covered with Surface Layers

It is possible to derive the interaction energy between particles with multilayer structures [8, 16, 17]. Consider the interaction between two parallel similar plates separated by a distance h (Fig. 88.8).

Let the thicknesses of the plate core and the surface layer be L and d, respectively. The interaction energy per unit area between the plates is thus given by

$$V(h) = -\frac{1}{12\pi}\left[\frac{A_{232}}{h^2} - \frac{2A_{123}}{(h+d)^2} + \frac{A_{121}}{(h+2d)^2} + \frac{2A_{123}}{(h+d+L)^2} - \frac{2(A_{232}+A_{121})}{(h+d+L)^2} + \frac{A_{121}}{(h+2d+2L)^2} + \frac{2A_{123}}{(h+3d+L)^2} - \frac{2A_{123}}{(h+3d+2L)^2} + \frac{A_{232}}{(h+4d+2L)^2}\right] \tag{88.45}$$

For very small h ($h \ll d$ and $h \ll L$), Eq. (88.45) becomes an expression of the interaction energy between the two surface layers of substance 2 in a medium 3:

$$V(h) = -\frac{A_{232}}{12\pi h^2} \tag{88.46}$$

For large h such that $L \gg h \gg d$, on the other hand, Eq. (88.45) approaches the interaction between the two plate cores of substance 1 in a medium 3:

$$V(h) = -\frac{(A_{232} - 2A_{123} + A_{121})}{12\pi h^2} = -\frac{A_{131}}{12\pi h^2} \tag{88.47}$$

89.1 INTRODUCTION

In 1913, J.W. McBain [1] proposed the idea of self-assembled aggregates in aqueous solution. The amphiphilic molecules have the remarkable ability to form a variety of self-assembled structures in aqueous or nonaqueous media depending on composition and temperature such as micelles, liquid crystals, and vesicles. The thermodynamics of the micelle would reflect a balance of repulsive interaction between the surfactant headgroups and van der Waals's attractive forces between the hydrocarbon tails [2, 3]. At any local packing environment, the packing free energy per molecule f is the sum of the average interaction (steric and/or electrostatic) energy per molecule resulting from headgroup repulsion f_h, the surface energy associated with the hydrocarbon–water interface f_s and the chain (hydrocarbon tail) contribution to the free energy f_t as follows;

$$f = f_h + f_s + f_t \tag{89.1}$$

All three terms, f_h, f_s, and f_t, depend on the average cross-sectional area per molecule at the interface a_s, and on the local interfacial curvatures [4]. The geometry of the aggregates formed may be predicted by the critical packing parameter (CPP) of an amphiphilic molecule, CPP = $v/a_s l_c$, where v is the volume of the lipophilic chain having maximum effective length l_c and a_s. Generally, hydrophilic amphiphiles having large headgroups self-assemble into spherical micelles (CPP $\leq 1/3$) in a dilute aqueous region. A reduction in a_s, namely, an increase in CPP, tends to induce micellar growth. The spherical micelles often undergo 1D growth to form long, linear cylindrical micelles on change in the concentration or temperature, on the addition of salt, or in the presence of specific counterions. These cylindrical micelles, which are commonly modeled as rods, consist of a cylindrical body and two hemispherical endcaps [5.6]; both the body and the endcaps have the same diameter; however, some theoretical [7,8] and experimental [9,10] evidence suggests that the endcaps actually have a larger diameter than the cylindrical body. The molecules packed at the hemispherical ends have excess free energy, called the *endcap energy*, and a thermodynamic driving force for the linear growth [11]. They can reach a few nanometers to micrometers in length. When the number density of these long aggregates exceeds a certain threshold value, they entangle with each other to form a transient network called *wormlike micelles* or *giant micelles* [12], which exhibit viscoelastic properties.

When the equilibrium condition for a wormlike micellar system is disturbed, it tries to relax and restore the equilibrium condition within a definite time τ_R. A system that deforms faster than it relaxes exhibits an elastic property characteristic of a solid material with a Hookean constant G_0, called the *shear modulus*. For a slow deformation, the stress imposed on the system dissipates easily, and behaves as a viscous fluid with a zero-shear viscosity η_0. In many cases, there is only one characteristic relaxation time for wormlike

Encyclopedia of Biocolloid and Biointerface Science, Volume 2, First Edition. Edited by Hiroyuki Ohshima.

micellar systems; in such cases the rheological properties can be interpreted in terms of the Maxwell model of a viscoelastic fluid [13, 14], consisting of an elastic spring with the Hookean constant G_0 and a dashpot with viscosity η_0. The variation of elastic (storage) modulus (G') and viscous (loss) modulus (G'') with shear frequency ω is given by the equations

$$G'(\omega) = \frac{\omega^2 \tau_R^2}{1 + \omega^2 \tau_R^2} G_0 \tag{89.2}$$

$$G''(\omega) = \frac{\omega \tau_R}{1 + \omega^2 \tau_R^2} G_0 \tag{89.3}$$

where τ_R is the Maxwelllian relaxation time. As may be evident from the equations, in the low-frequency region, $\omega \ll \omega_c$, G' and G'' scale with ω according to $G' \propto \omega^2$ and $G'' \propto \omega$. In the high-frequency region, or more specifically, in the region of $\omega \ll \omega_c$, however, G' attains a plateau value equal to G_0, whereas G'' shows a monotonic decrease. The shear frequency corresponding to $G' - G''$ crossover is $\omega_c = 1/\tau_R$. For wormlike micellar solutions, the τ_R and G_0 gives information about average micellar length and the number density of the entanglements in the transient network, respectively. A $G'(\omega)$ versus $G''(\omega)$ (Cole–Cole) plot would give a semicircle for Maxwellian behavior. The terms G_0, τ_R, and η_0 are related as follows:

$$\eta_0 = G_0 \tau_R \tag{89.4}$$

Alternately, the following relationship allows one to estimate η_0 by extrapolating the complex viscosity values ($|\eta^*|$) to zero-shear frequency:

$$|\eta^*| = \frac{(G'^2 + G''^2)^{1/2}}{\omega} = \frac{\eta_0}{\sqrt{1 + \omega^2 \tau_R^2}} \tag{89.5}$$

The wormlike micelles are often called *living polymers* as they break and re-form spontaneously, and their molecular weight fluctuates with time [15], unlike the conventional polymers, where the covalently bonded repeat units maintain constant molecular weight. The mean field model developed by M. Cates and coworkers [16–18], has shown that the viscoelastic behavior for wormlike micelles consists in two processes: reptation (reptilelike motion of the micelle along its own contour) and reversible scission of micelles, taking place at two timescales, namely, reptation time τ_{rep} and breaking time τ_b. It is assumed that when a chain breaks, the two resulting chains become uncorrelated and recombine with the micellar end in a random way. For fast scission kinetics ($\tau_b \ll \tau_{rep}$), a single-exponential stress decay is observed, and the viscoelastic behavior of such systems in the low-frequency region follows the Maxwell model with a single relaxation time τ_R, given by $(\tau_b . \tau_{rep})^{1/2}$. Although the Maxwell equations predict a monotonic decrease of G'' in the high-frequency region, wormlike micelles usually deviate from this behavior, showing an increase of G'' in the high-frequency region and a deviation from the semicircle predicted by the Maxwell model in the G'' versus G' (Cole–Cole) plot. This deviation is often associated with the stress relaxation by additional "faster" processes such as Rouse modes of cylindrical micelles, analogous to polymer chains. The minimum value of G'' in the high-frequency region is related to L according to the relation.

$$\frac{G_{min}}{G_0} \approx \frac{l_e}{L} \tag{89.6}$$

where l_e is the entanglement length, that is, the contour length of the section of wormlike micelles between two entanglement points. For flexible micelles, the correlation length ξ, which gives the mesh size of the micellar network, is related to l_e according to

$$l_e = \xi^{5/3} / l_p^{2/3} \tag{89.7}$$

The persistence length l_p provides an estimate of micellar flexibility. Even though the micelles are flexible, at a small length scale (comparable to l_p), they behave as rigid rods. The correlation length ξ is related to T and G_0 as follows:

$$\xi \approx \left(\frac{kT}{G_0} \right)^{1/3} \tag{89.8}$$

The combination of Eqs. (89.7) and (89.8) yields an equation that relates l_e to G_0 as follows:

$$G_0 \approx \frac{kT}{l_e^{9/5} l_p^{6/5}} \tag{89.9}$$

For $\tau_b \ll \tau_{rep}$, the living-polymer model predicts the following scaling laws for the viscoelastic parameters [19]: $G_0 \approx \phi^{2.25}$, $\tau_R \approx \phi^{1.25}$, $\eta_0 \approx \phi^{3.5}$, and $\frac{G_{min}}{G_0} \approx \phi^{-1.75}$. When $\tau_b \gg \tau_{rep}$, the micelles behave like ordinary polydisperse unbreakable polymers, and the stress–relaxation function is strongly nonexponential. For neutral or highly screened ionic micelles [20], the zero-shear viscosity scales as $\eta_0 \propto \phi^{5.25}$. For branched or interconnected micelles, the exponents of the scaling laws are significantly different [21, 22]. For a saturated interconnected network, $G''_{min}/G_0 \ \phi^{-0.75}$ has been proposed [23].

Analysis of small-angle scattering data using indirect Fourier transformation (IFT) followed by deconvolution [24–26] allows us to extract information about the shape and internal structure of the aggregate without having an a

priori assumption of the model. An brief description of the principle involved is presented here.

The overall scattering intensity $I(q)$ for the systems of monodisperse spherical particles is given by

$$I(q) = nP(q)S(q) \tag{89.10}$$

where $P(q)$ is the intraparticle contribution, known as the *form factor*, and $S(q)$ is the interparticle contribution or structure factor. When the system is sufficiently dilute, $S(q) \approx 1$, the spatially averaged $I(q)$, is given by

$$I(q) = 4\pi \int_0^\infty p(r) \frac{\sin(qr)}{qr} dr \tag{89.11}$$

where $p(r)$ is the pair distance distribution function (PDDF), which provides the overall information about the shape and of the scattering particles such as micellar aggregates. The Fourier transform of $p(r)$ gives $P(q)$. The PDDF for a particle of an arbitrary shape with a scattering density difference of $\Delta\rho(r)$ is given by

$$p(r) = r^2 \Delta\tilde{\rho}^2(r) \tag{89.12}$$

where $\Delta\tilde{\rho}^2(r)$ is the convolution square of $\Delta\rho(r)$ averaged for all directions in space. The form factor and the structure factor can be determined by the *generalized indirect Fourier transformation* (GIFT) technique [27–29] simultaneously from the scattering data without any assumption for the form factor, whereas we need appropriate assumptions for the interparticle interaction potential for the structure factor. A hard-sphere interaction model is the common choice. The detailed theoretical description on the method has been reported elsewhere. Note that when particle geometry deviates from an ideal spherical symmetry, the output parameters from $S(q)$ analysis are no longer exact. Nevertheless, the GIFT approach efficiently suppresses the influence of the interparticle interference scattering in the calculation of $p(r)$ and allows us to deduce a sufficiently reliable $p(r)$ value.Wormlike micelle systems are most commonly reported in ionic surfactants, especially with cationic surfactants with long hydrophobic chain (C16 or longer) induced by adding salts, strongly binding counterions or cosurfactants [30–39]. Ionic surfactants, however, are sometimes undesirable for commercial products, because of their toxicity and sensitivity to electrolytes. Growing environmental awareness has prompted the search for nontoxic and biodegradable nonionic surfactants from renewable sources for the formation of wormlike micelles. Therefore, it is important to understand the underlying basic principle of the formation and rheological properties of nonionic systems and have novel insight into the thermodynamics of micellar growth.

89.2 WORMLIKE MICELLES IN NONIONIC SURFACTANTS

Nonionic surfactant solutions can undergo temperature- or concentration-induced micellar growth through adequate modulation of the specific surface area and interfacial curvature [40–42]. Fluorocarbon surfactants show high hydrophobicity and CMC lower than the hydrocarbon surfactants of similar chain length, high electronegativity, relatively large van der Waals radius, and less conformational freedom that produce bulky and stiff chains with their skeletons covered by a dense electron-rich environment. The resulting high cohesive energy facilitates a more dense packing at the interface, that is, small interfacial areas per molecule, which favors micellar growth. The compound $C_8F_{17}SO_2(C_3H_7)N(CH_2CH_2)_{10}H$ (Fig. 89.1a) is one of the nonionic fluorocarbon surfactants that shows interesting phase behavior [43]. It forms a micellar solution over a wide range of compositions (up to 38 wt% at 5°C) at low temperature. Hexagonal (H_1), bicontinuous cubic (V_1), and lamellar (L_α) liquid crystalline phases are formed successively with an increase in surfactant concentration. Micellar solutions at low temperature transforms into highly viscous solutions with increasing surfactant concentration. Small-angle X-ray scattering (SAXS) patterns show a broad scattering band, ruling out the possibility of the presence of an isotropic micellar cubic phase. With increasing temperature, the viscosity of the solution gradually decreases, and ultimately, a less viscous easily flowing isotropic solution is formed. At higher temperatures, clouding behavior is observed.

Figure 89.1b shows the variation of η_0 of $C_8F_{17}EO_{10}$ with concentration. The low surface area of fluorinated surfactant favors micellar growth and an onset of the overlapping of wormlike micelle leading to η_0 increase even at low concentration; the η_0 of 2 wt% $C_8F_{17}EO_{10}/H_2O$ is $\sim$ 4 orders of magnitude that of water. With further increase in concentration, the viscosity shows a maximum and then decreases. The η_0 versus temperature curves (Fig. 89.1c) for concentrations between 1 and 7 wt% also show a maximum. The η_0 of 1 wt% $C_8F_{17}EO_{10}/H_2O$ increases by ~ 2 orders of magnitude on increasing temperature from 5°C to 35°C. The temperature for viscosity maximum ($T_{\eta\text{-max}}$) shifts to lower values with increasing surfactant concentration. The viscosity of the micellar solution is very sensitive to the concentration at low temperatures, but at and above 25°C, the viscosity is nearly the same over a wide range of concentrations (2–25 wt%). At high surfactant concentration, the degree of hydration of the EO chain decreases. This reduces the specific surface area and increases aggregation numbers, inducing decrease in the spontaneous curvature of the aggregate and favoring 1D micellar growth increasing the viscosity. With an increase in concentration, the formation of micellar joints with faster relaxation is expected to take place at lower temperatures,

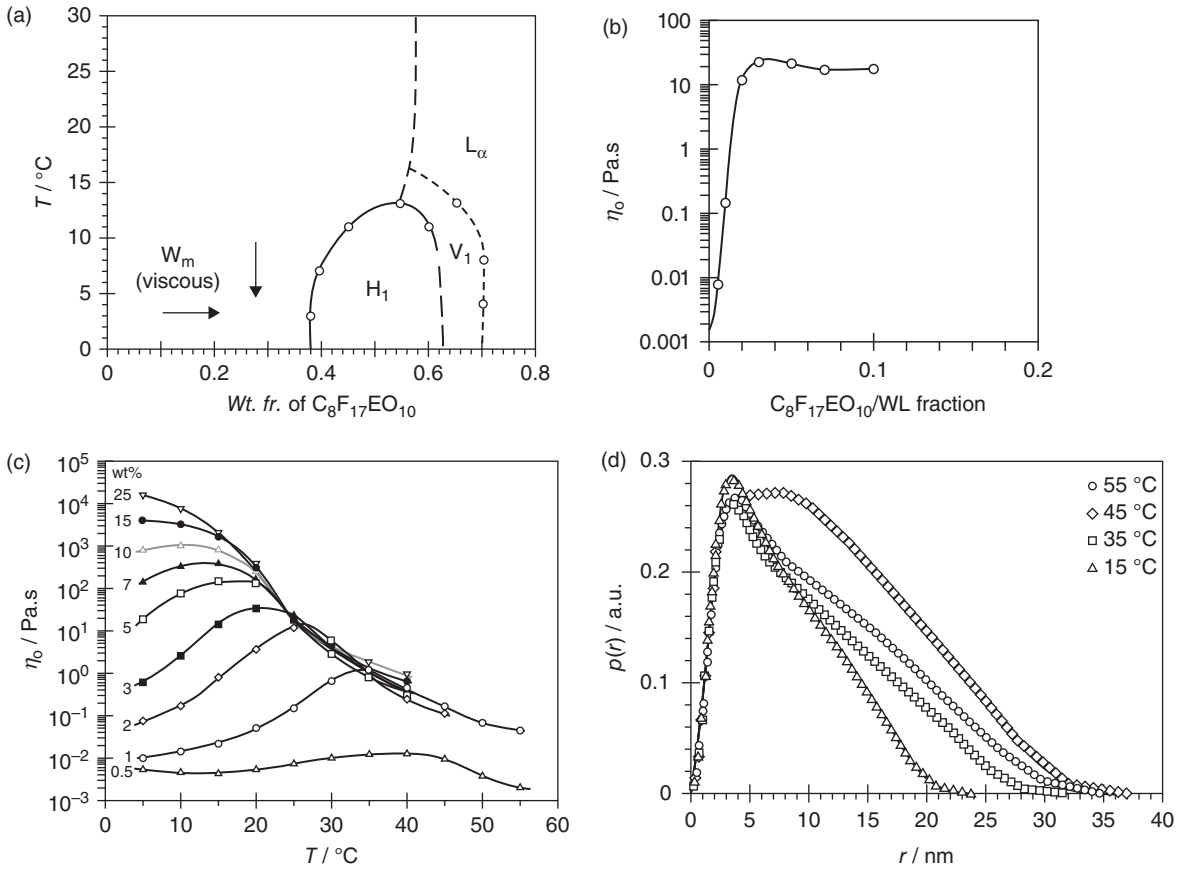

FIGURE 89.1 (a) Partial phase diagram of $C_8F_{17}EO_{10}/H_2O$ binary system; W_m, H_1, V_1, and L_α stand for micellar, hexagonal, bicontinuous cubic, and lamellar liquid crystalline phases, respectively. The arrows in the W_m domain show the direction of the viscosity increase for the systems at surfactant concentration of 15 wt% and above. At lower concentrations, viscosity increases and then decreases with increasing temperature. (b) Variation of η_0 with $C_8F_{17}EO_{10}$ concentration in water at 25°C. (c) Variation of zero-shear viscosity (η_0) as a function of temperature at different concentrations (in wt%) of $C_8F_{17}EO_{10}$ in water. (d) Pair distance distribution function, $p(r)$ of 1 wt% $C_8F_{17}EO_{10}$/ H_2O binary system at different temperatures. (Panels (a), (c), and (d) reprinted from Acharya et al. 2006 [43], pp. 20224–20234; reproduced with permission of the American Chemical Society. Panel (b) reprinted from Sharma et al. 2007 [47], p. 223; reproduced with permission of Elsevier.)

which can explain the gradual shift of $T_{\eta\text{-max}}$ toward lower temperatures.

Figure 89.1d shows the $p(r)$ curves of 1 wt% $C_8F_{17}EO_{10}/H_2O$ solutions with increasing temperature. The local maximum and minimum in the $p(r)$ function in the low r region arise from the productive contribution of the negative and positive electron densities from the hydrophobic core and hydrophilic shell, respectively. The value of r corresponding to the maximum inflexion after the second maxima of the $p(r)$ function gives the cross-sectional diameter of cylindrical aggregate, including the headgroup. The $p(r)$ plots at 15°C, 35°C, and 45°C are typical of rodlike particles. The D_{max} increases with increasing temperature, while the cylindrical cross-sectional diameter of the aggregates remains almost constant (≈ 5.8 nm). It should be noted that the D_{max} measured is not the actual length of the micelles as it is biased by the maximum resolution (or q_{min}) of the measurement. Nevertheless, the trend in the variation of D_{max} values as obtained here can be taken as the evidence of 1D micellar growth with increase in temperature. The 1D micellar growth seems to continue even above 35°C ($T_{\eta\text{-max}}$), until 55°C. Importantly, there is a significant change in the pattern of $p(r)$ observed in the middle-r region, which suggests a gradual evolution of the local structure toward a lamellar pattern, with nil curvature and a packing parameter close to 1.

A more hydrophilic nonionic fluorinated surfactant, $C_8F_{17}EO_{20}$, forms isotropic micellar solution over a wide concentration range (~ 80 wt%) in water at 25°C [44]. However, it can form viscoelastic wormlike micelles only with a less hydrophilic cosurfactant, $C_8F_{17}EO_1$ [45], $C_8F_{17}EO_3$

[46], or $C_8F_{17}EO_{10}$ [47]. With successive addition of the cosurfactant, viscosity of aqueous micellar solution of $C_8F_{17}EO_{20}$ increases rapidly, reaches a maximum, and then decreases, and ultimately phase separation occurs. The viscosity increases by ~ 5 orders of magnitude that of pure water. It has been suggested that after the saturation of micellar growth, further addition of cosurfactant to the system results in the formation of joints that can slip along its length, thereby allowing a faster and easier way of stress relaxation [48,49] and causing a decrease in viscosity. There are reports on micellar connections or branching points [50, 51]. On the other hand, addition of perfluoropolyether oil, $(C_3F_6O)_nCOOH$, and perfluorodecalin oil, $C_{10}F_{18}$, to the viscoelastic solution of $C_8F_{17}EO_{20}/H_2O/C_8F_{17}EO_3$, decreases the viscosity until phase separation. Small-angle X-ray scattering (SAXS) measurements confirm that $C_8F_{17}EO_1$, $C_8F_{17}EO_3$, and $C_8F_{17}EO_{10}$ induced spherical–cylindrical while fluorinated oils, $(C_3F_6O)_nCOOH$ and $C_{10}F_{18}$ induced wormlike–sphere micellar transition in $C_8F_{17}EO_{20}/H_2O/C_8F_{17}EO_3$ system responsible for different rheology.

Similarly, a mixture of nonionic dimeric poly(oxyethylene) gemini surfactants having the structure, $(C_{n\text{-}2}H_{2n\text{-}3}CHCH_2(OCH_2CH_2)_mOH)_2(CH_2)_6$ with alkyl and ethoxy chain lengths ranging from $n = 12-20$ and $m = 5-30$ can also form wormlike micelles in aqueous solution [52], especially for the $n = 20$ and $m = 15$ surfactant, a shape transition is accompanied by an increase in viscosity at low concentration and gelation at higher concentrations. The size and shape of micelles formed have been determined using small-angle neutron scattering (SANS).

The hydrophobic sterol group of poly(oxyethylene) cholesterol and poly(oxyethylene) phytosterol ether surfactants are of natural origin; they can also be a good candidates for wormlike micelle formation. The interfacial curvature of poly(oxyethylene) alkyl ethers [53], poly(oxyethylene) cholesteryl ethers ($ChEO_m$) [54–56], poly(oxyethylene) phytosterol ethers ($PhyEO_m$) [57–62] micelles can be tuned to induce sphere-to-wormlike micelles transition. Aqueous micellar solutions of $ChEO_m$ and $PhyEO_m$, where $m =$ 10,5,20,30, can solubilize a considerable amount of $C_{12}EO_n$, where $n = 3$–4 system at 25°C. Successive additions of $C_{12}EO_n$ to the aqueous micellar solutions of the $ChEO_m$ or $PhyEO_m$ results in optically isotropic highly viscous samples that show shear birefringence. At higher mixing fractions of $C_{12}EO_n$, phase separation takes place, and a vesicular dispersion is observed in the multiphase region due to the decrease in surfactant layer curvature with the incorporation of $C_{12}EO_n$. In $ChEO_{10}/H_2O/C_{12}EO_n$ systems [63], with decreasing headgroup size (smaller n), a sharp increase in η_0 begins at lower $C_{12}EO_n$ concentration and micellar growth occurs more "rapidly." On increasing the n of cosurfactant, a higher cosurfactant/surfactant ratio is required to form viscoelastic solution, which is attributed to the decreased ability of the cosurfactant to reduce the aggregate curvature. While an increase in m of the $ChEO_m$ shifts it toward higher concentrations (see Fig. 89.2a).

Structural information on the mixed systems can be extracted from X-ray [64, 65] and neutron-scattering measurements [66]. SANS measurement in dilute mixed nonionic system ($ChEO_m$+$C_{12}EO_n$) provides evidence for 1D micellar growth (see Fig. 89.2b). The $p(r)$ functions indicate

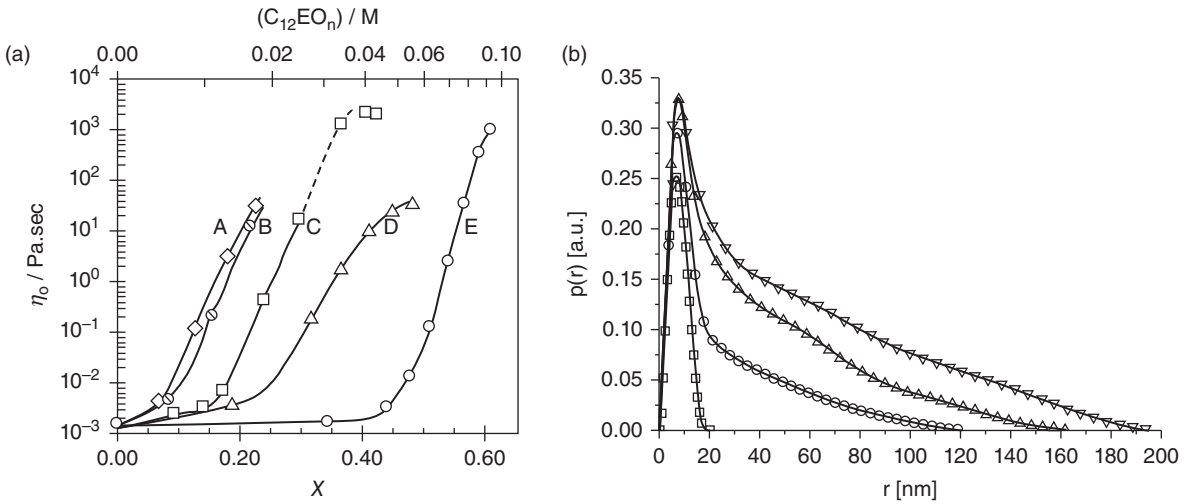

FIGURE 89.2 (a) Variation of η_0 with mixing fraction of $ChEO_n$ (X) in different 0.06 M $ChEO_{10}/ChEO_n/H_2O$ systems: (A) $C_{12}EO_1$, (B) $C_{12}EO_2$, (C) $C_{12}EO_3$, (D) $C_{12}EO_4$, and (E) 0.06 M $ChEO_{15}/C_{12}EO_3/H_2O$. (b) Pair distance distribution functions $p(r)$ for 1 wt% of $ChEO_{10}$ and 0 wRt% (squares), 0.05 wt% (circles), 0.10 wt% (upward-pointing triangles), and 0.15 wt% (downward-pointing triangles) $C_{12}EO_3$, respectively. (Both panels reprinted from Moitzi et al. 2005 [66], p. 16161. Reproduced with permission of American Chemical Society.)

that the geometry is close to a sphere for $ChEO_m$ (where $m = 10,20,30$) alone. Addition of $C_{12}EO_n$ induces spherical to cylindrical micelles transition. Figure 89.2b shows elongation for an increasing concentration of $C_{12}EO_3$, in agreement with the conclusions drawn from rheology. The decay to large r values is not linear, but is slightly convex, indicating polydispersity in length. It should be noted that a length of 200 nm (for 0.15 wt% $C_{12}EO_3$) is longer than the resolution of the instrument, so only qualitative analysis is possible in this case.

Alkanolamides like lauryldiethanolamide (L-DEA) and cocamid monoethanolamide (C-MEA) are also capable of transforming spherical micelles of $ChEO_{20}$ into wormlike micelles. The wormlike micelles could be obtained with lower concentration in the case of the L-DEA-added system, while a higher maximum η_0 could be obtained with a C-MEA-added system. Rheological, SAXS measurements and cryo-TEM (see Fig. 89.3) images confirm the formation of wormlike micelles on addition of alkanolamides in both cases [64, 65].

Lipophilic monoglycerides, like monolaurin ($C_{12}MG$), monocaprin ($C_{10}MG$), and monocaprylin (C_8MG), can induce wormlike micelles in aqueous micellar solutions of $ChEO_{10}$ [67]. Higher amounts of small hydrophobic tailed surfactant, C_8MG (0.60), compared to those of $C_{10}MG$ (0.34) and $C_{12}MG$ (0.30), are needed to induce the 1D growth. Aliphatic oils, ethyl butyrate (EB), and ethyl caprylate (EC) and cyclic oils such as peppermint (PP), and tea tree (TT) oils can also induce wormlike micelle formation in aqueous micellar solutions of $ChEO_{10}$. The wormlike micelles with maximum η_0 are obtained in the order $C_{12}MG > C_{10}MG > C_8MG$ for the monoglycerides, while for the oils, they are obtained in the order TT > PP > EC > EB. Both SANS and cryo-TEM confirm an increase in contour length on the addition of C_nMG and oils. The oils intercalate at the core–shell interface of the micelles. In the presence of an entangled network, however (at higher cosurfactant concentration), the addition of oil reduces the viscoelasticity, possibly because of competition with the monoglyceride surfactant and solubilization of the oil in the hydrophobic core, ultimately leading to phase separation. In yet another report, wormlike micelles have been observed in an aqueous mixture of poly(oxyethylene) phytosterol ether ($PhyEO_m$; $m = 10,20,30$) and glycerin fatty acid monoester (C_nGFA; $n = 8,10,12$) [60]. The η_0 value increases dramatically with changing ratio of C_nGFA in the system. The rheological measurements confirm the presence of entangled wormlike micelles in $PhyEO_{10}/C_8GFA/H_2O$ and $PhyEO_{20}/C_{10}GFA/H_2O$ systems.

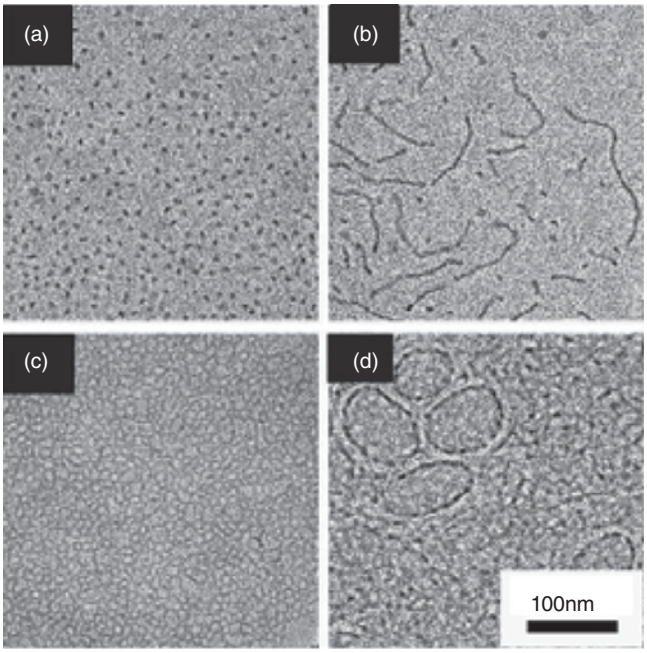

FIGURE 89.3 Cryo-TEM micrographs of micelles formed by 2 wt% $ChEO_{20}$ with (a) no L-DEA, (b) 1 wt%, (c) 2 wt%, and (d) 2.6 wt% of L-DEA. (All panels reprinted from Shrestha et al. 2011 [65], p. 12877. Reproduced with permission of American Chemical Society.)

Among those forming wormlike micelles, substantial work has focused on sugar-based surfactants [68, 69]. Aqueous binary solutions of sucrose alkanoate surfactants (C_xSE, where $x = 12,16,18$) can form viscous wormlike micellar solutions over a wide range of concentration and temperature [70–73]. Such micelles have also been reported in an aqueous mixtures of sucrose dodecanoate (C_xSE, where $x = 12,16$) and poly(oxyethylene) ethers ($C_{12}EO_n$) [74]. A successive addition of C_mEO_n or monolaurin (ML) to the aqueous micellar solutions of sucrose alkanoates promotes highly viscoelastic micelles in the system that disappears with further addition of cosurfactant followed by phase separation, observed for all the cases studied (see Fig. 89.4a). The value of η_0 increases by several orders of magnitude if a small amount of C_mEO_n is added to $C_{16}SE$ and then decreases at higher ratios C_mEO_n/C_xSE ratios (R) up to phase separation. The η_0-increasing capacity is in the following order: ML $\approx C_{12}EO_1 \approx C_{12}EO_2 > C_{12}EO_3 > C_{12}EO_4$. A comparatively higher concentration of the more hydrophilic ethoxylated amphiphile is needed for similar rise in the $C_mEO_n/C_xSE/H_2O$ system.

The $p(r)$ functions of 5% $(C_{16}SE+C_{12}EO_3)/H_2O$ at different mixing fractions of $C_{12}EO_3$ (W_1) (see Fig. 89.4b) are typical of cylindrical aggregates [75, 76], with nonlinear (slightly convex) decay at large r values indicating polydispersity in length. In the $C_{16}SE/H_2O$ binary system the maximum dimension of the aggregate is ~12.5 nm. On addition of $C_{12}EO_3$, the maximum length increases, and at a composition corresponding to the maximum viscosity, it is ~23 nm (the actual length is limited by the resolution limit). The data confirm the elongation of the micelles with addition of $C_{12}EO_3$. Further increase in $C_{12}EO_3$ concentration decreases

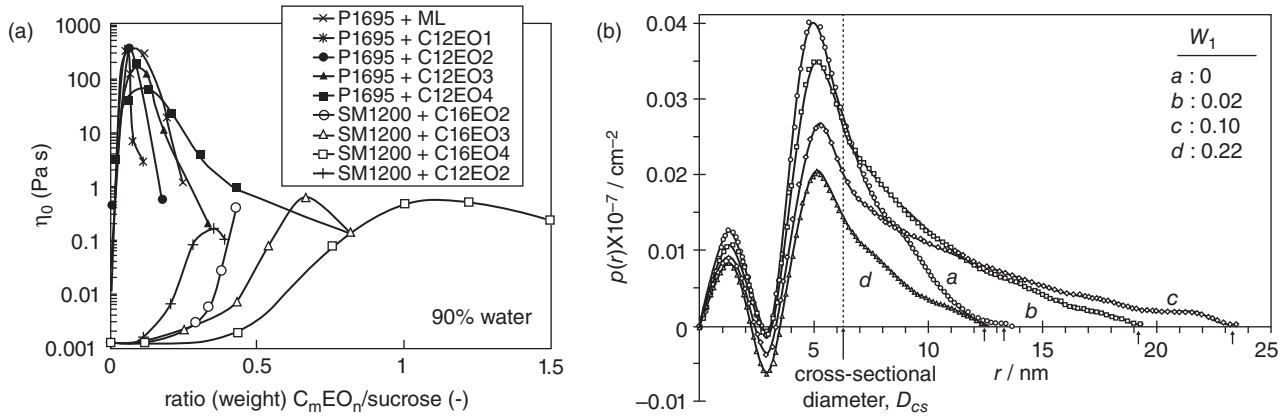

FIGURE 89.4 (a) Zero-shear viscosity η_0 for ($C_xSE + C_mEO_n$) + 90% H_2O at various C_mEO_n/C_xSE ratios (R) (ML = monolaurin). (b) Pair distance distribution function $p(r)$ for 5% ($C_{16}SE + C_{12}EO_3$) system at different mixing fractions of $C_{12}EO_3$ (W_1). (Panel (a) reprinted from Maestro et al. 2004 [74], p. 14009; reproduced with permission of American Chemical Society. Panel (b) reprinted from Acharya and Kuneida 2006 [76], p. 401; reproduced with permission of Elsevier.)

the aggregate size, in consistence with the rheological data.

The oil induced structural transition in the micellar aggregates is of particular relevance for their use in cosmetics or pharmaceutical applications. The effects of oils in the rheology of $C_{16}SE/C_{12}EO_3/H_2O$ and $C_{16}SE/C_{12}MG/H_2O$ systems have been reported [77]. When $C_{12}EO_3$ is added in the presence of decane, most of the $C_{12}EO_3$ is solubilized in decane(hydrophobic core), and the availability of $C_{12}EO_3$ at the interface is very low. Further addition of $C_{12}EO_3$ increases its interfacial concentration and the curvature of the C_mSE/H_2O aggregate is reduced, increasing the viscosity. On the other hand, as $C_{12}MG$ is not soluble in decane, it is readily adsorbed at the interface regardless of the presence of decane, and hence the tendency to increase the viscosity by $C_{12}MG$ is almost the same as in the system without oil. These oils, in the absence of $C_{12}EO_3$ or $C_{12}MG$, do not increase the viscosity of $C_{16}SE/H_2O$. On the other hand, relatively rigid and elongated amphiphilic oil, *p*-xylene, is preferentially solubilized in the surfactant palisade layer, and it increases the viscosity of $C_{16}SE/H_2O$ binary solution sharply even in the absence of $C_{12}EO_3$ or $C_{12}MG$ [78]. Moreover, less cosurfactant ($C_{12}EO_3$ or $C_{12}MG$) is needed to induce micellar growth, and also micellar branching, which causes the viscosity decrease after the maximum, at lower cosurfactant fraction. SAXS confirms that further elongation of long wormlike micelles is favored by *p*-xylene, while decane promotes the formation of globular, small micelles, responsible for the different rheological behavior.

Another research team further confirmed that monohydroxy alcohols (C_3–C_9) can also induce wormlike micelles formation in sucrose monohexadecanoate ($C_{16}SE$) [79]. The η_0 of the aqueous micellar solution of $C_{16}SE$ increases, shows a maximum, and then decreases for all the alcohols except for 1-propanol. Rheological study confirms the presence of wormlike micelles. Micelles show 1D growth with alcohol and lead to branched micelles at higher concentration, losing the viscoelastic properties. Long-chain alcohol induces higher maximum η_0 and slow relaxation time τ_R.

In aqueous binary solutions of poly(ethylene oxide)–poly(propylene oxide) (PEO-PPO), block copolymers can aggregate into temperature-sensitive wormlike micelles as confirmed by rheological study [80]. In aqueous mixtures of poly(butadiene-*co*-ethylene oxide) (PBD_{46}-PEO_{30}), copolymer and a commercial nonionic surfactant (Triton X-100), long micelles have been observed by cryo-TEM [81].

Nonaqueous wormlike micelles or reverse wormlike micelles are formed by lipophilic surfactants in nonaqueous solvents. The most popular system forming reverse wormlike micelles investigated so far is a ternary mixture of lecithin/H_2O/oil [82–84]. Lecithin, a zwitterionic phospholipid with two alkyl chains, forms globular or ellipsoidal micelles in a variety of organic solvents. A trace amount of water into lecithin reverse micellar solution can induce axial micellar growth and exhibit viscoelastic behavior due to the entanglement of long cylindrical micelles into a transient network [85, 86]. The η_0 increases by several orders of magnitude. This increase depends on the molar ratio of water to lecithin. Another team of investigators reported wormlike micelles in lecithin/decane system by substituting water with urea, sucrose fatty acid esters [87, 88], sugars of RNA and DNA, and polyglycerol [89, 90]. The substituting additives form hydrogen bonds with the phosphate group of lecithin, thereby reducing the interfacial curvature of the molecular assembly and inducing an axial growth of lecithin micelles, leading to the formation of reverse wormlike micelles. The η_0 increases by $\sim$ 6 orders of magnitude. Similarly, other researchers [91, 92] replaced water with a trace amount of a

bile salt, sodium deoxycholate, in lecithin/hydrocarbon oil–based reverse wormlike micelles. They proposed that facially amphiphilic bile salts promote the longitudinal aggregation of lecithin molecules into viscoelastic wormlike micelles. The η_0 increases by ~ 5 orders of magnitude, which is controlled by the molar ratio of bile salt to lecithin. They [91,92] have also illustrated the formation of light-responsive reverse wormlike micelles in a combination of lecithin/*p*-coumaric acid/oils [93]. Shrestha et al. have reported that addition of relatively less lipophilic nonionic surfactant sucrose dioleate, SDO to semidilute solutions of sucrose trioleate (STO) in hexadecane forms transient networks of viscoelastic reverse wormlike micelles even in the absence of water. The η_0 increases by ~ 4 orders of magnitude, determined by the mixing fraction of SDO and STO [94]. The growth of reverse wormlike micelles has been confirmed by small-angle scattering (SAXS or SANS) experiments.

89.3 CONCLUSION

Viscoelastic wormlike micellar solutions are formed in both binary and mixed nonionic surfactants and amphiphilic block copolymers. Experimental techniques such as rheology, small-angle X-ray scattering, and cryo-TEM provide evidence of the change in morphology and size when wormlike micelles are formed, and also provide valuable information on the dynamics of the systems, which show several relaxation and diffusion mechanisms, associated with micellar breaking, micellar reptation, and entanglement. Micellar growth in 1D is favored by an increase in the average surfactant molecular packing parameter, which can be induced by a reduction in the effective surface area when a cosurfactant is added to the system. The wormlike micellar solutions formed by ethoxylated nonionic surfactants are very sensitive to temperature, and dehydration of the surfactant headgroups promotes elongation. The rheological behavior of nonionic wormlike micelles is affected by the additives. Relatively hydrophobic cosurfactants that tend to reside in the surfactant palisade layer and reduce the specific surface area favor larger elongation, whereas long and bulky oils, which tend to be solubilized in the micellar core, induce a rod–sphere transition, thereby decreasing viscosity. In mixed systems, the effect of oil also depends on the solubility of the cosurfactant in the oil phase. Reverse wormlike micelles can be formed in nonpolar solvents, even in the absence of ionic components or water. The possibility of obtaining highly viscoelastic wormlike micellar solutions with nonionic surfactants expands the field of applications and provides new insight on the study of living polymers.

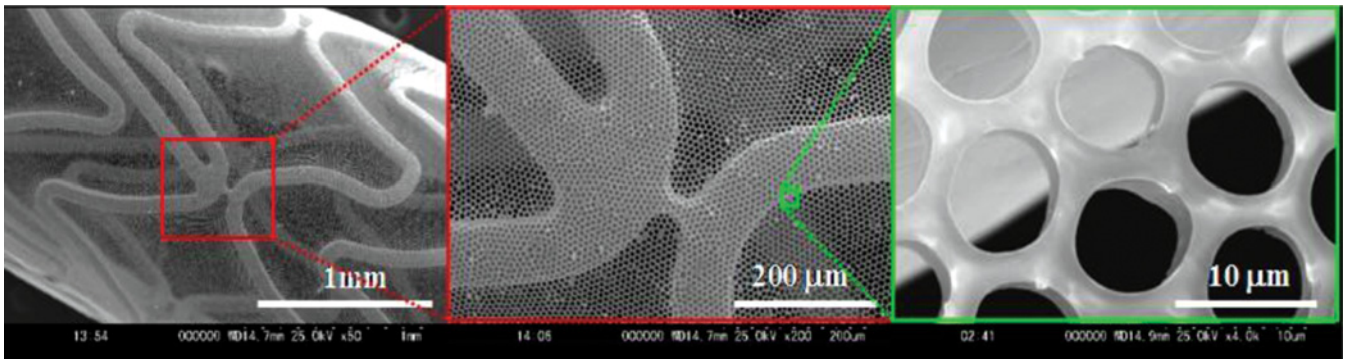

FIGURE 6.11 Novel stent covered with a vertically open-pored honeycomb film.

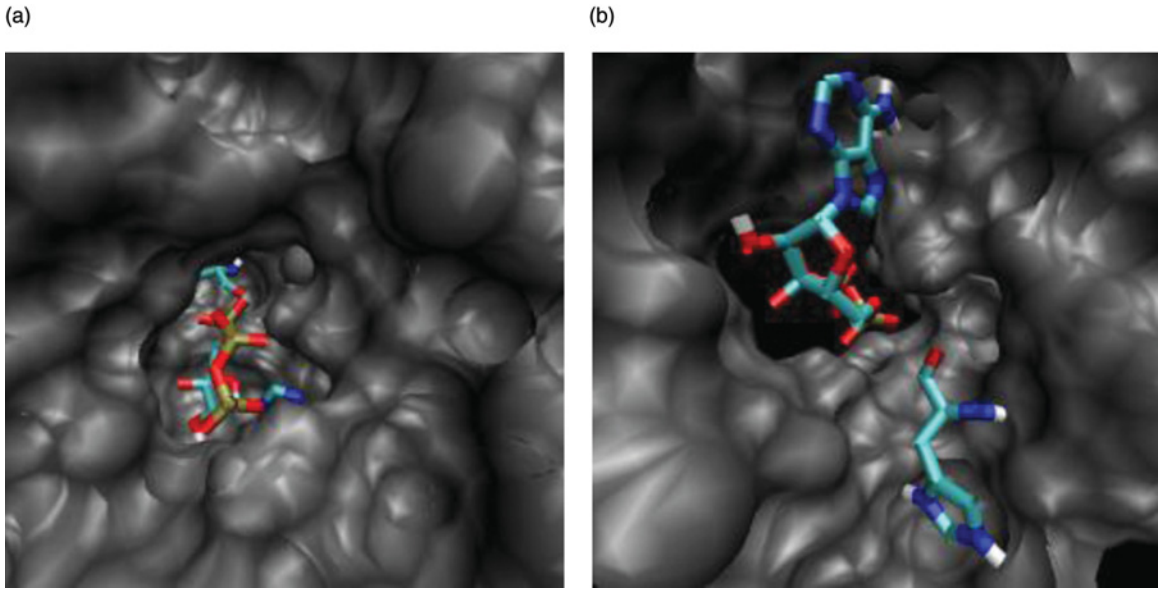

FIGURE 14.2 The active-site geometry of HisRS (1KMN.pdb) from *Escherichia coli* [26]. The ATP and histidinol are shown as bound substrate and substrate analog (analog of histidine), respectively. Two different views of the active site are shown: (a) from the perspective of the active site as viewed from the opening of the cavity; (b) as viewed from the amino acid binding site (few residues are omitted for clarity). The opening of the active site is ∼1.1 nm, and the tunnel length spanning the substrate and analogue is ∼1.7 nm. Images are prepared using VMD [108].

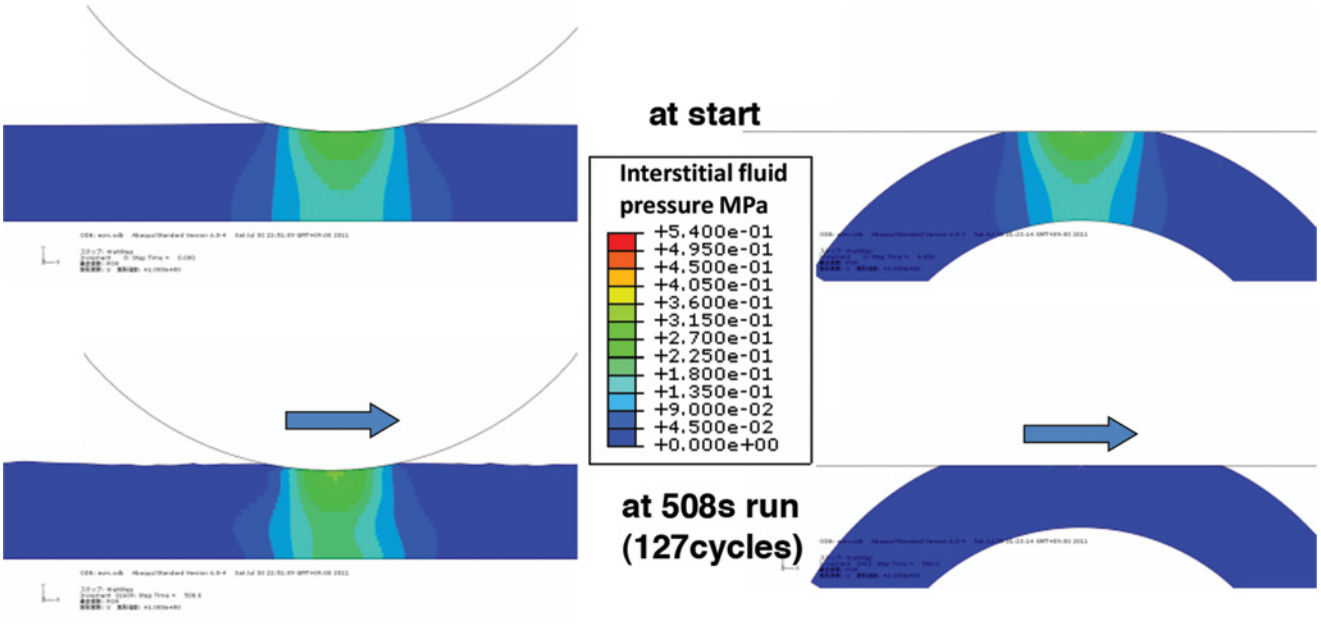

FIGURE 22.5 Changes in interstitial fluid pressure of articular cartilage: (a) on/off loading to cartilage; (b) continuous loading to cartilage (modified from Ref. 26).

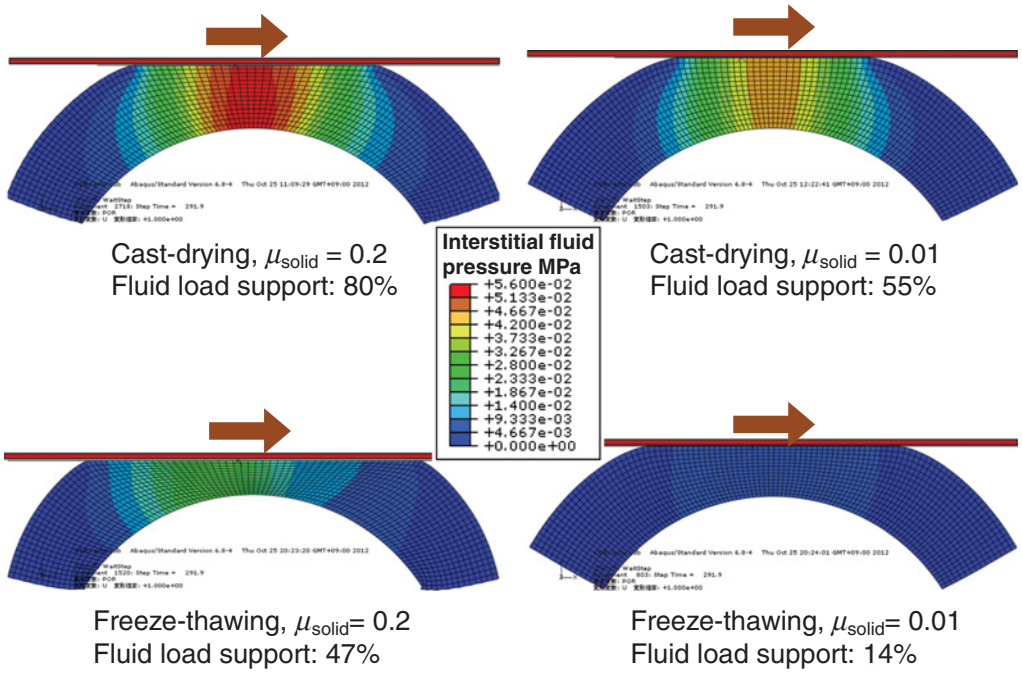

FIGURE 22.12 Changes in interstitial fluid pressure and fluid load support of PVA hydrogel [41].

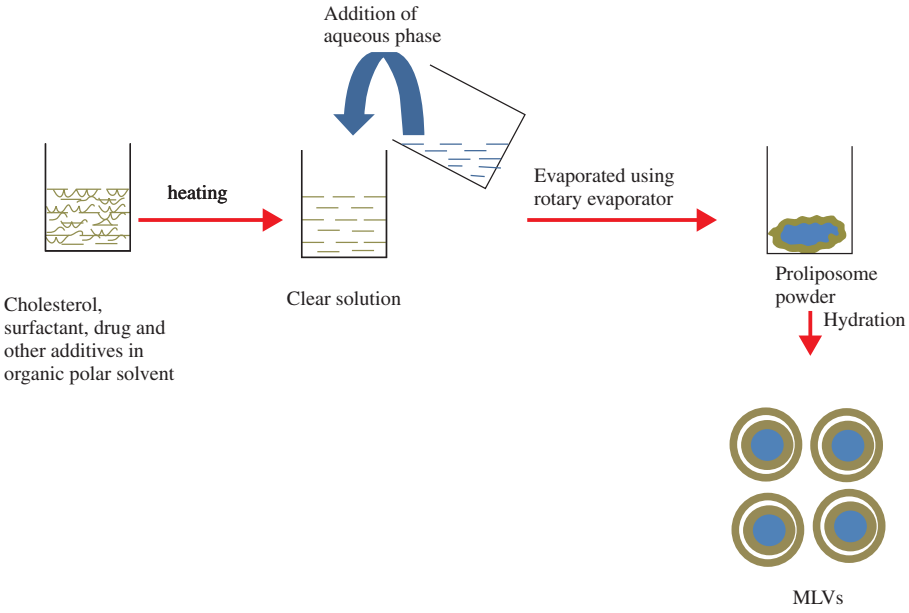

FIGURE 23.7 Formation of liposomes from proliposomes.

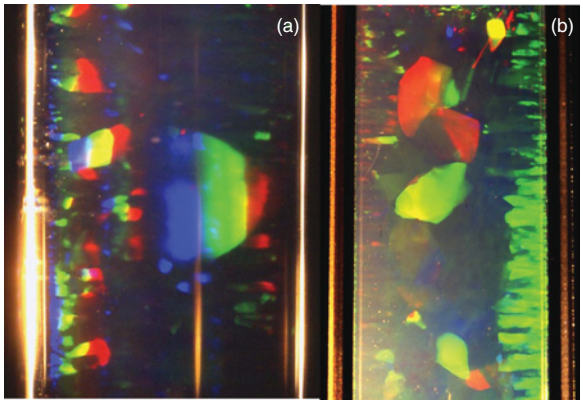

FIGURE 28.1 Close-up images of colloidal crystals in test tube (a) and in a plain cell (b) at 25°C. (a) CS91, ϕ; = 0.00083, 18 days after preparation and 1 h after mixing; (b) CS81, ϕ = 0.00095, 7 days after preparation and 40 min after mixing.

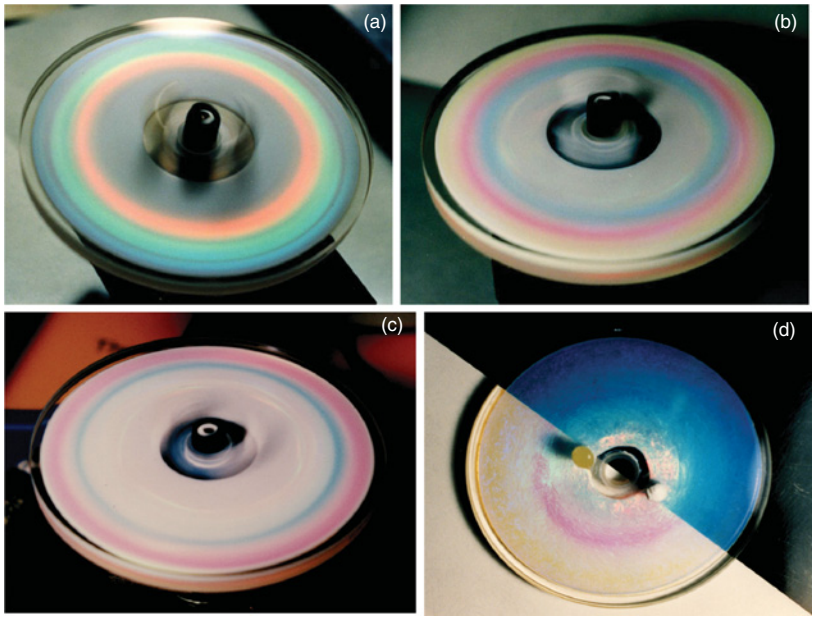

FIGURE 28.8 Close-up color images of colloidal single crystals of D1K88 (a,b) and D1B72 spheres (c,d) in a rotating cell. ϕ_{D1K88} = 0.0617, ϕ_{D1B72} = 0.0820. Images captured with (a) obtuse-angle illumination and (b,c) acute-angle illumination, and (d) photograph showing the observation cell on black and white papers.

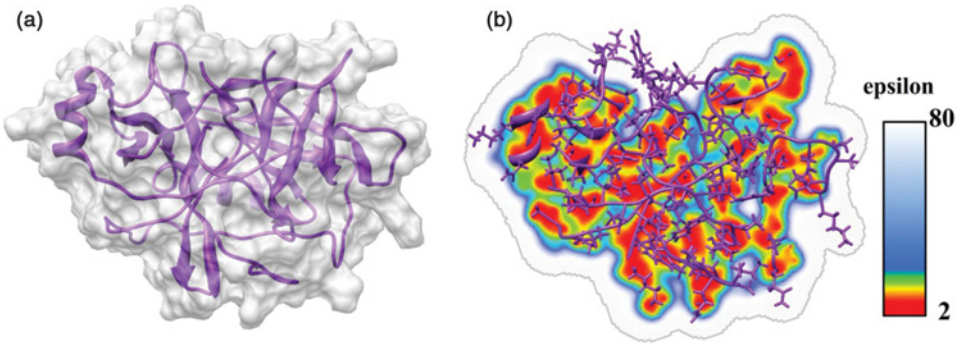

FIGURE 29.4 (a) Structure of the Bovine Eglin protein (PDB ID 1ACB); (b) dielectric distribution of the Gaussian smooth method for this protein. [Molecular graphics and analyses were performed with the UCSF Chimera package. Chimera is developed by the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (supported by NIGMS P41-GM103311).]

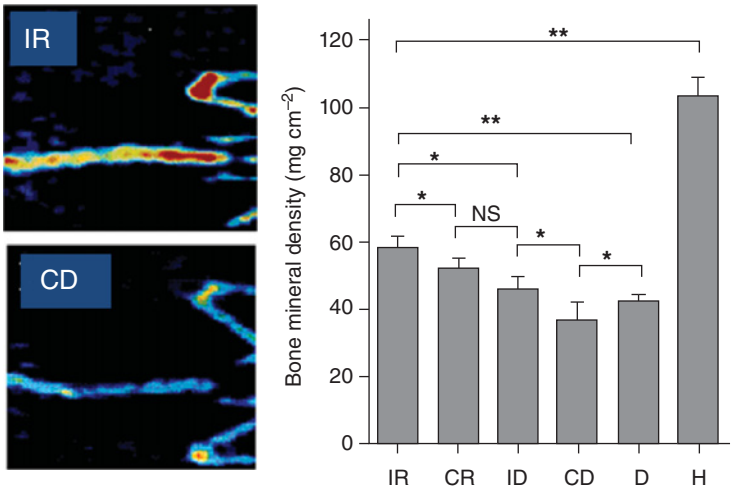

FIGURE 31.3 BMD of implanted apatite cement containing estradiol in osteoporotic rats.

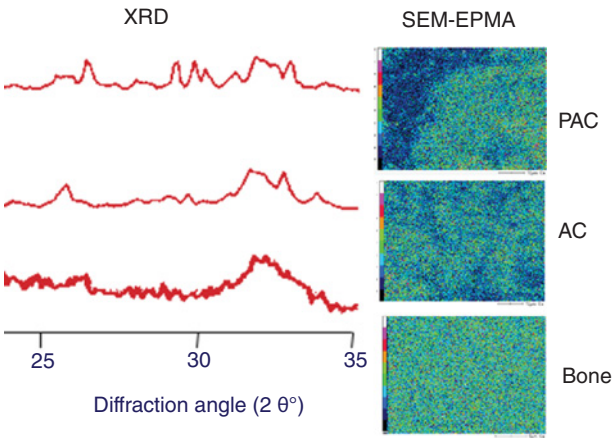

FIGURE 31.4 Effects of grinding of element dispersibility of AC and PAC by electron probe microanalyzer.

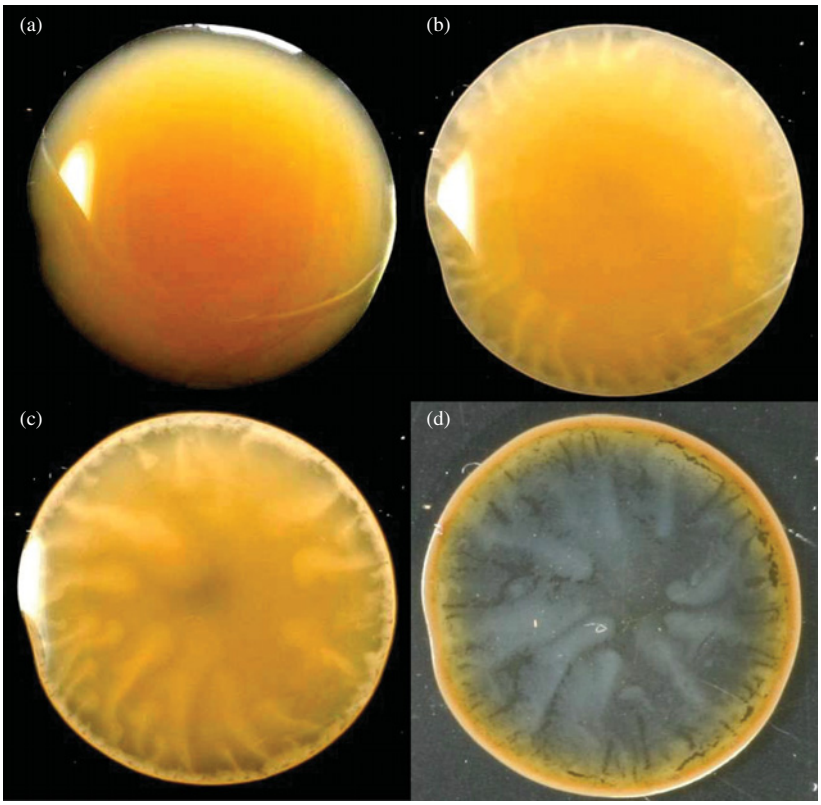

FIGURE 32.1 Convectional, sedimentary, and drying patterns of coffee (for iced coffee) with cream on a coverglass at 27°C, 1.26 wt%, 0.1 mL: (a) 10 min; (b) 50 min; (c) 1 h 40 min; (d) 3 h 25 min after setting.

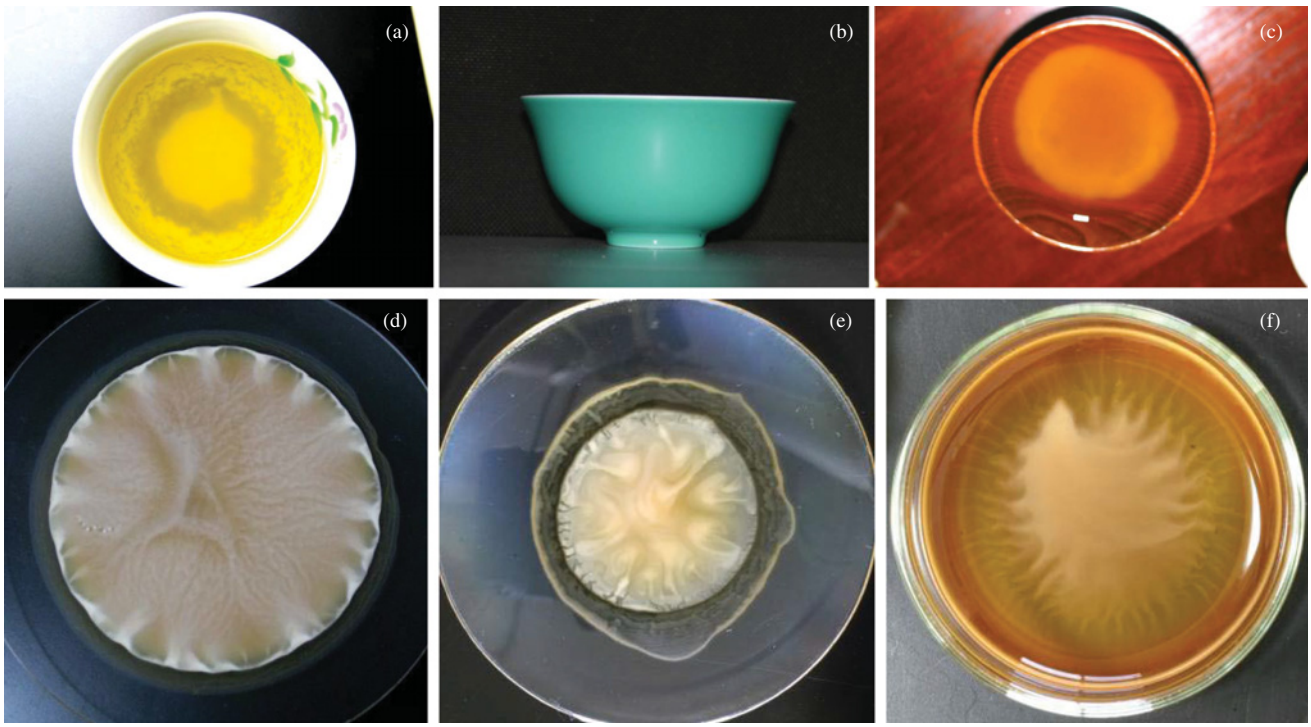

FIGURE 32.3 Typical examples of broad ringlike (a–c), cluster (d), bundle (e), and flamelike (f) sedimentation patterns of (a,b) green tea, (c) miso soup, and (d–f) coffee. (a) In a teacup at 24°C; (b) side view of a teacup; (c) in a bowl at 24°C; (d) in a watchglass (150 mm), 10 mL, 2.3 wt%, with cream, from 70°C to 20°C, after 12 h 25 min; (e) in a watchglass (50 mm), 1 mL, 0.7 wt%, with cream, after 9 h 20 min; (f) in a glass dish (42 mm), 3 mL, 2.3 wt%, with cream, after 20 h 5 min.

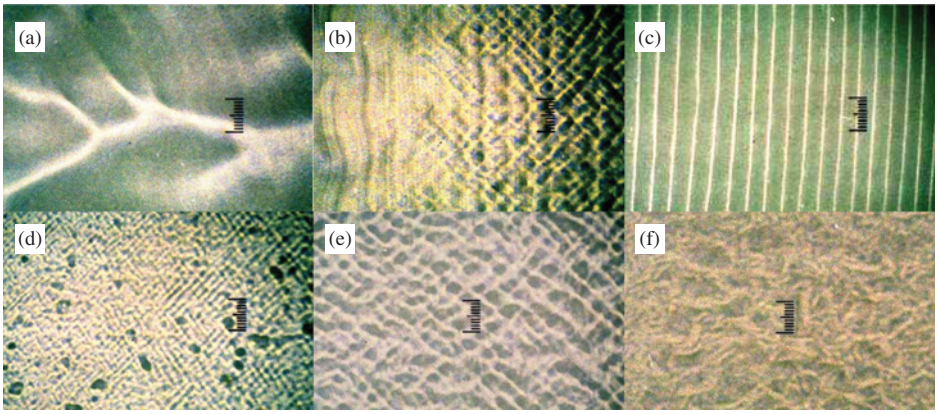

FIGURE 32.7 Typical examples of microscopic drying patterns of (a,b) pNIPAm(200-0.5): (c) pNIPAm(200-2); (d) pNIPAm(200-10); (e) pNIPAm(400-5); (f) pNIPAm(1500-5) at 45°C (humidity 35%, full scale at 100 μm): (a) 1.01 wt%, on a watchglass; (b)1.01, watchglass; (c) 0.039, glass dish; (d) 2.4, glass dish; (e) 0.97, glass dish; (f) 3.1, coverglass.

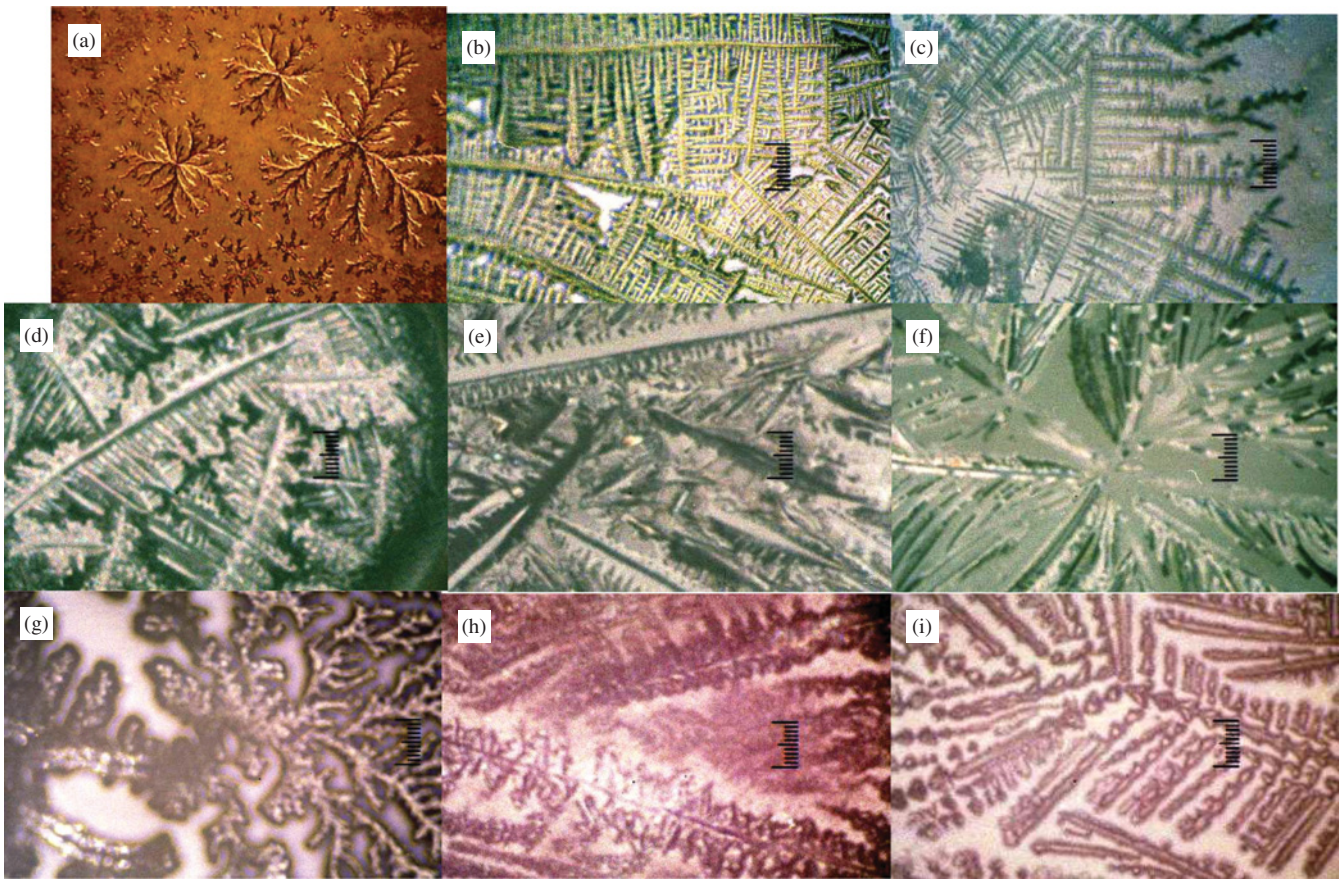

FIGURE 32.10 Typical examples of microscopic patterns of biopolymers: (a) NaPDGA + NaPLGA (1:1) [103], [NaPGA] = 0.01 monoM, on a coverglass, 0.1 mL, at 25°C; (b) NaPLGA + NaCl [103], [NaPLGA2] = 0.008 monoM, [NaCl] = 4 mM, on a watchglass, 0.7 mL, 25°C; (c) PDL-HBr + PLLHBr [40], [PDLHBr] = [PLLHBr] = 0.00005 monoM, on a watchglass, 0.7 mL, 24°C; (d) NaHLA [108], [NaHLA] = 0.004 monoM, [NaCl] = 0.06 mM, on a coverglass, 0.1 mL, at 25°C; (e) NaCMC2 [106], [NaCMC2] = 0.008 monoM, [NaCl] = 0.04 M, on a coverglass, 0.1 mL, 25°C; (f) βCD [107], [βCD] = 0.01 M, on a glass dish, 0.7 mL, at 20°C; (g) NaDNA [42], [NaDNA] = 0.01 monoM, on a watchglass, 0.7 mL, at 25°C; (h) KPolyA [109], [KPolyA] = 0.00414 monoM, [KCl] = 0.06 M, pH = 6.6, at 20°C; (i) PolyA + PolyU [110], [PolyA] = [PolyU] = 0.002 monoM, [KCl] = 0.01 M, on a coverglass, 0.1 mL, pH = 6.6, at 25°C. Full scale is at 100 μm (a–g) and 50 μm (h,i).

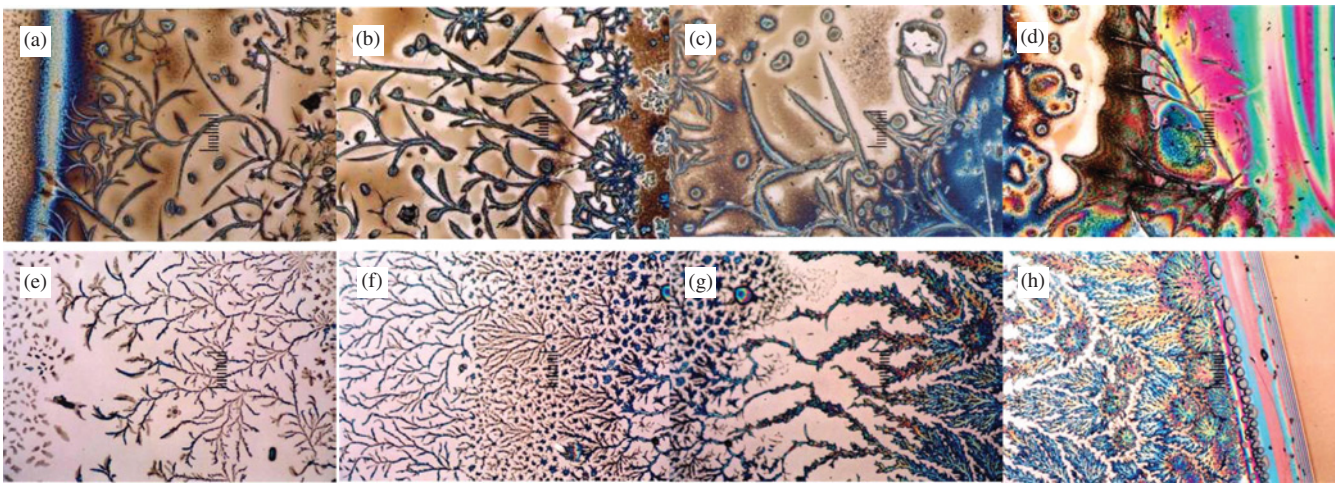

FIGURE 32.12 Microscopic drying patterns of Ge:GeO_2 film. (a–d) code 23b, on Si, 5×, full scale at 200 μm; (e–h) code 24b, on Si, 40×, full scale at 25 μm, from the central area to the right edge.

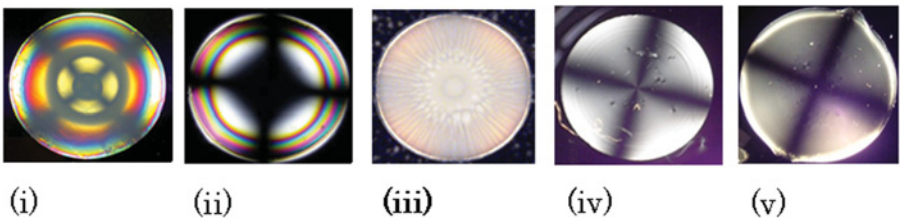

FIGURE 39.2 Gels observed under crossed nicols for polymer solution/medium systems using the boundary condition (a) or (c) in Fig. 39.1. The gels prepared under condition (a) were excised perpendicularly to the long axis of the dialysis tube, and the gels prepared under condition (c) were stripped off the plates. The photographs were taken from the top view: (i) Curdlan in NaOH solution/$CaCl_2$ solution (from Ref. 14, Fig. 2); (ii) DNA in buffer of pH 9.2/$CoCl_2$ solution (from Ref. 17, Fig. 1); (iii) CMC in pure water/$CaCl_2$ solution (from Ref. 18, Fig. 1); (iv) chitosan in acetic acid solution/NaOH solution (from Ref. 24, Fig. 1a); (v) myosin in pure water/glutaraldehyde solution.

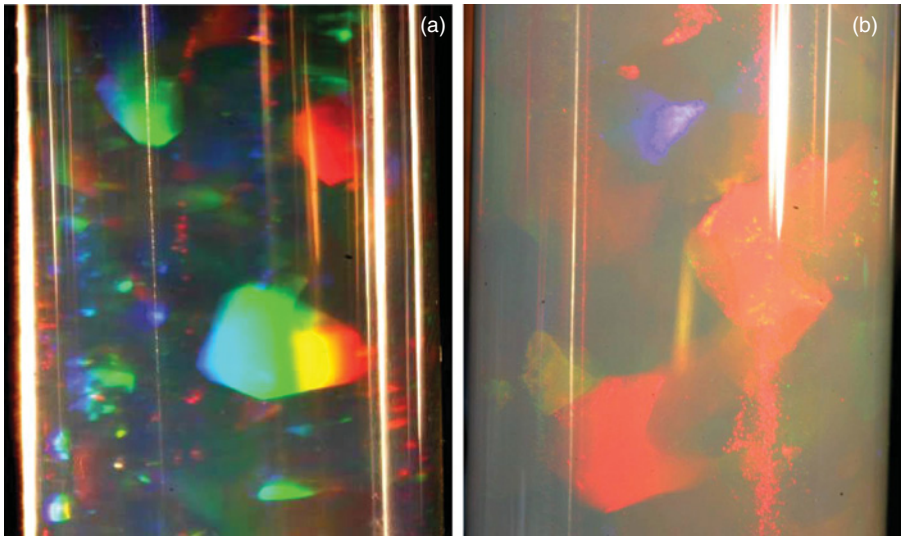

FIGURE 41.3 Close-up color images of PNIPAM(200-5) in a test tube: (a) [PNIPAM(200-5)] = 0.116 wt%, with resins, at 25°C; (b) 2.82 wt%, [NaCl] = 3.5×10^{-5} M, at 25°C.

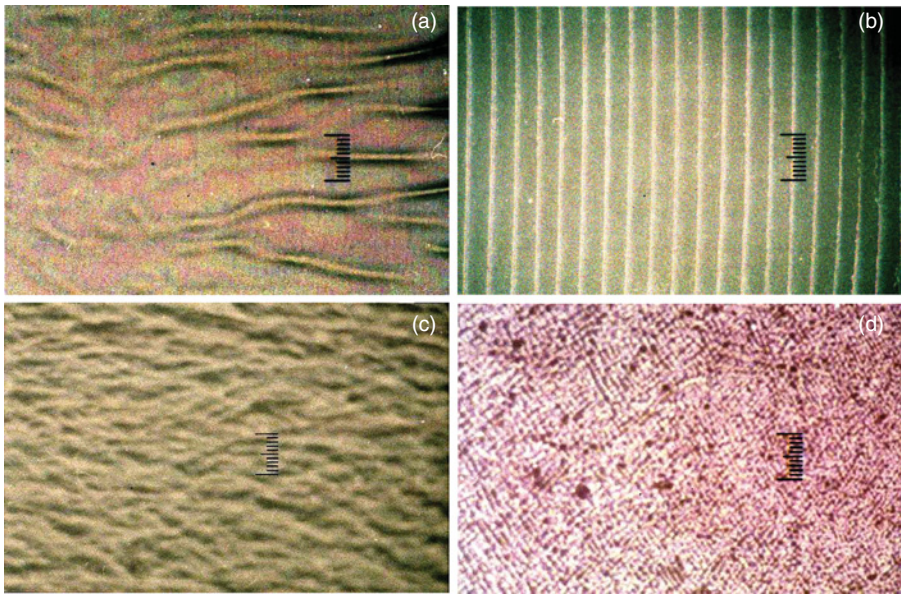

FIGURE 41.8 Typical microscopic drying structures of (a) *ordered spokelines*, (b) *ordered rings*, (c) *net* structure, and (d) *lattice*like ordered structures of the agglomerated particles of gel spheres. (a) pNIPAm(200-10), 0.119 wt%, on a coverglass, 20°C; full scale is 200 μm, (b) pNIPAm(200-0.5), 0.0336 wt%, on a glass dish, 45°C; full scale is 100 μm. (c) AIBA-P2VP(1), 3.45 wt%, on a watchglass, 22°C; full scale is 100 μm. (d) pNIPAm(200-5), 1.55 wt%, on a glass dish, 45°C; full scale is 200 μm.
